circumference scores were obtained from 724 respondents at nine North American correctional facilities. He reported that flaccidity to full erection for male sexual offenders has a mean of 32.6 mm and a standard deviation of 8.8 mm, and the scores are normally distributed. Ninety-five percent of circumferential change scores can be expected to fall at or below 47 mm. He contended that using anything less than 47 mm as an estimate of full erection is unacceptable by conventional scientific standards. Following this recommendation, 10 % erectile response converts to about 4.5 mm, 15 % 7 mm, and 20 % would be about 9 mm. For clinical purposes with circumference measurement, we use 10 % percentile response as the minimum response level. If the subject does not achieve 10 % erectile response to any of the stimuli, then he is classified as a nonresponder, meaning his responses were too low to interpret the PPG results. Fifteen percent and 20 % erectile responding is often used as the cut score indicating some minimal degree of sexual arousal.

However, Lalumière and Harris (1998) indicated that cutoff scores might not be needed. They reported that they were unable to find any minimum response level that increased validity. They noted that there is no discriminant validity data of which they were aware of that supported declaring low responder data as useless, except when responses to the neutral stimuli are higher. They also argued that there is a mathematical advantage to using standard scores because one can obtain information from low responders that is just as good as from high responders. One might question the advisability of interpreting data on low responders knowing the circumferential strain gauge is inaccurate below 2.5 mm, and low levels of responding might not be due to sexual arousal (Barbaree et al., 1999).

This author recommends use of both standard score and percentage of full erection (PFE) when interpreting data in the clinical setting. The clinician will oftentimes discover that the PPG results reflect the same rank order of age and gender preference using either the *Z* score (standard deviation from the mean) or PFE. This means that the individual's sexual arousal profile looks about the same regardless of whether the raw score is converted into *Z* scores or percentage of full erection. If the individual has higher sexual arousal to children than to adults, both measures are likely to reflect this same arousal pattern.

After each presentation has ended, the circumference tracing should continue to be collected for at least 30 s (Barbaree et al., 1999). I have observed with older subjects their sexual responsiveness is generally more gradual and takes longer than 30 s before reaching peak arousal. Therefore, you may want to continue to observe the tracing another 30 s. The next presentation should not begin again until the subject has returned to baseline. Unfortunately, some subjects may never return to their original flaccid baseline during the testing session. For example, in some cases a subject may have a stable baseline reading of 95 mm after placing the gauge on his penis, and then after 30 min his baseline drops 10–85 mm. Others might become aroused during a presentation and not return to the original baseline during the rest of the session. Variation of baseline of 3 mm appears to be acceptable (W. Burke, personal communication, July 10, 2009) and will not affect either the *Z* score or PFE because data collection begins at the start of each presentation. In cases where there are dramatic baseline shifts, one has less confidence in the accuracy of the data.

In a clinical practice, the PPG results may be of limited value unless the findings are shared with the subject; sharing results may provide the impetus for a particular subject to move past denial and minimization and help focus and motivate the individual to address his deviant sexual interests as treatment needs. During the testing the subject has been asked to estimate the percentage of his highest erectile response after each presentation. Therefore, it makes sense to provide him with the findings of the PPG in PFE as well. It is not uncommon for the subject to report during the testing that he was not aroused by any of the stimuli. Therefore, it may also be helpful to show him his arousal-tracing pattern of PFE on the computer monitor to assist in effectively communicating the PPG findings. This is an important juncture of communication between clinician and client. The client may have started the PPG session admitting to his offense behavior, but denying any ongoing deviant fantasies or urges. Presented with the results of a PPG, this may change; that is, an examinee presented with evidence of demonstrated sexual arousal to deviant stimuli might subsequently acknowledge recent or current experience of deviant sexual fantasies or urges (Schwartz & Cellini, 1999). This writer has heard candid admissions of sexual deviance on countless occasions after PPG testing results are shared with the subject.

Lalumière and Harris (1998) recommended using deviant index scores to determine the presence of deviant sexual interest (e.g., highest average deviant score to children minus highest average nondeviant score to adults). Their reasoning is that computing a numerical deviant index score enhances validity. They also indicated that if one obtains a single clinically significant score suggesting arousal to children, for example, but the deviant index does not support the conclusion of sexually deviant interest, one does not give weight to the deviant score because the subject's average sexual preference is not deviant. This author argues that in testing individuals with a history of inappropriate sexual contact with children, even a single clinically significant "hit" (e.g., response) to a child or sexual violence is clinical information that should not be ignored. Such information provides an important starting point for a dialogue with a client who may be denying or minimizing his interest in children. The clinician needs to bring this finding to an examinee's attention and ask him if he was aware of his arousal; under what other

circumstances this arousal has occurred; how often it has occurred; frequency of recent deviant sexual thoughts; and frequency of fantasies about children during masturbation. Faced with evidence of his sexual arousal to one deviant stimulus even when he had greater responsiveness to adults, the client may become more inclined to identify transient or persistent sexual interests in children. This is especially true when the findings from a PPG examination are combined with those of VRT (Maram & Koetting, 2004), and then further clarified when followed by a polygraph examination. The value of the polygraph in revealing previously unknown sexually deviant behaviors was demonstrated in a study of 109 individuals under the jurisdiction of the Colorado Department Corrections (Ahlmeyer, Heil, McKee, & English, 2000). The researchers reported the mean number of victims revealed by Presentence Investigative Reports and Sexual History Disclosure form nearly doubled from a mean of 61 to 109 victims after the first polygraph.

Court Challenges and Research Regarding the Penile Plethysmography

In U. S. v. Powers, 59 F.3d (1995), the Federal court determined the penile plethysmograph test did not meet the scientific validity prong of Daubert. Laws (2003) summarized the legal literature surrounding the admissibility of PPG evidence in court as follows: (1) the technique has been tested; (2) it has been peer reviewed and published; (3) the procedure has a known or potential rate of error; (4) there is standardization for operation and the PPG is generally accepted in the scientific community. Laws then opined PPG should not be accepted in Daubert. He indicated that to some extent items 1 and 2 have been met. The PPG has been tested thousands of times, and with highly unvariable results. Also, it has been peered reviewed and published hundreds of times. However, the absolute error rate is unknown (item 3), and adequate standards do not exist for administration of the procedure, failing to meet the criteria of item 4. In Powers it was argued that the district court erred in excluding the testimony that the penile plethysmograph test did not indicate pedophilic characteristics. The district court excluded this evidence because, in its opinion, the test did not satisfy the "scientific validity" prong of Daubert. The U.S. Court of Appeals 4th Circuit affirmed the lower Court's ruling, excluding the PPG results. However, the court also noted the plethysmograph test is "useful for treatment for sex offenders" and permitted the district court to impose this condition on an individual as part of their supervised release from custody. This particular decision prohibited the use of PPG results in the guilt phase of Federal criminal proceedings, but allowed it to be used in treatment.

In Berthiaume v. Caron, 142 F.3d 12, 1st Cir (1998), the PPG was described as "an accepted tool" and "a standard practice" in the field of sex offender treatment. Barker and Howell (1992), at the time, reported that there was much research to support the claim that the penile plethysmograph is a reliable and valid method of assessing erectile response in male sex offenders. They concluded that while the PPG is the best objective measure of male sexual arousal and could be useful in assessing and treating sex offenders, caution still must be exercised because of its limitations. These limitations included a lack of standardization, a high incidence of both false negatives and false positives, and the use of the PPG unsupported by other data as a predictive test. Barker and Howell (1992) suggested that the PPG is most effective in predictive situations when it is used in conjunction with multiple data sources.

In State of North Carolina v. Spencer, 459 S.E. 2d 812, 815, N.C. Ct. App (1995), the court reviewed the literature and case law and concluded that penile plethysmography was scientifically unreliable. They concluded that despite the sophistication of the current equipment technology, question remains whether the information emitted is a valid and reliable mean of assessing sexual preference.

In a more recent review, it was reported that a substantial amount of research data has been gathered and reviewed, and significant steps have been taken toward standardization. According to Launay (1999), "[T] he the validity of the technique for research and clinical assessment has been is now established."

Other than in the guilt-determination phase of court proceedings, phallometry is now widely considered appropriate for treatment and supervision of convicted sex offenders. The courts are now permitting plethysmographic testing for monitoring compliance of sex offenders with the conditions of their community placement as part of crime-related treatment for sexual deviancy (Sachsenmaier & Peters, 2002).

The scientific validity and reliability of the procedure has also earned acceptance in many jurisdictions during the presentencing stage of criminal proceedings, as well as for the parolee or probationer who is under community supervision. The standard of evidence required need only be sufficient indicia of reliability to support "probable accuracy," a standard analogous to preponderance of the evidence; this is a standard less stringent than the Daubert standard (U.S. v. Silverman, 976 F.2d, 1992; U.S. v. Herrera, 928 F.2d 769, 772, 6th Cir, 1991; U.S. v. Lee, 1998). As a result, the Courts are now more routinely upholding the use of PPG testing in administrative law cases and with probationers for evaluation and treatment (Berthiaume v. Caron, 142 F.3d 12, 1st Cir, 1998).

The debate over PPG use is not limited to the United States. In Canada, the Canadian Supreme Court (R. v. J.-L. J., 2000) ruled against admitting penile plethysmography into

evidence in a case in which a psychiatrist (who was a Canadian pioneer in the field) attempted to testify about the results of the penile plethysmography (previously recognized by the Courts as a therapeutic tool), as a forensic tool in criminal procedures. Similar to the United States, the court opined that although PPG test level of reliability in a court of law was not necessarily sufficiently reliable to identify or exclude an accused individual as a potential perpetrator of an offense (a criminal application), they identified it as quite useful in therapy because it yields information about a recommended course of treatment.

In summary, court rulings thus far have not provided a bright line regarding the admissibility of the PPG in court proceedings. Generally speaking, the PPG is not allowed in the guilt phase of criminal proceeding (an exception to this will be discussed later from People v. Stoll, 1989). The PPG, however, may be allowed in the sentencing phase of court proceeding, is often introduced during Sexually Violent Predator cases and in other civil proceedings, and is permissible for use in sex offender treatment.

Summary on Penile Plethysmograph

The PPG has been in use for sex offender assessment and treatment for over 50 years. Although there are a large number of published articles on the subject, there continues to be controversies regarding its validity and reliability. In particular, concerns have also been expressed as to the lack of common standards and procedures and the variability of PPG administration, results, and interpretation. Consequently, some have suggested and continue to believe that using the PPG is more of an art than science (Laws, 2003, 2009). Others strongly support its role in clinical assessment (ATSA, 2001, 2013; Marshall & Fernandez, 2003) and point out that although the procedure may show varied standardization, there are recognized functions for its use that share common aims and features and utility (O'Donohue & Letourneau, 1992), such as treatment planning and hypothesized motivation of the underlying offense.

The recommended procedures described here include using a lab that ensures privacy and discretion; using discriminating stimuli that have been standardized and validated; carefully screening the PPG session for faking; using video recording as well as other devices that require the subjects' consistent visual and auditory attention; and using measures to check breathing and muscle movement to reduce threats to reliability and validity. In a clinical practice, it is important that data be shared with the client in a manner that is readily understood. Therefore, during the posttest interview, it is recommended that data interpretation be shared in "percentage of full erection" to encourage a client to report his inner deviant experiences and actual behaviors with greater openness and accuracy. The presence of any significant deviant arousal, even when there is greater average arousal to adults, is important clinical information and should be included in the dialogue with the client.

At present, the PPG continues to be the most sensitive and reliable available physiological measure of sexual arousal (Howe, 2003). However, until there is a convergence of standardization, the PPG will continue to be colored by controversy, and its admissibility in court for certain functions will remain uncertain. Effective sex offender assessment requires leadership and communication to establish professional consensus, to yield agreed upon standards of practice in which improved validity and reliability studies can follow. In the interim, although the clinician must rely upon less than ideal guidance when administering and interpreting PPG data, in this author's opinion, there are sufficient arguments supporting its value to justify its continued use in clinical practice.

Viewing Time Measures

Several other measures have been used in an attempt to reliably measure sexual arousal and interest. These include facial electromyography, measures of penile temperature, volume, circumference, and motion (Krueger, Bardford, & Glancy, 1998). It is postulated that sexual arousal is not a unitary construct and identifies three stages of sexual attraction in males: (1) aesthetic response, a hedonic feeling response to the sexual stimuli in which the individual may keep the object of interest in view; (2) an approach response where the individual moves toward the sexual object of attraction with a desire for body contact; and (3) the genital response characterized by greater penile engorgement. The third stage is the purview of the PPG, which was the subject of the previous discussion in this chapter. An increasingly popular method for assessing sexual interest involves Visual Reaction Time (VRT) measures, which rely on increased visual response to potential objects of attraction (or the first component of Sing's model, the aesthetic or hedonic response).

Abel, Jordan, Hand, Holland, and Phipps (2001) reported visual reaction time measurement was originally based on the work of Rosenzweig (1942). Rosenzweig, in a study with 20 schizophrenics using the photoscope, was the first to report that VRT was a good objective device for identifying sexual interest. Subsequently, Wright and Adams (1994) (in a study of 80 subjects using a VRT test) found that sexual arousal interfered with cognitive processing. Specifically, they found that individuals showed a longer reaction time to slides depicting preferred sexual partners than to nonpreferred sexual partners or neutral scenes.

Abel et al. (2001) addressed the difficulty and the importance of determining what motivates a person to sexually molest a child when developing an effective intervention

strategy to prevent future molestations from occurring. Support for the use of VRT as a measure to differentiate child molesters from non-child molesters and to identify individuals who are concealing their interest in children has been repeatedly reported in the literature (Abel et al., 1998, 2004; Harris, Rice, Quinsey, & Chaplin, 1996). Although Harris et al. (1996) reported that VRT was less intrusive than the PPG and significantly discriminated between child molesters and normals, they also noted the PPG was still better at discriminating these categories than VRT measures. Maram (2005; Maram & Koetting, 2004) found that use of VRT and the PPG incrementally increased discriminant validity, especially with child molesters of male youth. This finding supports the combined use of these instruments in the clinical setting.

Perhaps the best-known and most frequently used VRT measure is the *Abel Assessment for sexual interest*™ (AASI). The AASI has hundreds of licensed sites throughout North America authorized to administer the AASI testing instrument. The AASI was developed to function as a viable alternative to the PPG (Abel Screening, Inc. 2004). The licensed site setup cost to run AASI testing is significantly less than what is required for a PPG lab. The test comes with a training manual, Abel and his associates conduct training workshops several times a year and there is an online examination for qualified users. In addition, Abel and others at Abel Screening are available for consultation. In comparison to the PPG setup cost for the hardware, software, office space, laboratory equipment, and training, the AASI is a particularly economic alternative. In addition, it is not nearly as intrusive as the PPG (no one has to take their clothes off or attach devices to their genitals) and it does not cause the anxiety and distress often experienced by individuals taking the PPG. Using AASI as an inexpensive replacement to the PPG can be appealing to many sex offender evaluators and treatment programs and may explain the popularity and wide use of this instrument. However, as previously indicated, using the AASI and the PPG together has the advantage of increasing the individual's candor and willingness to cooperate with treatment.

Both the AASI and PPG have advantages and disadvantages based on the specific methods used. Although PPG and VRT measure different phenomenon, they both should be at least conceptually related to sexual interest and sexual attraction.

Research and development of the AASI demonstrated the test has criterion validity based on its ability to discriminate between non-child molesters and admitting child molesters. Abel has also demonstrated that the AASI was resistant to falsification based upon a statistical regression model designed to discriminate between "lier-deniers" child molesters and non-child molesters (Abel et al., 2001).

About the AASI

The AASI is a two-part examination. The first part is the VRT procedure relative to images of individuals of varied ages and races as well as a detailed questionnaire examining sexual interest, arousal, and behaviors. Both VRT data and self-report data are used together to assess respondents' sexual interest(s) and to calculate probability values that reflect the likelihood that a respondent has pedophilic sexual interests (Abel et al., 2001) The VRT is an ipsative measure, meaning the individual's standard scores are not normed to others, but compared only to the individual's personal scores to the visual stimuli administered as part of the procedure. In other words, the person's sexual interest to images of children, adolescents, and adults is normed only for the individual and is not compared to others.

Questions About AASI Reliability and Admissibility in Court

Like other assessment instruments, the AASI-2 has its detractors and its admissibility in court has been challenged. Smith and Fischer (1999) reported in their study that the Abel Assessment for Interest in Paraphilias used with juvenile sexual offenders in residential and day treatment failed to demonstrate adequate reliability and validity. They concluded there was no evidence that the test produced reliable scores for adolescents that could screen deviants from normal individuals or could diagnose specific pathology in deviant subjects. Abel et al. (2004) responded to Smith and Fischer's article with a counterargument to their criticism, citing numerous flaws in their study, the most central of which was the authors' failure to determine whether members of their control group were really "non-child molesters" or lacked sexual interest in children. The importance of this determination was underscored in a 2001 study (Zolondek, Abel, Northey, & Jordan, 2001) that reported information gathered from 485 males younger than 18 who were being evaluated as possible juvenile sex offenders. More than 60 % reported involvement in child molestation. Of the boys who reported never being accused of child molestation, 41.5 % reported they had molested a younger child.

Abel (personal communication, February 5, 2008) indicated that the AASI should not be used in making a diagnosis, nor does he claim it to serve that purpose. He pointed out that not all sexual abusers of children have a sustained sexual interest in children. He describes unpublished data showing VRT sensitivity as .44 and specificity of .81 when using a very high cutoff score to limit false positives. His study was based on 7,773 admitted sexual abusers of minors (children

or adolescents) and 365 non-sex offender community volunteers. He notes, "the sensitivity would be even higher if one only considered individuals who sexually abused children instead of combining the sexual abusers of children and sexual abusers of adolescents."

Letourneau's (2002) study demonstrated the utility of the AASI with adult male offenders. She investigated the reliability and validity of VRT and PPG in a sample of 57 sex offenders incarcerated at a high-security military prison. She reported the results indicated adequate internal consistency for both measures. The convergent validity and assessment of clinical usefulness indicated that both measures accurately identified sexual offenders against boys. The VRT, but not the PPG, also significantly identified offenders against adolescent girls. However, neither measure reached statistical significance in identifying offenders against adult women or against young girls.

The AASI has been used in various criminal court proceedings and on numerous occasions has been ruled as admissible evidence. For example, in U.S. v. Stoterau, 07-50124 524 F.3d 988, 9th Cir (2008), the district court ruled that Mr. Stoterau could be subjected to the AASI as a condition of his supervised release. Similarly, the Ninth Circuit, Central District of California, ruled that the district court may require AASI as a condition of supervised release (2006). The U.S. District Court of Louisiana ruled the AASI met the Federal Daubert standard (G. Abel, personal communications, February 5, 2008).

However, the AASI has not been uniformly accepted by all the courts. In Ready v. Commonwealth of Massachusetts, 2002, the AASI was found not to meet the Daubert standard for scientific validity because the original research study that developed the "rule of thirds" used to score the VRT (The "rule of thirds" refers to the cutoff score used to determine if sexual interest to an age and gender category was detected by the test) was never published (G. Abel, personal communications, February 5, 2008).

The AASI, as well as the PPG and polygraph examination, results are admitted into evidence generally without challenge when both sides stipulate to its use in an evaluation of sexual interest and arousal. Additionally, the California Superior Court has ruled that an expert may rely on standardized psychological tests in formulating an expert opinion (People v. Stoll, 1989). This allows the expert to offer an opinion about an individual's character relying upon their assessment of the individual using standardized testing such as the AASI, PPG, and polygraph without the Frye standard applying, which prohibits admissibility of evidence in the court of new or novel scientific techniques that are not generally recognized as sufficiently established by the scientific community (Frye v. United States, D.C. Cir, 1923, 293 Fed. 1013). In other words, in Stoll, the scientific technique(s) which formed the basis for the expert's testimony are not required to be tested as generally accepted by the scientific community. This opens the door for ethical issues since Stoll allows the defendant to present expert opinions of good character to show non-commission of a crime. However, an expert may not ethically report the findings of the AASI, PPG, and polygraph as evidence that the individual did not commit a sexual offense.

VRT in the Clinical Setting

Using the AASI in the clinical setting is fairly straightforward. Testing should be conducted in a location that minimizes distraction. Testing begins after the individual receives standardized instructions and successfully completes a practice test of 15 slide images. Following the practice session, the client is administered 160 slide images of the AASI on a computer screen. The slides consist mainly of clothed male and female models (there are no nude images) of different ages, ranging from age two to adulthood. The client is instructed to imagine being sexual with each image and then after becoming familiar with each slide, they are to indicate their perception of how aroused or disgusted he or she would become by the idea of being sexually involved with the slide image depicted. The individual indicates their degree of "disgust" or "arousal" by pressing numbers ranging from 1 to 7, which ranks the image from a "1" of very low interest and highly disgusted to a "7" which indicates the image is highly sexually arousing. Approximately, a client requires30 min to complete the VRT.

The second part of the AASI test is a comprehensive questionnaire concerning sexual interest, arousal, and behaviors, as well as questions about history of sexual abuse, cognitive distortion questions about statements which individuals who molest children often endorse, and social desirability questions to assess the individual's willingness to be truthful. There are different versions of the questionnaire for men, women, adolescent boys and girls, and special needs populations. Typically, the questionnaire requires about 45–60 min to complete. However, some individuals agonize over their responses to questions and take much longer. For clients with reading, cognitive problems with special needs, evaluators may need to anticipate at least 2 h and/or multiple testing sessions to complete the questionnaire.

Disingenuous responding or faking is an obvious concern of any type of psychological testing. As discussed previously, PPG is vulnerable to faking. Lanyon and Thomas (2008) reported that no research on AASI could be found that utilized non-admitters or deliberate faking. They concluded that the ability of VRT procedures to detect deceptive responders is unknown. Gray and Plaud (2005), in an investigation of test sensitivity of PPG and AASI with 63 participants (17 subjects were excluded because of low

responding on PPG testing) in an outpatient treatment program. Reported that both the AASI and PPG measures were able classify pedophiles to a high degree. The plethysmograph was able to classify 65 % of the participants correctly, while the AASI was able to correctly classify 79 % of those participating in this study. Gray and Plaud (2005) also observed what they referred to as a reflective responder, i.e., individuals who attempt to employ dissimulation on the AASI. They devised a formula to be used with the Abel Assessment graphs to detect for reflexive responders and report significant improvement in sensitivity.

THE AASI provides interpretation and training to its authorized users on the administration and interpretation of an individual's test results. The data from a particular test administration is electronically transmitted back and forth between Abel Screening, Inc. and the evaluation site. The raw data is computer-scored and returned as a sexual interest graph, which displays eight bars of the appropriate ethnicity, gender, and age category for the Caucasian and African-American client. Each bar has a *Z* score associated with each of the two age and gender categories of children, plus two gender categories of adolescents and adults, totaling eight individual age and gender categories. There are also other potential paraphilic interests measured, the most significant of which are the measures of sexual interest in male and female adult object sadomasochism. Bars at or below the vertical cutoff score (using the rule of thirds as the cutoff determinate) showed on the graph reflect suspected high sexual interest in that category. For instance, a client may have bars at or above the cutoff of adult females, adolescent females, and male children 2–4 years old. This profile suggests the individual appears to have sexual interest in adult and adolescent females, with suspected interest in prepubescent children. The mathematical formula used to calculate the *Z* score is proprietary information and not available for public dissemination. There has been criticism of AASI about secrecy surrounding the specific mathematical formula embedded in the test interpretation. Abel (Personal communications, February 5, 2008) defended this position saying the release of such information would compromise the test's utility for future test-takers. He maintains the accuracy and validity of the AASI, like the majority of psychological tests, is partially dependent on the test-taker not knowing how the test works. Also, to disseminate such information compromises the aspect of a naïve normative group. Further, as Abel noted, the Standards for Educational and Psychological Testing (specifically Standards 11.7 and 11.8) address such protection of copyrighted material. He pointed out with the advent of the Internet it is even more critical to safeguard the information that would compromise the usefulness of the test. In addition, Dr. Abel fully acknowledges his commercial interest in the proprietary nature of the software, which is within his rights protected under law.

Discussing the Result with the Client

After the individual completes the AASI testing, the clinician may discuss the test results with the client. More often than not, when describing the findings to a client with sexual interest detected to prepubescent children, the client reacts defensively and denies this attraction, sometimes claiming that they may have accidentally pressed the wrong number, or somehow used the computer incorrectly. It is helpful at this point to then discuss the results of the PPG, which generally reveals an arousal pattern to children similar to the AASI. Frequently, the resistive client begins to disclose more about their sexual appetite, but usually not everything. It is after the completion of the AASI-2, PPG, and then the polygraph examination that the client is likely to be most revealing about past sexual behaviors and current interests.

The Polygraph: Its History

Knowing what is truth and what is a lie has likely been a subject of conversation among people since language first evolved. Daniel Defoe in 1730 was not the first to suggest that "taking the pulse" was a practical and more humane method of identifying a criminal in his essay entitled "an Effectual Scheme for the Immediate Preventing of Street Robberies and Suppressing all Other Disorders of the Night." Defoe wrote:

> Guilt carries fear always about with it; there is a tremor in the blood of a thief, that, if attended to, would effectually discover him; and if charged as a suspicious fellow, on that suspicion only I would always feel his pulse, and I would recommend it to practice. The innocent man which knows himself clear and has no surprise upon him; when they cry "stop thief" he does not start; or strive to get out of the way, much less does he tremble and shake, change countenance or look pale, and less still does he run for it and endeavor to escape. (Matte, 1996)

In the 1900s, C. Lombroso, M. D. (an Italian criminologist) applied blood pressure-pulse test to actual criminal suspects on several occasions while assisting the police in identification of criminals. By the turn of the twentieth century, Verdin of Paris, a manufacturer of physiological apparatus, was producing ink-recording polygraphs with pneumatic tambours. Later, S. Veraguth (1907) began using word-association tests with the galvanometer. His observations of the galvanic phenomena and emotions noted that emotional complexes, unveiled in word-association experiments, made an ascending galvanometer curve, in contrast with the rest curve of non-crucial stimuli (as reported in Matte, 1996).

Larson, a University of California medical student, employed by the Berkeley California Police Department, invented the modern portable lie detector in 1921 (Matte, 1996).

Since then the polygraph has been used in many thousands of police interrogations and investigations and now is an essential part of many sex offender treatment programs. However, as with other psychophysiological measures, it is controversial among researchers and is not always judicially acceptable (Bellis, 2013).

Polygraph Research

Modern-day research conducted on psychophysiological veracity (PV), which is the polygraph examination, involves three types of validation studies: the analogue study, the field study, and the hybrid study. The analogue study employs a mock crime paradigm, whereas a field study involves testing of real-life suspects of criminal offenses. The hybrid study attempts to avoid weaknesses of both analogue and field studies by combing the best features of each. Most of the research conducted consists of analogue studies, which is problematic because the psychodynamics are quite different in mock paradigms (analogue) studies than in real-life cases. The analogue studies are appealing to researchers because absolute truth is known and it is easier to study because the investigator has complete control over the experiment. However, the analogue studies fail to duplicate three major emotions normally responsible for autonomic arousal in real-life suspects: fear of detection by the guilty examinee, fear of error by the innocent examinee, and anger by the innocent examinee. In spite of the shortcomings of analogue studies, many studies have shown remarkable results attesting to the validity of the PV examinations (Matte, 1996). In a field test of real-life criminal guilty knowledge tests (an investigation of 40 innocent and 40 guilty subjects), Elaad, Ginton, and Jungman (1992) reported that over 97 % of the innocent and nearly 76 % of the guilty subjects were correctly classified. Incredibly, some investigators have reported correctly identification of 100 % of innocent as truthful with no inconclusive findings and no errors (Mangan, Armitage, & Adams, 2008).

However, as a scientific tool, some researchers continue to find polygraphy of questionable validity (Iacono, 2008). Iacono considered the Mangan et al.'s methods flawed because the confessions in that study were obtained by the polygraph examiner who interrogated the examinee after deciding the test was failed. Iacono wrote, "Although largely ignored by the polygraph profession, this flaw inherent on confession-based field studies of polygraph validity has been known to confound these studies for over two decades. Hence, contrary to Mangan et al. (2008), their study design does not provide for an adequate estimate of polygraph test accuracy." (p. 25)

The American Polygraph Association website (http://www.polygraph.org), not surprisingly, reports studies more supportive of polygraph testing. They report researchers having conducted 12 studies of the validity of field examinations, following 2,174 field examinations, which reported an average accuracy of 98 %. Further, researchers conducted 11 studies involving the reliability of independent analyses of 1,609 sets of charts from field examinations confirmed by independent evidence, providing an average accuracy of 92 %. Researchers also conducted 41 studies involving the accuracy of 1,787 laboratory simulations of polygraph examinations, producing an average accuracy of 80 %. It was also reported that in 16 studies involving the reliability of independent analyses of 810 sets of charts from laboratory simulations, there was an average accuracy of 81 %. In summary, these studies indicate between 80 % and 98 % accuracy, giving strong support for the continued use of polygraph testing.

Polygraph: How It Works

The polygraph examination is really just a measurement tool of a person's autonomic nervous system. In the psychophysiological veracity (PV) examinations, the ear of the subject is the receptor that receives the potentially threatening question or stimulus from the polygraph examiner. The stimulus is transmitted from the ear to the reticular activating system (RAS). The RAS, part of the brain that regulates sleep–wake transitions, can influence the state of arousal depending on the nature of the stimulus. When a question is perceived as threatening, impulses trigger a sympathetic system response, which when activated prepares the body for "fight or flight" with secretion of hormones (epinephrine and norepinephrine). This causes constriction of the arterioles leading to the stomach, significantly reducing the amount of blood normally routed to the stomach, producing the nauseated feeling sometimes referred to as "butterflies." Norepinephrine affects the skin capillaries in the same manner, producing pallor in the face seen when one experiences severe fright, as well as coldness or clamminess of the hands and fingers due to the reduction in the volume of the blood in those extremities. The heart begins to pump blood harder and faster, increasing blood pressure, and pulse rate. Salivary glands in the mouth secretion change causing "dry mouth." There is a tensing of the involuntary muscles, in addition to constriction of the cardiovascular system, causing a tightening of the involuntary muscles in the stomach inhibiting diaphragm-intercostal muscular complex, causing less than average air intake at a time when the brain needs more than an average amount of oxygen because of increased mental activity. Consequently, stimulation of the respiratory muscles by the brain will also cause some breathing changes. Sweat glands are stimulated releasing perspiration, the iris of the eyes dilate, and contraction of the anal and urinary sphincters occurs, along with relaxation of the bladder (Matte, 1996).

When the test subject is presented with a threatening question, the previously described physiological reactions can occur. The polygraph instrumentation attached to their body records a variety of these changes.

There are numerous commercial companies supplying polygraph equipment (Lafayette Instrument, Axciton System, Stoelting, and Limestone Technologies). For about five or six thousand dollars, one can purchase a polygraph computerized system. The polygraph system uses four basic components to record the examinee's physiology. There are the thoracic and abdominal breathing devices consisting of two hollow corrugated tubes attached to a unit by a rubber hose and fastened around the subject's upper body with a beaded chain or Velcro® trap. This breathing or pneumo unit is low pressured and measures the inhalation/exhalation causing the tubes to expand and contract reflecting changes in the subject's breathing pattern (Matte, 1996).

The galvanic skin response component senses small changes in the skin resistance to electricity caused by the sweat glands activity in the bodies' fight or flight protective response to threat or danger. Galvanic skin conductance is measured by electrodes placed on the fingertips of the examinee's nondominant hand (Matte, 1996).

The fourth component is a cardio-sphygmograph, which measures blood pressure, rate, and strength of the pulse beat. The cardio-sphygmograph is a medical blood pressure cuff containing a rubber bladder that is wrapped around the upper arm against the brachial artery (Matte, 1996).

Before one can become a polygraph examiner, basic polygraph training is required. Accredited APA training generally consists of 12 weeks full-time residential training including theory and hands-on lessons with simulated cases, followed by several weeks of practical training with actual examinees. The topics covered include scientific foundations of polygraph, physiology, psychology, testing protocols, instrumentation, and interviewing and interrogation techniques. Regarding polygraph examination of sex offenders, APA By-Laws require a polygraph examination to be administered by a well-trained and competent polygraph examiner who has completed an additional 40 h of specialized instruction and certification training approved by APA on Post Conviction Sex Offender Testing (PCSOT). In addition, to maintain certification, 30 h of continuing education training is required every 2 years. Examiners conducting PCSOT are required to spend at least 15 h specific to the issues dealing with testing, treatment, or supervision of sex offenders.

The PCSOT examiner uses three screening tests: Maintenance Exam, Sex Offense Monitoring Exam, Sexual History Exam I—Victims, Sexual History Exam II—Compulsivity. The PCSOT diagnostic exams included: Instant Offense Exam—event-specific; Instant Offense Investigative Exam—multi-facet; Prior Allegation Exam—event-specific; and Prior Allegation Investigative Exam.

In practice, the types of polygraph examinations conducted in the PCSOT field are as follows (T. Tipton, personal communications July 23, 2007):

- Sex History examination: Covers several different activities and sexual behaviors, excluding the offense for which the examinee is on probation. Areas covered include past sexual habits, other victims, sexual deviance, sex abuse, physical abuse, alcohol/drug use, etc., during the examinee's lifetime.
- Disclosure examination: Specifically refers to the offense(s) for which the examinee is on probation. The test should be conducted if there is a significant discrepancy between the offender's version of the offense and the reported version of the offense. Used to assist in evaluating denial of offense.
- Maintenance/Monitoring examination: Refers to the period of time since examinee last took a polygraph examination, generally a 3–6 month period. Issues covered include compliance to probation/therapy rules, alcohol/drug use, contact with victim or minors, exposing or peeping, use of pornography, etc.
- Monitoring examination: Involves the commission of sexual offenses or other probation/therapy restrictions to a narrower line of questions. Focus on whether or not the offender had committed a sexual reoffense during the period of supervision.
- Specific issue/Incident examination: An exam concerning one issue or incident, identical to the disclosure in that it concerns one event, possibly travel out of state.

Although PCSOT coursework includes familiarity with the psychological issues relevant to sex offenders and some interviewing techniques (American International Institute of Polygraph, 2009), the polygraph examiner must acquire the knowledge and understanding of how a sex offender might think and feel about their sexual behavior and interests. The pretest and posttest interviewing skill required of a good examiner is an art that can be acquired with experience.

Working with the Polygraph Examiner

The polygraph examiner is an important member of the collaborative effort of a sex offender management strategy and must work closely with the community supervision officer and the sex offender treatment provider. Generally, the PCSOT are conducted in the polygraph examiners' office. However, this can create a time and information gap. Too often after information is revealed for the first time in a PCSOT and by the time the report reaches the clinician, the client has created a story to minimize the importance of the new information. Practically, what works best is when the supervision officer and clinician are both nearby during

the examination. This allows the examiner direct access to the officer and clinician and client to clarify issues and concerns that may arise during the pretest interview. Then, subsequent to the posttest interview, the officer and clinician appear in the examining room and hear directly from the client what he has disclosed to the polygraph examiner. The client still may attempt later to distort or somehow minimize any new revelations in his therapy group about his sexual behaviors and interests. However, the clinician is now better able to assist the client to remain on track.

Appling the PPG, AASI, and Polygraph in the Clinical Setting

Thus far, the history, science, and the application of the PPG, AASI, and Polygraph examination have been considered for the sex offender client in evaluative and clinical settings. Integrating these physiological tools is not a new suggestion, nor is it complicated. It was reported earlier that combining measures of sexual interest and arousal incrementally increases the validity of classifying individuals with sexual deviance. Thornton has also suggested combining the PPG and the polygraph to increase PPG sensitivity (Laws, 2009). Information obtained from polygraph examination can have obvious value to the individual's treatment as well as contributing to community safety. This information is enhanced by the obtaining data from the AASI and PPG. The combined results of these three procedures can be used to help the client better identify (and become more motivated to face) their problems associated with sexual deviance. It is suggested that the evaluator and clinician work closely with the client with deviant sexual interests, sharing findings reflective of sexual deviance on the AASI, which is likely to be denied, and then following that with information about deviant sexual arousal from the PPG. The next step requires the evaluator and clinician to communicate with the polygraph examiner about the individuals' testing results and have the polygraph investigation probe further about the individual's behavior. This layering and integration of information from AASI to PPG and polygraph can be expected to increase the client's treatment motivation. When an individual is candid about their internal experiences and past and recent behaviors, he can be encouraged and guided in treatment toward focusing on and overcoming psychological or criminogenic needs that contribute to the potential for sexual recidivism. Thus, the use and integration of psychophysiological assessment practices, over time, can provide an individual information and assistance in the development of a more balanced, nondeviant lifestyle, with the development of motivation, understanding, and skills to minimize the chances of sexual reoffending.

Forensic Evaluations of Sexual Offenders: Principles and Practices for Almost All Sexual Offender Appraisals

Harry M. Hoberman and Rebecca L. Jackson

Introduction

The formal evaluation of identified or alleged sexual offenders is an activity of great significance. Evaluations of individuals, by definition, involve compiling a range of relevant information about a person (the assessment process), organizing and analyzing the existing set of "data," "facts," "hypotheses," and prior appraisal(s) of that person, and, most commonly, offering one or more contemporary appraisals or opinions about the individuals as they bear on specific psycholegal questions about the individual. As with any psychological or, more broadly, mental health appraisal, an evaluation requires an iterative process of assessment and consideration nomothetic or group-based information and idiographic or case-specific information to determine what opinions might be offered. The cumulative material collected, integrated, and interpreted from various multiple assessments and the resulting findings or conclusions of sexual offender evaluations can and do play a critical role in the disposition of such offenders. Despite a long history of concern about the established public health significance of sexual offending and dispositions for sexual offenders, it remains surprising how little has been written about the methods and process of the comprehensive evaluation of such individuals. Of the limited professional publications regarding the assessment of sexual offenders, most articles are directed at seemingly "pure" clinicians (e.g., potential treatment providers) for the purpose of evaluating a sexual offender for treatment amenability and planning. Those few articles about the "clinical" evaluation of sexual offenders are themselves relatively limited, in both length and substance. Compared to this circumscribed literature on the so-called "clinical" assessment of sexual offenders, even less has been published regarding the so-called *forensic* evaluation of sexual offenders (perhaps with recent exceptions in the domain of risk assessment). Generally, as Nicholson (1999) wrote regarding forensic psychology: "Across disciplines the application of scientific knowledge and principles and professional experience to legal issues is referred to as forensics. Forensic psychological assessment, then, refers to the application of the principles and procedures of psychological assessment to address questions raised in legal contexts; it can be conceived as an interdisciplinary specialty within psychology that requires specialized training experience and scholarship" (p. 121). From a United Kingdom perspective, Mullen (2000) wrote: "Forensic mental health defined more broadly is an area of specialization that, in the criminal sphere, involves the assessment and treatment of those who are both mentally disordered and whose behaviour has led, or could lead, to offending." (p. 307). He indicated that, in particular, applied mental health work relative to risk assessment and risk management clearly—and increasingly—fell into the realm of forensic mental health. More recently, following Heilbrun (2001), Heilbrun, Grisso, and Goldstein (2009) have discussed and attempted to define what is referred to as Forensic Mental Health Assessment (FMHA) as those assessments of various mental states, psychological phenomena, and behavioral predispositions relevant for or related to legal questions about human behavior. They identify FMHA as "a domain of assessments of individuals' intended to assist legal decision makers in decisions about the application of laws requiring considerations of individuals' mental conditions, abilities and behaviors." (p. 15)

Virtually all evaluations of sexual offenders are, in fact, forensic evaluations. Just as Forensic Psychotherapy is typically defined as that which pertains to "justice-involved clients," forensic evaluations can and should be considered as any evaluation or appraisal of an alleged or convicted sexual

offense that is "justice-involved" or in anticipation of "justice involvement" (e.g., Mitchell et al., 2013). In contrast, historically, forensic evaluations of sexual offenders have been viewed as a mere subset of sexual offender evaluations. However, at the present time, almost all appraisals of sexual offenders are initiated or implemented to address a definite or potential disposition in the criminal justice system (e.g., pre-plea evaluations and presentencing evaluations, determinations of possible enhanced sentencing), court-ordered or expected perspectives on treatment amenability and progress as a factor in disposition, release from detention, or, in certain jurisdictions, identification as a so-called "sexually violent predator" (SVP) or some similar designation. Consequently, the reality is that many or, in fact, almost all evaluations or appraisals of sexual offenders are either directly or indirectly of a forensic nature.

As Meloy (1989) and Nicholson (1999) have indicated, the term "forensic" is derived from the Latin "forensis" meaning of the forum, understood as in the public or legal forum. Thus, a forensic evaluation would be any evaluation that is (1) ordered by a legal entity; (2) related to a legal proceeding (e.g., likely or possible adjudication), and/or (3) has implications for the community or "public." Broadly, "Forensic Mental Health" (FMH) is defined or conceptualized as the application of scientific, technical, or specialized professional knowledge and procedures of the mental health field for the purposes of matters involving the courts, or the larger legal and political system. The key emphasis is on the services provided (e.g., the context) and not a professional's typical area of practice. Thus, any evaluation that takes place within the context of a judicial order or a broader judicial context (e.g., contemplated legal considerations or actions) is by definition a forensic evaluation. Any evaluations which are initiated by anticipated or active legal proceedings are forensic and are inherently "for the court" and, by extension, "for the public" forum.[1] In North America, this would typically include most initial treatment amenability assessments or intakes, treatment progress reports, treatment summaries, and release reviews, activities traditionally viewed as "clinical" and falling outside the realm of forensic mental health. Perhaps the *only* type of evaluation of a sexual offender not to be considered forensic would involve those assessments of sexual offenders who voluntarily seek treatment for sexual offending issues relative to a self-defined concern (e.g., distress) and prior to any actual or anticipated legal involvement. Thus, when considering the referral for or implications of evaluations of sexual offenders, it seems clear that virtually all such appraisals take place either as a result of or in anticipation of a legal context. Consequently, evaluations of sexual offenders, even those traditionally considered of a more pure "clinical" nature, are most accurately forensic in nature and should be governed by the same principles and procedures as those more "traditionally" viewed as of a forensic nature; that is, for sexual offenders, what have typically been considered as "clinical" evaluations should necessarily be regarded as forensic evaluations unless appropriately justified as completely independent of the criminal justice or larger judicial processes.

The purpose of this chapter is to describe relevant principles, methods, and other considerations in conducting adequate and informed forensic evaluations of sexual offenders (e.g., *most* evaluations of sexual offenders) and to discuss a set of domains and procedures (interviews, tests, questionnaires, and rating scales) for collecting relevant, reliable, and admissible information for assessing and appraising the various psycho-legal questions that the judicial system might pose regarding sexual offenders. While some of this material might seem minor or irrelevant to persons who conduct what were previously viewed as clinical evaluations (but which are more accurately conceptualized as forensic evaluations), the experience of an adversarial hearing can quickly expose the pitfalls of undertaking an evaluation with legal implications when one is naïve to the host of legal, ethical, scientific, professional, and other substantive issues that surround forensic evaluations.

By definition, forensic mental health evaluations have two components. First, they are evaluations "for the court" or "for the public" to supply professional review practices and opinion-generation for legal decision-making, often about issues that have an important bearing on public safety. Second, to that end, they are evaluations that apply the principles and procedures of psychological, psychiatric, and other mental health professional disciplines to address specific sets of questions or issues raised regarding sexual offenders in legal contexts. Legal contexts are, by definition, adversarial ones; that is they involve two opposing interests or claims and the outcome is disputed. For specific types of cases, the judicial system often relies on the specialized knowledge or experience to inform its decision-making; forensic evaluations and expertise relate to the generation, judgments, and/or communication of information that relates to a legal issue. This "information" (typically provided in the form of an opinion and the basis for that opinion) is provided to judicial entities, often referred to as a trier of fact and/or law (TFL). A trier of fact (TF) can be a judge or a jury; the trier of law (TL) in a legal issue is always a judge (or panel of judges). The purpose of any forensic evaluation is to bring information in the form of a clear, well-substantiated opinion to a legal setting that provides useful information to the TF/TL so that they, in turn, can make a more informed decision about the individual for whom they must make some determination. Forensic mental

[1]It is of note that in the United Kingdom, the practice of forensic mental health practice is defined as almost exclusively as that occurring in or in anticipation of involvement with the penal and secure hospital settings.

health professionals (FMHPs) are any mental health professionals (MHPs), independent or agency-based, who practice mental health care that is either anticipated for a court or legal proceeding (e.g., a potential or scheduled hearing, such relegated to dispositions or conditional release) or related to an existing court mandate (e.g., court-ordered evolutions or treatment). FMHP must be able to translate psychological—or more broadly mental health—information including the state of knowledge in the fields relevant to a case and/or the results of a particular mental health evaluation, into a legal framework that has particular concerns with the admissibility of information and occurs within an adversarial system. In addition, forensic mental health practitioners recognize the great significance of maintaining a neutral role relative to the persons that they evaluate or offer opinions about; they are advocates for their scientific and professional findings and not for a particular individual/client.

Forensic evaluations of alleged and adjudicated sexual offenders generally pertain to the disposition of a particular sexual offender or, in select cases, a specific legal conclusion and, as such, typically play a very significant role in a range of matters concerning such persons. Persons occupying central roles in the criminal or civil commitment proceedings of sexual offenders may lack the necessary background to understand or appreciate both issues related to sexual offending and the methods and results of a forensic psychological evaluation. In most cases, one cannot expect or assume that attorneys for the parties or judges are particularly conversant in the multiple, interacting fields relating to the forensic evaluation of recidivistic sexual offenders. As a result of lacks, gaps, or even mistaken knowledge regarding sexual offenders by the TFL, the role of a conscientious, comprehensive, and rigorous forensic evaluation can typically be of great significance to a particular legal matter. Judicial officers and juries may give considerable weight to the opinions of professionals they believe have credibility or have deemed to be "experts" in a field such as sexual offending. Consequently, an appropriately conducted forensic evaluation offering well-considered conclusions based on structured methodology and informed by a reasoned understanding of the extant scientific literature can have great impact on the disposition of a sexual offender. Conversely, the results of a poorly rendered, incomplete, or erroneous evaluation can result in a negative outcome for one or both parties.

Frequently the nature of an evaluation for a legal or pubic context will result in "live" testimony about a report derived from a forensic evaluation but that is not always the case. There are a number of situations, including "high-stakes" legal matters such as civil commitment, where the report(s) of evaluators may be all that is "admitted" to a judge (e.g., provided to the judge for their consideration) without questioning by attorneys for opposing sides and those reports may be central to the judicial officer's decision. Consequently, on many occasions there is the opportunity for the methods and conclusions of a forensic evaluation to be challenged in court. However, it may often be the case that a legal decision with significant implications for a particular sexual offender may be made based largely on just the report submitted regarding the forensic evaluation and resulting opinion. Such reports of a forensic evaluation may be "admitted" into evidence; in this way, the author of forensic evaluation is typically functioning as an "expert" in the judicial proceeding, whether he or she is formally or informally identified as such by a court.

The matters at issue and the methods required for forensic evaluations of sexual offenders can be quite complex. Forensic evaluations of sexual offenders involve the intersection of multiple areas of substance and process: knowledge of the relevant legal issues to the specific forensic task; the nature of sexual offenders and sexual offending; the methods of conducting evaluations of persons in forensic contexts generally and sexual offenders specifically (e.g., the particular ethics and methods of forensic assessments); both general and special assessment techniques for acquiring relevant multisource information; detailed information about the history of the particular individual being evaluated; the quality and scientific integrity of the available information about sexual offenders, including knowledge about treatment options and outcomes as well as risk assessment; the integration of specific information about a particular offender with the general literature on sexual offending; and the application of the specific results of the evaluation, in the context of general knowledge about sexual offending, to the specific psycho-legal question before the court. Unfortunately, the assignment of forensic evaluators (typically by court administration or agencies) in many jurisdictions is often more a matter of convenience, familiarity, and cost and much less a matter of expertise in forensic evaluations in general or sexual offender evaluations in particular. Thus, evaluators may be (1) clinicians who are general practitioners who have limited knowledge of or experience with sexual offenders, or even more broadly, criminal offenders, or in making informed determinations of risk for violence; (2) clinicians who provide treatment and related assessments for sexual offenders but who lack knowledge or experience in conducting forensic evaluations; (3) forensic evaluators who lack knowledge or experience with sexual offenders or who lack knowledge of the literature on risk assessment for dangerous or violent behavior. A key element relative to conducting forensic evaluation of sexual offenders is competency across a broad range of areas, all of which are very important. Clearly, there are many professionals who should not conduct forensic evaluations of sexual offenders due to lack of knowledge, lack of familiarity with methods of evaluation, and/or inexperience.

Ideally, an appropriate professional for conducting a forensic evaluation of a sexual offender is one who has relevant knowledge of or experience with sexual offenders, is

knowledgeable about the specific issues and methods involved in forensic evaluations, and is educated about risk assessment of dangerous behavior, such as risk assessment for sexual offender recidivism. In general, conducting a formal assessment of sexual offenders would direct that the evaluator be familiar with the current state of all relevant research on sexual offenders (McGrath, 1991). Forensic evaluations of sexual offenders *require* that evaluators possess a substantive and comprehensive knowledge of the existing literature regarding the scientific research conducted on sexual offenders and on sexual and nonsexual predisposing conditions associated with such offending and/or criminogenic needs, elements of theories of sexual offending, and risk assessment, in particular. Over the past 15 years, the professional mental health literature regarding sexual and other violent offenders has expanded dramatically. Moreover, the sophistication, controversies, and complexity of both theory and empirical findings in this area have also increased to a point where it has become a very broad and complex area requiring significant training, knowledge, and experience. An evaluator must be able to compare what is known about a particular sexual offender (idiographic features) to the accumulated data on the characteristics of sexual offenders in general (nomothetic or group information). Since this is an evolving science, it is incumbent upon such evaluators to stay current with all emerging information about sexual offenders. More generally, it is also essential that a person conducting an evaluation of a sexual offender that will or may become part of a legal decision be knowledgeable of the methods and instruments (e.g., record review, structured psychological assessment including tests and interviews) that are relied on to develop an opinion about a particular offender. If a particular case entails an actual court hearing, such evaluators must be able to explain the particulars of those methods and instruments, including their limitations. Consequently, persons conducting forensic evaluations of sexual offenders must be well-trained in the general range of tools of mental health assessment and those that are more specific to the domain of sexual offender characteristics and issues. Finally, persons conducting forensic evaluations of sexual offenders should have an appreciation of (1) the meaning of a "forensic" role; (2) the key legal standards that allow the results of an evaluation to be brought to the court; and (3) the specific legal issue(s) that a report and/or testimony are intended to address.

Qualifications for Forensic Evaluations

Since 1962, psychologists have been afforded the opportunity to be recognized as "experts" in U.S. courtrooms if deemed qualified to provide admissible testimony (e.g., Jenkins v. U.S., 1962; of particular note, this was a case involving an attempted sexual offense and the key issues were "mental disorders"). MHPs who are requested to provide forensic evaluations explicitly or evaluations that are likely to be used in legal proceedings have several obligations. It is recommended that such MHPs who evaluate sexual offenders (1) have an advanced degree in a recognized mental health discipline and (2) documented up-to-date training and supervised experience evaluating this population (in using the key assessment procedures such as tests and other psychological measures) necessary for the evaluation. MHPs who elect or are designated to perform designated or de facto forensic evaluations must be capable of demonstrating their competence in both the issues and procedures of a forensic evaluation. Competency in the evaluation of sexual offenders and, more specifically, the forensic evaluation of sexual offenders should be listed with state licensing bodies. Most mental health professions have codes of ethics that prohibit the members from practicing outside their area of expertise as well as codes of ethics that are considered binding. More specifically, the Association for the Treatment of Sexual Abusers (ATSA, 2004, 2014) has continued to formulate and promulgate standards of care and ethical guidelines for the assessment of sexual offenders.

Finally, it is important to note that beyond ethical recommendations for professional evaluators, within particular professions more specific aspirational guidelines may apply to such professionals. Thus, psychologists should be familiar with the original Specialty Guidelines for Forensic Psychologists (SPGF: 1991) as well as the revised SGFP (2011). Psychiatrists should be familiar with the Ethics Guidelines for the Practice of Forensic Psychiatry (2005), while social workers are guided by the Code of Ethics of the National Organization of Forensic Social Workers (1987) and related National Association of Social Workers' Code of Ethics (1999a). For professionals of other disciplines who conduct forensic evaluations of sexual offenders, a review of the available guidelines for other disciplines should provide a reasonable orientation to the ethical issues that surround such work. Such professional guidelines differ from standards, such as those in the professional associations' ethics codes, in that they are aspirational rather than mandatory. They are intended to facilitate the continued systematic development of the forensic activities of particular professions and to facilitate a high level of practice by MHPs.

Authorities in the area of forensic mental health are quite clear about the importance of the expertise and qualifications necessary to conduct forensic mental health evaluations. As Heilbrun and Brooks (2010) emphasize relatively untrained or individuals lacking in the necessary set of fundamental skills required for FMHA should not provide such forensic services. They point to evidence that many forensic or "intended as forensic" reports "are deficient in their thoroughness, relevance and accuracy" (p. 236) Heilbrun and

Brooks (2010) noted that "Poor practice is marked by very substantial limitations that grossly impair its relevance, accuracy, helpfulness or overall quality. Such limitations … include extreme brevity, a very short interview, relying on self-report only without testing, records, or third-party information using outdated or entirely irrelevant tests, making substantial errors in scoring or interpretation, or failing to grasp the relevant legal constructs associated with the evaluation … there is good reason to think that poor practice of [FMHA] has the potential to harm the accuracy of legal decision making … across a range of legs decisions …." (p. 242) Heilbrun and Brooks argue that forensic reports and opinions prepared by MHP with specialized forensic training generally reflect significantly better "work product." Further, across a series of studies and reviews, Garb (1989, 1992, 1998) has emphasized the critical role that training plays in enhancing the quality of psychological assessment and their resulting conclusions. Thus, for forensic evaluations of sexual offenders—and particularly for such evaluations for so-called high-stake decisions such as civil commitment—there should be a premium placed on the utilization of well-trained, knowledgeable, and experienced forensic evaluators.

Forensic Evaluations Are *Not* Clinical Evaluations, While Most "Clinical" Evaluations *Are* Forensic Evaluations: Variations of a Forensic "Ethic"

All evaluations of sexual offenders to address particular psycho-legal issues at the request of a court or in anticipation of an eventual court hearing (again including treatment amenability or treatment status (relative progress) in mandated sexual offender treatment) are *forensic* psychological evaluations. Rosner (2003) provided a simplified notion of the four steps in conducting forensic evaluations. Following his analysis, those steps can be described as: First, what are the *specific psycho-legal issues* involved? Second, what are the *legal criteria* that must be addressed to provide information about that issue? Third, what are the *data or information* that are necessary or central to allow the evaluator to understand the individual in the context of related psycho-legal issues? Fourth, what is the reasoning that is used to integrate and apply the data or information to allow for a reasonable or rational psycho-legal opinion? Heilbrun (2003) has offered a similar set of the four major components of a forensic evaluations, generally and as they might apply specifically to such evaluations of sexual offenders. They include (1) preparation, (2) data collection, (3) data interpretation, and (4) communication.

Greenberg and Brodsky (1998) stated that forensic evaluations entail the application of the principles and processes of mental health science and practice in assessment to forensic or legal issues. A forensic MHP's thinking is focused on the primary forensic task of *critically* or *skeptically* examining the people seen within a particular psycho-legal context, and not on treating them or advocating for an individual in any capacity. A forensic evaluation is time-limited and not an ongoing process. Such evaluations in cases involving sexual offenders attempt to answer questions about the nature of an individual's psychosocial characteristics and/or "psychiatric" status (or more broadly mental disorders), significant characteristics of their past, and their current presentation in terms of relative openness (or defensiveness) and as they might relate to disposition and/or future behavior.

Recognizing that a forensic psychological evaluation is *not* a traditional, clinical "for diagnosis and/or purely treatment planning clinical evaluation is critical. Over 15 years ago, in a seminal article, Greenberg and Shuman (1997) wrote about some of the *irreconcilable* differences between the therapeutic and forensic approaches to evaluations, specifically with regard to so-called role conflicts. In a forensic context, the cognitive set of the MHP is one of neutrality, objectivity, and detachment, as opposed to the supportive, accepting, and empathic stance of a clinician. The professional's role is evaluative and the relationship with the subject may even be adversarial, as opposed to the "helping" role that characterizes the therapeutic relationship. The most important competencies are in the area of forensic examination techniques relevant to the specific legal claims and the application of mental health knowledge to the psycho-legal criteria used in legal adjudication. In a forensic context, the work is examiner-structured and much more structured than therapy might be. In therapy, most of the information is received from the person seeking treatment (e.g., self-report), with relatively little scrutiny of that information by the clinician. In a forensic context, however, litigant or party information is always supplemented with and compared to that of collateral sources; subject-supplied information is carefully scrutinized by any evaluator or clinician acting in forensic role or context and not accepted at "face value" as "true." While a clinician is supportive of the individual's claimed subjective experience, attempts to "benefit" the client and to act as an advocate for that patient, the forensic MHP advocates for the critical analysis of results of the overall information available and the implications of their evaluation in the context of the immediate or eventual legal process. Obviously, the principle of advocating for the results and implications of an evaluation (as opposed to a current or potential client) can create difficulties for clinical personnel providing forensic evaluations (such as for treatment amenability or needs) and particularly for those providing forensic treatment. In such roles, the MHP must balance society's need for critical, well-founded judgments about a particular sexual offender (with public safety concerns quite commonly paramount) with concerns about alienating the subject's potential motivation and pursuit of treatment.

Greenberg and Brodsky (1998) broadened this discussion of the incompatibility of clinical and forensic roles and attempted to define a "forensic ethic" that can be applied to any MHP involved in conducting evaluations that are ordered by or are likely to be utilized by the public via the judicial system (e.g., forensic work). This ethic includes the following components for forensic MHP as evaluators: they *remain dispassionate* as to the legal issues they examine; they are *skeptical* rather than accepting of the information presented to them; and they work to avoid forming a therapeutic alliance with the people they examine for forensic purposes. In addition, the individual examined by an MHP serving in a forensic role bears the burden of convincing that professional of the accuracy and the merit of their report of events and themselves. The forensic ethic further includes that forensic MHPs are wary of the vested interests of the parties they examine (e.g., for sexual offenders, commonly a desire for less severe sanctions and/or a less restrictive disposition); maintain a belief system that encompasses fairness, impartiality, and objectivity toward the participants in the legal dispute; are expected to have the ability to tell others, often in a very public forum, about what they have learned from and about the person they have examined; and have the responsibility to respect the rights of all parties involved in a psycho-legal matter, including the examinee and the community. As Greenberg and Brodsky (1998) argued, the question is not whether as experts forensic MHP can make better decisions than judges or juries; the significance of their role pertains to whether the legal system can do a better job with their input rather than without it. As Greenberg and Brodsky wrote, if the legal system can make more informed and therefore more just decisions with their input, then forensic MHP have contributed significantly to the judicial process. As relative experts, forensic MHPs provide factual, scientific, and opinion information to help a judge or jury make the ultimate legal decisions in the matter before the court.

Relative to providing an appropriate "Forensic Mental Health Assessment" (FMHA) Heilbrun (2001, 2003) identified a set of 29 principles for forensic mental health assessment, identified as either established or emerging relative to professionals serving in a forensic role. Among these 29 FMHA principles that seem most relevant to the evaluation of sexual offenders are the following: identify the relevant forensic issues; accept referrals only within one's areas of expertise (or competence); avoid playing the dual role of clinician/advocate and forensic evaluator; use multiple sources of information for each area being assessed; determine whether the individual understands the purpose of a forensic evaluation and the associated limits on confidentiality; use relevance and reliability/validity as guides for seeking information and selecting data sources; obtain relevant historical information; assess relevant clinical characteristics via reliable and valid ways such as structured psychological assessment; assess legally relevant behavior; use third-party information in assessing response style; use testing, as part of structured psychological assessment when indicated, in assessing response style; utilize evidence from both case-specific, idiographic (comparing the individual to his own behavioral history and functioning at other times) and nomothetic (comparing an individual's functioning on relevant dimensions to that of similar populations) sources in assessing *clinical or predisposing conditions and causal connections*; use scientific reasoning in *assessing causal connections between clinical or predisposing conditions* and functional abilities; be careful, impartial, and thorough when presenting the data and reasoning in a report; provide and describe data so that the source of any specific finding or conclusion is clear; and, as necessary, base opinions on psycho-legal issues on the basis of the results of a properly performed comprehensive forensic evaluation.

Heilbrun (2003) identified that for most principles of FMHA, there was some difference in their applicability to sexual offender-specific FHMA. For 16 of the principles, some modification was required, with Heilbrun noting: "These modifications reflected the difference in focus between evaluating the "clinical condition" of offenders generally in the particular aspects of functioning related to sexual offending, which are typically aspects of thinking, personality, arousal, and behavior rather than mental disorder. It is also important to modify the kinds of tools used, considering those validated for sexual offenders, and focusing particularly on the kind of forensic issues raised in such sexual offender-specific FMHA (reoffense risk and potential for risk reduction). However, these modifications are relatively minor, and fit comfortably within the domain of the larger principle" (p. 182). Heilbrun concluded: "This analysis suggests that a set of FMHA principles like this can offer substantial guidance in the forensic evaluation of sexual offenders" (p. 182). He noted that, with relatively few modifications, his proposed principles could provide a framework to guide the process of forensic evaluations with such individuals.

Most recently, Covell and Jennifer Wheeler (2006) revisited the issues of "irreconcilable conflicts" between therapeutic and forensic roles, specifically for sexual offender "specialists." They noted that the issue of dual role conflicts in the field of sex offender management had historically received little or no attention. However, they also pointed out that recently that this has changed. For example, in Washington State, clinicians offering treatment and evaluations services are discouraged from providing forensic evaluation and treatment services to the same client in order to avoid potential bias and questionable conclusions. Similar to the perspective of this chapter, Covell and Wheeler pointed out that if the purpose of an evaluation of a sexual offender is "to provide clinically relevant data to a third party, who must make an important decision about the offender," then such

evaluations necessarily are forensic sexual offender evaluations. Since most therapeutic sexual offender evaluations take place under the aegis of court order, possible litigation, and/or community corrections supervision, while one goal may be to inform treatment planning and delivery, necessarily that same information has implications for other decisions about the sexual offender to third parties. Thus, it appears that there is an increasingly convergent perspective that most evaluations of sexual offenders are, in fact or principle, forensic mental health evaluations.

General Legal Issues Central to Judicial Consideration of Forensic Evaluations and Related Opinions

Courts necessarily impose limitations on the types of information that they will consider from mental health professionals in providing the results of their evaluation and related opinions as a form of "expert witness" testimony. Judicial entities are required to allow only particularly "useful" information to be provided to TFL; this is referred to as the admissibility of evidence in the form of a report (and its elements) and the opinion of a forensic evaluator. Historically, the basis for the admissibility of expert opinion was rooted in the determination that the subject of that opinion was beyond the normal experience of the average trier of fact. An early decision (involving the admissibility of polygraph evidence), *Frye* v. *United States* [293 F. 1013 (D.C. Cir. 1923], defined the principle for evidentiary admissibility that the information provided by the expert "must be sufficiently established to have gained *general acceptance in the particular field* in which it belongs" (emphasis added). This standard for admissibility was known as that of "general acceptance" within the relevant "scientific community." Nicholson (1999) has written that the "general acceptance standard" described in Frye was meant to apply to then novel scientific evidence and targeted not the expert's opinion per se but rather the theories and methods from which the expert's opinion was derived. Similarly, Hoge and Grisso (1992) noted, "Frye does not mention accuracy, validity, or even 'general acceptance' of the opinion or conclusion that the expert reaches on the basis of these theories and methods" (p. 69).

Some 50 years later, Congress passed the Rules for Evidence (RFE 702–705) governing Expert Witnesses Testimony and Opinion in the Federal Rules of Evidence (Article 7, 1974) which were developed to provide guidelines for cases in Federal court. Some states have also used the Rules as models or guidelines for the admissibility of such testimony, so it is useful to review the rules here. Rule 702 on "Testimony by Experts" states:

> If scientific, technical or other specialized knowledge will assist the Trier of Fact to understand the evidence or determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise.

Rule 703 describes the appropriate Bases of Opinion Testimony by Experts: "The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence." Relative to the *Frye* test of general acceptance, Rules 702 and 703 have been viewed as broadening the potential scope of expert testimony and thus creating a potential conflict between the Rules and the *Frye* precedent. In *Daubert v. Merrell Dow Pharmaceutical, Inc.* [509 U.S. 113 (1993)], the U.S. Supreme Court ruled in favor of the Federal Rules of Evidence and the doctrine of a broader admissibility of expert opinion. Briefly, Daubert had listed four factors that courts *could* take into account in making the gatekeeping assessment—whether a theory or technique has been tested, whether a technique or theory has been subjected to scientific peer review or published in scientific journals, whether there was a known or potential rate of error involved in the technique or theory (e.g., inter-rater reliability and/or "predictive accuracy" or discrimination), and even some evidence of general acceptance among relevant professional communities. Often, the *Daubert* decision is viewed as articulating a middle ground where new research not yet generally accepted could be permitted, while poor quality science and nonscientific clinical perspectives that had obtained "general acceptance" would be excluded. In effect, the standard established by *Daubert* was one in which the credentials of the expert witness go to the credibility of the witness, not to the admissibility of the testimony. Further, the value of expert opinion was to be determined on the basis of direct and cross-examination by the attorneys for the parties and the presentation of contrary evidence, including other expert opinion. The Trier of Law functions as the "gatekeeper" for the admissibility of expert testimony. Per the decision, the FRE/Daubert criteria were not meant to be applied by the judiciary as "a definitive checklist or tests…" and mandatory; rather, they were to be considerations along with relevancy. *Daubert* is viewed as representing a trend toward a more demanding level of scrutiny by courts, one in which scientific evidence of research supports the forensic expert's evaluation methods, procedures, and resulting opinions and the larger body of knowledge and practice in a particular area. At the same time, Daubert provides for the admissibility of more novel information that may not have reached the level of "general" acceptance but nonetheless is well founded in its development. According to *Daubert*, the trial court must determine whether the proposed expert testimony regarding "scientific knowledge" has a reliable foundation

(appropriate data and methods) and is relevant to the proceeding. *Kumho Tire Co. v. Carmichael*, 526 U.S. 137 (1999), was a U.S. Supreme Court case that expanded the *Daubert* standard to expert testimony from nonscientists (e.g., technical or specialized knowledge), based on the premise that it could be difficult to distinguish between scientific and technical knowledge. The reliability of proposed evidence (e.g., a forensic evaluation) is to be evaluated on the basis of whether the methods and the background data have been subjected to empirical testing and received peer review and/or been published in peer-reviewed journals. Further, the known or potential error rates are also to be considered. The general acceptance of the substance of the expert testimony in the field can be a consideration. The potential relevance of the opinion from a forensic evaluation is that the information provided by the expert has a valid scientific or professional connection to the key issues in the legal matter. In Kumho, the Supreme Court clearly indicated that district courts have relatively broad latitude to determine how they will assess the reliability of expert testimony as a component of the decision to admit expert testimony.

Finally, the Federal Rules of Evidence were modified by Congress in 2011 so that the language was clarified; they now read:

A witness who is qualified as an expert by knowledge, skill, experience, training, or education may testify in the form of an opinion or otherwise if:

(a) The expert's scientific, technical, or other specialized knowledge will help the trier of fact to understand the evidence or to determine a fact in issue;
(b) The testimony is based on sufficient facts or data;
(c) The testimony is the product of reliable principles and methods; and
(d) The expert has reliably applied the principles and methods to the facts of the case.

Another U.S. Supreme Court decision of relevance is that of General Electric Company v. Joiner (1997) which allows the court to consider whether an expert has extrapolated appropriately (or in appropriately) from an accepted premise to a particular conclusion.

Relevant Issues in the Forensic Evaluation of Sexual Offenders

Understanding and Clarifying the Nature of the Specific Psycho-Legal Issue

As noted, the evaluator, both in conducting a comprehensive forensic evaluation and in providing a full and integrated report of the available data and opinions, is involved in an attempt to assist the court in its decision-making process. Initially, this task requires clearly understanding what question or issue is the focus of the forensic evaluation. Psycho-legal questions are typically based in statutory language and case law that has developed regarding the relevant issue. While the legal system and its relevant players should be expected to make available to forensic evaluators the relevant statutes and any subsequent amendments, forensic evaluators are responsible for and should make it a point to obtain a copy of and regularly review the relevant statutes and/or administrative codes relating to their forensic tasks. Ideally, evaluators should attempt to repeatedly seek clarification and updates about evolving case law and the specific questions their evaluations and reports should address based on who has requested their opinion. As noted later, it is useful to review the requisite statutory questions while preparing an evaluation and to note or paraphrase the language that directs the forensic evaluation within the body of a report.

The Forensic Opinion

As noted, the goal of a forensic evaluation is the education of the TFL by attempting a comprehensive evaluation of an individual, developing an opinion or appraisal regarding how a particular legal context applies to that individual, and describing in detail the basis for that opinion. Consequently, the forensic evaluator attempts to collect, review, consider, and integrate information ("the database") that can allow them to opine about the psycho-legal questions that exist in the current legal matter. At the risk of being simplistic, this means two things. First, the forensic evaluator should attempt to come to an opinion about the identified psycho-legal questions. It is conceivable that this may not be possible for a particular evaluator or expert and they should so inform the retaining party or the court. For example, it would be inappropriate for a MHP to agree to offer opinion or testimony relative to a statute that they do not regard as legal or acceptable to their personal values (e.g., constitutional, for example) unless that is the actual subject of a case. Second, the evaluator must conduct a sufficiently thorough and critical analysis of the available essential sources of information (e.g., primarily through record review and the results of a direct evaluation) and then be able to offer a credible explanation of how they reached particular judgments and opinions about a particular offender, in the context of the specific case information and existing science and other professional knowledge regarding issues related to sexual offending. Per Rosner's model, a forensic evaluation must provide clarity and depth relative to describing and explaining what and why critical elements form the basis of the expressed opinion. Heilbrun et al. (2009) proposed that: "Opinions should be data based, including thorough consideration given to all sources of information; comprehensive notes of litigant's interview responses; results of all psychological tests and instruments; information provided by third parties; and a

review of records. Relevant studies, published in peer review journals on issues related to the specific case, should be considered as well." (p. 55)

In providing an opinion via a written report and/or in live testimony, forensic MHP evaluators are almost always asked to affirm that their appraisal process was based upon records and procedures typically relied upon by professionals doing similar work and that they have a relative confidence of opinions generated in an evaluation or report, typically to "a reasonable degree of professional certainty." The term "reasonable degree of psychological or professional certainty" remains a concept without precise meaning; Heilbrun notes that there appears to be no consensus as to what this means. It is likely that scientific certainty is not the appropriate standard to use for FMHA because FMHA incorporates both scientific data (e.g., psychological tests, results of scientific studies) as well as idiographic data (information about and/or provided by a litigant). Faigman (2006) noted that the term medical or psychological certainty "has no empirical meaning and is simply a mantra repeated by experts for purpose of legal decision makers who similarly have no idea what it means. Case-specific conclusion, in fact, appears to be based on an admixture of knowledge of the subject, experience over the years, commitment to the client or case, intuition, and blind faith...." (p. 1224) Nicholson (1999, citing Black, 1988) points out that reasonable professional certainty refers to an evaluator or expert's confidence in their opinion and not to the accuracy or general acceptance of the theory.

Potential Limitations of Self-Report in Forensic Evaluations, Particularly of Sexual Offenders

By nature, as noted, forensic evaluations in general occur within an adversarial context: two parties are pursuing differing and opposing goals. Consequently, an independent forensic evaluation of the key party almost always involves some subtle or explicit element of perceived coercion and/or desired gain by the subject of the evaluation; these elements are viewed as playing a potentially significant role in the manner of presentation of persons subject to forensic evaluations in most contexts. As Heilbrun et al. point out: "Forensic assessments differ significantly from traditional clinical evaluations in the presence of substantial external incentives to deceive the forensic examiner." (p. 49) Melton, Petrila, Poythress, and Slobogin (2007) wrote of forensic evaluations generally: "… because of the greater need to consider alternative views and to corroborate examinee/litigant reports about legally relevant events, the examinee's unique perspective is only of secondary importance in forensic evaluations." (p. 45) Greenberg and Shuman (2004) called attention to the fact that a substantial number of required "diagnostic criteria" for psychiatric categories reference internal events (so-called subjective "symptoms," in contrast to more objective "signs" such as behavior) and thus involve the veracity or ability of an individual in providing self-report. Greenberg and Shuman also emphasize that litigants are likely to be motivated to report symptoms in line with the "incentives" or their goals for a particular legal case. Given the nature of how most sexual offenders find themselves in an evaluation context in a manner related to potential or pending legal actions, similar issues are likely to exist with regard to the evaluation of sexual offenders and may well be considerably more acute or significant than in the appraisal of other litigants.

Further and more specifically, a reliance on self-report by known sexual offenders has already been identified as quite problematic both as a source of general information about themselves and more specifically regarding their sexual offending history. Dissimulation, in particular defensiveness and outright lying, is viewed as a highly common, if not endemic, characteristic of both alleged and convicted sexual offenders, particularly when queried about their sexual offense history (e.g., Beckett, 1994). Generally, Gudjonsson (1990) showed that "other-deception" or impression management was particularly characteristic of violent and sexual offenders in a forensic evaluation, indicating that they underreported undesirable personality characteristics and psychopathology; he speculated that such persons attempted to give the impression that they were basically considerate people irrespective of what their alleged offenses suggested.

Generally, a significant group of sexual offenders are characterized by antisocial, narcissistic, and borderline traits and Personality Disorders; another, albeit overlapping group of sexual offenders are also characterized by significant psychopathic traits. Generally, persons with significant degrees of maladaptive personality traits experience those traits as "ego-syntonic" and not as problematic. Thus, Logan (2009) noted that both self-insight and honesty are likely to be questionable in the assessment of more self-centered individuals and is more meaningfully assessed via interpretations of interview responses and record review (as opposed to direct questions about the presence of maladaptive traits). Jackson and Richards (2007) reported that that offenders' ability to accurately report on their personality characteristics is hampered by their emotional and affective deficits. In addition, Logan also identified that egocentric or narcissistic individuals are not particularly useful sources of information with regard to their risk for potential future harm or success in the community. Clipson (2003) wrote: "The evaluation of sexual offenders offers a challenge unlike that found in either a general clinical practice or even in a forensic setting. All forensic assessments must address the possibility that the person being interviewed may minimize, deny, exaggerate, or feign a psychiatric disorder to obtain a desire outcome. The sexual offender in particular is prone to be dishonest about his behavior for several reasons" (p. 128). The Center for Sexual Offender Management (CSOM) in a paper on the role of

assessment in sexual offender management stated: "*Self-report is inherently unreliable*" (p. 5, emphasis added).

More specifically regarding their sexual histories, Earls (1992) has noted: "The reticence on the part of the offender is different from most clinical situations … it also poses difficulties when attempting to determine the nature and magnitude of the problem" (p. 233). More particularly, as one writer put it, "[S]exual aggressors have a marked propensity to lie about, deny, and minimize information concerning their deviant sexual behavior" (McGrath, 1990, p. 507). Context-based dishonesty about one's sexual offending history has been scientifically demonstrated. Kaplan et al. (1990) compared reports of sexual offenders on parole in two different settings. In a criminal justice setting, offenders disclosed only 5 % of the sexual offenses later admitted to in a traditional clinical or mental health setting (where confidentiality was provided). [Of note, Abel et al. (1987) reported that offenders revealed approximately 20 % more types of sexual deviancy when re-interviewed by experienced interviewers.] Consequently, regarding general behavioral history, personality characteristics, and sexual offending history, a sexual offender's comments in the records and in a direct evaluation must be carefully examined, compared and analyzed in terms of their context and not simply taken at face value. Alleged or convicted sexual offenders rarely present for evaluation in a truly voluntary manner; they are generally defensive relative to a specific evaluation. This defensiveness may be manifested by minimizations, by denial, or by statements that the individual cannot or does not remember. Kennedy and Grubin (1992) noted four patterns of denial from a cluster analysis of responses by convicted sexual offenders: (1) males who admitted offenses but denied causing any victim harm, (2) males who externalized responsibility for their sexual behavior by blaming their victims or others, (3) offenders who admitted their offense but attributed those behaviors to altered mental states or temporary behavioral aberration, and (4) offenders who were characterized by total denial of their offense (the largest group). Generally, such presentations are particularly true for evaluations that are part of an adversarial process, relative to those perceived as for treatment evaluations. Further, many sexual offenders, particularly repeat offenders, are characterized by single or multiple sets of cognitive distortions, rationalizations, and denial. These beliefs may, in certain cases, rise to the level of a delusional belief (such as non-bizarre, but firmly held convictions). Thus, in discussing their beliefs about historical circumstances of sexual offenses or themselves, such offenders may present as quite convinced of the validity of their beliefs and memories or recollections. Further, from the perspective of the offender, reporting their sexual offense histories may be viewed as possibly eliciting negative responses from evaluators (e.g., disapproval, condemnation). Perhaps more importantly, such reporting, particularly for alleged and non-adjudicated offenses, certainly carries a risk of eliciting further negative consequences from the judicial system.

In short, issues of veracity permeate the self-reports and therefore the records of most sexual offenders. Consequently, the availability of objective psychometric tests with validity scales in the records and their use in a current direct evaluation offer some means of gauging a respondent's approach to self-disclosure and impression management over time and at the time of the most current evaluation. Further, congruence between the offender's report and those of collateral sources (such as victims, probation or correction officers) and therapists can provide support for judging the quality and truthfulness of an offender's self-report and self-evaluation.

Importance of Multiple Sources of Information

Generally, psychological assessments should be multi-trait, multi-method evaluations (e.g., Campbell & Fiske, 1959). This involves collecting information about multiple aspects of an individual (e.g., varied personality, social and psychosexual characteristics) from multiple perspectives or methods (e.g., sources of information such as interviews, records, and self-report via structured psychological testing and ratings). This issue is of particular importance in the forensic evaluation of a sexual offender given the potential limitations of the self-report of the offender; the availability, use, and comparison of multiple types of information are considered essential. As Heilbrun (2003) pointed out "multiple sources of information serves several important functions in forensic assessment: minimizing the error associated with a single source, assessing the impact of evaluatee's deliberate distortion of sensitive information, and providing a way to communicate the thoroughness of the evaluation. Other writers have emphasized that forensic evaluators typically rely on three primary kinds of data to form their psycho-legal opinions: third-party information (e.g. documents or records and/or the reports of persons other than the examinee), standardized psychological testing, and interviews of the examinee. These three different sources of information have been labeled the so-called forensic data triangle" (Gagliardi & Miller, 2008).

When information from multiple sources such as self-report, collateral records, and collateral interviews provides a consistent portrayal of an individual, it is more likely that this information is accurate. Conversely, inconsistency and disagreement across sources should alert the forensic clinician to the presence of inaccuracy in at least one of the sources. Thus, any forensic psychological evaluation involving sexual offenders should include a multi-method, multisource assessment. No one method or source (self-report, records, testing, or collateral perspectives) is necessarily protected from the possible taint of distortion.

Consequently, the overall value of the evaluation, its reliability and validity, is dependent on the evaluator's ability to collect and review varied historical information, typically to obtain their own contemporaneous data (e.g., via direct evaluation involving structured psychological assessment), to test hypotheses by examining the body of extant data for convergence and divergence, and to assemble an integrated opinion based on the totality of available information. By its very nature, a forensic evaluation should be comprehensive; it should aim to collect, examine, analyze, and integrate the relevant information that allows for the psycho-legal question to be adequately addressed.

Record Review

A key principle of forensic mental health evaluations is the review of all relevant records available for the purposes of the evaluation and report. Many forensic evaluators would argue that in almost all forensic evaluations that record review is central and the *sine qua non* of most forensic opinions. Melton et al. (2007) stated "archival and third party information is a mandatory component of most forensic evaluations." (p. 53) These authorities noted that third-party data are more important in forensic evaluations due to a greater need for accuracy, differences in responses style of litigants, and the greater scrutiny that a forensic evaluator's conclusions receive. In addition, they note that efforts to confirm or disconfirm statements provided by examinees and to weigh their accounts against information from records and other sources can "significantly improve the weight assigned to the examiner's conclusions." (p. 53) Records often provide the most specific and contemporaneous description of past events that then informs many of the central questions, issues, and demands related to psycho-legal appraisals and opinions. Given the nature of the assessment issues that characterize the evaluation of sexual offenders, it is imperative that the evaluator have received and carefully reviewed the records *prior* to interacting with an examinee. Such a record review is important in that it can provide a range of perspectives on the offender, sometimes over multiple observers and over time. Heilbrun (2003) emphasized the importance of using relevant and reliable methods for seeking information and selecting data sources. He also emphasized that: "…the amount of historical information needed in FMHA is often greater than therapeutic evaluation, but the need for history also depends on the nature of the legal question and associated forensic issues…with specific sexual offender FMHA, there is consistently a question regarding the person's sexual offending and, often the risk of its recurrence. More detailed history on previous sexual offending, on the patterns of thinking, feeling, arousal, and behavior associated with offending and on protective factors, is therefore likely to be important." (p. 178) Relevant records for forensic evaluations of sexual offenders include such domains as criminal history; police reports; court records and presentence reports; offender and victim statements about crimes; records related to social history, previous psychological, social service, medical, and mental health evaluations and services (including any past treatment, particularly specialized sexual offender treatment); and jail, prison, and community corrections records.

Quite in contrast to a therapist who may often support the ego-syntonic perspective of a client, the forensic MHP's eventual role is to offer opinions regarding the validity of an examinee's personal history as well as the behavioral and psychological aspects of the subject's background and current status. Thus, as Meloy (1989) suggested the forensic evaluator necessarily engages in a critical "investigation" of what the examinee may represent as his characteristics and personal history. Rather than a posture of "support" and "acceptance" when it comes to reviewing and considering information about an examinee, the forensic evaluator necessarily takes a position of skepticism and scrutiny, whatever the potential disposition question may be. As Greenberg and Shuman (1997) pointed out: "A competent forensic evaluation almost always includes verification of the litigant's accuracy against other information sources about the events in question" (p. 53). This requires that all relevant and available records about a respondent be carefully and thoroughly reviewed, with particular attention paid to discrepancies between the respondent's past and present report (e.g., of sexual offenses, treatment course, perceived risk of reoffending) and the reports of others. Such collateral sources of information are used to either corroborate the respondent's report or to identify incongruities and to suggest possible sources of such divergence of opinion (e.g., defensiveness). Consequently, "[T] he need for historical accuracy in forensic evaluation leads to a need for completeness in the information acquired and for structure in the assessment process to accomplish that goal…" (Greenberg & Shuman, 1997, p. 54).

In reading records pertaining specifically to the history of sexual offenses, it is essential to bear in mind that much of this material was obtained through the criminal justice system. This context is an adversarial one, with possible punitive sanctions contingent on what was self-disclosed by an alleged or adjudicated offender. Further, victims of a sexual offense may refuse or be reluctant to testify or the testimony of minors may be considered problematic from an evidentiary perspective. Consequently, plea-bargaining is far more common than trials in criminal matters of sexual abuse (Brooks, 1996). Serious sexual crimes may then be bargained down to lesser sexual offenses or even nonsexual offenses. This may lead to a judicial record in which the nature of the actual sexual offense is not well described and may not result in an

adjudication that clearly conveys sexual motivation. Judges as TF or TFL may not become aware of an offender's actual history of sexual crimes and lenient sentences may result, which themselves may later be interpreted in a manner that minimizes the sexual offender's estimated future risk of dangerousness. As Rice et al. (2006) demonstrated, rapsheet sexual violence reflects approximately ½ of sexually motivated crime for particular offenders, particularly for more serious violent offenses. Consequently, it seems clear that a sanitized and minimized picture of sexual offenders and sexual offending provides the basis for the research literature; in turn, beliefs about sexual offenders based on these incomplete or misleading data are adopted and promulgated by the professional communities. In addition, just as the criminal justice system can obfuscate the actual nature of sexual offending, the same is often true in treatment settings. This can occur for several reasons. First, from a more benign perspective, the time demands on clinicians may lead to very circumscribed and generic records about treatment experiences, often reduced to numerical ratings with no specific referents for terms like "deviant arousal," "distorted cognitions," or "maladaptive attitudes." Second, and less benignly, when treatment settings (even forensic settings where sex offender treatment is effectively or directly mandated by the judicial system for purposes of public safety) view their role as primarily advocates for offenders, there can be both intentional and unintentional behavior on the part of clinical teams which results in obscuring the nature of the participation of an offender in treatment. As noted elsewhere, generic treatment notes indicating simply that certain types of interventions were employed with insufficient detail to know the basis for those interventions, the means used to measure relative success or failure, and/or reliance on self-report of the offender become effectively useless for many or most forensic evaluations. Unless treatment materials are "detail rich," so that an independent evaluator reviewing records can discern with some degree of precision what has actually taken place in sex offender treatment, relatively little can be concluded one way or another about an individual's relative progress in treatment, effectively rendering the records of that treatment experience moot or irrelevant for a particular offender. Given the more general findings of a lack of effectiveness for sex offender treatment for sexual offenders in general (e.g., Hoberman, 2015), the basis for determining treatment progress must be made on an idiographic level for a particular offender, requiring offender-specific detailed information about their offense-related treatment presentations and substantive individual, group, and assigned work. Consequently, forensic evaluators, who by definition serve the court and public, should be prepared to regard sex offender treatment records with skepticism; if an offender is alleged to have changed, such a claim must be supported via detailed, well-reasoned, and well-documented information about the nature of that offender's experience in a particular treatment setting.

Further, forensic evaluators must be aware of any "legacies of distortions or omission" from previous evaluators' ignorance of or disregard of actual records regarding both historical behavior and previous evaluations. It is often the case that previous evaluators have lacked access to some or often many original and/or relevant records and, as a result, their perceptions, findings, and conclusions about an individual reflect that. As a consequence, their context for appraising a particular offender and perspectives about that individual are based on distortions or omissions about important aspects of his background. Too frequently, prior summaries of "facts" about an individual's criminal history (and specifically their sexual offending history) have simply been "passed along" from one report to another. In addition, existing records essentially consist of a combination of the offender's self-report and professional judgment largely based on that self-report. Given the noted tendency of sexual offenders to dissimulate or distort information about themselves and their offenses, an evaluator must be vigilant regarding "legacies of falsehoods" based on the subject's biased or distorted view of his history that may run through the records. Alternately, biases about sexual offenders in general or a particular respondent's alleged or known sexual misconduct may influence the record review as preconceived biases color the manner in which both observations and interpretations of the offender's behavior in general and sexual behaviors are reported. Consequently, it is a best practice, to make a serious attempt to obtain all records regarding the subject, particularly the earliest ones available.

Records may be provided or authorized by the referral source or one or all parties to a legal matter may provide them. Generally, for forensic evaluations, it is useful to request that the attorneys for both parties in a legal proceeding provide what they deem are the appropriate set of records or identify records that they would like you to consider. If an evaluator does not receive expected or typical sets of documents from the referral sources, those records should be requested before initiating any interview with the respondent (with notice and communication to the court if necessary). As a forensic evaluator reviews the available records, one should be careful to consider and request relevant records (e.g., previous law enforcement and/or evaluation and/or treatment records) that may not have been available to you. Persistence about obtaining as comprehensive a set of documents as possible should be viewed as evidence of the forensic evaluator's competence and fairness. At some point during a direct evaluation, it can be useful to inform the subject of what records you have reviewed and inquire (and note) if there are other records they are aware of which they think exist and would like you to consider. If important record sources were not available for review, that lack of availability and the possible implications should be noted that in your report or testimony, in addition to the records that you did review, and discuss any implications for your

opinion related to the absence of such information. It is noteworthy that many forensic evaluations of sexual offenders (and particularly civil commitment proceedings) often represent the first time that a relatively comprehensive set of records regarding a particular individual has been compiled and able to be reviewed. Consequently, a different perspective of the examinee may emerge as a result of an MHP having the opportunity to examine and integrate many sources of information—including some previously unavailable—about the individual under consideration.

Archival records may reveal a number of important findings. First, there may be apparent and even blatant contradictions in the information a respondent shares at different times to different persons. While this may be simply a function of different levels of denial and/or rapport at different times and with different evaluators, it may be that the respondent's own recollections of his history of sexual offenses changes over time. It may also be a function of interviewer variability; different interviewers possess different levels of skill, knowledge, or commitment and their questioning reflects this status. As noted, Abel et al. (1990) reported that offenders revealed approximately 20 % more types of sexual deviancy when interviewed by experienced interviewers. In addition, interviews may be dominated by the agenda of a current issue or reflect an ignorance of previous criminal and/or sexual offense history so that certain questions are not asked and, as a result, relevant facts do not appear in the record. Second, records often demonstrate that sexual offenders' perceptions of themselves have often differed markedly from those who have evaluated them. Overall, then, an alleged or convicted offender's comments in the records must be carefully examined in terms of their context and not simply taken at face value. Third, the records can be critical to the determination of a respondent's actual sexual offending history and the presence of psychiatric and predisposing conditions; they are also essential for providing the basis for key risk assessment procedures for future dangerousness and for describing these and other elements that can provide the basis for a determination of the relative probability of sexual reoffending.

The types of records that should be expected to be available to an evaluator include but are not limited to:

- Criminal investigation or law enforcement reports, interviews with both offenders and victims about sexual offenses, including those that remained allegations and those that resulted in convictions;
- Juvenile records of criminal behavior and correctional and treatment experiences, particularly if a history of juvenile sexual offending exists;
- Mental health and Chemical Dependency treatment records;
- Any previous clinical or FMH assessments or evaluations, including previous test results or interpretive reports;
- Legal proceedings where charged sexual offenses were adjudicated, including judicial dispositions;
- Pre- and Postsentence Investigations, parole, and/or probation reports and records;
- Correctional system records, including those pertaining to education, work, mental health, medical, discipline, disposition plans, and specific sexual offender evaluations and treatment records.

Carefully reading this volume of original information, which may include handwritten, illegible, or poorly duplicated records, may take many hours; this is an important fact for the evaluator, the attorneys, and the TFL to be made aware of. As a practical note, it is critical to read and review the available records carefully. Just as the limited availability of records regarding an individual can limit a forensic evaluator's ability to draw a conclusion, a large number of available records may impose other burdens on an evaluator. If one is not being compensated for all of one's time or the review is otherwise time-limited, then the professional must make some determinations or negotiations as to what records will be reviewed, typically in consultation with the providers of those records. If this is the case, then the forensic evaluator should clearly indicate what records were and were not reviewed, any apparent ways this might have affected the evaluation, and most particularly the opinions and/or conclusions developed over the course of the forensic evaluation. In reviewing records, evaluators should be alert to evolving distortions or misinformation about a subject; anecdotally but quite commonly, there can be a drift from more extreme impressions regarding an individual to less extreme ones. This can occur because previous evaluators or treatment personnel were not familiar with the official earlier reports of an individual and have come to rely on the offender's representation (a typically more sanitized version) of his personal and criminal history and current presentation, often in a highly restricted environment. Subsequently, this representation comes to replace the original and more accurate observations or behaviors of the offender and creates a "legacy of distortion" about the offender's history that provides a contaminating filter through which they are viewed.

The Direct Forensic Evaluation of Sexual Offenders

Most commonly in forensic evaluations of sexual offenders, one has the opportunity to or is required to conduct a "direct" or in-person evaluation of a sexual offender as part of a forensic evaluation. The direct evaluation includes any personal contact with a sexual offender, typically including structured psychological assessment, e.g., the administration of standardized psychological testing and structured and unstructured

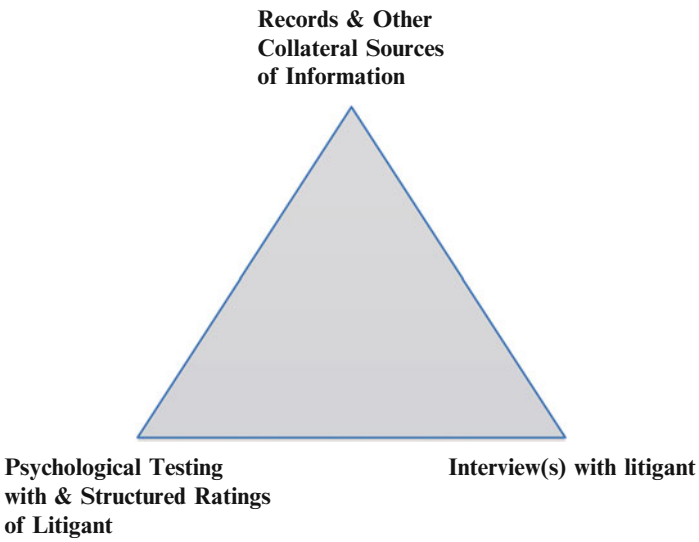

Fig. 1 Forensic data triangle

interviews. Depending on the type of forensic evaluation and the jurisdiction, the offender may be compelled to participate in the evaluation (e.g., may face some formal or natural sanctions if portions of the direct evaluation are refused). Other times, the offender may participate in a more voluntary capacity and may be invested in providing particular information to a forensic evaluator. This is particularly true in forensic evaluations relating to dispositions, treatment progress or status, and release decisions. Direct evaluations typically consist of two primary components: structured psychological assessment (e.g., psychological testing, structured interviews and rating scales) and case-specific interviews. Record review, structured psychological assessment, and structured/semi-structured interviews constitute the "three-legged stool" or "forensic data triangle" for developing the basis of a forensic findings and related opinion (Fig. 1).

Unique Elements of a Direct Forensic Evaluation

As with any FMHA—an evaluation with an explicit or implicit forensic context—the issue of deliberate misrepresentation for personal gain must always be considered; as Sewell and Salekin (1997) recommended, dissimulation should be considered in all evaluations with alleged or adjudicated sexual offenders. Meloy (1989) has suggested that there are six distinguishing characteristics of a forensic interview or evaluation; these are presented below.

1. Coercion or a lack of voluntary participation is inherent in such evaluations; the evaluator must consider the ways in which coercion will affect the process and tailor the assessment process to minimize the impact of coercive factors.
2. In forensic evaluations there is always a waiver of confidentiality and privilege.
3. The forensic direct evaluation is likely to be a critical means to obtain information that, in context, can be communicated to nonmental health professionals.
4. As a result of the coercive context, conscious distortion of information provided during forensic evaluations is almost always present. Among other distortions, Meloy speaks to dissimulation as the concealment or minimization of psychiatric "symptoms" and maladaptive personality characteristics that actually exist as well as historical information. Such "dissembling" is often indicated by the "suspicion index": a marked discrepancy between experiences and behaviors that the examinee reports and those apparent in the records, other objective findings (e.g., structured psychological assessment), and/or a lack of cooperation during the evaluation.
5. Forensic evaluations and their results will likely be "disliked and disparaged" by at least one party given the adversarial nature of litigation.
6. "Forensic [evaluations] compel the forensic clinician to assume the role of a *forensic psychological investigator.* The attitude is one of impartiality and objectivity. The expectation is that data will accumulate that will eventually answer the psycho-legal question that prompted the evaluation" (p. 340).

Given the identified issues regarding self-report relative to sexual offenders and the likelihood that an evaluator may be presented with a significant amount of archival records, the interview offers the subject a singular opportunity to provide his clarifications and perspectives on the records and to present himself in a manner that he wishes the evaluator and the justice system to consider in the context of his history.

Informed Consent and Limits of Confidentiality

In conducting an evaluation that is court-ordered or that one believes will be considered or reviewed by a court, it is imperative to disclose to the offender the specific purpose of the forensic evaluation, namely that it is a means to provide the court information to use in its decision regarding the relevant psycho-legal question (e.g., risk, treatment amenability, or meeting the criteria for civil commitment). It is also important to communicate that a forensic psychological evaluation is different from a clinical one. Most important, the examiner must address the issue of confidentiality—namely, that his or her evaluation will likely result in a written report and/or oral testimony and that the information the offender shares is not subject to confidentiality as it might be were the evaluator serving in a clinical role. In other words, one must clearly distinguish the evaluator's role as a court—or statutorily—designated examiner or as an expert witness for one or the other party. Relative to the *Specialty Guidelines for Forensic Psychologists* (2011) or other similar standards, evaluators should make clear that their role is to provide an impartial assessment and that they are neutral to outcome, regardless of being court-appointed, retained by a party to litigation, or in any way acting in a manner in anticipation of potential litigation or judicial decision-making.

It should be pointed out that there are often times when a sexual offender may elect to decline or refuse any direct evaluation by the forensic evaluator. This obviously should be noted in the report and/or in testimony. In such cases, professional ethical standards typically require that the evaluator indicate what, if any, limitations on the conclusions reached were affected by this lack of one particular source of information.

The Administration of Psychological Testing and Interviews in Forensic Evaluations

It is generally accepted that psychological testing will typically precede structured, semi-structured, and other forensic interview practices. Since psychological tests are self-report instruments, they provide a unique opportunity for the individual of concern to describe himself or herself to an evaluator at a particular time. While contextual factors will always play a role in potentially shaping the subject's responses, a goal of an evaluation is to minimize the effect of other influences. A key one is the potential effect of interview questions, both the topic of those questions and the developing perception of the interviewer by the subject. Consequently, to reduce such possible contaminating influences, forensic evaluators almost always administer psychological testing prior to initiating formal interviews. Ideally, psychological testing can be both administered and scored prior to such interviews, thereby providing opportunity for an evaluator to interact with and discuss the results or questions raised by such testing with the subject during the interview, both to seek clarification of information and to provide the subject the means to comments on what might appear to be particularly relevant findings. As a colleague noted: "One of the most significant ways to guide an interview is to utilize the content of the testing completed prior the interview. This also allows an evaluator to put some "meat" on the bones of the information one obtains from the testing and provide some direction for interpretation. In order to accomplish this, it's preferable to administer the tests first and follow this with the interview, not the other way around. There is another reason the testing should go first if possible. Often the litigant becomes defensive and/or the forensic interview gets adversarial; as necessary, the interviewer must confront the evaluatee with discrepancies in their own accounts or presentations of information or conflicts with the available records. The testing session(s) following possible confrontations will likely be affected and on more than one occasion after a tough interview the client refused to take the tests. In addition, doing the testing first typically allows the development of some rapport and cooperation that may even add legs to the interview even when it is adversarial and contentious" (Riedel, 2012)

While this should be obvious and well known to professionals, including attorneys representing alleged or adjudicated sexual offenders, testing is intended to be administered under standardized conditions. Per the American Psychological Association (APA, 2007): "Psychologists enhance the validity of evaluation results by adhering to standardized procedures (when the techniques they use outline standardized administration procedures) and by developing and sustaining rapport with the examinee. In most testing manuals, standardized procedures and recommended practices for developing and sustaining rapport specify that only the psychologist and the examinee are present in the assessment setting." (p. 1). The APA notes studies showing various compromised findings when testing is administered with third-parties present; such findings also have been demonstrated with interviews. Having additional persons present or observing the testing is likely to have particularly significant effects in forensic contexts, particularly when the outcomes are viewed as "high stakes" by the litigant.

Structured Psychological Assessment

Given the established issues and limitations of unstructured sexual offender self-report via interview, two sources of information become particularly significant in the forensic evaluation of sexual offenders. First, as previously discussed, records are typically paramount in providing previous

self-reports by an offender as well as third-party observations and/or reports by a variety of other sources regarding the offender in question (e.g., collateral reports), all of which most commonly carry the primary weight relative to psycho-legal considerations. However, the second key source of information in forensic evaluations of sexual offenders is Structured Psychological Assessment (see Hoberman & Riedel, 2015); as noted, in general, psychological testing and structured ratings are one of the three common legs of forensic evaluations in general. Structured Psychological Assessment (SPA) is understood as a structured, norm-based (nomothetic) set of methods or approaches for collecting and organizing subject self-report via psychological testing, structured interviews, and professional ratings. Standardized assessment tests and other measures served as controlled opportunities for data collection, quantification, and hypothesis-generating about personality and human behavior; as such, they reduce dependence on examiner's own subjective judgments and, consequently, minimize potential sources of bias and error in obtaining description of psychological characteristics. Results of valid psychological tests provide probabilistic or actuarial evidence that an individual shares personality and behavioral characteristics associated with similar-responding members of the comparison or reference group. Such standardized assessment practices create an opportunity to obtain information from various informants (particularly the subject of the evaluation) to be compared and contrasted with similar information provided by the informant in the past. Consequently, for some period of time, there has been an increased emphasis for mental health professionals in both clinical and forensic settings to utilize available and scientifically validated structured psychological assessments. As both Otto and Heilbrun (2002) and Archer, Stredny, and Wheeler (2013) note, there are limitations in the availability and empirical support for specialized forensic tests relative to specific forensic issues (e.g., there is no specific test for parenting capacity or for determining a mental defect or abnormality). As a result, such authorities point out that traditional "clinical" assessment tools have and continue to play a common and crucial role in most areas of forensic evaluation and per the latter authors "such tests have become widely accepted for use in forensic evaluations" (p. 7). Similarly, Otto and Heilbrun (2002) demonstrated that traditional psychological testing was widely utilized by FMHP in addressing a range of forensic issues; such psychological testing was rated as either essential or recommended by the majority of forensic evaluators in criminal matters for example. As Heilbrun et al. (2009) noted psychological testing data frequently serve as an additional source of information for forensic opinions; forensically relevant instruments provide a means of assessing clinical constructs most relevant to the evaluation of the individual and issues involved in the psycho-legal matter. Further, Heilbrun et al. emphasize that tests and related measures (e.g., structured clinical ratings) that quantify human abilities, traits, motivations, and "abnormalities" can serve to minimize effects of examiners' own judgments, thereby reducing sources of bias and error in describing psychological phenomena. Such formal nomothetic assessment procedures provide a key "third leg" of the elements of forensic evaluations. Psychological tests, in particular, by generating empirically based hypothetical interpretive statements based on persons who endorsed similar types and degrees of items (nomothetic perspective) provide a unique opportunity for comparison with collateral data, particularly archival data. This allows for determinations of current structured self-report relative to be analyzed for convergence or divergence over time, situation, and source of information (an idiographic perspective). Consequently, evidence-based assessment procedures such as structured psychological assessment methods should be the practice or aspiration of all evaluators of sexual offenders.

Certainly, SPA currently occupies a central role in almost all types of other forensic evaluations, including competency to stand trial (e.g., Goldstein, Morse, & Shapiro, 2003) and mental status at the time of a crime (e.g., Stafford, 2003), parenting and child custody matters (e.g., Otto, Buffington-Vollum, & Edens, 2003), and personal injury cases (e.g., Greenberg, 2003) for the range of issues that must typically be addressed to provide useful information for court-related matters. As each of those authorities indicates, psychological testing involving multiscale or multidimensional inventories are particularly important and useful, even if they do not necessarily provide a definitive answer to specific forensic questions. The elements of SPA can provide a broad perspective of an individual's past and current functioning, validity indicators (if present) can be a key source as to an individual's response style (e.g., defensiveness), and the findings of such instruments provide a potentially rich source of information to be combined with other sources of data (e.g., record review) and inform other structured assessment methods. Studies such as those by Borum and Grisso (1995), Lally (2003), Archer et al. (2006) and Archer and Wheeler (2013) indicate that the use of psychological tests in forensic evaluations is very common and generally accepted practice for virtually all domains of forensic psychological evaluations. In particular, Bow et al. (2010) conducted an online survey of experienced forensic psychologists that found that the Minnesota Multiphasic Personality Inventory-2 (e.g., Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989, 2001) and the MCMI-III (Millon, Davis, & Millon, 1997; Millon, Millon, Davis, & Grossman, 2006, 2009) were, in that order, the two most commonly used tests among forensic psychologists. Almost all of these psychologists utilized the Pearson Assessments interpretation, with over 60 % and nearly 80 % (respectively for each test) relying on computer-generated interpretive reports. The majority of forensic psychologists recommended repeating these tests within 6–12

months after a previous administration. Over 90 % of the respondents opined that the MMPI-2 met admissibility criteria for expert testimony, while over 70 % indicated that the MCMI-III met such criteria.

Standardized psychological tests and professional rating scales provide a broad range of information relevant to almost all areas typically of interest in the forensic evaluation of sexual offenders and this information provides various perspectives, all of which are based on the subject's own self-report (but interpreted relative to standardized norms or structured professional ratings). Heilbrun (2003) noted that a primary principle for FMHA stresses "the value of assessing clinical characteristics using tests and tools that have been derived and validated for this purpose, a population similar to that of the individual being evaluated, and its validation process documented in published research and a test manual" (p. 178). Yet as he and others (e.g., Archer et al., 2013) acknowledge, few psychological tests exist for more narrow or circumscribed psycho-legal purposes or questions. Consequently, as Heilbrun notes that standardized psychological assessment must be considered and applied "somewhat broadly …with 'clinical characteristics' including the patterns of thinking, feeling, arousal, and behavior associated with offending" (p. 178). In addition, he noted the importance of using psychological tests and other specialized measures in the determination of exaggeration or minimization of symptoms (or other clinical characteristics) as particularly helpful in assessing an individual's response style. Heilbrun noted:

> Among other justifications, results of such testing can allow the evaluator to calculate how heavily to rely on self-report in the course of assessment. Sexual offender-specific FMHA would need to consider specialized measures that are particularly applicable to sexual offenders, particularly those sensitive to defensiveness…" (p. 179)

As noted, such testing can be utilized both in an idiographic manner (to compare individual's responses on current testing to their previous responses on the same or similar tests) and nomothetically (comparing their responses to a group-based or normative sample of persons). Later, the application of a particular test administration or series of administration in the context of records, other collateral sources, and interviews can be utilized by evaluators to draw integrated, data-based inferences about psycho-legal issues. In short, using tests and other assessment approaches that have been developed and validated for general and specific purposes can facilitate the informed consideration of how similar clinical conditions and personal characteristics are to those in "known groups" and to a particular individual relative to the relevant legal issues at issue.

Psychological tests are typically only sold to professionals who possess the requisite training and licensure to use them. For persons lacking such experience or credentials, it is highly recommended that some mechanism be developed so that a properly credentialed colleague can administer such tests. Since the "chain of custody" of testing materials is an important ethical issue for forensic psychologists, ideally it should be the evaluator's (or the designated test-administrator's) policy to be present or available when the respondent completes the test questions. Obtaining valid test results, where those results may play an important role in determining case disposition, certainly justifies the added expense of ensuring the quality and integrity of test-taking. Consequently, the evaluator or an appropriately trained representative of the evaluator should supervise all testing in such matters. When it is necessary to administer tests orally to respondents who are identified as having a reading disorder or other, more general intellectual limitation, then the evaluator should be the person who administers the tests, with more time devoted to the assessment approaches as necessary.

In addition, the validity of SPA is of particular importance in the context of adversarial settings such as forensic evaluations. First, such measures have been developed and studied scientifically, they are standardized and norm-referenced, and they demonstrate good psychometric properties that have been shown to be defensible and accepted across a variety of forensic contexts. Second, as with most forensic evaluations, it seems clear and likely that individuals on their own may or will affect particular presentations related to their "goals" or secondary gain. In sexual offender evaluations, an intent to appear less symptomatic or deviant may lead to a "press" on the part of the person being assessed to respond to test items or present information in such a way as to minimize maladaptive personality traits or deviant sexual behaviors or interests (e.g., to "fake-good" or affect positive impression management). Simple, transparent questionnaires are particularly suspect as substantive sources of information, particularly when they contradict the available behavioral information and thus may provide relatively useless information for the development of a forensic opinion.

Along with personal motivation to misrepresent or unconsciously distort information that potential or alleged sexual offenders provide during an evaluation, an additional source of contextual misinformation exists. It appears increasingly common for persons advising potential or alleged sexual offenders regarding their participation, presentation and even "history" in various assessment components of evaluations. Consequently, in forensic or "clinical"/forensic settings, one must be aware that there is evidence that a significant number of attorneys may attempt to "coach" or advise their clients in responding to standardized psychological assessment. For example, in one study, almost half of a sample of practicing attorneys and somewhat smaller percentage of law students surveyed believed that when clients were to participate in a direct evaluation involving psychological testing, the client should "always" or "usually" be given information about the nature of validity

scales used in such testing, as well as coaching as to what types of answers to provide or to avoid (e.g., Wetter & Corrigan, 1995). Other authorities have written about the implications and consequences (and sometimes negative to the evaluatee) as a result of advisers, including attorneys, relative to their client's presentatioins (e.g. Cato et al., 2002; Gutheil, 2003; Lees-Haley, 1997; and Youngjohn, 1995).

In addition, various information about psychological tests and clinical ratings scales is now available on various publically accessible web sites and, anecdotally, in correctional and other institutional facilities across jurisdictions. As Heilbrun (2001) noted the more information a subject possesses about validity scales of psychological tests, the more effectively they can dissimulate substantive "findings" on those tests; in situations, where an evaluatee produces test results markedly discrepant from collateral sources, this possibility should be considered. Consequently, there is always reason to be concerned that some individuals who are provided with or obtain information about the nature of tests and rating scales may be able to affect their presentation style on a test or to manipulate detection of maladaptive symptoms and traits.

Practically speaking, it may be increasingly important to ask an examinee in what ways he has prepared for the evaluation. Specifically, he might be asked generally what he has read or been told about the proposed nature, content, or approach for the evaluation, whether he has read or been told about any material regarding the specific tests chosen for administration (e.g., books about specific tests or rating scales), whether he has received advice from *any person* as to recommended responding for the specific tests ratings or other assessment procedures chosen for administration or if he has sought or received information from the Internet or other respondents about evaluations or specific tests, and what he knows about how responses to the particular tests or ratings may be utilized. This may become a particularly important concern if an offender's most recent test results are markedly discrepant from the results of previous testing or if the offender seems unusually "prepared" for the direct evaluation with circumscribed, seemingly "pat" descriptions of his sexual offense history. This may particularly significant if current accounts of sexual offending history are markedly discrepant from multiple, previous and convergent ones and/or the individual now blames external systems or factors for prior sexual offense admissions and/or the evaluatee now represents that he misunderstood terms (e.g., admitted to sexual arousal to children but claims they meant persons of age but under 18 or claims that they didn't understand the meaning of "forced" relative to a sexual offense. The evaluator may also ask the offender whether he has read or received verbal information or advice regarding the subject of risk assessment and/or ask him to affirm that he has not done so (as part of informed consent, for example).

Useful Psychological Tests in Forensic Evaluations of Sexual Offenders

SPA is of particular use in the forensic evaluations of sexual offenders. The primary meta-analyses have demonstrated a relatively consistent set of psychosocial characteristics or psychological meaningful risk factors have been shown to be associated with sexual reoffending (e.g., Hanson & Bussière, 1996, 1998; Hanson & Morton-Bourgon, 2004, 2005; Mann, Hanson, & Thornton, 2010). These psychological meaningful risk factors (PMRF) are viewed as manifestations of underlying vulnerabilities or predisposing characteristics toward sexual offending; they can also be understood as "criminogenic needs." They include deviant sexual interests; antisocial orientation and other maladaptive personality characteristics; social relationship issues and social deficits; and broad issues with self-regulation. In addition, it should be noted that as Heilbrun (2003) wrote: "For sex offender-specific FMHA, the area of 'mental disorder' must be interpreted sufficiently broadly and flexibly to include a focus on the patterns of thinking, feeling, and arousal that contribute to criminally deviant sexual behavior and the risk that such behavior will recur." (p. 177) Further, as Hoberman and Riedel (2014, 2015) have elaborated on in more detail, measures of SPA can provide valuable, even critical information about impression management, psychologically meaningful risk factors (e.g., both static and dynamic risk factors related to increased propensity for sexual offending), diagnostic and other functional psychological/psychiatric characteristics (e.g., such as self-regulation and self-control), and risk assessment.[2] Testing as a central component of SPA can provide a particularly valuable perspective on the potential mental disorders relevant to a forensic evaluation of a sexual offender [and from a unique source (the examinee)]. In particular, as DSM-5 and, more broadly, research in the mental heath field have identified that psychopathology increasingly appears best understood dimensionally, with individual differences in degrees of the presence or absence of key psychological characteristics. SPA provides a particularly useful means of identifying and quantifying relevant dimensions of thought, motivation, affect, and behavior from the perspective of the individual *and* compared to normative data.

Many of the commonly recommended and utilized psychological tests in the clinical and forensic evaluation of sexual offenders are comprehensive or "broadband" tests, typically personality tests, that include questions and produce results about numerous relevant areas for the evaluation of sexual offenders, including impression management and

[2]The reader is referred to Hoberman and Riedel (2015) for a considerably more detailed description of psychological tests, professional ratings, and structured interviews recommended for use in forensic and true clinical evaluations.

multiple substantive areas of interests (e.g., likely personality traits, information about attitudes and nature of deviant sexual interests and sexual preoccupation). Hoberman and Riedel termed such tests as Multi-Dimensional Psychological Tests (MDPT); among these tests, recommended choices of MDPT include the Minnesota Multiphasic Personality Inventory (MMPI-2; Butcher et al., 1989; 2001), the MMPI-2 Restructured Form (MMPI-2-RF; Tellegen et al., 2003; Ben-Porath & Tellegen, 2008), the Millon Clinical Multi-Axial Inventory (MCMI-III; Millon et al., 2006, 2009), and the Personality Assessment Inventory (PAI; Morey, 1991, 1996). Generally, as Clipson (2003) noted the MMPI-2 and the MCMI-III are the most typically utilized MDPTs in sexual offender evaluations. Meloy (1989) identified the MMPI as the forensic evaluator's "workhorse" in adult forensic evaluations "due to the enormous amount of research available concerning its clinical use, and the sensitivity of its various indicators of distortion" (p. 333); similarly Pope, Butcher, and Seelen (2006) identified that there is considerable research on the forensic application of the MMPI-2. In contrast, Mullen and Edens (2008) noted in published court cases, the PAI is rarely used in isolation; rather, it is typically utilized in conjunction with other MDPT tests, particularly the MMPI-2 and/or the MCMI-III. In part, this may have to do with its significant face validity generally and specifically regarding antisocial characteristics. Another MDPT that has a particular focus on deviant sexual experiences and behavior as well as key impression-management scales are the original MSI (Nichols & Molinder, 1984) and the more recent MSI II (Nichols & Molinder, 1996a, 1996b, 2000); these tests were designed to measure the sexual characteristics of adult male sexual offenders and can be used both as part of psychosexual or sexual deviance evaluation and also to measure treatment progress. As a note, with the exception of the MMPI-2, the various MDPT are all somewhat transparent to an examinee and it is not uncommon for persons with substantial, well-documented histories of particular behaviors and other personal characteristics to deny or minimize those on these tests. On the MMPI-2, regarding the higher likelihood of "faking good" for sexual offenders, Graham, Watts, and Timbrook (1991) found that L and K scale scores were typically much higher than the F scales but noted that the detection of fake-good profiles was more difficult than detecting fake-bad profiles. In a meta-analysis, Baer and Miller (2002) found traditional indices of underreporting yielded a mean effect size of 1.25, suggesting that underreporting respondents differ from those responding honestly by a little more than 1 standard deviation, on average, on these scales. However, they also found that when test takers had been coached about the presence and/or the purpose of validity scales, underreporting is more difficult to detect. The results of so-called validity scales and convergence of substantive MDPT results with personal history documented in the available records give confidence that the examinee is providing a straightforward and veridical portrait of himself. In contrast, divergence between test results and personal history should provide the basis for a higher "suspicion index" and seeking clarification or explanation from the examinee.

As a practical note, as is typically the case in forensic evaluations in general, MDPT and other self-report tests are best administered early in the sex offender evaluation process, typically at the time that informed consent is secured. If possible, such testing should be scored and interpreted prior to conducting direct interviews with an offender. In this manner, the evaluator is alerted to possible impression management on the part of the examinee as well as in possession of the more substantive findings of the tests (e.g., whether the offender has admitted, denied, or minimized specific types of personality characteristics and sexual experiences/behaviors).

Several books provide information about the MMPI-2 and, in particular, its use in forensic contexts (e.g., Ben-Porath, Shondrick, & Stafford, 1995; Caldwell, 1997; Pope et al., 2000, 2006). Weiner (1995) indicated that the MMPI-2 was a sound instrument for forensic purposes and was readily defended in its use in such contexts. Sellbom and Ben-Porath (2006) noted that, in general, the MMPI-2 meets both the criteria of evidentiary admissibility under both *U.S. v. Frye* (1923) and *Daubert v. Merrell Dow Pharmaceuticals, Inc*. (1993). Further, in terms of its admissibility, there are over 350 state appellate court and 250 federal court citations naming the MMPI as an issue in a case. Specifically, in *People v. Cooper* (64 111. App. 3d 880,381 N.E. 2d 1178, 1978), a case involving an allegation that an individual was a sexually dangerous person, the MMPI test report was noted to be the type of report normally relied on by psychiatrists and could be considered by an expert witness in determining the mental state of the individual in question (Greenberg & Greene, 1998). McCann & Dyer (1996), McMann (2002), Dyer (1997), Dyer (2005) and Craig (2006) have advocated for the use of the MCMI-III in forensic settings, while Rogers et al. (1999) have offered a more critical view of the test in such settings. Dyer and McCann (2000) have pointed out that the identification of personality disorders per the MCMI-III satisfies criteria for most scales and may be viewed as better than the MMPI-2. The case of *People* v. *Stoll* (783 P.2d 698 Cal. 1989) and other case law are cited by as providing support for the admissibility of the MCMI based on its widespread acceptance and its place as a standard part of the psychologist's testing battery. Regarding the PAI, its use in forensic settings has been summarized by Edens et al. (2001), while Mullen and Edens (2008) provide a survey of case law related to the PAI.

In addition, to the MDPT, at least one narrow-band measure of a construct strongly related to sexual offending should be routinely included in forensic evaluations of sexual offenders. Hare (1985) developed the Psychopathy Checklist (PCL); this measure was revised in 1991 as the Psychopathy Checklist-Revised (PCL-R, including scoring

sheet, rating booklet, and Technical Manual) and appeared in a second edition in 2003 (along with an updated form of the PCL-R rating scale scoring sheet, a new Interview Guide, and a significantly expanded Technical Manual, all published by Multi-Health Systems). The PCL-R is a rating scale designed to assess the personality traits and behaviors related to traditional concepts of psychopathy (Cleckley, 1950, 1982). The PCL-R-2nd identifies psychopathy as a constellation of interpersonal, affective, and behavioral characteristics, including such domains as impulsivity, lack of empathy, lack of remorse, conning/manipulative, etc. It has been regarded as the "gold standard" for the assessment of psychopathy (e.g., Burros Mental Measurements, 2005). Scores on the PCL-R correlate with the Psychopathic Deviate and Mania scales of the MMPI-2 and with the Antisocial and Narcissistic scales of the MCMI-III. Lally (2003) found that the PCL-R was rated as recommended for sexual violence evaluations (and violence evaluations more generally) by 62 % of experienced forensic psychologists; it was the only psychological measure that was recommended by the majority of those psychologists. DeMatteo et al. (2014) reported that challenges to the admissibility of the PCL-R in court were rare and typically unsuccessful. Although concerns have been raised about the reliability of the instrument in adversarial sexual offender proceedings (e.g., Murrie, Boccaccini, Caperton, & Rufino, 2012), Harris, Rice, and Cormier (2013) showed that file-only scoring of the PCL-R based on good archival material closely matched the clinical scoring typical of routine forensic practice. Harris et al. (2013) also found that file-only total scores were significantly higher than file-plus-interview scores. Agreement was best for PCL-R Factor 2 and Facet 4 scores (e.g., the more behavioral items). Harris et al. indicated that lower agreement in "clinical" use was related to (1) lower degrees of training and practice regarding the PCL-R (leading to measurement error); (2) "partisan allegiance" to outcome; and (3) the effect of more psychopathic subjects to contaminate the interview data and experience (as a result of their psychopathic traits). In support of this last point, it should also be noted that in their large updated meta-analysis, Leistico, Salekin, DeCoster, and Rogers (2008) also found that the association between violence and file-alone PCL-R scores was significantly larger than file-plus-interviews.

While the common method is for the PCL-R to be rated based on both records and the administration of a semi-structured interview, as several studies have demonstrated, with adequate archival materials, ratings for PCL-R items can be made in the absence of an interview (e.g., Quinsey, Harris, Rice, & Cormier, 1998, 2006). As the Hare Technical Manual notes in some situations "it may prove impossible to conduct a useful interview. In others, the individual may refuse to be interviewed or to cooperate with the clinician. A considerable amount of research…indicates that reliable and valid PCL-R ratings can be made solely on the basis of collateral information if it is of sufficiently high quality" (Hare, 2003a, p. 19). It is noted that a reliance on file review alone may lead to providing lower rated item scores on some of the interpersonal and affective (Factor 1) items, particularly for more psychopathic individuals. Consequently, "Descriptive statistics … indicate that field-based PCL-R ratings are, on average, several points lower than standard ratings" (Hare, 2003a, 2003b, p. 19).

Considerations and Strategies in Forensic Interviews with Sexual Offenders

Interviews should possess both a "scientific" and an "artistic" dimension, as others have suggested (e.g., Pithers et al., 1989). That is, such interviews should have some significant element of structure, to reduce information variance and to provide full coverage of the range of possible behaviors, historical events, and personal phenomenological experiences (e.g., sexual fantasies and urges). Clearly, simply using what is "known" about an offender through the available records is likely a mistake and risks perpetuating falsehoods and misconceptions that may exist within records, simply because no one has yet queried the respondent more broadly or in more depth.

The "artistic" element of the interview with a sexual offender is based on the evaluator's ability to establish a "working alliance" with the examinee, even in the face of adversarial perspectives. While a therapeutic alliance often entails accepting the client's report without challenge, a working alliance relates to treating the examinee with respect and neutrality as well as the likelihood of challenging reports that are discrepant with other sources at some point during the evaluation. With denial and minimization often strongly present, the possibility of reactance, resistance, and refusal to cooperate by the examinee may exist. An evaluator must be able to discuss an individual's criminal and sexual offense history without appearing judgmental or reacting in any obvious emotional manner; reviewing the records can help to desensitize an evaluator to any extreme aspects of a sexual offender's record. Early or abrupt confrontation of a sexual offender's report, beyond being disrespectful and relatively incompatible with forensic principles, may quickly lead to a refusal to cooperate with the forensic interview. However, in forensic direct evaluation, strategies designed to minimize defensiveness by framing the interview within a therapeutic context (e.g., Beckett, 1994; McGrath, 1990) are not entirely appropriate. Confrontation may be necessary at some point and/or around some issues presented by the offender. Generally, this may best be accomplished toward the end of the direct forensic interview, with the evaluator preserving for the later part of the evaluation those incidents or elements of the sexual offender's history that might be most likely to be experienced as provocative or otherwise problematic.

As with any individual participating in a forensic evaluation, an examinee should be treated with respect. The potential value of an interview from a sexual offender's perspective is to have an opportunity to present his view of his past behaviors and experiences and of his future risk to the community. Consequently, it is incumbent upon the examiner to create an atmosphere in which the subject feels that an attempt will be made to understand his perspective about himself and his history. Framing the interview portion of the evaluation in this manner can accomplish a great deal toward establishing an interactive and impartial framework for the evaluation.

Nonetheless, the adversarial context within which most forensic evaluations take place and its character as a forensic rather than a traditional or "non-forensic" therapeutic, clinical evaluation means that there are limits to the means by which information is elicited from a respondent. Particular strategies for the structure of the interview process for sexual offenders, many of which were also suggested by McGrath (1990), are ethical and useful to the goals of the interview; any of these strategies can work to minimize denial and maximize self-disclosure and discussion. These are actually quite similar to interventions recommended by Meloy (1989) to "ferret out" distortion in forensic interviews in general. Overall, per McGrath, the interviewer can begin with issues of a less threatening nature, such as personal history. Questions regarding an individual's youth and adult development can also be posed in such a manner as to develop an affirmative and collaborative set; such questions allow the evaluator to use his or her professional skills to facilitate the respondent's having a sense that his perspective is being heard and understood. Generally, posing questions likely to be responded to affirmatively (e.g., developing a so-called "yes set") can be productive. Using clinically "leading" inquiries such as "how often have you done such a behavior?" communicates an assumption of the behavior in question and places the burden of denial on the offender (McGrath, 1990). Similarly, Adkerson (1996) suggested using the techniques of prediction and mind reading to facilitate greater accurate disclosure. By communicating in such a direct fashion, the respondent may appreciate that the evaluator expects that such behavior may have occurred and will not be shocked by the respondent's response. Direct questions about sexual offense history can also provide a permissive tone; such a straightforward approach can communicate to sexual offender that he can respond more directly and clearly himself and with less hesitancy and deception. Asking similar questions or variations of the same question over the course of an interview(s) is also a valuable strategy in eliciting information about the offender and his history. There is particular utility in assessing a sexual offender over the course of several days of evaluation (or over time), typically with a mixture of testing and interview time; one is able to observe the individual during varying degrees of stress, boredom, and fatigue. Finally, the sequence of interviews should include attempts to present the sexual offender with any discrepancies that exist *within* the record or *between* the record and his current interview, particularly in the areas of sexual offense history, treatment course and progress, and information pertaining to his relative risk in the community. As Clipson (2003) suggests this is typically best left to the end of a direct evaluation.

Sometimes, if a sexual offender is clearly upset and angry at his involvement in the forensic evaluation at the initial meeting, it can be useful to begin an interview process by offering him a chance to speak to what is most important to him and for the evaluator just to listen. This opportunity to ventilate, in the face of an adversarial proceeding where much can be at stake, can defuse some anger, so that the possibility of later eruptions of anger and frustration is reduced. Rapport during the interview portion of the evaluation can also be initiated or maintained through the acknowledged use of a structured background and diagnostic interviews in which the evaluator demonstrates to the examinee that he or she must ask the same questions of all interview subjects for the integrity of the assessment. The range of questions, some or many of which may not apply to a particular respondent, and may even seem strange or "crazy" to him, can even serve as a source of some humor during the interview process. One can sometimes minimize denial and resistance either by reframing the question to ensure that the respondent clearly understands it or by offering the same question later in the interview.

As noted, if an offender provides information that is distinctly different from the available records or from previous evaluation sessions, it is usually wise to avoid confronting him about these discrepancies too early in the evaluation process. Eventually, however, an evaluator should address such discrepancies, perceived dishonesty, and most important, any differences in versions of the history of the respondent's alleged and adjudicated sexual assaults. However, as McGrath (1990) suggested this goal should be guided by a "progressive-approximation" strategy and best done within a context of some rapport and motivation on the examinee's part to cooperate. This way, information is obtained initially through what the sexual offender shares voluntarily. Typically, it makes good sense to reserve questions about broader or discrepant sexual offense and criminal history until later in the interview, particularly if there are differences between this current self-report or among past reports by the respondent, victims, and collateral sources. As noted, later in the interview process is typically the optimal time to confront a sexual offender about more general discrepancies or apparent dishonesty. Overall, then, an evaluator must start where the respondent "is at" and decide what optimal progression of interview topics and methods will work best with a particular individual.

From a practical perspective, if an interview is allowed or required, clearly, the most adequate forensic evaluation of a sexual offender through interview can best be accomplished through spending considerable contact time with the respondent. Extended contact may provide the basis for an acquired familiarity, reduce negative expectations and anxieties, and thus provide the opportunity for a working alliance to develop. This may be a difference from "traditional" clinical assessments of sexual offenders for treatment planning purposes; however, it is similar to assessments in other forensic contexts. Thus, forensic interviews should be comparable to interviews involving personal injury, sexual harassment, or civil commitments of the mentally ill and dangerous where similar issues are at stake. Further, as in all forensic interviews, the length of the respondent's sexual history, the complexity and severity of his psychological and psychiatric characteristics, and his manner of presentation at interview times should determine the actual length of time of contact with the subject. Ideally, the actual face-to-face contacts with the sexual offender should consist of lengthier sessions and occur over more than 1 day, depending on logistical factors, the offender's defensiveness, cognitive capacity (including intellectual and attentional abilities), and the extent of his sexual offending and other criminal, correctional, and therapeutic history. Often individuals present for forensic interviewers with some attempted, even coached, versions of their history and verbalized self-perspective. Often over an extended interview(s), such facades become vulnerable and the subject becomes much more open and genuine in their historical accounts and self-presentation.

Information acquisition is greatly facilitated by multiple interviews over a number of days, as just noted; this allows for multiple questions directed at similar areas of behavior, framed in somewhat different contexts to facilitate information comparison across interviews. Further, evaluation over several sessions can provide the opportunity to initially administer and score psychological tests early in the evaluation process and then to use later interview time to seek to confirm or disconfirm hypotheses generated by these tests. Finally, multiple interviews provide a much greater opportunity to observe a respondent's interpersonal style. However, this goal may often not be logistically possible given various contextual or situational factors.

In general, the process of the forensic interviews should be standardized both in terms of specific procedures and the areas to be covered. Content-wise, the interview portion of the evaluation usually takes the following order: (1) personal, developmental, social, and medical history; (2) diagnostic and personality trait evaluation; (3) general mental health, correctional, and sexual offender-specific treatment history; (4) sexual and sexual offense history; (5) risk assessment and proposed plans for the future; and (6) treatment amenability and expectations. In the course of this inquiry, likely criminogenic needs to be addressed in treatment should be identified and the type of treatment and/or other dispositions may also be discussed. Testing and questionnaire administration can be interspersed throughout the evaluation days, as they often serve as useful breaks from the demands of the interview format. Generally, it is useful to ask the individual to provide his perspective on his history of criminal and sexual offenses and any experiences with correctional and treatment programs. At the end of the interview process, the subject should then be confronted with information in the records about those same areas, including showing or reading those records to the examinee, and asked to provide clarifications of the discrepancies. Finally, it is important to ask the examinee, what topics or incidents that they consider relevant that may have been missed or what other information they wish the evaluator to consider in coming to an opinion.

Issues Regarding the Validity of Interviews with Sexual Offenders

It is notable that there is no empirical literature that indicates that a direct interview with a sexual offender necessarily provides reliable and valid information (e.g., Becker & Quinsey, 1993). As Salter (1988) wrote:

> …the clinical interview is used with sex offenders, without the degree of confidence one ordinarily assigns to it. A client entering therapy for depression, anxiety, or marital or family difficulties can be expected to be relatively honest with his/her therapist. The client is experiencing distress and is seeking help in alleviating it. It would be as foolish to lie extensively to a therapist regarding the distress as it would to show a physician one part of the body. There is, of course, a universal tendency for people to try to make themselves look good…[T]he clinical interview with the sex offender, particularly before he has begun the process of treatment, must be assigned different degree of weight in the overall assessment. He is typically afraid to tell you, and even himself, the truth… [E]ven a cursory reading of the literature should inform the novice sex offender therapist that a clinical interview cannot be trusted, especially one conducted prior to treatment. (pp. 186–187)

Salter pointed to the landmark study by Abel, Osborn, and Twigg (1985), which found that objective measures of sexual arousal (via plethysmograph) and self-report coincided in only 30 % of the sample despite a guarantee of confidentiality. Of the remaining the sample (e.g., those with discrepant information), when confronted with the discrepancy between their own report of deviant arousal and psychophysiological results, 70 % of the discrepant reporters subsequently admitted to additional deviant sexual arousal/behavior. In short, 50 % of this sample, despite confidentiality guaranteed, initially lied about their sexual deviance until confronted with other evidence of that deviance. As Salter

stated: "A clinical interview is thus utilized in working with sex offenders, but as much for a check on the offender's level of denial and to obtain information unrelated to the sexual deviancy as to obtain reliable information" (p. 187). Further, in many forensic evaluations of sexual offenders, with the likelihood of varying degrees of deception, distortion, and minimization, it is clear from reading the records of many sexual offenders that there are apparent and blatant contradictions in the information they share at different times with different persons and that their self-perceptions often differ markedly from the perceptions of those who have evaluated them. Thus, there may be differences in information revealed to law enforcement officials at the time of the investigation of a complaint, to a judicial officer at trial or sentencing, to a probation officer in a presentence report, and to evaluators and therapists in treatment settings.

As Earls (1992) concluded in discussing the assessment of sexual offenders: "[T]here is surprisingly little empirical research concerning the reliability and validity of the information obtained in a clinical interview (p. 234)… we can expect the validity of data obtained in the initial interview is fairly low (p. 235)… the end result may underestimate the frequency and seriousness of the client's previous sexual offences" (p. 237). A general interview itself is unlikely to produce "truth" regarding an offender's sexual offense history or his risk of future dangerousness, as is the case in other forensic contexts where self-interest may be significantly present. Nonetheless, the interview can provide important information about a sexual offender that can then be compared with and integrated with the other sources and types of information available to the forensic evaluator. However, the likelihood of underestimation of an individual's history of sexual offenses, experience of deviant sexual fantasies and urges, and other information relevant to the psycho-legal questions must be kept in mind throughout the forensic evaluation.

Thus for some the necessity of a case-specific interview in the evaluation of a sexual offender can be questioned. Certainly some forensic practitioners may consider this aspect of a direct evaluation of a sexual offender a potentially useful source of information but not an absolutely necessary one. For example, Jackson and Hess (2007) noted that in the high-stakes arena of Sexually Violent Predator (SVP) evaluations, while the majority of evaluators "recommended" the use of an interview, only 17 % considered the interview "essential" and 2 % considered that aspect of a direct evaluation as irrelevant. However, professional ethics typically require attempting a case-specific interview in addition to SPA relative to offering an opinion regarding the sexual offender's current mental status and present and past psychological/psychiatric characteristics. In addition, in most cases direct forensic interviews provide an opportunity for key or critical information, both about historical events from the perspective of the examinee and the particular manner in which the subject presents himself and manifests key elements of personality (e.g., the presence o absence of relatively psychopathic or other maladaptive personality traits). Repeated interviews over time often provide key information about the subject's veracity about key events related to their legal situation, attitudes about and affective experiences relative to their current situation and past behavior as well.

Structured Interviews

Personal and Social History Interview One of the best means of obtaining background information about an individual is to use the *Interview and Information Schedule* (IIS) included in the materials provided for administering and scoring the Hare Psychopathy Checklist-Revised (PCL-R). This IIS is a semi-structured interview that can elicit much of the information necessary to make the judgments required for scoring the PCL-R (Hare, 1991). However, it also provides coverage of educational, occupational, family, marital, and criminal history and ensures that the evaluator covers each of these areas in sufficient detail. Interviews such as the IIS, as semi-structured instruments, allow for such flexibility that an individual's characteristic interactional style is able to emerge. There are areas that the IIS does not cover, however, including developmental and sexual history, which should be addressed in this part of the evaluation. Further, to use the IIS, an evaluator should be familiar with and experienced in the background and scoring procedures of the PCL-R so that sufficient information is obtained to score the PCL-R using the norms that include interview-derived information. According to Hare (1991), the IIS will take 90–120 min. Other potential sources of formal questions for the evaluation of personal and social history in sexual offenders are provided by Beckett (1994) and the Psychosexual Life History (Nichols & Molinder, 2010).

Structured Diagnostic Interviews Traditional assessment among mental health professionals has typically relied upon unstructured interviews, where individual clinicians pose questions they select or which "occur" to them to particular individuals and record those individual's responses to those asystematic questions and behaviors demonstrated during the interview according to the clinician's personal perception and judgment. However, "standard" unstructured psychiatric interview procedures lack reliability and/or validity. Thus, in an early study of the nature of disagreement among clinicians, Ward, Beck, Mendelson, Mock, and Erbaugh (1962) found that *information variance* (differences among clinicians in questions asked and observations made) accounted for 33 % of the differences while *criterion variance* (differences among clinicians in applying uniform standards of the

degree of clinical symptoms present) accounted for 63 % of those differences; actual variability in the client's "presentation" accounted for only 5 % of the differences in clinician disagreement. Blashfield (1992) also showed that clinician's utilizing unstructured methods often did not systematically apply diagnostic standards; such an example of *criterion variance* resulted in misdiagnosis in over 50 % of the instances studied. As a consequence of such non-standardized practices, traditional clinical interviewing has long been recognized as lacking in the psychometric properties necessary for scientific and judicial acceptance.

Based upon findings such as those of Ward et al. (1962) and Blashfield (1992), mental health researchers have long understood and utilized more structured interviews [e.g., the Schedule for Affective Disorders and Schizophrenia (SADS; Spitzer & Endicott, 1978)] as well as formal diagnostic criteria [Research Diagnostic Criteria (RDC), the International Classification of Diseases (ICDs) or the Diagnostic and Statistical Manuals (DSMs)] to optimize reliable and valid diagnostic assessments. Such approaches have also been recommended for forensic evaluators as well (e.g., Hoberman, 1999; Hoberman & Riedel, 2014, 2015). As Nicholson (1999) pointed out, investigations incorporating the use of structured diagnostic interviews yield substantially higher reliability estimates for most personality disorder diagnoses. He wrote

> studies have demonstrated substantial discrepancies between research diagnoses based on structured interviews and diagnoses given in typical clinical practice, even for axis one disorders; moreover, the discrepancies are greater for patients diagnosed in state hospitals and community mental health centers and for those diagnosed in University—affiliated hospitals (p. 130)

That is, research involving structured interviews and diagnoses based on formal criteria are typically more accurate than diagnoses provided for clients diagnosed in community clinical settings.

Structured, or more commonly, semi-structured diagnostic interviews allow the interviewee to provide their own perceptions or opinions to standardized sets of questions but allow professional judgment by the evaluator as to whether symptoms or personality traits characterize the individual. As Rogers (1995) stated:

> The essence of structured interviewing is its standardization of the interview process … structured interviewing standardizes (a) the clinical inquiries and subsequent probes, (b) the sequencing of clinical inquiries, and (c) the systematic ratings of patients responses. The resulting uniformity allows for direct comparison across psychologists, clinical settings, and diagnostic groups." (p. 1)

He identified a number of advantages of structured interviews including increased reliability; reduction of information and criterion variance; comprehensiveness (more diagnostic possibilities are covered and diagnoses, particularly those of less frequency, are not missed as often). A primary disadvantage of existing structured diagnostic interviews is that existing interviews may not cover all of the diagnostic possibilities of interest.

Rogers (1995, 2001) presents a relatively comprehensive review of many of the available systematic diagnostic interviews for assigning diagnoses for both episodic and more chronic mental disorders. Regarding such interviews, a distinction is made between structured and semi-structured interviews; in the former, *only* the prespecified questions are asked, while in the latter, evaluators are allowed to utilize their own questions to *supplement* (but not replace) standard, required questions and optional probes. Quite recently, Samuel et al. (2013) in an extensive longitudinal study found that clinician's diagnostic ratings were collectively never more informative than those from a semi-structured diagnostic interview; semi-structured interviews and self-report questionnaire diagnoses consistently predicted significant variance in psychosocial functioning beyond clinician ratings.

Diagnostic Interviews: Personality Disorders: Meta-analyses of risk factors for sexual reoffending have identified a set of maladaptive personality-related predisposing risk characteristics associated with such recidivism (e.g., Hanson and Bussière, 1996, 1998; Hanson & Morton-Bourgon, 2004, 2005; Mann et al., 2010). Antisocial attitudes and behavior have been identified as one of the primary "paths" or causal factors associated with sexual offending (e.g., Barbaree, Langton, & Peacock, 2006; Doren, 2005; Roberts, Doren, & Thornton, 2002) and models of sexual offending also indicate the importance of these characteristics (e.g., Ward & Beech, 2006, 2015). In addition, narcissism/entitlement, callousness/indifference to others, dispositional/trait anger, violence-supportive attitudes, social neediness/desires for social acceptance, impulsivity, and other self-regulatory deficits have also been found to show significant associations with sexual offending per the aforementioned meta-analyses and other research (e.g., Hoberman, 2014a). Consequently, the assessment of such personality dimensions has particular importance. Antisocial, narcissistic/self-interested, and emotionally unstable personality characteristics are often ego-syntonic and, consequently, persons with such traits and behavioral histories are often unaware of or minimize the presence of such characteristics in themselves. In addition, persons with maladaptive characteristics associated with social anxiety, issues with belonging, interpersonally dominant, callous, lacking in remorse or guilt, social conflict, and detachment are also at risk for future sexual offending.

For forensic evaluations of sexual offenders, a formal assessment of relevant personality disorders is essential, both for treatment planning and in identifying PMRF. Per the former DSM-IV-TR (APA, 2000), a Personality Disorder is defined as an enduring pattern of inner experience and

behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two or more of the following areas: (1) cognition, (2) affectivity, (3) interpersonal functioning, or (4) impulse control. The enduring pattern is inflexible and pervasive across a broad range of personal and social situations and leads to clinically significant distress or impairment in important areas of functioning. A particular issue regarding the assessment of Personality Disorders is that such conditions are often "ego-syntonic" for the individual; that is, thought individual is not aware that their behaviors or traits are maladaptive, problematic, or impairing. One might say that they experience their particular cognitions, emotional style, social relations, and/or self-regulation as acceptable parts of their identity. Ten specific Personality Disorders were identified in the DSM-IV-TR as a category formerly known as Mixed Personality Disorder but later termed Personality Disorder Not Otherwise Specified (PDNOS). It is noteworthy that several studies cited by Rogers (1995) indicate that research studies have typically found that a very significant percentage of clinical samples received four or more Personality Disorder diagnoses on Axis II when systematically assessed; virtually none of the subjects in clinical samples met criteria for just one personality disorder diagnosis. In particular, if an individual satisfies the criteria for one diagnosis within so-called "dramatic-erratic-emotional" cluster, he is likely to satisfy the criteria or have other maladaptive personality traits for other diagnoses within that cluster. Similarly, Verheul, Bartak, and Widiger (2007) noted that PDNOS (as OSPD was known in DSM-IV) as a "mixed" Personality Disorder was the most commonly diagnosed Personality Disorder in clinical practice.

Most recently, the recent DSM-5 (APA, 2013) re-enumerated the same ten specific Personality Disorder categories described in DSM-IV-TR. They changed Personality Disorder NOS to either "Other Specified Personality Disorder" or "Unspecified Personality Disorder." The former category applies to presentation in which symptoms characteristic of a personality disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of function predominate but do not meet the full criteria for any of the specific disorder among the ten specific disorders. The "Other Specified" category is used in situation in which an evaluator chooses to communicate the specific reasons that an individual's presentation does not meet the criteria for a specific Personality Disorder; in fact the example offered as the "specific reason" is "mixed personality features." However, the DSM-5 also recognized the various problems related to a categorical system of classification of mental disorder and, in particular, Personality Disorders. They noted that a categorical approach did not capture the significant clinical reality of overlapping or shared symptoms across more narrow diagnostic categories and the heterogeneity of conditions captured within specified categories. Consequently, the DSM-5 now provides an alternative DSM-5 model for Personality Disorders where Personality Disorders are characterized by two primary dimensions: (1) impairments in personality function (self and/or interpersonal) and (2) one or more pathological personality traits. While recognizing the validity and the significance of a dimensional approach to organizing and classifying mental disorders, including Personality Disorders, the DSM-5 elected to maintain a categorical classification of Personality Disorders as "bridge" to from past to updated more dimensional diagnostic practices.

Interviews for DSM-IV-TR/DSM-5 Several formal diagnostic interviews have been developed to assess the presence of maladaptive personality traits and Personality Disorders. Given the continuity between the DSM-IV-TR and DSM-5, they continue to offer a structured means of providing an examinee to provide self-reported information regarding personality characteristics. The Structured Interview for DSM-IV Personality (SIDP-IV) (Pfolhl, Blum, & Zimmerman, 1995) is a clinical interview to determine the presence of the individual symptom that in clusters define the personality disorders described by DSM-IV. Using questions that are grouped on a "thematic" basis (e.g., self-concept, social relations, etc.) to minimize response sets, this semi-structured interview allows for the systematic assessment of all elements or traits, which compose the DSM-IV personality disorders. Although the SIDP was developed to take approximately 90 min to administer, in actual assessments, it is rarely possible to administer the SIDP in less than 3–4 h, particularly if a respondent is quite talkative or elaborative. Per Rogers (1995), the SIDP's earlier versions (e.g., that for DSM-III-R) demonstrated good inter-rater reliability, relatively clear boundaries for specific personality disorders, and clarity in the assignment of the diagnosis of Mixed Personality Disorder or Personality Disorder NOS. Other systematic diagnostic interviews for Axis II disorders include the Structured Clinical Interview for Diagnosis on Axis II (SCID-II) (Spitzer, Williams, Gibbon, & First, 1990) and the Personality Disorder Interview-IV (PDI-IV) (Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995). On the SCID-II (a structured interview), for each diagnostic criterion, the individual is typically asked 1–2 standard questions and, if affirmative responses are received, the examinee is then asked to provide examples.

The PDI-IV is identified as a semi-structured interview; it assesses diagnostic criteria for ten established and two proposed personality disorders. The companion book provides detailed information about the Personality Disorders, their relevant traits, and the interview itself. It can be administered in one of two formats: by thematic area (e.g., the questions regarding personality disorders are organized by nine topical

areas, similar to the SIDP) or by disorder. Each personality trait or criterion is assessed by at least two and generally three or four standards questions and there are a small number of branching questions as well. Given the number of questions, the complete PDI-IV can take up to 2 h to administer. Consequently, its optimal use can be in the application of questions to those disorders of greatest clinical and forensic interest. An advantage of the PDI-IV is that an evaluator can select one or more particular Personality Disorder categories to inquire about for a particular offender utilizing a semi-structured format. It is recommended that the section on Antisocial Personality Disorder should always be administered for sexual offenders, with additional utilization of sections on Borderline, Histrionic, Avoidant, Schizoid, and/or Schizotypal Personality Disorders as indicated by history (records), current testing, or earlier interview responses. There is mixed evidence for the reliability of the PDI-IV relative to the presence or absence of particular Personality Disorders, with Antisocial Personality Disorder having the highest level of reliability. While the earlier version of the PDI-IV was originally studied using graduate student ratings, experience has demonstrated that "the more talented, dependable, and insightful the interviewer, the better these results" (Widiger et al., 1995, p. 10).

As noted, the relative degree of Psychopathy that characterizes a sexual offender should be assessed and rated in all forensic psychological evaluations of such individuals. The IIS mentioned earlier provides an essential means of collecting relevant information when a direct interview can be conducted with an offender. In addition, Gacono (2000) developed a PCL-R Clinical and Forensic Interview Schedule that provides additional and useful questions to attempt to elicit specific information that informs the ratings of individual PCL-R items. This Interview Schedule can be used on its own or integrated into the use of the IIS itself.

More generally, aspects of the diagnostic evaluation of a sexual offender regarding Personality Disorders typically follow quite naturally from questions concerning general areas of his personal and social history. This is particularly true when assessing potential personality traits using thematically organized, structured interviews. Thematic areas of interest concerning an individual's mood, interpersonal relations, reactions to stress, and the like are an effective bridge to more specific questions about episodic psychiatric symptoms. While a structured approach presents the respondent with some unusual questions that he may at first experience with discomfort, the evaluator can point to the fact that he or she is using a structured instrument and must ask all respondents the same questions due to the structural requirements of the interview. Such interviews also provide continuity in the development of a limited rapport and cooperation.

More traditional psychiatric disorders (those formerly classified on Axis I of the DSM-IV-TR) may also be important to assess as part of an evaluation of sexual offenders, as such disorders appear more common among persons identified or referred for sexual issues (e.g., Kafka & Hennen, 2002; Marsh et al., 2010; Raymond, Coleman, Ohlerking, Christenson, & Miner, 1999). Consequently, for Axis I disorders, the Structured Clinical Interview for Diagnosis (SCID) (Spitzer et al., 1990) or the semi-structured Schedule for Affective Disorders and Schizophrenia (SADS) (e.g., Spitzer & Endicott, 1978) can be administered. Reliable and valid use of both the SCID and the SADS require that evaluator have received extensive formal training in the use of either instrument.

Unfortunately, none of the structured diagnostic interviews available include questions specifically referring to sexual disorders, including the paraphilias. As McGrath and Purdy (1999) have noted the DSM-IV-TR is characterized by distinct "limitations for the diagnosis of sexual offenders. For example, there is no specialized diagnosis for several types of sex offenders such as men who have a sexual preference for adolescents or who sexually assault adult women" (p. 67); others such as Marshall (2007) have pointed to the long time opposition of the American Psychiatric Association to defining a diagnostic category that "could obviously accommodate persons who rape" (p. 20).[3] Though the DSM-IV-TR is the most widely accepted authority in the United States for psychiatric diagnosis, other diagnostic systems such as the International Classification of Diseases (ICD) exist. The development of proposed criteria for sexual disorders for the DSM-5 was expected to correct for some of the limitations of the DSM-IV-TR. However, beyond distinguishing between paraphilias and paraphilic disorders, it appears that DSM-5 may simply maintain those perceived limitations. As McGrath and Purdy concluded, given the inadequacies of the DSM-IV, "descriptions of sex offenders problems that go beyond the formal diagnosis are often very helpful to the referral source" (p. 67).

Per DSM-IV-TR, the general diagnostic criteria for a Paraphilia indicate that the essential features of are recurrent, intense sexually arousing fantasies, sexual urges, or behaviors generally involving: (1) nonhuman objects, (2) the suffering or humiliation of oneself or one's partner, or (3) children or other nonconsenting persons that occur over a period of at least 6 months. According to DSM-5 (APA, 2013), the term Paraphilia now denotes any intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal, consenting adult human partners. In distinction, a

[3]However, it should be noted that the DSM-5 category of Sexual Sadism Disorder was reworded in such a manner that it likely would apply to many sexual offenders who perpetrate rapes: "Over a period of at least 6 months, recurrent and intense sexual fantasies, sexual urges, or sexual behaviors involving the physical or *psychological suffering* of another person."

Paraphilic *Disorder* is a paraphilia that causes harm to others or distress and/or impairment to the individual who is characterized by it. Initially, several additional or revised paraphilias were suggested for inclusion in DSM-5, some similar to ICD-10 and some that had previously been classified as "Not Otherwise Specified." Preliminary research found that the application of the proposed DSM-5 categories provided reliable and more discriminating results when applied to more persistent sexual offenders (e.g., Wilson, Pake, & Duffee, 2011). However, several proposed specific Paraphilic Disorders, such as Coercive Paraphilic Disorder and Hebephilic Disorder, were formally omitted by the DSM-5; while language applying to the former was included in the updated criteria for Sexual Sadism Disorder, the latter category would be classified as an Other Specified Paraphilic Disorder.

Unfortunately as suggested previously, relative to diagnosis, many sexual offenders undergoing a forensic evaluation are likely to deny the existence of identified deviant sexual fantasies and urges as well as offending or nonnormative behaviors. Consequently, just as questions about deviant sexual behavior (or criminal sexual history) are best reserved for the end of the interview, so should questions regarding the type, variety, presence, and intensity of the range of deviant or atypical sexual fantasies, urges, and/or behaviors.

An important consideration for forensic evaluators to increasingly be aware of relates to changing views of mental disorders and conditions. Prior to DSM-5 (Marshall, 2007) "concluded that these [DSM] criteria leave a lot be desired and that a more helpful approach would be to rate the features of each type of sexual offender along dimensions ranging from normal to seriously problematic….[It] is clear is that incidence of comorbid disorders is sufficiently high to warrant concerns about how to effectively address these additional disordered aspects of sexual offenders in treatment." (p. 16) Increasingly sophisticated and accumulating research is identifying that dimensional approaches to maldaptive and/or impairing behavior is largely dimensional (e.g., Krueger et al., 2002, Krueger, Markon, Patrick, Benning, & Kramer, 2007; Krueger, Skodol, Livesley, Shrout, & Huang, 2007; Markon & Krueger, 2005; Markon, Krueger, & Watson, 2005). Clearly, the conceptualization and classification systems of mental and personality disorders are moving steadily in the direction of dimensional models as opposed to more arbitrary categorical systems of such conditions. Obviously, DSM-5 took a big step in this direction by providing both a categorical and more dimensional perspective for describing personality disorders; it seems likely that such a dimensional approach will increasingly be applied to other mental disorders, including the Paraphilic Disorders. For example, there is increasing evidence that agonistic paraphilias (e.g., those involving coercive or nonconsent and sexual sadism disorder) are best viewed as related and dimensional (Knight, Sims-Knight, & Guay, 2013; Mokros, Schilling, Weiss, Nitschke, & Eher, 2014). Given the known and accepted heterogeneity of sexual offenders, particularly with the high degree of crossover sexual deviance in fantasy, urges, and behavior, it seems inevitable that the future will lead to persons (generally) and offenders more specifically being viewed dimensionally relative to a range of deviant sexual interests as well as the "degree" to which those interests apply to a particularly individual.

Other Areas of Inquiry for Forensic Evaluations of Sexual Offenders

General Criminal History Inquiring about apparently nonsexual criminal offenses can be an important source of information about several relevant areas for evaluations of sexual offenders; the range of types of criminal offenses, as well as the age of onset of arrests, is important information to acquire. First, information can be obtained about the onset, duration, and variety of general antisocial behavior. Second, a history of criminal behavior directed at or involving harm to others can provide useful information relevant to evaluating the respondent's propensity for violent behavior; the use of weapons or threats may inform an understanding of the person's psychological approach to or personal style of victimization. Third, certain criminal behaviors may actually represent potential sexual offenses that were interrupted or were undertaken for the purposes of gratifying deviant sexual interests (Adkerson, 1996). For example, breaking and entering charges may have been precursors to rapes; they could also have provided opportunities for collecting items for an individual's fetishes, as could the shoplifting of particular items. The details provided in the records and in the subject's accounts of their general criminal offending often provide useful information about personality and related characteristics of the offender, particularly relative to their motivators, dishinibitors, and responsivity to contextual factors.

Treatment and Correctional History It is important to ask the sexual offender to provide information about any prior mental health treatment experiences, including what diagnoses he may have received, the types of treatment he received, his experience of the therapists he has worked with, and his perception of his clinical progress. Regarding any previous experiences in sexual offender treatment, sexual offenders should be asked to describe in as much detail as possible the elements and course of their treatment, to the degree that they remember, those aspects of their treatment they found most valuable, why those aspects were viewed as valuable, and what specific cognitive, behavioral, and affective changes resulted from treatment.

Most institution-based sexual offender treatment programs are psychoeducational or cognitive-behavioral in nature. Consequently, much of the information, models, and intervention strategies are fully provided for sexual offenders via handouts, lectures, group discussion, and the like. Too often, it appears that sexual offender treatment is delivered in a manner akin to the common rule for public speaking: (1) tell the offender what you intend to tell them or want them to know about a treatment principle or practice; (2) tell the offenders to write what they've read or been told about a treatment principle or practice; and (3) then have the offender verbalize what they have read or been told about a treatment principle or practice in groups. This becomes apparent when sexual offenders are interviewed about their treatment experiences and are sometimes able to recite or name the elements of various treatment components, such as assault or offending cycle, victim empathy, and relapse-prevention. However, it appears that many offenders cannot explain the rationale for addressing these intervention areas in their particular case or describe them in any more detail than what they read from in a workbook or heard presented in group. It often appears that there has been little or no substantive understanding, let alone integration, of the substance of treatment content or any significant cognitive, emotional, or behavioral change as a result of the treatment. It is therefore critical for the forensic evaluator to conduct a careful, detailed assessment of the sexual offender's verbalized experience in treatment and then to critically consider their understanding and application (or anticipated application) of concepts, strategies, and changes that they have taken away from such programs. In addition, several practices have become increasingly common in forensic treatment programs, correctional and otherwise. First, sexual offenders are allowed to keep possession of their paperwork (e.g., homework such as journals, sexual autobiography, offense cycles, relapse prevention plan, etc.) and the treatment provider or agency maintains no copies. Too often such paperwork becomes "unavailable" (lost, destroyed) when a forensic evaluation takes place. In addition, treatment records themselves are often generic, indicating that someone "successfully" disclosed offense history, developed their offending cycle, worked on their relapse prevention plan, and so on. Unfortunately, no information is provided about the particulars of either the work product itself (its content) or the manner or means by which it is determined to have been a "successful" assignment completion. Consequently, treatment records may provide little useful information relative for a true forensic evaluation.

Failure to enroll in, dropout from, termination from, and/or non-completion of a sexual offender treatment program should be carefully explored. If the sexual offender reoffended after previously receiving treatment, query him about his perception of the relationship or lack thereof between treatment participation and/or completion and the subsequent reoffense. Any psychiatric or medical conditions he has been diagnosed with in the past or present should be defined and clarified; any medications he has been prescribed should be identified, as should his opinion about the relative effectiveness and specific changes, if any, which resulted from the medications.

It may be useful to utilize a structured means of reviewing key aspects of sexual offender treatment programming. Two examples of measures that can be used to guide an analysis and/or rate treatment progress are The Sex Offender Treatment Rating Scale (SOTRS; Anderson, Gibeau, & D'Amora, 1995) or the Sex Offender Treatment Intervention and Progress Scale (SOTIPS; McGrath, Lasher, & Cumming, 2012; McGrath, 2015). The SOTIPS is also described in McGrath (2015). As an example, the SOTRS was developed to provide a measure of an individual's relative progress in sexual offender treatment; it assesses elements of both process and outcome in such treatment. The SOTRS consists of several areas: insight, deviant thoughts, awareness of situational risks, motivation, victim empathy, and offense disclosure. Each area is rated on a 6-point scale, with each point defined by behavioral descriptors. Anderson et al. present data indicating that the SOTRS had high internal consistency, inter-rater agreement, and test–retest reliability. The SOTRS can be used as a guide for reviewing treatment records and interviewing a sexual offender with a history of sexual offender treatment in terms of his progress through sexual offender treatment and also to provide a relative rating in each of the six areas noted above. The SOTRS can also be used when the sexual offender has never participated in formal sexual offender treatment. Given the behavioral descriptions of the rating scales, the respondent can be interviewed about each area and assigned a rating.

Sexual Offense History Questions concerning a respondent's known and alleged history of sexual offenses are typically left to the last portion of a planned forensic evaluation. Typically, it is the area in which a sexual offender consistently demonstrates the most affect during the interview. Offenders may become upset and whatever fragile rapport may have existed previously can quickly become threatened. Alternately, some offenders offer remarkably circumscribed reports of alleged sexual offenders; this seems particularly true for persons who have participated in some time of offense disclosure as part of a sexual offender treatment experience. Open questions can provide the desired entry into this area, in which the respondent is asked to review what he believes his sexual offense history to be. Later, the evaluator should address more specific questions based on the available record of convictions and allegations. Discrepancies between current admissions or descriptions of sexual offenses and the offender's records should be

identified and the offender provided an opportunity to clarify those differences. Finally, discrepancies between the offender's reported history and what is known about sexual offenders in general may be explored.

A forensic interview can be particularly important for potentially obtaining information about an individual's course of sexual offenses from the offender's perspective. The interview can be a means of getting a more detailed picture of the sequence and nature of acts that constituted potential criminal sexual misconduct and its relationship to possible varied and/or cumulative predisposing conditions. This is particularly important in SVP cases, where an evaluator must opine about the presence of a "serious difficulty in control." Thus, an interview, particularly if it focuses on the behaviors involved in sexual offenses, provides a means of identifying the "modus operandi" of a particular sexual offender (e.g., Hazelwood & Burgess, 1995; Sjöstedt, Långström, Sturidsson, & Grann, 2004); it can allow for the clarification of the existence of a characteristic behavioral profile of a particular sexual offender. In reading law enforcement interviews of sexual offenders and the accompanying summaries, it is obvious that law enforcement have their own unique agenda in acquiring information; they are too often interested in an admission of the details of sexual acts only because it tells them what type or level of criminal sexual conduct will be charged. They may also attempt to identify general patterns of that type of sexual conduct over multiple victimizations or victims. Consequently, they may not attend to details about the nature of each specific sexual offense with each specific victim. Further, given the evidence that rapsheet sexual offending often misclassifies clear and likely sexually motivated offenses (e.g., Rice et al., 2006), it is particularly important to provide the opportunity for offenders to offer information that relates to the degree of sexual motivation related to rapsheet "violent" and criminal offenses. Although sexual offenders may deny or choose not to corroborate sexual motivation in likely sexual offenses, it can be useful to attempt to collect information via interview (in conjunction with information from criminal justice data) to create a "behavioral map" of each incident or set of incidents with each specific victim. McGrath (2015) has provided an outline that can serve as a guide to collecting information pertaining to an offender's sexual offense history. In contrast to earlier, more direct questions in a direct evaluation about an individual's background, in inquiring about a sexual offense history, it is typically more important to initially provide more open-ended queries regarding particular and suspected sexual offenses. All too frequently through leading questions, assessors provide the offender with easy—and potentially false—"answers" further; the potentially more detailed response to questions about sexual offense history may often provide a "window" regarding how the individual views himself, his victim, and/or other people more generally as well as his psychological mindedness and insight. Later, after an offender has had the opportunity to discuss his account of his sexual offending history, more specific questions based on the records should be utilized to identify and potentially resolve discongruities between previous accounts, the existing records, and current accounts.

In addition, alleged sexual offenders are rarely charged for each act or incident of sexual misconduct against each victim; rather, multiple acts may be collapsed into one or two charges. Charges for sexual offenses often result in plea bargains to lesser sexual offenses or even to nonsexual offenses (e.g., assault); several charges against an offender may be "merged" into one conviction or dropped altogether (e.g., Rice et al., 2006). This may be particularly true where an alleged victim is particularly young, vulnerable, or damaged by a sexual offense. In addition, since some sexual offenders may have victimized a specific victim more than once, they may evidence or report difficulty in remembering or reporting the details of particular incidents or sequences of sexual abuse. A forensic interview provides an opportunity to re-clarify the detailed nature of the behavior that the offender reports transpired and the basis for arrests or charges. Regarding undetected or uncharged sexual offenses, it is reasonable to ask a sexual offender to provide information about sexual acts or attempted acts that have not been reported, which may or may not be noted in archival materials. Obviously, sexual offenders have the protection of the Fifth Amendment, but such questions are appropriate topics to be pursued in a forensic evaluation (at least in a general manner) and both positive responses and refusals based on the right against self-incrimination are to be noted.

Sexual History and the Assessment of Deviant Sexual Arousal and Behaviors The evaluator should attempt a direct assessment of the respondent's deviant sexual arousal and behavior, followed later in the interview process by an attempt to obtain a formal sexual history. Topics to be covered include:

- First remembered sexual experience
- Childhood sexual behavior
- Age of onset of first masturbation
- Frequency of masturbation during childhood, adolescence, and adulthood (by day and week)
- Any periods of especially frequent masturbation, and factors that might account for the increased frequency
- Age of onset of first shared sexual experience
- Age of onset of first sexual intercourse experience
- Frequency and number of sexual partners during adolescence and adulthood
- Number and type of partners while in a "committed relationship"

Respondents should also be asked about their history of sexual fantasies and urges; however, as self-report about a central area to possible sexual deviance, it is quite likely that a sexual offender may not be honest about such fantasies. Sexual preference is probably best conceived of as consisting of sexual attraction gradients, where different categories of persons or behaviors exist on a continuum based on the degree of sexual arousal that they generate. Beckett (1994) offers a set of useful assumptions to inform the evaluator in querying about the sexual fantasies of an offender. The sexual offender should be asked about their ideal offense fantasy, one typically developed to create the highest arousal value. This may often represent the joining or integration of sexual preferences and nonsexual motivations. Adkerson (1996) suggests asking directly about the ideal victim profile (age, gender, physical features, genitalia and breast development, personality traits, and mannerisms), environmental conditions, interpersonal aspects, and the offense scenario. Given the substantial evidence of significant crossover paraphilic behavior, it is important to inquire about the wide range of possible atypical sexual fantasies and behaviors over an individual's lifetime. Areas to cover include use of pornography, attendance at adult book stores and video parlors, cyber porn, prostitution, obscene phone calls and 1–900 phone calls, voyeurism, exhibitionism, fetishism, frotteurism, bondage and other forms of sadomasochistic behavior, and bestiality. It can be useful to ask the respondent what other types of sexual behaviors he has been involved in that, if others were aware of it, might be problematic. Also ask about the age of onset and frequency of all fantasies and such behavior, as well as the age and gender of the target, the target's relationship to the respondent, and the circumstances of the imagined or real acts (e.g., the degree of force or threatening verbalizations). Further, it is useful to ask about the extent to which atypical sexual fantasies occupy the individual's mental life and his perceived control over urges to enact paraphilic thoughts and urges.

The evaluator should inquire about current masturbatory fantasies and frequency as well as the frequency of arousal (without masturbation) to inappropriate sexual images or to sexualization of staff, other inmates, and so on. While some sexual offenders will openly share deviant sexual fantasies spontaneously, experience has indicated that at evaluation, most subjects either offer socially "appropriate" reports of their sexual fantasies, claim that they no longer have sexual fantasies, or state that they have complete control over deviant fantasies. In addition, given the evidence that deviant sexual interests and urges are believed to persist over time (e.g., DSM-IV-TR and DSM-5) and that sex offender treatment is ineffective in changing such interests (e.g., Hoberman, 2015), if an offender claims that their deviant interests have simply decreased substantially or been "eliminated" after adjudication, it becomes important to inquire by what means such claimed "change" in those interests are said to have occurred.

Self-Reported Risk Assessment and Release Options Future dangerousness or risk of recidivism is a multidimensional concept that incorporates the likelihood of reoffending (and also the escalation or de-escalation of offending behavior). As part of the evaluation process, it is valuable to explore with a sexual offender his own perspective on his relative risk of reoffending. Assessing the risk of recidivism is typically a critical element of any evaluation of sexual offenders since it is often central to making a determination of the type and intensity of disposition. Since this is often a central question to forensic evaluations of sexual offenders, one can preface this discussion by the statement of the obvious, namely that there are concerns about his likelihood of reoffending; the subject is then asked to respond to this concern. It is useful to ask him to rate his likelihood of reoffending on a scale of 0–10 (where "0" represents no risk and "10" a very high risk). He can then be asked to explain the factors that he considers as ones which lower and raise his relative risk.

Further, if disposition is a relevant issue to the particular forensic evaluation, the sexual offender should be asked to explain in detail any plans he has made alone or with correctional personnel's assistance for his release. Both short- and long-term plans should be investigated; employment and treatment plans, specific sources and types of social support, and availability or plans for appropriate sexual outlets should all be explored. If any risk factors for reoffending have been previously discussed, he should be asked to comment on these and confronted if his explanation is inadequate. Further, he should be asked about the nature of the environment he expects to return to in the community; specifically, he should be queried about the types and number of stressors he is likely to encounter, as well as how he expects to cope with these stressors. It is useful to thoroughly explore the individual's expectations regarding the nature and sources of stress and his range of and experience with coping strategies, particularly if there may be issues of community notification and/or registration. Given the likelihood that a sexual offender may be subject to some form of ongoing state intervention (e.g., registration, probation) if released to the community, his insight into the stressful implications of these conditions should be explicitly considered. Again, the sexual offender should be specifically questioned about his judgment of the likelihood that this and other stressors may be related to an increased risk of sexual recidivism.

Collateral Sources of Information In general, forensic evaluations place a central and substantial role on the acquisition of information from so-called collateral sources. Such sources provide a context to obtain confirming or disconfirming information about a party's self-report of personality and behavior.

Collateral information is usually obtained from persons who have varying degrees of familiarity with the party, particularly in capacities that relate to the psycho-legal questions at hand. The forensic evaluation of sexual offenders almost always involves substantial amounts of records, which are, in effect, collateral sources. Generally, such records are the primary source of collateral perspectives on a sexual offender. However, in select cases, the evaluator may feel the need to contact particular individuals, including victims, treatment providers, and correctional case managers or parole/probation officers to obtain additional information or clarifications of such material in the records. However, unless court-appointed, it may be necessary to obtain proper informed consent from the subject of the evaluation or a court order authorizing such types of contacts in order to obtain such information.

Psychophsyicological Measures of Deviant Sexual Interest and Behavior Psychophysiological assessment instruments can be particularly valuable for forensic evaluations of sexual offenders. Procedures including the penile plethyhsmograph (PPG), the polygraph, and viewing time measures (VTM) rely on an individual's often involuntary physiological reactions. Consequently such measures can provide and independent and more objective means of collecting useful information that is not reliant on an offender's self-report. Both they are endorsed by the Center for Sex Offender Management (CSOM) and ATSA (2014) as potentially useful instruments for sexual offender evaluations. Per the ATSA (2014) Practice Guidelines, psychophysiological assessment measures are recommended as one component of a sexual offender evaluation; evaluators cautioned to interpret the results of such assessment measures in conjunction with all other relevant assessment information, such as the individual's offending behavior, in developing opinions about the offender. Psychophysiological measure results are not to be used as the sole criterion or source of data regarding decisions regarding sexual offenders. Per CSOM's recommendations for assessment, the PPG is "arguably the most objective and reliable method of assessing deviant arousal," although they noted issues with standardization and the possibility for subjects to use various strategies to suppress the manifestation of their arousal. Polygraph, by measuring specific physiological changes believed to be associated with deception, may be particularly useful as means of verifying an individual's sexual offending history. Various studies indicate that the administration of sexual history or full disclosure polygraphs is associated with greater admissions of deviant sexual fantasies and urges as well as much more extensive sexual offending behavior (e.g., Abel et al., 1985; Ahlmeyer, Heil, McKee, & English, 2000; Hindman & Peters, 2010). After post-conviction polygraphs, English, Jones, Pasini-Hill, Patrick, and Cooley-Towell (2000) found that reports of same sex victims, both male and female victims, juvenile and adult victims, and hands-off offenses doubled or tripled. Reports of unadjudicated victims are significant since non-adjudicated victims (typically disclosed in treatment) show an equal and independent association with later sexual offense recidivism (e.g., Hanson, Steffy, & Gauthier, 1993). As with other instruments, there have been issues raised regarding reliability and validity of the polygraph; in particular, like the PPG, the potential exists for some individuals to use "countermeasures" to regulate and dissimulate their physiological responses. As noted, extensive information exists via the Internet and, anecdotally, such information is available or can be made available to sexual offenders by peers or advisors even while incarcerated or otherwise institutionalized.

Regarding PPGs, Hall, Proctor, and Nelson (1988) found that fully 80 % of inpatient adult sexual offenders asked to inhibit all sexual arousal were "successful" in doing just that; Looman et al. (1998) reported similar results without instructing offenders. Marshall and Fernandez (2000a, b) concluded, "…numerous studies have shown that rapists and child molesters are able to both inhibit arousal to preferred stimuli and degenerate arousal to nonpreferred stimuli." (p. 293). As the updated ATSA Practice Guidelines state: "Because the sensitivity of phallometric testing is lower than its specificity, the presence of atypical/deviant sexual arousal is more informative than its absence. Results indicating no atypical/deviant sexual arousal may be a correct assessment or may indicate that a client's atypical/deviant sexual interests were not detected during testing." (p. 73). At the same time, there are no controlled research studies that indicate that persons can change their relative sexual interests via specific interventions often included in sex offender treatment (e.g., Hoberman, 2015). Consequently, defensiveness as a form of impression management seems the most probable explanation when sexual offenders with extensive histories of sexual offenses and/or high levels of sexual preoccupation "flat-line" the PPG results or show little or no arousal to sexual stimuli that match their past self-reports of deviant sexual interests or their actual criminal sexual history. PPG results are considered "sensitive" (evidence of deviant arousal indicates a true positive finding) but less sensitive (less accurate at identifying true negatives or persons who lack deviant sexual interests). Consequently, while positive findings on PPG typically provide useful and accurate information about an individual's deviant arousal patterns, little or nothing can be concluded from low or no arousal patterns to deviant sexual stimuli among individuals in general good health. Viewing time measures assess the amount of time spent viewing particular slides of types of persons and comparing them to self-reported arousal. Currently, available VTM research is more limited than that for the PPG and the polygraph. Relative to the issue of potential

dissimulation, increasingly evaluators are following a PPG or VRT administration with a simple single-issue polygraph to determine if the individual attempted to engage in deceptive practices during the psychophysiological measure; anecdotally, in practice this procedure appears to be particularly useful. From a legal, evidentiary perspective, while the results of psychophysiological measures may not always be admitted directly into evidence (most typically the polygraph), they may be considered by an expert witness or forensic evaluator as informing their opinion, given that they are usual and customary sources of potential information in sexual offender evaluations generally. In addition, the personal and sexual criminal histories collected from individuals prior to anticipated psychophysiological evaluations are often rich sources of information on their own and potentially to be discussed with the examinee.

Generally, as noted for forensic evaluations, with their significant emphasis on multiple methods of assessment, more sources of data are almost always preferred. Specifically, for forensic sexual offender evaluations, the potential utility of psychophysiological measures is directed at the areas that most sexual offenders are most likely to dissimulate about (e.g., deviant sexual experiences and behavior) and may be likely to provide distorted data about such experiences and behavior. Nonetheless, such sources of potential assessment data are potentially valuable and attempts to include such practices as a standard part of forensic sexual offender evaluations are highly recommended as one component of forensic sexual offender evaluations. Thus, Stinson and Becker (2008) examined a combination of instruments (including the PPG, a VTM, and the MSI II) and they found that the combined measures, plus a self-report test of sexual fantasies involving children, identified 98 % of their child molester sample. Similarly, Tong (2007) found convergent validity for three sex deviance measures [PPG, VTM, and the MSI II].

Treatment Amenability As McGrath has written, "Amenability to treatment refers to an offender's ability, willingness and motivation to enroll in treatment" (p. 148). McGrath identified consensus among treatment providers regarding whether a particular sexual offender may be amenable to sex offender treatment. These include (1) acknowledgment by an offender that he has committed identified sexual offenses and that he takes responsibility for those offenses; (2) an offender must consider his sexual offending problem; (3) an offender must have "at least some motivation to control the problem;" and (4) the offender must be willing to follow the requirements of available or designated treatment programs. In particular, McGrath emphasized that "Over time…acknowledgment of guilt and responsibility is critical because treatment interventions rely fundamentally on the offender's ability to identify and change the feelings, thoughts, and behaviors that were proximal to his sexually aggressive act" (p. 148).

However, as Garb (1998) pointed out, most research has revealed substantial variability in treatability decisions and that there was little evidence that FMHPs are able to predict treatment response with more than modest accuracy. Similarly, McGrath (1993) noted that opinions about amenability to treatment are not predictions about the likely *effectiveness* of treatment with a particular sexual offender. Thus, it becomes incumbent on forensic evaluators to identify evidence-based primary and secondary considerations that can serve to direct recommendations about the probability of the appropriateness of interventions and what might reasonably be expected in terms of sexual offender treatment course and outcome for particular individuals.

Forensic Risk Assessment

Sexual offender risk assessment involves using the results of a forensic evaluation to characterize or estimate the likelihood or probability that an individual with characteristics similar to the examinee will commit a future act of violence, particularly a new sexual offense. Thus, risk assessment is to be distinguished from "risk prediction," which involves a dichotomous decision that a particular sexual offender either will or will not sexually reoffend. Such absolute predictions that an examinee will or will not reoffend cannot be justified and are never warranted. Risk assessment can also be viewed as a component of risk management, where the likelihood of future sexual offending can inform decisions about possible dispositions and/or interventions. The nature and relative accuracy of sex offender risk assessment has improved markedly over the past 20 years and continues to evolve in its sophistication and comprehensiveness.

In considering the variety of potential approaches to gauging future risk of sexual recidivism including (1) general base rates for sexual reoffending; (2) the combined results of so-called actuarial measures; (3) other individual risk factors associated with sexual offending; (4) structured clinical or professional judgment; (5) dynamic measures of criminogenic needs of psychologically meaningful risk factors; and (6) special considerations.

Base rates provide a metric for considering the average risk for future sexual offending. However, the core of risk assessment involves the use of so-called actuarial instruments, which effectively provide adjusted base rates based on the consideration of multiple risk factors associated with sexual reoffending that have been statistically combined. It has been argued that actuarial methods have been recognized as superior to unstructured "clinical" judgment around psychological issues (e.g., Grove & Meehl, 1996; Meehl, 1954; Grove et al., 2000), including risk assessment (e.g., Quinsey

et al., 1998, 2006). For sexual offenders, recent meta-analyses and other multivariate studies of the sex offender recidivism literature have identified largely "static" or historical factors that are empirically related to recidivism (e.g., Hanson & Bussière, 1996, 1998; Hanson & Morton-Bourgon, 2004; Quinsey, Lalumiere, Rice, & Harris, 1995). Following directly from this body of research, actuarial risk assessment instruments (ARAI) have been developed largely through a so-called "actuarial" methodology; these ARAI can be considered as attempts to develop adjusted base rates for groups of sex offenders with particular numbers and types of easily measured risk factors. Actuarial methods are typically ones that rely on objectively identified factors associated with an outcome of interest; an actuarial scale specifies *which factors* are selected for examination and the relative *"weight"* that factor has as part of the assessment of some outcome. Actuarial scales are statistical means of selecting and combining easily obtained information and examining the degree to which those particular variables are associated with some future outcome (e.g., predictive accuracy). Starting in the mid-1990s, several ARAIs were developed that have been repeatedly demonstrated to show moderate predictive accuracy of sex offender recidivism for adult male sexual offenders. More specifically, these actuarial instruments provide estimates of the degree of risk (probability) of a future sex offense for sex offenders with particular numbers or degree of risk factors (Doren, 2002; Hanson, 1998; Quinsey et al., 1998, 2006). Different instruments rely on different "outcomes" to measure sex offender recidivism, ranging from convictions to arrests; other instruments rely on broader outcomes in an effort to address the dramatic underreporting of sexual offending. In short, actuarial measures have been developed which utilize statistical combinations of a limited number of risk factors and their association with the likelihood of rearrests or reconvictions for different behaviors for varying measures of future sex offenses.

Actuarial RAIs include the Static-99 (Hanson & Thornton, 1999), the Static-99R (Helmus, Hanson, Thornton, Babchishin, & Harris, 2012; Helmus, Hanson, Thornton, Babchishin & Harris, 2015), the Static-2002R (Hanson & Thornton, 2003; Helmus, Thornton, Hanson, & Babchishin, 2012; Helmus, Hanson, Thornton, Babchishin & Harris, 2015), the Minnesota Sex Offender Screening Tool-Revised (MnSOST-R: Epperson, Kaul, & Hesselton, 1998; Epperson, Kaul, Huot, Goldman, & Alexander, 2003), the Sex Offender Risk Appraisal Guide (SORAG, Quinsey et al., 1998, 2006; Rice & Harris, 1997, 2014, 2015; Rice, Harris, & Lang, 2013), or the Violence Risk Assessment Guide-Revised (the new VRAG-R, Rice et al., 2013). At present, per the Association for the Treatment of Sexual Abusers, actuarial assessment is regarded as one of the two core risk assessment methodologies for sexual offenders. There are now sufficient empirical studies in the scientific literature that provide independent cross validation of these actuarial instruments. Each has been found to possess at least moderate predictive accuracy. In addition, the confidence intervals for each of these ARAIs overlap; this means that their respective predictive accuracies are not significantly different from each other. Therefore, studies published to date indicate that there are at least several actuarial instruments that provide reasonable predictions of sexual recidivism, with no apparent advantage to any specific test.

Based upon several considerations, currently, the use of multiple actuarial measures has been endorsed by multiple individuals [e.g., R. K. Hanson, Personal communication, 2008; Barbaree in Langton et al., 2007; Doren, 2010) based on several considerations. Scientifically, there is no "best" instrument; they possess equivalent degrees of predictive accuracy from a measurement perspective. In addition, since the different actuarial instruments contain unique as well as overlapping variables they each measure recidivism using different sets of risk factors. The relative ranking of risk by the different actuarial instruments may be different for different individuals. Issues in scoring of the different measures will make less of a difference when multiple measures are utilized; multiple actuarial instruments lead to increased reliability in identifying the relative risk of a particular offender. Finally, to the degree that a "set" of (multiple) actuarial measures converge in identifying that an offender is at higher risk, then there can be increased confidence in concluding that that sex offender is at higher risk for sexual reoffending.

An alternative method for risk assessment and management of sexual offender recidivism is the use of structured clinical judgment or structured professional judgment (noted previously, abbreviated as SPJ). The PCL-R (Hare, 1991) is the most researched structured clinical rating scale in the area of violence assessment and has been shown by various meta-analyses to be specifically associated with sex offense recidivism (Hanson & Bussière, 1996, 1998; Hanson & Morton-Bourgon, 2004, 2005; Hawes, Boccaccini, & Murrie, 2013). Two other instruments also provide a structured professional risk assessment for sexual reoffending recidivism, the Sexual Violence Rating Scale (SVR-20; Boer, Wilson, Gauthier, & Hart 1997), and its putative replacement the Risk for Sexual Violence Protocol (RSVP; Hart, Kropp, & Laws, 2003).

In addition, recently, there has been a scientific and forensic interest in the manner in which additional "dynamic" or "psychological" risk factors ("criminogenic needs) may interact with static risk measured by the ARAIs. Several instruments have been developed over a period of time to provide scientifically reliable and valid measures of such risk factors. These include the Stable-2007 (Eher et al., 2012; Hanson, Harris, Scott, & Helmus, 2007), the Violence Risk Scale: Sex Offender Version (VRS: SO; Olver, Wong,

Nicholaichuk, & Gordon, 2007; Olver & Wong, 2014, 2015), and the Structured Risk Assessment-Forensic Version (SRA-FV) (e.g., Thornton & Knight, 2009, 2014).

Finally, other factors to be considered relative to mitigating or aggravating risk for sex offense recidivism include age (at onset of sexual offending and at release), medical status, past sex offender treatment experiences, and, the reported results of any recent or current sex offender treatment. Since there is, at best, minimal scientific evidence that sex offender treatment as it was historically or currently implemented has been scientifically demonstrated to reduce sexual offense recidivism or even to change personal characteristics (e.g., Hoberman, 2015), each offender must be carefully evaluated in an idiographic manner to determine if that individual has obtained substantive benefit from sexual offender treatment. Mere participation in sex offender treatment offers little information about actual or substantive treatment-related changes or gains. Specifically, an evaluator must utilize multiple sources of information to form an opinion about the range and depth of understanding (insight) of an offender's unique criminogenic needs as they have been operative in their sexual offending, the degree to which they were "taught," extensively practiced, and can implement interventions that have been empirically demonstrated to reduce sexual offense recidivism, the extent to which they have internalized both self-regulation and values associated with self-control, and the intensity and demonstration of their commitment to enacting significant cognitive, emotional, and behavioral change and the likely robustness of that commitment in the face of historical and general situational antecedents of offending pathways.

Report Writing: Developing and Documenting Opinions and Their Basis

In the process of conducting a forensic evaluation, the development of a written report is the typical means of memorializing the extensive review of information about a sexual offender and integration of that information with the results of the current direct evaluation and the extant scientific and professional knowledge. The forensic report provides the means to document available and relevant information that was considered by the evaluator and the process by which those sets of information provided the basis for conclusions or opinions offered by the evaluator. For forensic evaluations, the written report submitted prior to a hearing or trial provides the opportunity to provide detailed documentation of (1) what information in the records the evaluator considered, (2) the results of the current direct evaluation and its limitations as a source of information, (3) how the information from the records and the direct evaluation were considered or interpreted relative to the history of a particular offender (and against the background of the general literature regarding sexual offenders), and (4) what conclusions were inferred or derived from the database regarding the examinee and direct evaluation relative to scientific knowledge and professional experience. It is the multiple methods employed, the data available from those methods, and nomothetic and idiographic analysis of the subject in the context of available scientific/professional knowledge that determines the results of the evaluation—and not the offender or a retaining attorney.

It is relatively rare that after conducting a forensic evaluation of a sexual offender that one would not be required to compose a formal report. However, unless court-appointed, retaining attorneys can and do make decisions about whether an informed forensic opinion is likely to be favorable for their client and can choose to not have an evaluator produce a written version of that opinion. Thus, in a number of situations, unfavorable forensic opinions that are not court-ordered typically "disappear" from the potential consideration of those involved in making decisions or crafting dispositions about a particular offender. In most situations though, as Meloy (1989) argued, that one's "paper trail" via a report is more important in forensic work and to one's professional standing as an evaluator than in any other area of mental health. The forensic report is an essential means to present information and informed opinion that needs to be communicated to nonmental health professionals. If the essential forensic task is to provide assistance for the court or public in understanding and using the information obtained through a forensic evaluation, then the forensic report should be characterized by qualities such as thoroughness and clarity regarding reporting the extant data and the opinion of the evaluator. As Meloy (1989) has stated: "*Thoroughness* means that every issue is explored if it is relevant to the forensic issue being addressed" (p. 328). A written report memorializing the forensic evaluation and opinion is a critical, and often the central, evidentiary component of many specific legal proceedings for sexual offenders. It is often the linchpin for the discussion of the issues of a particular case. Consequently, the consensus among authorities in the general forensic community is that the report from a forensic evaluation must be comprehensive, thorough, and clear in its critical review and analysis of the "database" regarding an examinee. Further, as Weiner (1995) and others have pointed out, persons who conduct forensic evaluations should be able to express their opinions and conclusions in writing and testimony in a clear, relevant, informative, and defensible manner.

As has been emphasized at several points, almost all evaluations regarding sexual offenders are and should be regarded as forensic in nature. Consequently, the great majority of reports regarding such evaluations should be viewed as reports on behalf of a court, potential legal proceeding, or

"the public," regardless of who requested the evaluation. Written forensic reports can vary somewhat in length and content depending on the amount of relevant data collected about an individual, the number and complexity of psycho-legal questions and considerations to be addressed, and the perceived need to provide adequate documentation of the information and process utilized to develop each aspect or element of opinions. As a result, no single set of guidelines is appropriate for reports related to forensic evaluations. For very narrow referral questions, less elaborated or detailed reports may be acceptable, whereas for more complex or broad referral questions (e.g., initial civil commitment evaluations or release evaluations), a brief report should be viewed as quite inadequate. In addition, the length and detail of written forensic psychological reports may be related to jurisdictional standards or customs where TF/TFL may expect relatively lengthy and well-documented reports (which they may employ in drafting proposed findings of fact). In addition, certain "initial" and "progress/summary" reports will serve as foundational sources of information against which later forensic reports and opinions will be compared; consequently, such reports should be as comprehensive, detailed, and clear as necessary to provide an adequate basis for later comparison.

In addition, in composing a forensic report regarding a forensic sexual offender evaluation, it is important to keep in mind that such reports are likely to be considered and utilized within an adversarial context. While it might be argued that more abbreviated reports are preferable, in many instances of forensic evaluations of sexual offenders the nature of the adversarial process is such that it is important to report in detail the information relied upon by the evaluator to determine or inform the basis for his opinion so that it is more readily available to the evaluator (particularly if testimony may be required). Weiner (1999) wrote that whenever mental health professionals are called to testify in a legal proceeding, their testimony on direct examination would typically be based on their written report. That in turn means that everything within the report may be subject to question on cross-examination. As a result, an evaluator should be careful about the information that they report and the manner in which they identify how they weighed and integrated information with regard to reaching their opinions. Given the issues of memory generally and memory biases, careful documentation of relevant information in the body of the report is useful for potential testimony by an evaluator. Consequently, in composing a report, evaluators should consider and prepare for potential questions that an attorney or the court might pose about the source, nature, and implications of the information reviewed and opinions rendered. Weiner argues that as a basic principle, mental health professionals performing forensic evaluations should limit their reports to information and opinions that they would feel comfortable and confident stating in the courtroom and be able to defend their opinions and their basis against reasonable challenge. In reports and related testimony, the forensic evaluator should be careful to distinguish any elements of their opinions that they are basing on "clinical experience" and that may not have a valid scientific foundation. To the extent it is offered or requested in a court proceeding, "clinical" opinion or judgment must clearly be stated as one professional's opinion and not as an "expert opinion" (e.g., an opinion that is reasonably and reliably based in the scientific knowledge or particular experiences). Persons conducting forensic evaluation of sexual offenders should always attempt to be cognizant of the limitations of the foundations of their opinions and resulting conclusions. Any opinions are typically expressed with a "reasonable degree of professional certainty," which as Nicholson (1999) noted "refers to the expert's confidence in his opinion and not to the accuracy or general acceptance of that opinion" (p. 127).

Grisso (2010) analyzed critical reviews by experienced forensic evaluators of sample forensic reports by forensic psychologists. They identified a number of discrete factors recommended for improving forensic reports. Among the most relevant from our perspective are the following. First, in general, such reports should be organized in a manner that is logical and assists the court or public's understanding. Second, forensic reports should present multiple sources of data. Relative to multiple data sources, an examinee's self-reported data should be considered as a basis for an opinion; such data should play a primary role in the opinion only when other reasonably reliable sources of data offer corroborative or logically consistent support for that self-report. Third, evaluators a encouraged to describe and report all data that would be important (e.g., lay the foundation or provide the basis) in addressing the psycho-legal referral question and identify the sources of specific types of and methods by which such data were obtained. Fourth, when reporting on the results of past psychological testing or evaluations, an evaluator should report only those data they consider relevant for addressing the psycho-legal questions in the present case. In addition, when reporting test data from the current evaluation, offer explanations of their normative or nomothetic meaning related to particular scores and don't necessarily describe them as attributes of the examinee. Fifth, it was suggested that a report contain one section in which the relevant foundational evaluation data is reviewed and a separate section in which inferences and opinions are described in a manner that relies on the earlier database review. Sixth, it was suggested that, in relying on multiple sources of data, an evaluator describe the events and examinee's behavior that relate to attributes of the individual related to the psycho-legal questions. Lastly and more generally, with regard to interpretations and opinions, evaluators were encouraged to provide a clear explanation and justification for each important opinion

or conclusion that they offer, summarizing the relevant data that they view as either logically or scientifically supporting the elements of their opinion. Grisso (2010) summarized, stating: "…it is essential in forensic reports, because legal cases require that all evidence, and the basis for (origin of) any evidence in the case, must be revealed in the event that is needed for discovery and verification of evidence on which the examiner's opinions are based" (p. 111).

From these perspectives, several recommendations follow. To begin with, it is important that forensic evaluation reports identify the data sources relied on for the evaluation; these can be listed in paragraph form or as a bulleted list. It is also important to identify the relevant applicable psycho-legal standard or definition of the basic psycho-legal questions that directed the particular evaluation. Such standard definition should generally quote or paraphrase the language from the applicable statute or administrative code.

More importantly, several substantive considerations are particularly relevant in composing an appropriate forensic report of a forensic mental health evaluation of a sexual offender which relate to reviewing the information collected and considered about the individual, elaborating the basis of decision-making and opinions relative to the active psycho-legal issues, and providing a clear, comprehensive, and organized report that provides the basis for explaining the information and opinions

One primary aim of a forensic report is to provide formal documentation and critical analysis of the sources of information ("the database") that provide a basis for rendering opinions on the psycho-legal issues involved in a particular matter or with regard to a particular examinee. In almost all forensic psychological evaluations, evaluators should encounter a considerable amount of data that may vary in its informational value. A critical function of the forensic evaluator is to review and identify the most significant information found amongst the extensive information collected or provided as part of a particular evaluation process. As Gagliardi and Miller (2008) wrote: "Probativeness and information relevance comprise…overarching considerations for the forensic report writer. Probativeness is the degree to which evidence proves or disproves an asserted fact; relevance is whether a particular fact matters to resolving the legal issue in the case" (p. 543). Thus, a key function of the forensic evaluator in writing a forensic psychological report is to review and organize the large set of potentially available material from records (and other collateral sources), interviews, and testing in an organized and coherent fashion. In some cases, previous evaluations or reports may provide a summary of what seemed to be the relevant areas pertaining to a particular sexual offender. However, it is quite common, perhaps even the rule, that across previous reports regarding a particular individual, there are often discrepancies or inconsistencies in the information that had been provided by the subject/individual. In addition, previous evaluators may have incorporated inaccurate information or misperceptions into both reported history and conclusions that are markedly at variance with either the "facts" or historical conclusions about an individual. Both of these phenomena constitute what might be referred to as a legacy of mischaracterization. Consequently it becomes important to not simply "rubber-stamp" (e.g., simply reproduce) the earlier information provided by a particular sexual offender or a previous evaluator but to carefully and critically review information apparently provided by an offender (and others) in previous evaluations as well as "data" from the current direct evaluation so as to clarify what is known or not known about a particular offender with regard to the various areas of the offender's criminal history, self-description, predisposing psychological characteristics and criminogenic needs, and reports of previous treatment or personal change experiences. Meloy (1989) emphasized the importance of thoroughness in reviewing the database regarding an individual undergoing a forensic evaluation. For Meloy, as for most other forensic evaluators, records and other collateral information as well as structured psychological assessment typically trump possible or apparent self-interested and/or distorted (e.g., simulated or dissimulated) interview responses of an examinee. As Meloy (1989) stated "Nothing discredits a forensic clinician more than the mere regurgitation of the interviewee's perspective in the report or through testimony. It is evidence of the clinician's laziness and naïveté, and may be very embarrassing if easily contradicted by information that was available…" (p. 328). Thus, a forensic evaluator should provide a reasonably detailed review of all the information that is available, to highlight consistencies and inconsistencies in the information available, and finally to provide a platform for the subsequent integration and application of that database in the formulation of an opinion.

A second aim of a forensic report is typically to provide an opinion that relates to or addresses the psycho-legal issues based upon a professional and scientifically informed evaluation as it applies to the particular individual at the focus of the legal case. The development of such an opinion assumes that an evaluator is knowledgeable about the appropriate subject areas for a particular type of evaluation, methods of data collection that provide the most useful information, and the accurate and current scientific knowledge of the field. In addition, the process of coming to a conclusion or opinion about how particular psycho-legal issues apply to a particular examinee is an iterative process that involves considering both idiographic and nomothetic information. Previous reports of behavioral history constitute initial idiographic information about a subject. Past and current SPA (e.g., psychological testing and structured interviews/ratings) provide bases for nomothetic considerations. Developing a comprehensive, integrated forensic opinion innately builds upon the

review of the database collected regarding the individual—their behavioral and/or psychosocial history based on the available records and the results of the current direct evaluation (in the context of the psycho-legal questions). More specifically, developing such an opinion relies on critically reviewing that database. Next, nomothetic considerations become significant: how does the particular sexual offender compare to standardized norms and criteria from available structured psychological assessment tools as well as what is known about sexual offenders, generally and similar to persons with his relevant history? Thus, a critical component of a forensic sexual evaluation is applying scientific and professional knowledge—that is, placing the individual's database within the context of the subject's own self-report and the evaluator's structured rating in both a normative, nomothetic context and that of existing scientific knowledge and experience. Among such issues to be considered is in what ways this sexual offender is similar to and/or different from other criminal or sexual offenders. Finally, an evaluator must consider the particulars of the examinee in relation to the nomothetic data and considerations and render an idiographic opinion about the particular individual being evaluated. Relative to the psycho-legal issues, are there particular data or concerns that are mitigating or aggravating relative to the disposition of this particular individual? Thus, the consideration of specific information about the sexual offender who is the subject of an evaluation should both be considered in the context of general knowledge about sexual offending and as well as in the context of case- or person-specific issues.

An issue that has been raised through the available forensic psychological literature has to do with whether or not forensic reports should contain opinions about the "ultimate" psycho-legal question(s). While some authors such as Melton, Petrila, Poythress, and Slobogin (1997) recommended against opining on ultimate legal issues, other writers note (Gagliardi & Miller, 2008) that many or most actual forensic reports contain such opinions. Allnutt and Chaplow (2000) recommended forensic psychological reports include "the evidentiary bases for each level of inference" related to the psycho-legal standards and the way this information applies to the relevant legal issues." Clearly in many jurisdictions, it is the expectation of the court or the trier of law that the expert expresses an opinion on the ultimate psycho-legal issues either in testimony or in their forensic psychological report. Further, Grisso (2010) notes that, historically, there has not been a consensus among forensic mental health experts as to whether it is essential to fully explain in a report the reasoning for one's opinion. However, he noted that, in more recent years, commentators have increasingly emphasized that forensic reports should describe how the evaluator's opinion is more specifically supported by available data and reflects the logic with which the evidence leads to the particular forensic opinion. There appears to be an increased emphasis on more detailed documentation (e.g., "the database") along with delineation of what information from multi-method sources and its analysis provides the bases relevant to the psycho-legal at issue for the opinion.

Thus, the third critical component of a forensic report is to provide a discussion of the various key factors that relate to the psycho-legal issues. Clearly, interpreting and applying the database from an evaluation, in the context of case knowledge, mental health scientific knowledge, and experience, is generally inferential in nature. Most forensic psychological opinions involve such issues as cognitive-affective-motivational and other psychosocial characteristics (e.g., personality traits, implications of behavioral history, motivators and elements of self-control, impairments, risk and potential dispositions) and thus involve inferences and are matters of opinion. Heilbrun (2003) discussed the notion that "scientific reasoning" may be used to construe the results of one source of information such as self-report as providing "hypotheses to be verified" or "disconfirmed" through information provided by other sources such as psychological testing record review or collateral information. Thus, a central feature of a forensic psychological report and testimony is that it provides, if possible, a delineation of the particular inferences or opinions that are relatively directly tied to the identification, review, and integration of information collected as part of such an evaluation placed in scientific context. The value of presenting a detailed and analysis of the database earlier in a report is that it allows for a more succinct presentation of the bases for inferences and interpretations for the forensic opinions later in the forensic report. That is, by providing a detailed description of the database, initially in the report it lays the foundation for a more informed and cogent analysis and interpretation of relevant psycho-legal issues. In many respects, the database review and analysis should both implicitly and explicitly suggest or direct the forensic opinion.

Conclusion

The purpose of this chapter was to provide a perspective of the key elements and appropriate procedures for conducting a forensic evaluation of sexual offenders. As indicated, virtually all evaluations of such offenders are actually forensic in nature, meaning that their initiation and their results are or will be utilized in the legal process regarding dispositions about alleged or convicted sexual offenders. Many professionals are involved in or are consumers of such evaluations—varied mental health professionals, corrections and probation personnel, attorneys, and triers of fact and law. Mental health professionals, many of whom lack formal and substantive forensic training and formal experience, must be aware of the particular principles and procedures that inform—and even govern—

forensic evaluations of sexual offenders. Members of the legal profession and judiciary would also benefit from the delineation of elements of a comprehensive approach to the forensic evaluation of sexual offenders so that they can become informed consumers of what is recommended as constituting an informed and useful evaluation. To be meaningful, an evaluation must be based on reliable and valid principles and procedures of evaluation methods (e.g., structured psychological assessment) and scientific findings as related to the psycho-legal issues that provide the context for information that is both admissible in a court of law and useful to attorneys of litigants as well as triers of fact and law.

While it might be assumed that general mental health professionals would be able to enact a meaningful or "forensically adequate" evaluation of a sexual offender, experience suggests that this assumption is flawed. Among mental health professionals who do conduct such evaluations, there are often glaring gaps in knowledge of substantive domains regarding the current scientific knowledge about sexual offenders, the empirically validated and potential determinants of sexual offending (such as psychologically meaningful risk factors or predisposing conditions), determinants of and methodological issues regarding the probability of future dangerousness of sexual offenders, and the component procedures of a comprehensive, methodologically rigorous evaluation that meets judicial standards for admissibility in court. In particular, far too many mental health professionals are simply unaware of the nature, ethics, and legal requirements for forensic psychological evaluations—evaluations that provide information relevant to psycho-legal questions. The forensic context imposes critical guidelines on the following: the competencies, general methods, and approaches to gathering information before and during the evaluation: the nature of the specific psychological/psychiatric instruments, tests, and questionnaires used (e.g., standardize psychological assessment); and the manner in which a large set of multi-method, multisource information obtained is considered and integrated. In particular, forensic evaluations *require* the guiding dimensions of skeptical and critical analyses of information and not simply advocacy for or against a particular individual. Consequently, a high value should be placed on the availability and utilization of well-trained, knowledgeable, experienced forensic evaluators, particularly for significant psycho-legal issues.

The forensic evaluation of sexual offenders is an important process with very significant results and implications. The results and application of such an evaluation almost always bear on balancing issues of civil liberties of the individual and the protection of the community. Given the magnitude of these issues, it is critical that a very high level of knowledge about the psycho-legal issues and the substantive field of sexual offending as well as the appreciation of sound, thorough, and comprehensive methods enacting and processing the data collection of such evaluations characterize forensic evaluations. Those involved in the legal decision-making regarding sexual offenders should not tolerate, let alone rely on, casual, uninformed, "usual and customary" forensic evaluations by individuals who lack the necessary preparation in terms of their knowledge of relevant substantive areas or methods of evaluation related to the assessment of sexual offenders. Comprehensive forensic evaluations of sexual offenders must be rigorous, including the best available methods for providing relevant information that can serve as the basis for informed decision-making about a particular individual under consideration. Such evaluations offer both the offender under consideration and the community concerned about public safety an important means of obtaining and contextualizing information that can allow a court of law to make reasoned, educated decisions about the disposition of particular sexual offenders.

Conceptual Model of Risk Versus Threat and Risk Management Versus Risk Reduction

Douglas L. Epperson and Christopher A. Ralston

The concept of risk is defined differently across diverse disciplines, such as mathematics, law, engineering, business, and even art and religion (Althaus, 2005). Given that sexual offender risk assessment and treatment sits at the crossroads of several disciplines (e.g., criminology, psychology, sociology, law, public administration), it is not surprising that risk is discussed in a variety of ways. The differences are often subtle and implicit, yet meaningful because they are sources of confusion and obstacles to constructive discussions about how best to assess, treat, and manage risk.

This chapter utilizes the epistemological traditions of mathematics, logic, psychology, and law to define risk as applied to sexual offender literature. In doing so, we will draw upon and refine previously specified models of risk, risk assessment, risk reduction, and risk management such as the Risk-Need-Responsivity Principle (e.g., Andrews & Bonta, 2003; Andrews, Bonta, & Wormith, 2006), the Integrated Theory of Sexual Offending (Ward & Beech, 2005), the Dynamic Supervision Project (e.g., Hanson, Harris, Scott, & Helmus, 2007), and Epperson and colleagues' Model of Risk and Threat (Epperson, Ralston, Fowers, Dewitt, & Gore, 2005).

After clarifying and reconceptualizing concepts and terms that are used somewhat inconsistently, we discuss the implications of this restructuring of risk assessment arguing that an accurate understanding of risk and related concepts, coupled with accurate risk assessment, can lead to more carefully thought out and effective risk management and risk reduction efforts. Finally, using the newly specified model of risk in conjunction with recent research findings, we provide possible explanations for both reduced rates of observed sexual recidivism and predictive validity indices in many established risk assessment tools over the past decade.

Risk, Risk Factors, and Risk Indicators

What is *risk*? As noted earlier, the definition varies somewhat across scientific disciplines. The single common element in those definitions is "the application of some form of knowledge to the unknown in an attempt to confront uncertainty and make decisions" (Althaus, 2005, p. 580). As applied to the disciplines of mathematics and logic, risk is viewed as a probabilistic statement about the likelihood of some event occurring at some point in the future (Althaus, 2005). This probabilistic view of risk is commonly implied when people discuss risk of sexual recidivism. More explicitly risk, as applied to sexual offender recidivism, is commonly interpreted as the probability that a known and sanctioned sexual offender will reoffend within some time frame, such as the next 10 years or before a specified age.

On the surface, this seems to be a fully satisfactory definition of risk. However, there is a major problem, which is that the probability of reoffending is dependent upon many factors. Examples of such factors include internal predispositions, such as an offender's degree of sexual preoccupation and/or impaired self-regulation skills, and externally imposed constraints, such as the intensity of community supervision, which limit opportunities for further offending. Such confounding of internal and external factors makes it difficult to have meaningful conversations about risk assessment, risk reduction, and risk management. The lack of precision in definition impedes our ability to make rigorous and logical analyses of risk-related concepts and tools (Althaus, 2005). What is needed is a model that facilitates a thorough separation, analysis, and discussion of internal (psychological) and external (environmental/contextual) forces that give rise to or inhibit future sexual offending. Therefore, we argue

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_17

for a definition of risk that includes the probabilistic elements of the mathematical-logical definitions, but limits them to the domain of internal factors per the tradition of psychology (Althaus, 2005; Heilbrun, 1997).

Within these parameters, we define risk as the probability that a known and sanctioned sexual offender will reoffend at some time in the future, in the absence of significant external constraints or modifications to the environment. In other words, if a detected sexual offender was released into the community without significant supervision, restrictions, or support resources, *risk* would be the probability that the offender would commit a new sexual offense within the specified period of time.

In this model, risk is viewed as inherent in the individual and resulting from the presence and dynamic interaction of relatively stable, individual characteristics that increase (risk factors) or decrease (protective factors) the likelihood of that individual reoffending sexually at some time in the future. Hereafter, these are collectively referred to as *stable risk factors*, and some examples are provided in Fig. 1. These stable risk factors are similar to Hanson, Harris, and colleagues' (Hanson & Harris, 2000; Hanson, Harris, Scott, & Helmus, 2007) stable dynamic risk factors and include deviant sexual interests, offense-supportive beliefs, sexual self-regulation problems, intimacy deficits, and impulse control dysfunction, among others (Hanson et al., 2007; Ward & Gannon, 2006). These factors not only correlate with sexual recidivism (Hanson et al., 2007) but likely also play a causal role in the offending process. Further, because these factors are assumed to be relatively stable, level of risk remains relatively stable over time. The assumption that underlies this psychological principle is that the best predictor of future behavior is past behavior. Past behavior does not cause future behavior; rather, it is the relative stability of personality that allows us to assume that roughly the same set of underlying stable risk factors that caused past behavior will be present in and influence future behavior.

The impact of stable risk factors on behavior is not simply additive because the simple presence or absence of one or more stable risk factors may be insufficient to explain behavior, particularly one as complex as sexual offending. Instead, these risk factors, though relatively stable within the individual, vary in degree from person to person and interact with each other to produce behavior. In other words, two sexual offenders may each have two risk factors present, yet represent different levels of risk because of the differing nature, strengths, and interactions of the two risk factors. One offender with high levels of psychopathy and moderate intimacy deficits may have a lower risk for a sexual reoffense than an offender with moderate deviant sexual drive and high impulse control deficits because of the greater salience and potential interaction of deviant sexual drive and impulse control deficits.

As described in the Integrated Theory of Sexual Offending (Ward & Beech, 2005), stable risk factors derive from complex interactions between the offender and social–cultural, developmental, and biological factors over the course of a lifetime (SEE Fig. 2). Because the resulting characteristics, including stable risk factors, are largely enduring, they

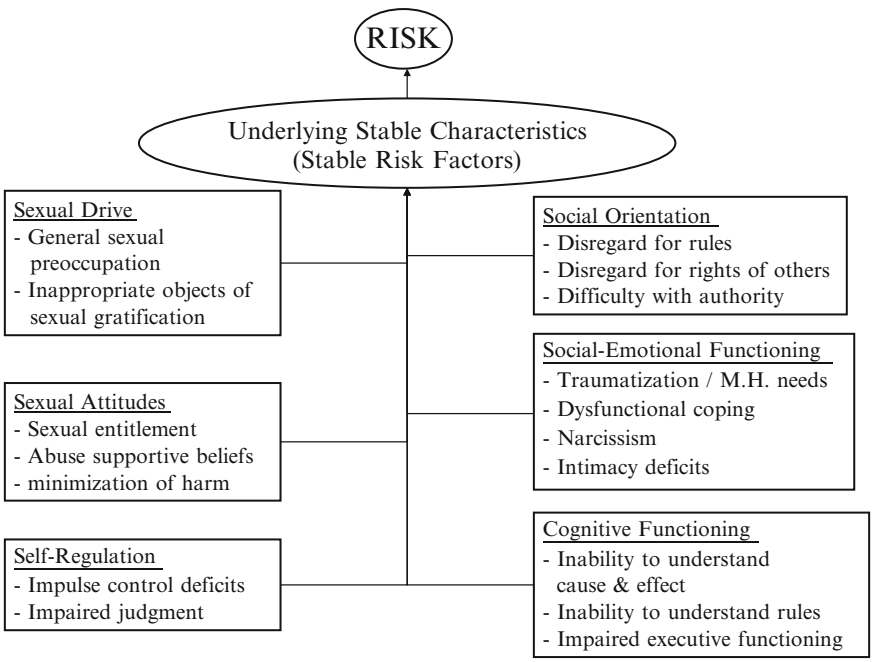

Fig. 1 Stable risk factors that increase the likelihood of an individual sexual offender reoffending sexually

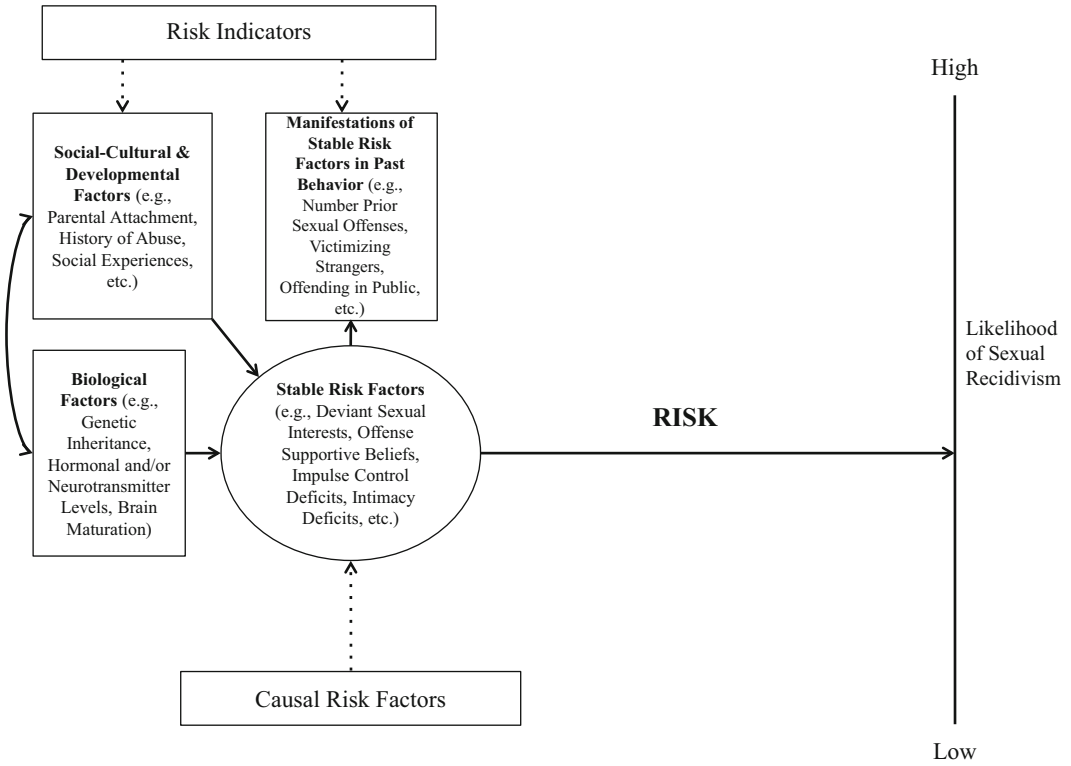

Fig. 2 Stable risk factors are influenced by biological and both socio-cultural and developmental factors. Prior manifestations of risk and both socio-cultural and developmental factors serve as risk indicators. In the absence of risk reduction or management, risk directly corresponds to the likelihood of recidivism

produce similar or patterned behavior over time. Consequently, past behaviors and historical events are correlated with, or predictive of, future behavior. In juvenile sexual offending, for example, historical events such as placement in special education or having been the victim of child abuse are correlated with juvenile sexual recidivism, as are past behaviors such as multiple adjudications for sexual offenses, committing a sexual offense while under court-ordered supervision, and committing a sexual offense in a public place (Epperson, Ralston, Fowers, DeWitt, & Gore, 2005). Other examples of historical events and past behaviors that are correlated with sexual recidivism can be found in the items of major actuarial risk assessment tools (e.g., Static-99, Static-2002, MnSOST-R, SORAG, etc.) or meta-analyses performed by Karl Hanson and his colleagues (e.g., Hanson & Bourgon, 2008; Hanson & Bussiere, 1998).

Presumably, prior actions that are correlated with future offending are behavioral proxies for underlying and relatively enduring risk factors and their interactions. For example, committing a sexual offense in a public place does not cause the individual to continue offending in the future. This action results from any number of underlying risk factors and their interactions, possibly sexual preoccupation or deviant sexual arousal, deficient self-regulations skills, or insufficient cognitive ability to understand rules or weigh risk and reward. Similarly, historical events that are correlated with sexual recidivism are presumed to be proxies or causal factors that shape underlying stable risk factors. Placement in special education may be a manifestation of underlying stable risk factors (e.g., impaired cognitive skills and/or self-regulation skills); whereas, having been a victim of sexual abuse as a child may have contributed to the development of underlying stable risk factors (e.g., distorted sexual attitudes, dysfunctional coping, and/or intimacy deficits).

Such events and behaviors are often referred to as static risk factors because they can change in only one direction (once you are a victim of abuse, you can only be further victimized, or once you have two convictions for sexual offenses, you can never have fewer than two such convictions). Because such events and behaviors are *indicative* of risk rather than causal, we refer to them as *risk indicators* to avoid any confusion, reserving the term *stable risk factors* to reflect causality.

In summary, risk is viewed as inherent in the individual, as defined by the constellation stable risk factors and their dynamic interactions. These stable risk factors derive from complex developmental interactions between psychological, social, and cultural factors that exert a causal influence on past and future behavior. Consequently, some historical events and behaviors identified by empirical research are

correlated with sexual recidivism. These are referred to as *risk indicators* in our model; environmental/contextual variables are not elements of risk in this model.

Environmental/Contextual Factors and Threat

Although environmental/contextual factors are not elements of risk in this model, they undoubtedly affect the degree of threat to the community presented by released sexual offenders. This section differentiates between *threat* and *risk* and describes the way in which environmental/contextual factors may increase or decrease *threat*.

It is clear that risk is more likely to manifest behaviorally (new sexual victimization) in some contexts than in others. In other words, the manifestation of risk is responsive to inhibiting and exacerbating contextual factors on a moment-by-moment basis (Hanson & Harris, 2000; Zamble & Quinsey, 2001). Contextual factors are those immediate environmental characteristics (e.g., presence or absence of antisocial peers) that interact with personal predispositions (risk), making the predisposition more or less likely to be manifested behaviorally in a new sexual victimization. Contextual factors often change as the individual moves from environment to environment.

Relative to *risk*, a person's *threat* to the community is the likelihood of reoffense, given the person's level of risk and contextual situation. In exacerbating contexts, threat can be higher than risk, and threat can be lower than risk in inhibiting contexts.

Contextual factors affect threat (the manifestation of risk) through their influence on acute internal states (see Fig. 3). Acute internal states are transitory changes within the individual (e.g., mood, impact of deviant thoughts, sexual arousal, intoxication) and are a direct result of the interaction between internal predispositions (stable risk factors) and the immediate environment (contextual factors). In the presence of certain contextual factors (e.g., substance abuse) and associated changes in acute internal states (e.g., intoxication and reduced inhibitions), threat may increase relative to risk. In contrast, other contextual factors (e.g., pro-social peers and role models in stable home and work environments) may produce changes in acute internal states (e.g., sense of well-being and life satisfaction, decreased negative affective states) and reduce threat relative to risk. Thus, it is threat rather than risk that changes across contexts.

Despite these moment-by-moment fluctuations in threat, risk remains relatively stable across time and situation because contextual factors impact acute internal states instead of altering stable risk factors. Consequently, the offender who is at "highest risk" to recidivate will still generally be a greater

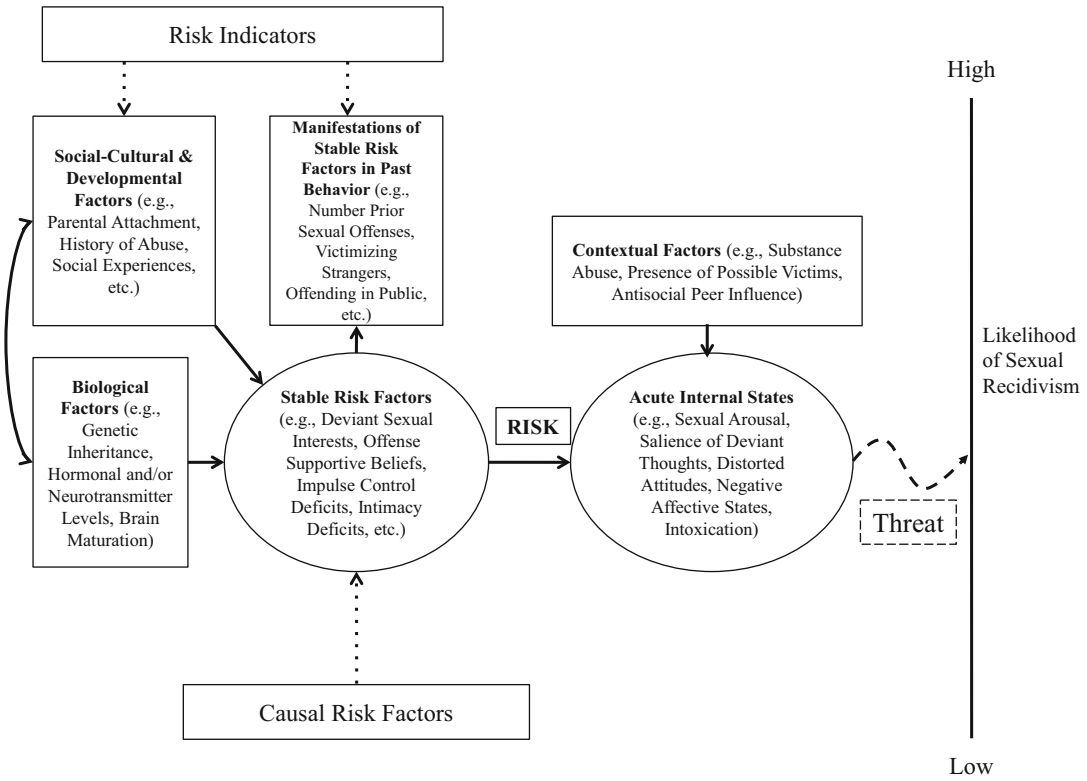

Fig. 3 The relation between stable risk factors and threat is mediated by acute internal states. Contextual factors can exacerbate or inhibit acute internal states

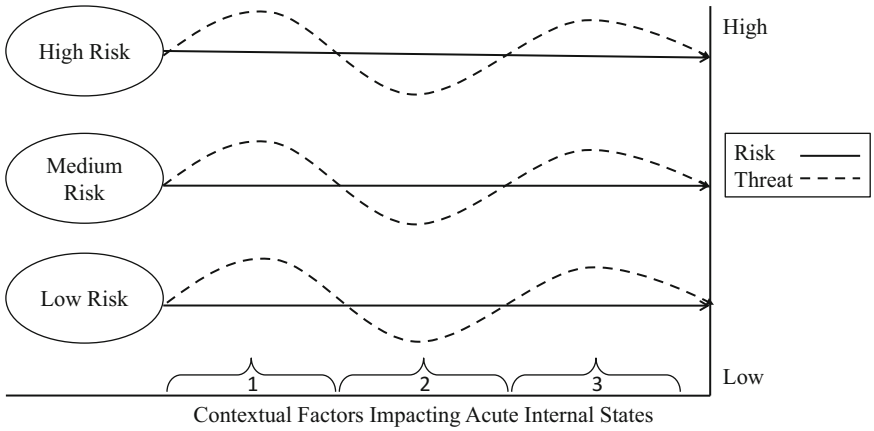

Fig. 4 Risk levels remain relatively stable, despite moment-to-moment fluctuations in threat

threat to the community in the presence of inhibiting factors than another offender who is "low risk" under exacerbating factors (see Fig. 4), unless highly controlled contextual factors are externally imposed as an intervention.

This distinction between risk and threat avoids confusion and results in more precise language. Models of risk in which contextual factors are counted as risk factors create an awkward and untenable situation in which the person's risk constantly changes despite there being no changes in the individual. Under those models, two offenders could have the same risk level but for very different reasons. Offender A could be moderate risk because of low levels of stable risk factors and a relatively unsupervised release environment, while Offender B could be moderate risk because of high levels of stable risk factors and a highly structured and supervised release setting. However, in the current model, Offender A would be low risk, but possibly approach moderate threat at times because of the unstructured release environment, while Offender B would be high risk, but possibly moderate threat because of his placement in highly structured and intensively supervised release conditions. As described below, this distinction between risk and threat enables us to more logically talk about placing offenders in more or less structured contexts based on risk.

Risk Management

The observation that contextual factors may alter threat relative to risk is precisely what opens the door to actively managing risk in the community. *Risk management factors* include all efforts external to the offender intended to constrain the contextual factors that might increase threat relative to risk, emphasize those contextual factors that might decrease threat relative to risk, and/or increase detection of pre-offense behaviors, all with the ultimate goal of inhibiting the expression of risk behaviorally in a new victimization.

In more common language, the goal of risk management is to make the threat of higher-risk offenders more similar to that of lower-risk offenders through interventions that control key components of the offender's environment and acute internal states. Using the same graphical representation, Fig. 5 completes the earlier diagrams in Figs. 2 and 3 by explicitly noting the potential for risk management efforts to lower threat relative to risk by constraining exacerbating contextual factors and emphasizing inhibiting contextual factors.

The ultimate goal of risk management, making the threat of high-risk offenders more like that of lower-risk offenders, is presented more vividly in Fig. 6. As with all interventions, the effectiveness of risk management efforts must be empirically verified and take into account individual differences in responsivity.

As described earlier, risk management factors indirectly affect threat through their influence on acute internal states (see Fig. 5). For example, one risk management strategy may be to reduce exposure to potential victims. Reduced exposure may, in turn, reduce the salience and potency of sexually deviant interests or arousal, thus inhibiting the expression of risk in the moment.

However, risk management factors also impact threat directly (see Fig. 5). Even if reduced exposure to potential victims does not reduce the salience and potency of sexually deviant interests or arousal, it still directly limits opportunities to reoffend. Intensive supervision provides an even more straightforward example. Because of intensive supervision, a probation officer may detect an offender in pre-offense behaviors that violate the offender's probation (e.g., contacting potential victims, substance abuse). Because of this detection of pre-offense behaviors, the offender may have his probation or parole revoked and be returned to custody, eliminating all opportunity to offend in the community, though a potential for sexual misconduct in custody remains. Correlational data suggests that well-developed, systematic tiered risk-management systems reduce the threat to the community, though we know less about the individual components of these systems (e.g., Duwe & Donnay, 2008).

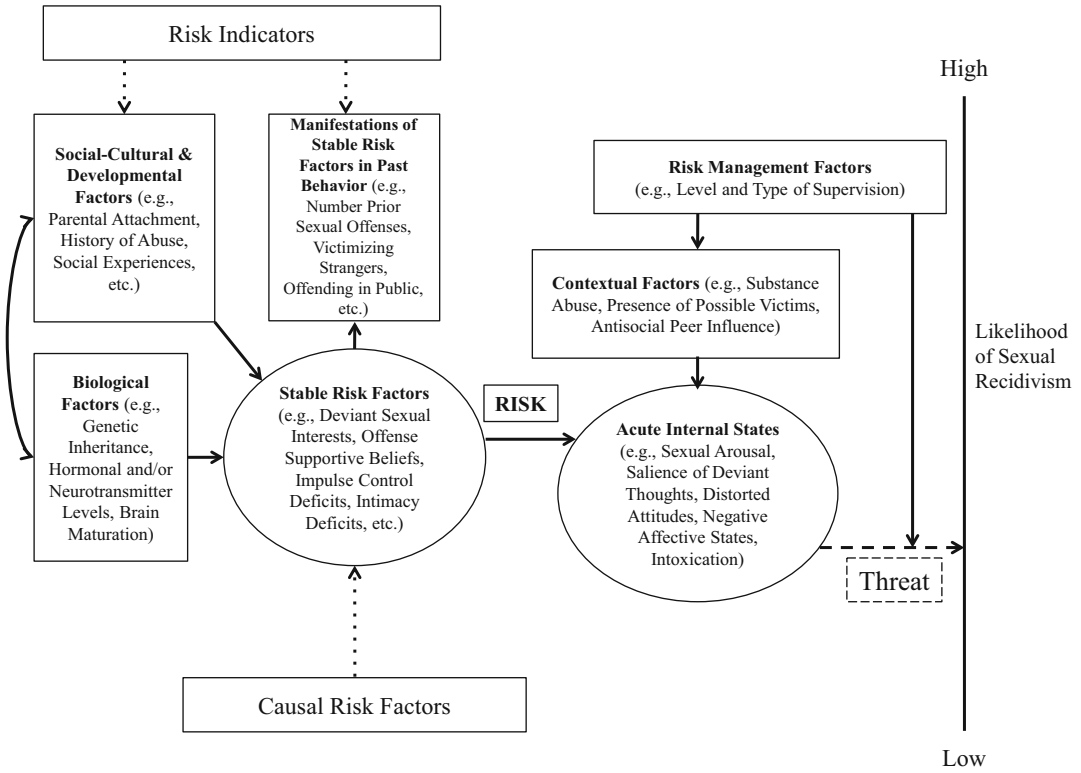

Fig. 5 Effective risk management reduces threat through its effect on contextual factors and early detection of pre-offense behaviors

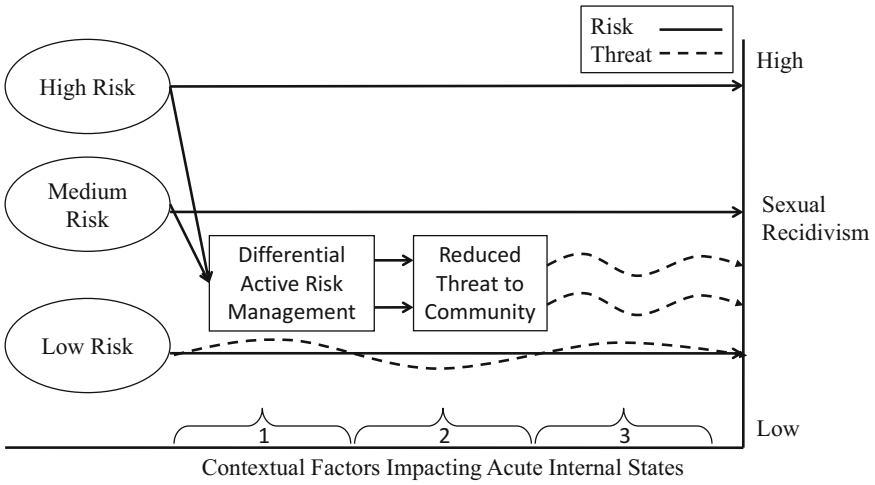

Fig. 6 The impact of effective risk management (risk is unchanged, but threat is reduced)

Risk Reduction

Risk management is not the only way to reduce threat to the community. Because stable risk factors are not static, sexual recidivism can also be prevented through the actual reduction of risk. *Risk reduction* necessarily results from changes in the individual because risk is inherent in the individual. If risk is reduced, so is the associated threat. Though there can still be changes in threat in response to contextual factors, the variance in threat has a lower baseline.

The majority of such changes in the individual presumably occur through treatment, and they would include decreased deviant sex drive, decreased distortions in sexual attitudes, decreased psychopathy, increased impulse control, the development of strategies to reduce "relapse," and the development of pro-social strategies to obtain a "good life" among others (e.g., Andrews et al., 2006; Ward & Gannon, 2006). Thus, the term risk reduction is reserved for conditions of documented changes in internal characteristics that reduce the individual's urge to sexually offend or increase the individual's ability to

internally inhibit acting on such urges. Reduction of risk, rather than the management of risk, is the goal and outcome of effective treatment as presented graphically in Figs. 7 and 8.

Historically, the results of treatment outcome studies have been fairly mixed; however, a recent meta-analysis by Hanson, Bourgon, Helmus, & Hodgson (2009) demonstrated positive gains for risk-need-responsivity-based treatments. A major limitation of many treatment programs is the poor quality of treatment outcome measures. Many treatment programs only measure outcomes based on whether or not treatment is completed. We believe that as treatment programs begin to measure treatment outcomes more specifically, and preferably behaviorally, based on important dimensions related to risk, resulting research will be able to better document who truly benefits from treatment and the associated reductions in risk.

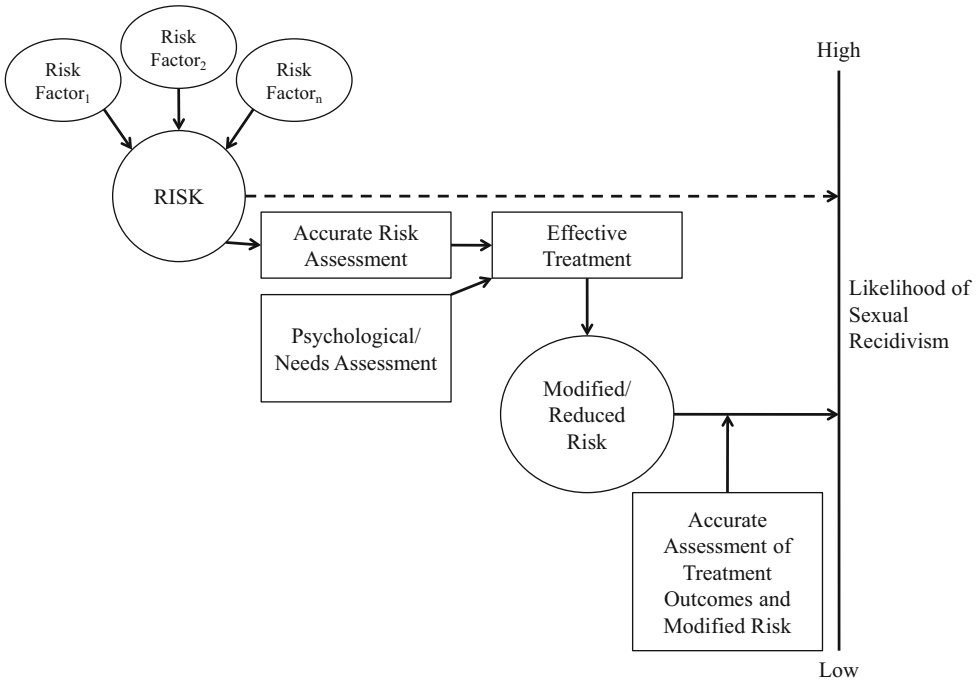

Fig. 7 Effective treatment reduced risk itself rather than managing risk

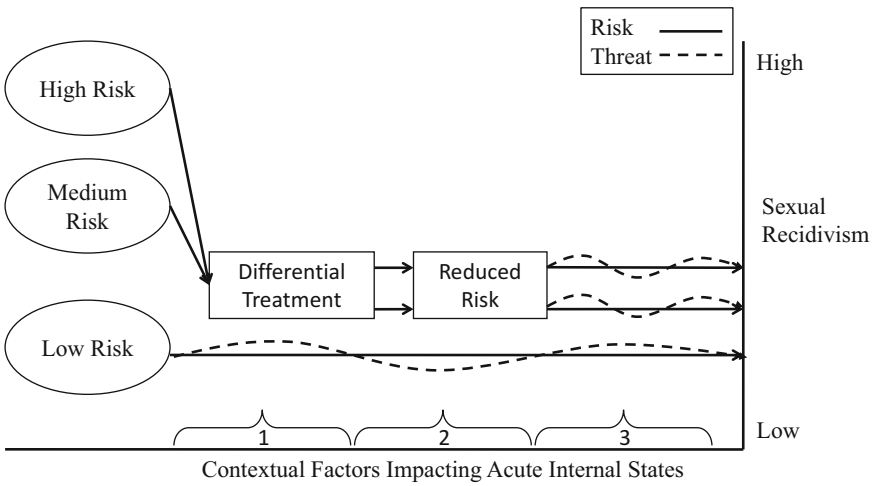

Fig. 8 The impact of effective treatment (threat is lowered by reducing risk itself rather than by managing risk)

Summary and Potential Benefits of the Current Model

In the current model, *risk* is inherent in the individual and is comprised of relatively stable characteristics that make individual offenders more or less likely to continue to sexually offend. Operationally, risk is the likelihood of the offender committing a new sexual offense within a specified period of time if left more or less to his or her own resources. Therefore, estimates of risk (sexual reoffense rates associated with risk levels) are generally best obtained from older samples of offenders released under conditions of "standard" supervision prior to the advent of broad community notification, intensive supervision, etc., in the mid-1990s.

Because risk is inherent in the individual, risk reduction results *only* through sustained changes in underlying, causal risk factors. Generally, such changes occur through focused treatment interventions. As treatment programs and outcome measures become more sophisticated and specific to underlying risk factors, better research can be conducted to determine what comprises effective treatment and to quantify resulting risk reduction.

The individual carries risk across a variety of contexts. Although contextual factors are not elements of risk and do not alter risk, they can increase or decrease the likelihood that risk will manifest in behavior (a new victimization). The increased or decreased likelihood of offending relative to risk as a result of contextual factors is defined as threat. Thus it is threat, not risk, that may vary across settings and situations.

This observation is the basis of risk management procedures, which are intended to reduce the threat relative to risk. Risk management interventions are defined as systematic efforts external to the offender to constrain the contextual factors that might increase threat relative to risk, emphasize those contextual factors that might decrease threat relative to risk, and/or increase detection of preoffense behaviors, all with the ultimate goal of inhibiting the expression of risk behaviorally in a new victimization. Operationally, threat is the likelihood of a new sexual offense given the offender's level of risk and risk management. If there is no risk management, risk and threat are essentially equal. With effective risk management, threat becomes lower than risk. In settings with active risk management programs, threat can be viewed as managed risk. Consequently, estimates of threat (sexual reoffense rates associated with risk levels and the management of that risk) are generally best obtained from more recent samples of offenders released under conditions of broad community notification, intensive supervision, etc.

Potential Benefits of the Model

We believe that this model provides greater precision of language and clarity of constructs. The clear distinction between risk and threat avoids some very confusing language. Without this distinction, one might state that an offender in a highly structured half-way house presents moderate or even low risk because of his release environment. When further queried about why this specific offender, rather than other offenders, was sent to the half-way house, or why this specific offender was not released under less restrictive conditions, the response is difficult. Essentially, the response would be because this moderate- or low-risk offender is actually a high-risk offender.

The description of this situation and response to the potential queries are very straightforward and parsimonious under the current model. The offender was sent to the highly structured half-way house because he is a higher-risk offender relative to others. By releasing him to a highly structured environment, his threat to the community is reduced relative to his risk and buys time for further efforts at risk reduction.

This model also more effectively sorts out elements of risk and risk reduction from elements of threat and threat reduction through risk management. Hanson and Harris (2000) found that an acute change in the offender's anger and subjective distress significantly predicted the short-term likelihood of sexual recidivism. They also noted that access to victims served as an acute predictor. Hanson and Harris (2001) included four "acute" factors in the *Sex Offender Needs Assessment Rating* (*SONAR*): substance abuse, negative mood (e.g., loneliness), anger, and victim access. It is important to note that in these discussions of "acute dynamic risk factors," no distinction was made between contextual events and acute internal states that inhibit or exacerbate risk. In the present model, acute internal states and external factors that modify threat are explicitly separated.

Acute internal states are the moment-to-moment changes within an individual that increase or decrease the likelihood that *risk* will manifest in a new sexual offense in that moment. They are "highly transient conditions that would only last hours or days… are rapidly changing environmental and intrapersonal stresses, conditions, or events that have been shown by previous research to be related to imminent sexual reoffence" (Hanson et al., 2007, p. i). Examples likely to exacerbate risk include sexual preoccupation, negative mood, sexual arousal, and intoxication (Hanson & Harris, 2001; Hanson & Harris, 2002), whereas positive mood and sexual satisfaction would inhibit risk.

Ward and Beech (2004) argued that some risk factors currently "labeled as acute risk factors would be better

viewed as triggering/contextual factors that push traits such as deviant sexual interests into states of deviant sexual arousal" (p. 275). Like them, we make this important distinction, describing all factors that impact acute internal states that either inhibit or exacerbate risk as contextual influences. Examples of contextual influences include substance abuse, presence and influence of social network (antisocial or otherwise), and presence of possible victims, among others.

The greater precision and clarity of constructs in the current model will also be used in following sections to highlight the critical importance of accurate risk assessment for effective risk management and risk reduction interventions, identify various approaches to risk assessment and their inherent advantages and disadvantages, discuss the problems of validating well-established risk assessment tools with more contemporary samples in the context of declining sexual recidivism base rates, and suggest some promising directions for future developments in risk assessment.

Critical Importance of Reliable and Accurate Risk Assessment

Distinguishing between *risk* and *threat* in the manner described earlier, as well as understanding that risk management factors can both decrease and increase threat, sets up the necessity for a "risk-need" approach to offender management (e.g., Andrews & Bonta, 2003). In such an approach, the highest risk sexual offender would be designated for the highest or more intense levels of risk management, and the lowest risk offenders would be designated for the lowest levels of risk management. The benefits are greater likelihood of prevention of new sexual offenses, effective allocation of very limited resources, and limiting possible negative effects of risk management for lower-risk offenders (e.g., warding off unintended exacerbation of risk in environments, particularly for lower-risk offenders).

The greater cost-effectiveness of matching risk management interventions with the level of risk presented in an environment of scarce resources is self-evident. Resources expended in trying to reduce the threat of low-risk offenders, who already pose a relatively minimal threat to the community, are resources that cannot be devoted to managing higher-risk offenders. Because effective risk management efforts in this population necessarily are more intense and costly, having inadequate resources dilutes or eliminates the effectiveness of risk management efforts. Without effective risk management, those higher-risk offenders pose a high threat to the community.

Unnecessarily expensive and restrictive risk management for low-risk offenders has two additional potential liabilities. First, it may unnecessarily deprive that offender of liberty interests that could be afforded to him or her by providing a less restrictive risk management strategy. Second, excessively restrictive risk management strategies with low-risk offenders may actually increase their threat to the community by creating negative acute internal states.

Unintended negative effects through risk management may be of even greater concern for juveniles because they are a low-risk population overall and are generally considered to be more malleable and responsive to treatment than adults. Examples of potential unintended negative effects of risk management efforts that are too aggressive may include stigma, isolation, alienation, vigilantism, lost opportunities, limited ability to reintegrate constructively into their community (Trivits & Reppucci, 2002), or contagion effects (e.g., Boxer, Guerra, Huesmann, & Morales, 2005). Such effects may actually exacerbate or even reinforce stable risk factors over time. For example, limiting participation in pro-social activities may induce further alienation and opportunities to develop the capacity for empathy and intimacy. In addition, simply mixing low- and high-risk juveniles who have offended sexually may increase the risk of the lower-risk juveniles through mere exposure to higher-risk offenders. So, in addition to appropriately allocating resources to those offenders that most require them, effective matching may also keep lower-risk offenders at low levels of risk and threat to the public.

Consequently, accurate matching of risk management strategies with risk is essential not only for cost-effectiveness but also for public safety. In order for optimal matching to occur, accurate assessment of risk is essential. In the absence of accurate risk assessment, decision makers must rely upon one of two strategies. The first is to apply an undifferentiated, "one-size-fits-all" risk management strategy to all sexual offenders, which is generally ineffective and problematic for the reasons already discussed. The second is to base risk management practices on idiosyncratic and unscientific judgments about the risk posed by individual sexual offenders, which is equally likely to be ineffective.

Just as effective risk management requires accurate risk assessment, so does effective treatment. Specifically, accurate risk assessment informs decisions about the necessary length and intensity of treatment, with higher-risk offenders presumably requiring a longer-term and more intense treatment experience to effectively lower their risk and divert them into a non-offending path. Of course, psychological and needs assessments would also be required to provide focus to treatment.

Failure to match treatment with risk and psychological needs based on accurate assessment generally produces undifferentiated, "one-size-fits-all," treatments. In an era of restricted resources, this often translates into treatments that are too intense and costly for very low-risk offenders and

inadequate for high-risk offenders. This approach to treatment is also more likely to mix low-risk and high-risk offenders, which may actually increase the risk of initially low-risk offenders through contagion effects. As noted earlier, contagion effects may be particularly problematic with juveniles, who are more malleable than adults; an important part of treatment may involve segregation of "low-risk" juveniles from higher-risk juveniles. In fact, for some very low-risk juveniles who have offended sexually, detection, segregation from higher-risk juveniles, and a basic psycho-educational intervention may be the only intervention needed. Resources saved with lower-risk offenders could be invested in longer-term, intensive treatment for higher-risk offenders.

This discussion emphasizes the importance of accurate risk assessment and the matching of risk with both risk reduction and risk management intervention to most efficiently manage scarce resources and maximize outcomes. The potential outcome of treatment is risk reduction and the associated decrease in threat. The potential outcome of risk management is managed risk and the associated decrease in threat.

Approaches to Risk Assessment

The model of risk and threat detailed above has important implications for risk assessment. The first is that risk is inherent in the individual and arises from the dynamic interplay of relatively stable internal risk factors. Thus, any type of risk assessment must focus on and account for the presence and interactions of stable risk factors within the individual and the likelihood that it will lead to future sexual offending behavior. The second is that valid assessments of risk can occur in three distinct ways, or some combination of the three ways: assessment of historical risk indicators, assessment of stable internal risk factors, or assessment of acute internal states that modulate stable risk factors. Each type of assessment has its own set of inherent advantages and disadvantages.

Assessment of Risk Indicators

One of the most widely known truisms in psychology is that the best predictor of future behavior is past behavior. This is not because past behavior causally determines future behavior; rather, it is because the underlying, relatively stable characteristics that produced past behavior are presumed to remain largely in place and will produce similar behavior in similar circumstances. In regard to sexual offending, past offense-relevant behaviors (e.g., prior offending characteristics) were the behavioral manifestations of underlying stable risk factors and their dynamic interaction. In other words, past offense behavior was the output of a complex, internal bio-psycho-social equation. Because we assume that those same stable risk factors persist, that internal equation would likely remain largely unaltered unless the sexual offender successfully completed a risk reduction program (i.e., sexual offender specific treatment). As a consequence, past offense behavior are *indicators* of risk, serving as proxies for underlying stable risk factors and their complex interactions (see Fig. 2).

Risk indicators not only include past actions that serve as behavioral proxies for underlying stable risk factors and their dynamic interactions but also historical events that are empirically linked to subsequent sexual offending. Some historical events represent classes of behaviors that represent behavioral proxies of underlying stable risk factors. For example, placement in special education, which emerged as a predictor of future sexual offending in research to develop the JSORRAT-II (Epperson et al., 2005) presumably results from a constellation of behaviors that reflect underlying deficits in cognitive ability, self-regulation skills, and/or emotional functioning.

Other historical events empirically linked to future sexual offending are indicative of risk through their presumed causal or etiological role in the shaping of stable risk factors (see Fig. 2). For example, an offender's own history of personal abuse has been shown to be associated with an increased likelihood of future sexual offenses in samples of juveniles who have sexually offended (Epperson et al., 2005). One could speculate that historical victimizations have an impact on cognitive scripts for intimacy, the offender's capacity for empathy and intimacy, or some other characteristic that could have a causal effect on future sexual offending (Connolly & Woolons, 2008; Simons, Wurtele, & Durham, 2008; Ward et al., 2006).

How risk indicators lead to stable risk factors is important to treatment (risk reduction) efforts; it is not essential information for risk assessment. Only the empirical relationship of indicators is essential to identify and weigh risk indicators in an empirically derived risk assessment measure.

Several validated risk assessments currently in use focus heavily on risk indicators. These include the Minnesota Sex Offender Screening Tool-Revised (MnSOST-R; Epperson, Kaul, & Hesselton, 1998), the Risk Matrix-2000 (Thornton, 2007), Static-99 (Hanson & Thornton, 1999), Static-2002 (Hanson & Thornton, 2003), Sex Offender Risk Appraisal Guide (SORAG: Quinsey et al., 2006), and the Juvenile Sexual Offender Recidivism Risk Assessment Tool-II (JSORRAT-II; Epperson et al., 2005). These types of risk assessments often rely on actuarial procedures for identifying a set of variables that optimally predict future sexual reoffense. Additionally, actuarial assessments fall into what is often described as second-generation risk assessments (Bonta, 1996; Campbell, French, & Gendreau, 2007). The hallmark of these assessments is that they are often atheoretical and rely on observation of reliable past behavior.

Such assessments have a number of advantages. As mentioned, they rely on observable risk indicators typically found in judicial case files. This is an advantage in three ways. First, there is no need to interact with the offender and risk presentation bias skewing the risk assessment. Second, most risk indicators are quite objective and rely upon specifically stated rules. For example, the first item on the JSORRAT-II, MnSOST-R, and Static-99 requires risk assessors to count the number of historical sexual offenses detected by the judicial system. Items of this type can often be scored quite reliably across scorer and time because they require little to no subjectivity in scoring. Third, most second-generation or actuarial risk assessments for sexual offenders require relatively minimal training to score. Usually, a 1- or 2-day workshop and some structure to avoid coder drift over time are all that is required to accurately score these tools, compared to years of post-graduate training required to score other psychological measures.

The second major advantage is that several risk assessments focusing on risk indicators have been validated with diverse samples across the U.S. and around the world. A recent meta-analysis of sexual offender risk assessment tools found the average effect size (*d*) for empirical-actuarial measures to be .67 in 81 validation studies (Hanson & Morton-Bourgon, 2009). Furthermore, this level of accuracy is a significant improvement over clinical judgment, which rarely exceeds chance level (Bengtson & LÅngström, 2007; Hanson & Morton-Bourgon, 2005; Hanson & Morton-Bourgon, 2009).

At the same time, a couple of key disadvantages accompany these types of risk assessments. Actuarial assessments, because they are atheoretical, provide little in focusing treatment and intervention. In the examples above, we noted that these risk assessments rely heavily on risk indicators. For these assessments, the criteria used to determine an item's inclusion is only that it correlates with sexual recidivism. Consequently, scores on such tools may not provide treatment providers enough information to strategically target their treatment interventions. Similarly, because these types of assessments rely heavily on historical risk indicators, they do not do a good job of determining when risk has been reduced through treatment or maturation.

Assessment of Risk Factors

Third-generation types of risk assessment attempt to improve upon the weaknesses of second-generation assessments. Specifically, the aim of these tools is to assist in determining appropriate intervention points for risk reduction efforts, as well as to determine when risk has been reduced (Campbell et al., 2007). Both are more theoretically derived than second-generation risk assessments and target underlying stable risk factors, acute internal states, contextual influences, or some combination of the three (see Fig. 2). Examples of tools primarily assessing stable risk factors that are typically used to target risk reduction efforts include the Sex Offender Treatment Needs and Progress Scale (McGrath & Cumming, 2003), STABLE-2007 (Hanson et al., 2007), Violent Risk Scale-Sex Offender Version (VRS-SO: Olver, Wong, Nicholaichuk, & Gordon, 2007) and, more recently, the Structured Risk Assessment-Forensic Version (SRA-F: Thornton & Knight, 2009). In addition, the ACUTE-2007 (Hanson et al., 2007) is an instrument that attempts to assess changes in acute internal states (e.g., emotional collapse) or contextual influences (e.g., victim access) that modulate risk upon release.

The advantages of these types of assessments primarily pertain to their ability to guide risk reduction efforts and potentially determine when risk has been reduced (or elevated). Compared with risk assessments focusing primarily on risk indicators, these assessments attempt to target potentially causal aspects of risk. Hence, they can be used to determine a course of treatment. In addition, many can be used to track treatment progress and to evaluate the effectiveness of treatment at termination.

Though there is some empirical support for the validity of several tools that focus on stable risk factors, there are also a number of potential problems. The degree to which these problems exist varies quite dramatically from tool to tool. First, because these tools tend to be more theoretically driven, they vary in terms of their use of risk factors that have received empirical support for their relation to sexual offending. For example, the Sex Offender Treatment Needs and Progress Scale asks risk assessors to gauge the degree of an offender's admission of offense behavior (Item #1) and acceptance of responsibility for their sexual offenses (Item #2). Both items are anchored on the highest risk end by denial. The literature on denial, however, has been fairly negative. A number of studies have shown no overall effect of denial on risk, which was also found in a relatively recent meta-analysis finding no relation to sexual recidivism (Hanson & Morton-Bourgon, 2005). Some more recent studies have reported mixed and sometimes contradictory results (e.g., Harkins, Beech, & Goodwill, 2010; Langton et al., 2008). Limited empirical support for a relation to sexual recidivism does not make such items theoretically unimportant in determining appropriate targets for treatment; however, insufficiently demonstrated relations likely limit the overall validity and usefulness in predicting future sexual offending.

The second potential disadvantage of these tools pertains to subjectivity in determining an offender's standing on some risk factors. Unlike most actuarial tools that rely upon counts of observable behavior, risk assessors are asked to judge the degree of specified characteristics. The extent of specific instructions, examples, and discrete categories for making

these determinations varies from tool to tool; however, most require some amount of subjective judgment on the part of the rater. This subjectivity has the potential to reduce reliability from scorer to scorer and across time without adequate training.

Third, some items on such scales also require raters to interact with and provide professional judgment about psychological aspects of the offender. This interaction has the potential to be influenced by the offender's presentation bias, or desire to fake good (or bad) and requires particular clinical skill to tease out truthful responses. This is problematic in two ways. First, an offender's reluctance or intentional attempts to present themselves favorably introduces problems for any tool's overall validity and reliability. Second, the skill required to tease out truthful responses may not necessarily be gained with 1- or 2-day training. Instead, it may require years of graduate-level training to obtain an advanced degree. This possible requirement, even if not explicitly stated in scoring manuals, limits who can potentially score such tools accurately.

The fourth disadvantage is really just a current limitation that can be remedied by additional research. Although early research on these tools is quite promising, there are relatively few validation studies completed to date—generally one to three studies for each of the instruments listed.

As this chapter was being completed, Mann, Hanson, and Thornton (2010) published a very informative meta-analysis of what they labeled "psychologically meaningful" risk factors or "propensities" (equivalent to what we have labeled stable risk factors). Their article advances the case for third-generation risk assessment tools and identifies empirically supported, promising risk factors. The reader is referred to that article for details. In brief summary, the empirically supported risk factors were: sexual preoccupation, deviant sexual interest, offense-supportive attitudes, emotional congruence with children, lack of emotionally intimate relationships with adults, lifestyle impulsivity or general self-regulation problems, poor cognitive problem solving, resistance to rules and supervision, grievance or hostility, and negative social influences. Promising risk factors included hostility toward women, Machiavellianism, callousness or lack of concern for others, and dysfunctional coping. Overall, there was strong congruence between the underlying risk factors previously listed in Fig. 1 and those identified as empirically supported in the Mann et al. (2010) meta-analysis.

Summary

In summary, risk assessments can take one or some combination of three approaches. They can assess historical *risk indicators*, an approach largely taken by second-generation actuarial risk assessments like the Static-99, Static-2002, SORAG, MnSOST-R, and JSORRAT-II. They also can assess *stable risk factors* or *acute internal states*, as in many newer third-generation approaches. All three approaches appear to have value, as demonstrated by significant improvements over chance-level prediction; however, their relative value may partly depend on the types of questions that are asked. If the question is "what is the likelihood of this sexual offender going on to commit a new offense?" assessments that target risk indicators will likely suffice. If the question is "how best should I target my treatment approach to reduce risk, and when will I know when risk has been reduced?" the choice of assessment should probably be one of the third-generation assessments.

Likely, the value of both approaches is maximized in a combined approach, such as the Dynamic Supervision Project (e.g., Hanson et al., 2007). In such an approach, actuarial assessment with a second-generation tool is used to determine base levels of risk. Assessment of stable risk factors is then considered in conjunction with base levels of risk to determine the offender's overall priority for sexual offender specific treatment, other risk reduction approaches, or risk management strategies. Should an offender be determined to be a sufficient priority for treatment or risk reduction, strategies could be targeted in areas identified through the assessment of stable risk factors. Once released, assessment of acute internal states could be monitored through supervision and environments modified by risk management to further reduce the overall threat the offender poses to the community. This approach necessarily relies upon valid risk assessment in all three phases, but if implemented successfully, benefits both the community and the offender by diverting them into non-offending pathways.

Possible Explanations for Reduced Rates of Observed Sexual Recidivism

Reports of sexual recidivism rates for sexual offenders from historical, landmark meta-analyses are approximately 13 % (Hanson & Morton-Bourgon, 2004; Hanson & Bussiere, 1998). Though an underestimation of the true rate of sexual recidivism due to underreporting, that rate has often been widely accepted as the typical rate at which sexual offenders are detected for a new sexual offense. However, there is reason to believe that rate is not stable and, in fact, declining over the past two decades.

Crime rates have fallen in both the United States (Federal Bureau of Investigation, 2007) and Canada (Public Safety Canada, 2007) over the past two decades, and this same trend appears evident for sexual offenses as well. Since the early 1990s, the observed rate of forcible rape reported through the FBI's Uniform Crime Reports has fallen from a high of 42.8 per 100,000 in 1992 to a low of 30.0 per 100,000 in 2007 (Federal Bureau of Investigation, 2007).

In addition, others have observed declining rates of sexual recidivism. For example, the Minnesota Department of Corrections (2007) found that 3-year rates of recidivism for sexual offenders released from correctional facilities dropped steadily from 17 % in 1990 to 3 % in 2002. Helmus, Hanson, and Thornton (2009) reported initial results from the aggregation of 18 Static-99 replications samples. They observed that the sexual recidivism rate for replication samples was approximately two-thirds the rate of recidivism found in the Static-99 development sample. The rate difference was reported to be most dramatic for sexual offenders scoring 4 or more, those at the "Moderate–High" and "High Risk" levels.

If these studies accurately reflect that the base rate for sexual reoffending is declining, what can account for this drop? Our distinction between risk and threat helps parse out the relevant questions to ask and identifies the types of data that could address those questions.

Recall that risk is defined as inherent in the individual and relatively stable across situations and time. Risk is reduced only through internal changes in key risk or protective factors, presumably through formal treatment. Thus, the goal of treatment is to reduce the risk of higher-risk offenders to levels of low-risk offenders. Operationally, the best estimate of risk would be the rate of sexual recidivism for unsupervised sexual offenders in an open environment, since their true rate of sexual recidivism would not be constrained by highly structured and restricted release environments.

In contrast, the likelihood of risk manifesting behaviorally in a new victimization can be constrained or exacerbated by external contextual elements acting on or triggering acute internal states, as described earlier. This varying likelihood of risk manifesting behaviorally across different situations was defined as threat. Thus, threat varies across situations, while risk remains relatively stable. Risk management involves the systematic imposition of external controls that minimize exposure to exacerbating elements and/or maximize exposure to inhibiting elements. When risk is being actively and effectively managed, threat can be viewed in some sense as managed risk. Thus, the goal of risk management is to manage risk in a way that the threat posed by high-risk offenders is more similar to that posed by lower-risk offenders. Operationally, the best estimate of threat would be the rate of sexual recidivism for sexual offenders released to highly structured environments (e.g., intensive supervision) relative to sexual offenders of comparable risk who were released to much less managed release environments.

The question of how to best explain decreased base rates of sexual recidivism in more contemporary samples condenses to whether the decrease is due to internal changes in contemporary sexual offenders (physiological, cognitive, personality), changes in conditions external to the offender (active risk management, passive risk management through cultural and social changes that effectively decrease opportunities to offend), or some combination of the two. Given that it is not uncommon for sexual offenders in contemporary samples to have been exposed to both treatment and risk management interventions (active and passive), it can be challenging to apportion differential responsibility for the decline in sexual recidivism rates.

There is evidence supporting the effectiveness of sexual offender treatment in reducing risk (Gallagher, Wilson, Hirschfield, Coggeshall, & MacKenzie, 1999; Hall, 1995; Hanson et al., 2002; Hanson & Morton-Bourgon, 2007; Lösel & Schmucker, 2005; Reitzel & Carbonell, 2006). However, can these modest effects account for the observed decline in sexual recidivism rates?

Just as treatments have evolved, so have risk management practices. Some of these changes were legally mandated. The Jacob Wetterling Crimes Against Children Act, which was passed in 1994, required states to set up sexual offender registries in order to better track sexual offenders in communities and to provide law enforcement with easy access to a pool of potential suspects in the event of a sexual crime. The Wetterling Act was amended in 1996 to allow law enforcement officials to release information about sexual offenders on the registries to the public. Also in the 1990s, a number of states enacted sexually violent predator laws that allowed states to indefinitely hold convicted sexual offenders in secure mental health institutions beyond the end of their prison sentence. Finally, a number of states implemented formal, tiered risk management systems anchored by actuarial risk assessment. This increased attention to sexual offending also resulted in community awareness and education that may have also limited opportunities for sexual offending.

Data from Minnesota (Epperson et al., 2011) provides an interesting illustration of this situation and some tentative answers. Epperson and his colleagues conducted a validation study of the Static-99 and the MnSOST-R with a more contemporary and exhaustive sample of 326 sexual offenders released from prison in 1997. In contrast to Minnesota offenders in the earlier development and validations samples for the MnSOST-R, these offenders were subject to registration, community notification, and civil commitment statutes. In addition, many had been exposed to more contemporary treatment and all were released to a tiered risk management system, with higher-risk offenders receiving more intensive supervision than lower-risk offenders. Both tools were successfully validated in that study. Using arrest for a new sexual offense (other than solicitation) as recorded in the FBI National Crime Information Center database as the criterion variable, the ROC-AUC was .66 for the MnSOST-R and .64 for the Static-99. Each of these values was statistically significant ($p \leq .004$).

Two interesting aspects of these data were the relatively lower indices of validity relative to older samples, which will

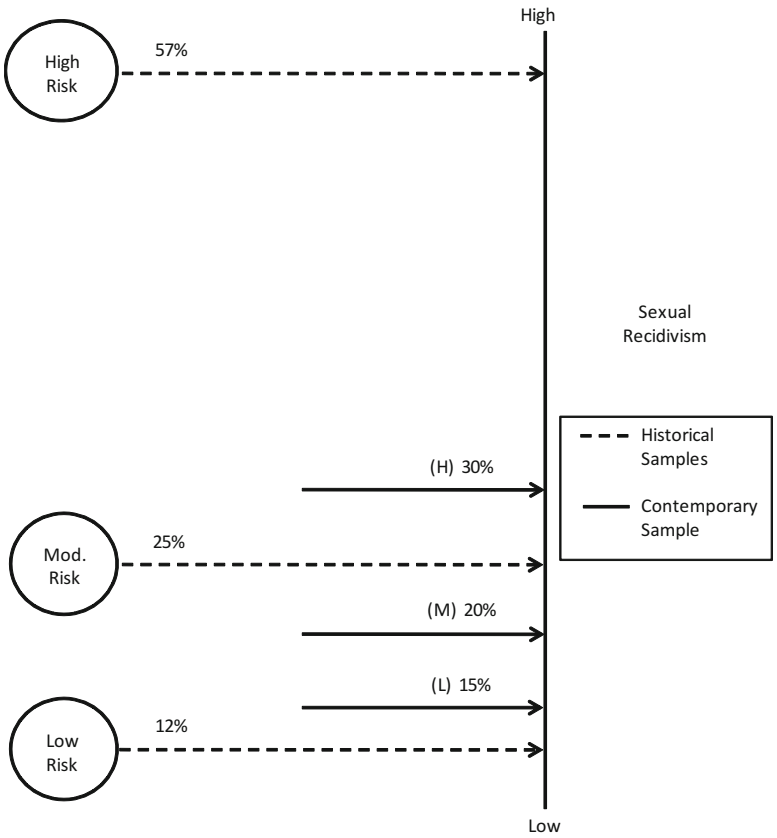

Fig. 9 Compressed sexual recidivism rates for high-, moderate-, and low-risk offenders in a more contemporary sample versus historical samples

be addressed later in this chapter, and the substantially lower rates of sexual recidivism for high- and moderate-risk offenders as summarized in Fig. 9. As indicated there, the range of sexual recidivism rates for the three risk levels is lower overall and much more compressed in the contemporary sample. The sexual recidivism rate for high-risk offenders in the contemporary sample was 30 %, which is a nearly 50 % reduction from the 57 % sexual recidivism rate for high-risk offenders in the historical samples. The difference in sexual recidivism rates for moderate-risk offenders in the two groups is not as dramatic; 20 % in the contemporary sample versus 25 % in the historical samples, but it still represented a 20 % decline. Low-risk offenders in the contemporary sample sexually recidivated at a slightly higher rate (15 %) than did low-risk offenders in the historical samples (12 %).

Because this was a naturalistic rather than experimental study, definitive explanations for this pattern were not possible. However, the authors noted that any explanation would need to account for the differential impact at the higher-risk levels and explored correlational evidence for consistency with one or more of the three primary possible explanations: (1) contemporary sexual offenders present lower risk relative to historical cohorts, presumably through more effective treatment focused on higher-risk offenders, (2) risk is unchanged, but threat is decreased relative to historical cohorts, presumably through more effective risk management focused on higher-risk offenders, or (3) both risk and threat are lower relative to historical cohorts.

Epperson et al. (2011) hypothesized that if the lower-risk explanation was accurate, two patterns would be apparent in the data: (1) a greater proportion of higher-risk offenders would enter and complete treatment, and (2) treatment completion would be associated with reduced rates of sexual recidivism. Their data was not consistent with either hypothesis. Low-risk offenders completed treatment at roughly four times the rate of high-risk offenders, and treatment completion was not associated with lower recidivism rates.

Civil commitment, which was in place for the contemporary sample but not for most of the historical samples, presumably partially explains the lower rate of sexual recidivism for high-risk offenders in the contemporary sample relative to high-risk offenders in the historical samples. If the lower threat explanation is accurate beyond civil commitment effects, Epperson et al. (2011) hypothesized patterns that should be apparent in the data. Given that higher-risk offenders, by policy, received more intensive supervision, they hypothesized that high-risk offenders would be more likely than low-risk offenders to be revoked and returned to prison. The rationale was that more intensive supervision of higher-risk offenders would allow for better detection of offenders engaging in pre-offense and other problematic behaviors, resulting in a revocation before a new victimization could

occur. In theory, without closer supervision, these offenders would not be detected until a new victimization had actually occurred. Additionally, a revocation often results in more prison time and a decreased opportunity to commit a new offense. The data was consistent with this hypothesis. The revocation rate of very high-risk offenders (65 %) was nearly twice that of low-risk offenders (33 %), and the revocation rate of high-risk offenders (56 %) was 170 % that of low-risk offenders.

Although not definitive, this data strongly suggests that the observed reduction in rates of sexual recidivism for higher-risk offenders, at least in this sample, was primarily due to external rather than internal factors. More specifically, there was no correlative support for a lower-risk hypothesis, but there was fairly strong correlative support for the lowered threat through risk management effects (imposition of external controls) hypothesis. Broadly speaking, risk management would include institutionally based risk management as well as social and cultural changes that make the greater possibility of detection evident to offenders (another type of external control). Duwe and Donnay (2008) reported similar conclusions about the critical role of external controls in reducing sexual recidivism in Minnesota based on extensive analyses of larger data sets spanning multiple years.

Some may mistakenly argue that the distinction between threat and risk is irrelevant to judicial or institutional actions such as civil commitment, community notification, and assignment to intensive supervision because only the likelihood of reoffending (threat in our model) is important to those decisions. In fact, the data just summarized suggests that the distinction is critically important because sexual recidivism rates could climb back to historical levels if we stop treating high-risk offenders as high risk.

This and other data emphasize the continuing importance of accurate risk assessment to ensure that both treatment and risk management interventions are appropriately matched with risk. Data continues to support and validate the basic correctional treatment principle of risk-need-responsivity (Andrews, Bonta, & Hoge, 1990). The accurate assessment of risk is an essential component of this principle.

While the questions of the relative contributions of treatment, active risk management, and passive risk management to lower recidivism rates are sorted out through larger and more refined research, the discussion above points to the importance of the distinction between risk and threat. This distinction also provides some insight into how to make sense of and use recidivism rates or risk estimates from different temporal cohorts. It suggests that if we are primarily interested in estimating risk (the likelihood of a new sexual offense under circumstances of relatively low or no supervision), then historical recidivism rates provide the best estimate. Conversely, if we are interested primarily in estimating threat (the likelihood of a new sexual offense given a specified level of risk and the relevant level of supervision), then more contemporary recidivism rates provide the best estimate.

Impact of Effective Risk Management on Sexual Offender Risk Assessment Validity Estimates

As indicated earlier, base rates for sexual recidivism have declined in recent years, but this reduction has not been uniform across actuarially determined risk categories. Instead, the reduced rates of sexual recidivism have occurred most prominently for higher-risk offenders (e.g., Helmus et al. 2009; Epperson, 2011). The potential origins of this trend and its impact on the risk and threat estimates associated with each risk level have already been discussed. However, this trend may also explain why validity indices from more contemporary samples tend to be smaller than in earlier studies, or even insignificant. Furthermore, it may serve as a warning that future validation attempts may see similar drops in validity coefficients if the criterion for failure is not redefined.

The area under the receiver operating characteristic (ROC) curve statistic (AUC) is one of the most commonly used indices of predictive validity for risk assessment tools. The AUC provides an advantage over correlational statistics because it is largely unaffected by the base rate of the event to be predicted (Quinsey, Harris, Rice, & Cormier, 1998; Swets, 1996; Swets, Dawes, & Monahan, 2000). However, this robustness assumes that differences in base rates do not reflect systematic bias in the samples. Relative to historical cohorts, sexual recidivism base rates for more contemporary cohorts of sexual offenders are biased in that the greatest reductions have occurred in the higher-risk categories as already described. Keeping in mind that the coordinates that form the ROC curve are defined by the sensitivity on the *x*-axis and 1-specificity on the *y*-axis associated with each of the possible cut scores of a risk assessment tool, the systematic bias just described flattens the ROC curve by decreasing the amplitude on the *x*-axis and increasing the distance on the *y*-axis for each coordinate. Because the curve is flattened, the area under the curve is decreased.

As an example, consider the data in Table 1 to represent the distribution of a historical cohort of sexual offenders on a hypothetical risk assessment tool with four possible scores (1 through 4). The frequency of non-recidivists and recidivists is listed by score, and the overall base rate of sexual recidivism is 17.5 %. Theoretical data showing a biased reduction in the base rate to 12.5 % are presented in Table 2. There are 20 fewer recidivists in this theoretical sample. The bias is that the reduction is entirely at the upper two scores. In this hypothetical example, successful risk management

interventions precluded new offenses by 10 offenders scoring 3 and 10 offenders scoring 4.

The impact of these changes on sensitivity and 1-specificity are provided in Table 3. As indicated there, for each possible cut score, there is lower sensitivity and higher 1-specificity for the hypothetical contemporary sample relative to the hypothetical historic sample. The resultant flattening of the curve is illustrated in Fig. 10. The concomitant decrease in the AUC in this illustration is from .81 (95 % confidence interval from .75 to .87) for the hypothetical historic sample to .73 (95 % CI from .65 to .80) for the hypothetical contemporary sample.

Table 1 Theoretical distribution of 400 historical sexual offenders without risk management at each of 4 possible scores on a hypothetical risk assessment device

Score	Non-recidivists	Recidivists	Row total
1	190 (95.0 %)	10 (5.0 %)	200
2	100 (86.2 %)	15 (13.8 %)	115
3	25 (55.6 %)	20 (44.4 %)	45
4	15 (38.5 %)	25 (61.5 %)	40
Column total	330 (82.5 %)	70 (17.5 %)	400

Table 2 Theoretical distribution of 400 contemporary sexual offenders with risk management at each of 4 possible scores on a hypothetical risk assessment device

Score	Non-recidivists	Recidivists	Row total
1	190 (95.0 %)	10 (5.0 %)	200
2	100 (86.2 %)	15 (13.8 %)	115
3	35 (77.8 %)	10 (22.2 %)	45
4	25 (62.5 %)	15 (37.5 %)	40
Column total	350 (87.5 %)	50 (12.5 %)	400

More important than the preceding statistical example is a conceptual explanation of the central challenge. When second-generation risk assessment tools were developed and initially validated, sexual offenders were generally released under standard correctional supervision for that time. By today's standards that supervision was mild, so risk and threat were largely equivalent because of the absence of effective, systemic social or institutional risk management programs. Consequently, it made sense to operationalize risk as a new sexual offense (sexual recidivism). In the absence of significant risk management, an individual's propensities to reoffend could reasonably be expected to manifest themselves in new offenses in proportion to the relative individual and interactive power of those propensities.

Systematic and aggressive risk management processes were implemented specifically to establish external controls in the environments of higher-risk sexual offenders in order to dampen or avoid triggering propensities and/or to make it

Table 3 Sensitivity and 1-specificity for all possible cut scores for the theoretical historical sample with no risk management and contemporary sample with risk management

	Historic-no risk management		Contemporary-risk management	
Cut score	Sensitivity	1—Specificity	Sensitivity	1—Specificity
1 & above	1.00	1.00	1.00	1.00
2 & above	0.86	0.42	0.80	0.46
3 & above	0.64	0.12	0.50	0.17
4 & above	0.36	0.05	0.30	0.07
5 & above	0.00	0.00	0.00	0.00

Note: The cut score of 5 & above, at which no offenders can score, is created to generate the origin of the ROC curve

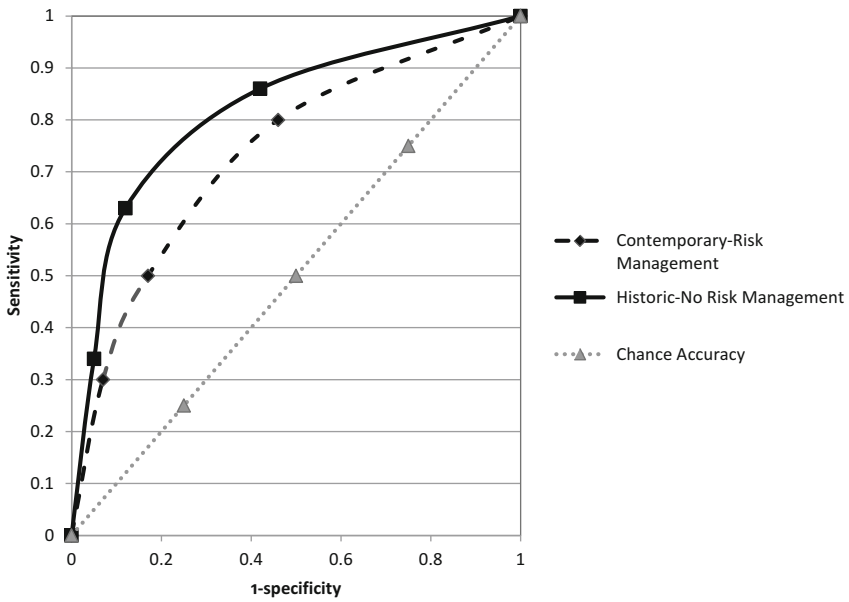

Fig. 10 Flattened ROC curve and decreased area under the curve resulting from a biased decrease in base sexual recidivism with fewer high-risk offenders recidivating potentially due to risk management effects

more difficult to act on them. The intended outcome of those risk management efforts was to decrease the threat of higher-risk offenders to a level as close as possible to that of lower-risk offenders. In other words, the objective of risk management is to make sexual recidivism rates of higher-risk offenders as similar as possible to those of lower-risk offenders. Furthermore, those risk management efforts were informed by actuarial risk assessments in many jurisdictions. In Minnesota, for example, a tiered risk management system anchored by actuarial risk assessment has been in place for more than a decade, and some elements have been in place even longer.

Consequently, attempting to validate an actuarial tool with a contemporary sample of sexual offenders released in the late 1990s or later, with failure defined as a new sexual offense, is like trying to validate a tool on its own residual variance—an impossible task. By way of illustration, imagine using a traditional research design to validate the MnSOST-R on an exhaustive sample of sexual offenders released from Minnesota prisons in 2003.

Each and every offender in that sample would have been classified largely based on his MnSOST-R score and either civilly committed or released to the community with a level of supervision that matched his risk. Consequently, to the degree that risk management is effective, higher-risk offenders correctly identified by the MnSOST-R would sexually recidivate at lower rates that are much closer, or even equivalent, to those of lower-risk offenders. When the analyses were conducted in this hypothetical study, they revealed a lower or even nonsignificant AUC. The obvious moral to this story is that successful risk management anchored by accurate risk assessment tools can result in those tools later being deemed inaccurate and abandoned if traditional validation methodology remains unchanged.

Clearly, second-generation tools have proven to be moderately accurate, as reflected in the recent meta-analysis by Hanson and Morton-Bourgon (2009). More importantly, they appear to have played a role in improved risk management and significant reductions in sexual recidivism by higher-risk offenders. To avoid the resulting paradox of abandoning them as a result of their success (lower or insignificant AUC's), we must at least partially evaluate tools by the success of the systems they anchor. If an actuarial tool anchors a risk management and/or risk reduction system that appears to be effective, caution should be exercised before abandoning the tool and the information that it provides because the cost could be increased sexual recidivism.

This in no way suggests that we cannot improve on the accuracy of risk assessment tools; rather, it suggests that we exercise some caution in how we proceed. For example, it may be possible to develop an actuarial tool (second or third generation) that predicts sexual recidivism better than older tools with contemporary samples. However, that would not suggest that the older tool should be automatically replaced with the newer tool. It would definitely mean that the newer tool predicts threat better than the older tool, but it does not necessarily mean that it assesses risk better. Before making that conclusion, it would be important to also validate the new tool on an older sample, if older data permitted, or use an alternative method for establishing its accuracy in assessing risk as well as threat. In some scenarios, it may make sense to replace an older tool with a newer one, but in other cases it may make sense to use both tools to assess risk and threat.

Conclusion

The research, treatment, and justice communities often discuss "risk" for a new sexual offense in varying ways. The present chapter was intended to propose specific definitions and clarifications to terms and to propose a model of risk and threat in the hope that these clarifications will facilitate future communication. The keys to this model are the distinctions between *risk* and *threat*. Whereas *risk* is a relatively stable set of characteristics that differentially predispose individuals to continue to commit sexual offenses, *threat* is the reduced likelihood of an individual of a given risk level to commit a new sexual offense in the presence of a modified environment (e.g., intensive supervision as part of risk management).

The chapter also proposed that there are at least two major ways to do risk assessment, one that focuses on indicators of risk and the other that attempts to assess risk directly. Both approaches have advantages and disadvantages and are better used to address different types of questions.

Finally, understanding the difference between *risk* and *threat* is potentially important to understanding two recent phenomena: the observed reduction in sexual recidivism rates and an emerging potential trend of reduced validity indices in newer validation studies with contemporary samples of offenders released with more aggressive and structured risk management systems. As risk management and reduction efforts improve, one would expect observed rates of recidivism to decline because both threat (through risk management) and risk (through risk reduction) are reduced. This is a positive result. At the same time, cross-validations of risk assessment tools will likely see a deflation in validity indices beyond what would normally be expected by shrinkage alone because in those validation attempts the tools will be predicting threat and risk, as opposed to risk alone. Thus, interpretation of the usefulness of any tool based on these newer indices must necessarily include a healthy amount of caution.

Risk Factors and Risk Assessments for Sexual Offense Recidivism

Dale Arnold and Marianne Davis

Research into risk factors for sexual recidivism is important for a number of reasons. Such knowledge can provide assistance to allocate resources to those most in need of intervention, it helps us identify the interventions that are most likely to be effective, and it helps us improve our understanding of the etiology of sexual reoffending. This chapter will review the risk factors that have been found to be related to sexual recidivism, with a focus on the static risk factors identified via meta-analysis. Limitations with sexual recidivism research and meta-analytic techniques will be described, and select variables, particularly those associated with counterintuitive findings from meta-analytic studies, will be discussed. Finally, the state of current sexual offender risk assessment methods will be described, and recommendations for improvement will be suggested.

Introduction

Current social policies for managing previously convicted sexual offenders include community notification, lifetime registration, and post-confinement detention. Although these efforts have stimulated fierce debate among the various stakeholders, there is no debate that it is critical, in light of the life-altering consequences of these policies, to be as accurate as possible in identifying those offenders who are most at risk to sexually reoffend.

One key element in accomplishing this goal is to identify the risk factors associated with sexual recidivism or repeated sexual offending (in contrast to risk factors for an *initial* sexual offense). In their influential article, "Coming to Terms With the Terms of Risk," Kraemer et al. (1997) define a risk factor as "a measurable characterization of each subject in a specified population that precedes the outcome of interest and which can be used to divide the population into two groups [the high-risk and the low-risk groups that comprise the total population]."

In sexual offender recidivism research, the outcome of interest is inherently difficult to measure. In part this is because many sex offenders do not reoffend, or, at least, most are not detected of reoffending. We are thus attempting to measure factors associated with a somewhat infrequent event, and it is always more difficult to detect significant relationships under such circumstances.

One of the reasons most sex offenders are not detected of reoffending is because a high proportion of sexual crimes are never reported to authorities. The US Department of Justice, which annually compares National Crime Victimization Survey data to law enforcement reports, found that only 55 % of the sexual crimes committed in 2009 against victims age 12 and older were reported to police (Truman & Rand, 2010). In 2008, 41 % were reported (Rand, 2009). In 1995 the figures were even lower in that only 32 % of rapes and sexual assaults were reported to law enforcement (Greenfield, 1997). Of the crimes that were reported that year, only about one-half resulted in an arrest (Greenfield, 1997). Looking at aggregate figures shows similar results in that Bureau of Justice Statistics findings for the years 1992 through 2000 documented that just 36 % of completed rapes, 34 % of attempted rapes, and 26 % of sexual assaults were reported to the police (Rennison, 2002). Because sexual crimes often go unreported, finding reliable risk factors for sexual recidivism is more difficult. Indeed, rather than identifying risk factors for sexual recidivism, the task might better be characterized as evaluating risk factors associated with particular offenders being arrested, charged, or convicted of sexually reoffending. It is possible that different risk factors are present for those who reoffend, but are not caught. Evaluating the

potential differences in these groups, however, is exceedingly difficult, if not impossible to conduct.

In order to overcome the fact that a high percentage of sexual offenses do not result in a new charge or conviction, some researchers have used broader definitions of recidivism by including institutional rule violations, reports to child protective services, and parole/probation violations. Studies that use more restrictive definitions of reoffense, such as convictions or sentencing occasions, show relatively lower rates of recidivism, while studies that use more inclusive definitions show higher rates (see Prentky, Lee, Knight, & Cerce, 1997).

Criminal justice system practices can also contribute to problems accurately identifying sexual recidivists. In looking at a sample of Canadian criminal histories, Rice, Harris, Lang, and Cormier (2006) found that 33 % of the offenders had convictions for nonsexual crimes that were either "clearly" or "probably" sexually motivated and that the Record of Arrest and Prosecution (RAP) Sheets identified only 60 % of the violent offenses that were sexually motivated. They came to the conclusion that one would need to multiply the number of offenders with convictions for violent sex offenses on their records by 1.48 to get a more accurate estimate of the actual number of offenders who had committed a violent, sexually motivated crime. Again, this affects researchers' ability to identify potential risk factors for sexual reoffense because they end up studying only the minority of offenders who have been convicted of committing a sexual offense. They miss studying a relatively larger group of offenders who have committed a sex offense, but are not identified as such.

Another issue to consider when evaluating sexual offense recidivism research is the follow-up period that is used. Although most recidivistic events occur within the first 5 years the offender is in the community, the cumulative number of recidivists will increase as the follow-up period increases (Harris & Hanson, 2004; Prentky et al., 1997). Thus, higher rates of recidivism will be detected the longer the samples are followed. Further, different types of offenders are known to recidivate at different rates, which can also affect outcome data, especially in studies with shorter follow-up times. For example, incest offenders have routinely been found to have a lower recidivism rate than extrafamilial child molesters. Likewise, Hanson and Bussière (1998) demonstrated that rapists tend to reoffend more quickly, but Prentky et al. (1997) suggest that over time, child molesters tend to reoffend more often. More recently, Helmus (2009) found significantly different recidivism rates among sex offenders depending on whether they came from routine correctional samples or from higher-risk samples where the subjects had undergone some type of preselection process.

Yet another issue related to this area of research is related to how the variables are statistically related to sexual offender recidivism. Specifically, most available studies of risk factors are those that investigate the effects of a single factor, that is, the relationship of a factor independent of other factors, to sex offender recidivism. It is possible that some risk factors act as mediator variables or moderators of other risk factors so that they only function as risk factors if other conditions are also present (e.g., a history of sexual abuse may only act as a risk factor for sex offender recidivism when an individual is unsuccessful at establishing intimate adult relationships). However, demonstrating statistical interactions between two or more factors is difficult. Thus, a conditional relationship between two possible risk factors, that is, one where a variable is a risk factor only when moderated by one or more other risk factors, is difficult to demonstrate.

Still another limitation to risk factor research is that most studies are conducted upon convenience samples. That is, they use the available information collected about offenders in a particular institution or country at a particular time, determine what factors can be gleaned from the information, and then investigate the relationship between the factors and sexual reoffending. Very few, if any, studies of risk factors for sex offender recidivism set out with a plan to collect information theorized to be related to reoffending and then evaluate those possibilities. Also, if important information is not collected, is collected but then rated inconsistently, or the ratings are not measured in the same way, a factor may not show a reliable (stable) association with later recidivism. For example, if information is not collected about the number of undetected sexual offenses an offender reports committing, then that variable (undetected sex offenses) may not be shown to be a "true" risk factor.

In short, there are a number of challenges to conducting research on risk factors for sexual recidivism. Given the nature of the construct, there is little that can be done to compensate for these inherent limitations, and competent researchers acknowledge these limitations and, as best they can, devise studies designed to address them.

Prior Research on Risk Factors for Sexual Recidivism

Prior to the oft-cited meta-analysis by Hanson and Bussière (1996, 1998), there were dozens of studies designed to identify which offenders were most likely to reoffend. For example, Rice et al. (1990, 1991) and Rice, Quinsey, and Harris (1991) found that subjects convicted of a new sex offense had previously committed more sex offenses, had been admitted to correctional institutions more frequently, were more likely to have been diagnosed as personality disordered, had higher scores on measures of psychopathy, and had shown more inappropriate sexual preferences. Using largely the same sample followed for a longer period of time (mean of 50 months), Quinsey, Lalumiere, Rice, and Harris

(1995) found that previous record of sexual offenses, previous general criminal history, non-married status, Psychopathy Checklist-Revised (PCL-R) score, and phallometric deviance index significantly differentiated sexual recidivists from non-recidivists. Similarly, Hanson, Steffy, and Gauthier (1993) found the variables that best predicted sex offense recidivism among child molesters were prior sexual convictions, admitted prior sexual offenses, boys only as victims, and no history of marriage.

Prentky et al. (1997a) identified three risk factors associated with recidivism as measured by rearrest among child molesters, including a degree of sexual preoccupation with children, more paraphilias, and number of prior sexual offenses. These three factors predicted a high percentage of child molesters who committed future sexual offenses when released from a treatment center for sexually dangerous persons.

Proulx et al. (1997) found that child molesters subsequently reconvicted for a sexual offense had higher pedophilic indices, had more previous sexual charges, more frequently had male victims, more frequently had extrafamilial victims, were more likely to live alone, and were younger. Relative to rapists, Proulx et al. (1997) found that rapists reconvicted of a sexual offense were younger and had more previous convictions.

Several other individual studies identified potential risk factors for sexual recidivism (see Craig, Browne, & Stringer, 2003, for a review). Although the findings from the various individual studies provided valuable information to examiners who were tasked with the job of selecting out the riskiest offenders, prior to having a meta-analysis that compared the factors, approaches to risk assessment were often idiosyncratic and included at least some variables that were subsequently found to be unrelated to risk (e.g., poor victim empathy). Likewise, there was little guidance on how one should go about combining risk factors, so that a final opinion (with good interrater reliability) could be reached. As criminal justice policies to manage sexual offenders began to be more restrictive and expensive to implement, it became increasingly important to accurately distinguish between relatively low- and high-risk offenders. Ultimately, the meta-analyses of sexual recidivism risk factors (and the actuarial scales that were subsequently developed) helped to address these needs.

Overview of Meta-analytic Procedures

The Hanson and Bussière meta-analysis (1996, 1998) and a subsequent meta-analysis by Hanson and Morton-Bourgon (2004, 2005) provided valuable information in the quest to identify and compare reliable risk factors clinicians can use to discriminate between lower- and higher-risk offenders. The risk factors identified in these studies became the building blocks for the development of several actuarial risk assessment instruments that are now routinely used to triage sexual offenders into different risk groups. Prior to describing the outcome of those studies, however, it's important to review the relative strengths and weaknesses of meta-analytic techniques.

Meta-analysis refers to the systematic statistical analysis of a large number of individual studies for the purpose of integrating the findings (Glass, 1976). The procedure takes the statistical results from different independent studies and combines them, thus potentially allowing effects to be discerned that perhaps could not be detected in the original studies (e.g., due to a small sample size). The power of a meta-analysis to detect relationships among variables is greatly increased by the large sample size that generally results from combining the studies. It is argued that meta-analysis is more objective and more comprehensive than traditional literature reviews and has the advantage of offering a quantitative means of ordering and integrating data (Wilson & Rachman, 1983).

At the same time, meta-analytic studies do have some important limitations. For example, Schlank (2010) points out a meta-analytic study can only compare the relationship between two variables. As a result, potentially important interactions moderated by a third variable may be overlooked, such as when a variable acts as a risk factor only when another variable is also present. She also notes that any limitations in the original studies will be carried over into the meta-analysis.

Criticisms of meta-analysis specific to the field of sex offender research have tended to revolve around a few particular issues. These include the selection process (which studies to include and which to exclude), the possibility of confounds (extraneous variables) affecting important variables, heterogeneity in the studies used (differences in sample sizes, subjects, definitions of variables, and follow-up periods), and the generalizability of the results.

The selection process, in general, and issues around the quality of the studies included in performing a meta-analysis, in particular, have raised intense debate over the years. Glass and Kliegl (1983) argue that Eysenck's (1978) comments regarding "garbage in–garbage out" are beside the point when it comes to meta-analytic procedures. All studies have some methodological flaws, and with meta-analysis, less than perfect studies can still provide useful information. Shapiro and Shapiro (1983) acknowledge that meta-analysis cannot transcend the limitations of the data used but suggest that rather than exclude studies of questionable quality, one can keep the data and examine the results of including marginal studies empirically. Beech et al. (2007) noted the difficulty among even experienced sex offender researchers to agree on what constitutes a good quality study. They note that it's not that one group of researchers is more stringent or restrictive than another when it comes to study quality but

rather that most of the studies deemed credible by one group may be considered inherently biased by another. They describe examining the reliability of experts' ratings of study quality and finding the degree of agreement among them was poor. In later discussions with the experts, they found they disagreed in principle, often vehemently, over what constituted a "good enough" study.

Lund (2000) writes that the ability of a meta-analysis to give practical answers to important questions depends on the nature of the studies that comprise the analysis. Looking specifically at the variable of denial, he reviewed the 1996 Hanson and Bussière meta-analysis and noted that when studies that defined denial differently were all included, sources of measurement error were combined and the likelihood of detecting a meaningful relationship reduced. Thus, a meta-analysis that shows a correlation of zero between two variables may or may not mean there is no relationship, depending on the consistency of the definitions used in the studies. Likewise, heterogeneity in other factors (e.g., different sample populations, different settings) can also act as sources of error. Lund (2000) concludes that though a strength of meta-analysis is the power it provides and thus the ability to detect even small effects, when it comes to looking at specific variables (e.g., denial or victim empathy), low base rates of recidivism combined with small effect sizes and small sample sizes can result in low statistical power, possibly resulting in a meta-analysis showing no relationship when in fact one exists. On the other hand, if large effect sizes are still observed despite all these, the relationships are likely to be more convincing (Lund, 2000).

In sum, meta-analysis is a powerful tool that has made significant contributions to the research into sexual recidivism risk factors. It is a tool with limitations, however, and the prudent practitioner will have an appreciation of both its strengths and weaknesses and use the results of meta-analytic studies with the appropriate caution.

Results of the Major Meta-analytic Studies of Sexual Offender Recidivism Risk Factors

While keeping in mind its limitations, when it comes to identifying risk factors for sexual recidivism, a meta-analysis has a clear advantage over a single study, as it becomes possible to more confidently comment about the consistency and reliability of an apparent relationship. Likewise, it allows the relative magnitude of the relationship between different risk factors to be compared (Hanson & Broom, 2005).

The Hanson and Bussière (1996, 1998) meta-analysis summarized 61 different data sets from six countries in an attempt to identify factors associated with sexual offender recidivism. Another goal was to determine if the factors associated with sexual recidivism were the same as or different from the factors associated with nonsexual violent recidivism and general recidivism. In the meta-analysis, the statistic used to measure the association between variables was *r*, drawn from Rosenthal (1991). (*r* is a correlation coefficient that looks at the magnitude and the direction of the relationship between two variables.) Aggregate findings were reported using the median *r* value and the weighted averaged *r*. Correlations from .10 to .19 were considered small, correlations from .20 to .29 were considered moderate, and correlations greater than .30 were considered large. In the end, 70 factors that had statistically significant correlations with sexual recidivism were identified. Most of these variables were either related to criminal lifestyle or sexual deviance. Some of the variables presumed by many to have a relationship with sexual recidivism were not supported (e.g., negative clinical presentation). The study also found that the strongest predictors for sexual recidivism were not the strongest predictors for nonsexual violent and general recidivism, which indicated a need for risk assessment procedures designed specifically to assess the risk for sexual recidivism (Harris & Hanson, 2010).

One of the most important findings from the Hanson and Bussière study was that no one factor was strongly enough correlated with sexual recidivism to function as a sole or primary predictor. Currently, then, the best decisions about future risk are those that are made by relying upon consideration of multiple variables or factors. It was also not clear, however, to what degree the more strongly correlated variables were associated with each other and shared overlapping variance, as no multivariate analyses of the data were conducted. (If there is overlapping variance, the variables are contributing both individually and jointly to recidivism and it is unclear to what extent any one variable is predictive.)

General findings from the Hanson and Bussière meta-analysis are summarized in Table 1, while individual findings will be described in more detail later in this chapter.

In 2004, a second meta-analysis studying predictors of sexual recidivism was completed, this one by Hanson and Morton-Bourgon (2004, 2005). This study was conducted to update the findings of the prior meta-analysis by incorporating data that had been collected since Hanson and Bussière completed their initial study (i.e., to include data gathered since 1996). This second meta-analysis was both more limited and expanded than the original study. Rather than repeating an analysis of all of the variables from the prior study, Hanson and Morton-Bourgon focused on findings that (a) were considered important to applied risk assessment and (b) were weak or controversial in the earlier review (e.g., denial, victim injury). Further, in contrast to the Hanson and Bussière study, which primarily examined static factors, the second meta-analysis also included dynamic risk factors. Static risk factors are those that, for the most part, do not change over time, such as number of prior offenses and having had boy victims. Dynamic factors are those that might change over

Table 1 Correlations (*r*) with recidivism for each category of predictor (Hanson and Bussière (1996))

	Type of recidivism		
Category	Sexual	Nonsexual violent	Any
Sexual deviance	.19 ± .01	.01 ± .03	.12 ± .02
Criminal lifestyle	.12 ± .02	.16 ± .03	.21 ± .02

Clinical presentation	−.02 ± .09	.16 ± .20	.09 ± .09	.12 ± .08

time, such as degree of sexual preoccupation and impulsivity. However, the distinction between what is a static and what is a dynamic risk factor is not always clear. Some writers have suggested that static risk factors may simply be a manifestation of dynamic risk factors. Thus, Beech and Ward (2004) suggested that static risk factors are significant because they act as markers of the past operation of dynamic risk factors.

Hanson and Morton-Bourgon's study used 95 data sets, 51 of which had not been included in the Hanson and Bussière meta-analysis and 12 that had been updated since the initial study. This time the standardized mean difference, *d*, was used instead of *r* to measure the association between variables and recidivism. The *d* statistic was chosen because it was deemed to be less influenced by recidivism base rates and more sensitive to variability than *r*. In other words, the *d* statistic was thought to better reflect the reliability of the relationship between a specific variable and sexual recidivism (Hanson & Morton-Bourgon, 2004).[1] Further, both the median *d* value and the weighted averaged *d* were provided. Values from .2 to .49 were considered small, values from .5 to .79 were considered moderate, and values greater than .8 were considered large.[2] It was pointed out that these thresholds were roughly equivalent to those used in the prior meta-analysis. In other words, *d* of .2 is similar to *r* of .1, *d* of .5 is similar to *r* of .2, and *d* of .8 is similar to *r* of .3.[3]

General findings from the Hanson and Morton-Bourgon meta-analysis are summarized in Table 2, while individual findings are described later.

More recently, Mann, Hanson, and Thornton (2010) have proposed that variables associated with risk for sexual recidivism, whether static or dynamic, are better termed "psychologically meaningful risk factors." These are conceptualized as individual propensities that may or may not manifest during a particular timeframe. They argue that static risk factors have predictive significance because they are markers of the past operation of dynamic risk factors. In the course of advancing this proposal, Mann et al. essentially updated the results of the two prior meta-analyses by Hanson and his colleagues, though only for four variables. This was done by integrating data from studies by Knight and Thornton (2007) and from the Dynamic Supervision Project (DSP; Hanson, Harris, Scott, & Helmus, 2007) using cumulative meta-analytic techniques described by Hanson and Broom (2005). The extent to which this analysis impacted the findings from the prior meta-analyses will be discussed when different categories of variables are described in the next section.

Review of Select Variables

In this section, specific results from the three meta-analytic studies described above will be presented in clusters of related variables. Because this chapter is most concerned with sexual recidivism, the data and discussion will not include nonsexual violent or general recidivism, and the interested reader is encouraged to review the original articles for more information pertinent to those types of recidivism. Further, as noted earlier, the distinction between purely static and purely dynamic variables is becoming increasingly fuzzy, and Mann et al. (2010) have proposed the term "psychologically meaningful risk factors" be adopted as a result. Because of this recommendation and because it is useful to review related concepts (e.g., a "static" factor of deviant

[1] However, Rice and Harris (2005) note that Cohen's *d* was designed for use where the scores being compared are continuous and normally distributed, a condition seldom met in risk assessment.

[2] Though in offering these operational definitions for small, medium, and large effect sizes, Cohen (1988) himself notes that the values chosen had no more reliable a base than his intuition (p. 478) and suggests they not be used if possible (p. 532).

[3] Rice and Harris (2005) also point out that when you have a base rate other than 50 %, the *r* values corresponding to the small, medium, and large effect sizes are even smaller.

sexual preference is related to the dynamic factor of "sexual preoccupation"), this section will list both static and dynamic factors when data is available. However, most of the discussion will be focused on the static nature of the factors. Finally, it should be noted that results from the meta-analyses considered most reliable are those where there was low variability between the individual studies underlying the finding. One way this was monitored in the meta-analyses was to calculate the *Q* statistic (Hedges & Olkin, 1985), which tests for the generalizability among the studies that contribute to a meta-analytic finding. A significant *Q* statistic indicates there was more variability across the studies than would be expected by chance and there would be *less* confidence in the finding. However, as Hanson and colleagues (1998, 2004) pointed out, when sample sizes are very large (e.g., greater than 1,000), even small differences between studies may be statistically significant. When the individual findings are presented below, a significant *Q* will be denoted by an *a*.

Sexual Deviance Variables

As expected, with few exceptions, variables related to sexual deviancy were found to be related to sexual offender recidivism. The findings from the three meta-analytic studies are summarized in Table 3.

Relative to these findings, it was expected by Hanson and colleagues that variables related to sexual deviancy or sexual preoccupation would be related to sexual offender recidivism. Likewise, according to Doren (2010), four factor analytic studies of risk assessment instruments, all done on independent samples, found that sexual deviance was a significant factor that contributed to the prediction of sexual offender recidivism. Further, in the first meta-analysis by Hanson and Bussière (1996), a phallometrically determined sexual interest in children was the single largest predictor. However, when reassessed with additional studies in 2004, that finding was not as robust. According to Hanson (personal communication, 2004), this was probably due to the fact that a single very large study (i.e., 4,000 subjects; Maletzky, 1993) was not included in the 2004 meta-analysis because it had used a liberal definition of recidivism (including "treatment failure").

Another finding that warrants comment is related to sexual preference for rape. Neither the 1996 nor the 2004 meta-analysis found this to be a significant predictor of sexual recidivism. However, when Mann et al. (2010) added the findings from Knight and Thornton (2007) to the 2004 meta-analytic results, the overall finding was significant (eight studies with no significant variability noted). Though the relationship was relatively small, it was deemed reliable and indicated that sexual sadism or a preference for coercive sex was associated with increased risk for sexual recidivism.

At this point, a discussion regarding why the correlations between variables assumed to be closely linked with sex offense recidivism are seemingly so low is warranted. First, as mentioned earlier, the low detection rate for sexual recidivism limits the extent to which two variables can be shown to have a relationship with recidivism (i.e., low base rate of detected recidivism). Second, finding seemingly unimpressive relationships between predictor and criterion variables in an applied context is not unique to meta-analytic studies of sexual offender recidivism. Meyer et al. (2001) illustrated significant,

Table 3 Select variables related to sexual deviance and victim choice

but low effect sizes (using *r*) from daily experiences. They found, for example, that the relationship between chemotherapy and surviving breast cancer was reported to have an effect size of .03; the relationship between post-high school grades and job performance was listed as .16; and the relationship between elevation above sea level and lower daily temperature in the USA was listed as .34. None of these correlations appear to be very large. In practical terms, however, they are meaningful. For example, Rosenthal (1990) reports that a study on daily aspirin use and reduced risk of death by heart attack had an effect size of .034. This translated into a 3.4 % reduced risk of heart attacks among the study participants. The results were significant enough that the study was terminated prematurely and the recommendation promptly made that men begin taking a baby aspirin a day to survive heart attacks. Looking at an example from the sex offender research, in the 1996 Hanson and Bussière meta-analysis, the correlation between prior offenses and recidivism was found to be .19, which may seem small. Yet Harris and Hanson (2004) found that offenders with a previous sex offense conviction reoffended at twice the rate as offenders without a prior sex offense conviction. In a practical sense, then, the correlation is meaningful. Therefore, although the effect size (especially when using *r*) may appear to be low to those unfamiliar with meta-analytic results, such a conclusion is unwarranted. Instead, it's important to interpret the results within the guidelines provided within the studies and described earlier (e.g., *r* of .2 and *d* of .5 are considered moderate effect sizes for the meta-analytic studies described in this chapter).

Antisocial Behavior and Psychopathy

One of the more robust findings in the research on sexual recidivism is the role of an "antisocial orientation," referring to a broad set of variables tapping antisocial behavior, self-regulation, problem solving, and substance abuse. Hanson and Morton-Bourgon (2004) found antisocial orientation to be one of the strongest predictors of sexual recidivism; in fact this variable set was second only to sexual deviancy in terms of its predictive power. Mann et al. (2010) also identified a number of these antisocial variables as "empirically supported risk factors," including general self-regulation problems, impulsivity and recklessness, employment instability, poor cognitive problem solving, offense supportive attitudes, grievance and hostility, noncompliance with supervision, and violation of conditional release. Noncompliance with supervision and violation of conditional release were the two strongest single predictors in the 2004 Hanson and Morton-Bourgon meta-analysis as well, though this was based on a limited number of studies (N=2,159, k[4]=3, and N=2,151, k=4, respectively) (Table 4).

Although the relationship between personality disorders and recidivism is addressed elsewhere in this book, it is worth noting that psychopathy, as measured by the PCL-R (Hare, 2003), was found to be a significant predictor of sexual recidivism. Several studies (though not all) have found

[4]N=number of subjects; K=number of studies.

those offenders who have the combination of high psychopathy and sexual deviance reoffend more often and more quickly than those offenders who do not have this combination (for a detailed discussion, see Jackson, 2008). Given the consistent findings that sexual deviance and antisociality are consistently the best two predictors of sexual recidivism, it's not terribly surprising the most extreme form of antisociality (psychopathy) is an especially robust predictor of sex offense recidivism. In fact, as Doren (2004) pointed out and a later meta-analysis demonstrated (Hawes, Boccaccini & Murrie, 2013), measures of psychopathy and deviant sexual interest interact to create a powerful "dynamic duo" for sex offense recidivism; that is, the presence of both primary factors for sexual reoffending indicates particularly elevated risk for future sexual offenses.

Demographics

Demographic variables were reviewed only in the 1996 meta-analysis (Hanson & Bussière), and other than age, none were found to be related to recidivism. Relative to the finding on the relationship between age and sexual recidivism, there was a small negative correlation indicating younger offenders were at higher risk than older offenders. Given the number of studies focused on this single variable since Hanson and Bussière first reported this finding in 1996 (i.e., at least a dozen studies per Doren, 2010), this variable serves as an excellent example of how a meta-analytic study can mask a rather complicated relationship between a single variable and sexual recidivism. To illustrate, it's noted that when the Static-99, the most researched actuarial instrument to date (Hanson & Morton-Bourgon, 2009), was first released, the age item was given a score of one if an offender was under the age of 25 and a score of zero if the offender was 25 or older, meaning that if a 30-year-old offender and a 60-year-old offender had the same score on the instrument, the associated group estimates would be identical. In particular, Barbaree and colleagues (see Barbaree & Blanchard, 2008, for a review) disputed this assumption and argued that older offenders were at considerably lower risk to reoffend sexually than younger offenders. Other researchers (e.g., most notably Doren, 2010) were skeptical of a uniform effect of "age" and pointed out that much of the data supporting a reduction in sexual recidivism risk among elderly offenders was based on cross-sectional data (e.g., groups of men at different ages) rather than well-controlled longitudinal studies involving the same offenders (Table 5).

More recently, a master's thesis by Helmus (2009), which included the largest combined sample of sexual offenders scored on the Static-99 at that time ($N=9{,}261$), discovered statistically significant variability in recidivism rates associated with the cut scores on the instrument (cut scores separate subjects into different groups based on their scores on the test). It was subsequently determined that age added to the prediction of sexual recidivism after Static-99 scores were controlled for, and it was determined this was one of the sources of variability observed during the process of updating the norms for the instrument. Further analysis by Helmus, Thornton, Hanson, and Babchishin (2012) demonstrated that when the original age item from the Static-99 was replaced with a revised age item with more differentiated age categories (i.e., <35 = 1; 35 to 39.9 = 0; 40 to 59.9 = −1; 60 + = −3), age no longer added to the prediction of sexual recidivism after the revised Static-99 (known as the Static-99R) was entered into a regression formula. Although debate about the impact of age on sexual offender recidivism continues, the modification to the age item on the Static-99R illustrates an acknowledgment that this single variable with a "small" correlation of −.13 has a far more complex relationship to sexual offense recidivism than the earlier finding by Hanson and Bussière (1996, 1998) suggested.

Table 5 Select demographic variables

Variable	Hanson and Bussière (1996) r_+	Hanson and Morton-Bourgon (2004) d	Mann et al. (2010) d
Age	−.13[a]	–	–
Low education	−.03	–	–
Minority race	.00[a]	–	–
Social class (low)	.05	–	–

[a]Denotes significant Q statistic (high variability)

Relative to minority race, it's worth noting both the median r and the weighted mean r were .00 ($k=7$, $n=2{,}505$). Further, this nonsignificant finding was replicated in Hanson and Harris (2000). To date no studies have shown a significant difference in sexual offense recidivism rates that is reliably linked to minority status within a Western culture. A related but separate issue is associated to whether or not actuarial risk assessment instruments (ARAI) predict equally well for different ethnic groups. Nicholaichuk (2001) found the predictive validity of two common ARAIs that primarily include static risk factors (e.g., RRASOR and Static-99) were equally predictive for Canadian native (Aboriginal) and nonnative sexual offenders. In contrast, a Swedish study by Långström (2004) found the Static-99 and RRASOR did not predict sexual recidivism for minorities (e.g., African Asian offenders) as well as they did for Nordic and European sexual offenders. However, it was noted those findings were confounded by the disproportionate number of recent immigrants among the minority groups studied. More recently, Babchishin, Hanson, and Helmus (2012) described preliminary results suggesting the Static-99R was more effective in predicting sexual recidivism with Aboriginal offenders than the

Static-2002R, while there was essentially no difference between the predictive validity of these instruments in other samples. Therefore, although recidivism rates may not be affected by minority status, it's possible that some ARAIs are more effective at predicting sexual recidivism for certain minority groups.

Social and Relationship Variables

Of the intimacy/social variables from Table 6, Mann et al. (2010) identified being never married, conflicts in intimate relationships, emotional congruence with children, and negative social influences as "empirically supported risk factors." This was defined as those risk factors where at least three studies, when "meta-analytically integrated," showed significant predictive ability for sexual recidivism. The effect for the risk factor needed to be "more than trivial" (i.e., average $d > 0.15$). Hostility toward women, Machiavellianism (i.e., use of deception and manipulation, from Thornton, 2003), and callousness/lack of concern for others were found to be "promising" risk factors, that is, risk factors where at least one study showed significant predictive ability for sexual recidivism and where there was some additional supportive evidence.

Loneliness, a Mann et al. (2010) "unsupported but with interesting exceptions" risk factor, predicted recidivism in the Dynamic Supervision Project (Hanson et al., 2007; $d = .35$), however not in the 2004 meta-analysis ($d = .03$). When the Hanson et al. (2007) findings were combined with the Hanson and Morton-Bourgon (2004) findings, the effect ($d = .09$) was nonsignificant. Mann et al. (2010) noted the considerable difference between the two studies and suggested further research was needed to clarify the role of loneliness. Likewise, Hanson and Morton-Bourgon (2004) pointed out the key issue may not be that an offender is lonely but rather how the offender copes with that loneliness. For example, those who retreat to masturbation (e.g., using sex to cope) might be at a relatively higher risk to reoffend than those who use nonsexual coping mechanisms.

Clinical Presentation Variables

Relative to victim empathy, neither the 1996 (Hanson & Bussière) nor the 2004 (Hanson & Morton-Bourgon) meta-analyses found it to be related to recidivism ($k = 3$ and $k = 5$, respectively). Mann et al. (2010) speculated that this could be because much of what is considered problematic victim empathy is actually the offender trying to distance himself from a deviant identity. They also speculated that lower-rated empathy may be part of the more general problem of callousness and lack of concern for others, factors that have been associated with recidivism (Hanson et al., 2007; Knight & Thornton, 2007). Other researchers (e.g., Fernandez & Marshall, 2003; Marshall, Hamilton, & Fernandez, 2001) suggest empathy is better construed as a cognitive distortion, particularly as it relates to distorting evidence of victim harm. This allows offenders to avoid a negative self-appraisal and continue to offend without feeling constrained by sympathy for their victims. Marshall, Marshall, Serran, and O'Brian (2009) also noted the "person specificity" of empathy and how, with respect to sex offenders, the research suggests they are not devoid of empathy per se but rather selectively fail to show empathy toward their own victims (Table 7).

One of the more surprising results of the 1996 Hanson and Bussière meta-analysis was the lack of a relationship

Table 6 Select intimacy/social variables

between denial (of a history of sexual offending) and recidivism. Denial was also found to be nonsignificant in the 2004 Hanson and Morton-Bourgon meta-analysis. Given the number of offenders who deny their sexual offending (between 50 and 87 %; Yates, 2010), these results were met with some skepticism. Lund (2000) qualitatively reviewed the studies Hanson and Bussière (1996, 1998) used in their analysis of denial and found some serious methodological concerns. He noted that denial was defined variously as denial (or minimization) of the offense, denial of responsibility for the offense, and as thinking errors. Some of the studies did not include a definition of denial. In many of the studies, deniers were excluded from treatment and thus had no opportunity to reduce their risk through receiving treatment. Lund also noted the studies examined in the meta-analysis had low base rates of recidivism, small sample sizes, low power, and a high probability of type I (false positive) errors. Also, denial was not the focus of the studies and was typically only assessed as a peripheral variable, further reducing the likelihood of detecting a meaningful effect. Lund suggested denial could also be interacting with other variables, such as level of risk, something that would not be detected in a meta-analysis. With regard to the 2004 Hanson and Morton-Bourgon meta-analysis, minimization was considered separately in order to provide a more coherent operationalization of denial. Still, in most of the studies examined, denial was conceptualized as a dichotomous variable (denier/admitter), which others have suggested is a poor proxy for such a complex factor (Langton et al., 2008). As with the Hanson and Bussière meta-analysis, the potential moderating effects of other variables on denial were not considered.

Yates (2010) reviewed the literature on denial and noted it has been variously defined as complete denial of the offense, minimizing the impact of the offense, external attributions of responsibility for the offense, denial of sexual deviance, denial of planning, and denial of denial.

She suggested most forms of denial represented common cognitive distortions that are used by many people, not just sex offenders, to justify and minimize responsibility for their behavior. In their review, Mann et al. (2010) identified denial as a risk factor that is "unsupported but with interesting exceptions", that is, a risk variable where the meta-analytic studies have not shown a significant effect but where either one large credible study did have a significant result or a significant result was found by examining subgroups of sexual offenders.

Nunes et al. (2007) also examined denial and found it was associated with increased sexual recidivism among low-risk offenders and with decreased recidivism among high-risk offenders. Analyzing their results, they found the risk item most responsible for the interaction effect was "relationship to victim." Denial was not associated with increased recidivism for offenders with unrelated victims, but was associated with recidivism for incest offenders. They subsequently replicated the results with two additional independent samples. While the pattern was not statistically significant in any one study, it was significant for all three samples combined and consistent across the three samples ($Q = .40$, $p = .82$). They hypothesized that denial could be a minor risk factor, more relevant when there are few other risk factors present, but losing relevancy when more powerful risk factors, such as sexual deviancy and criminality, are present. Harkins, Beech, and Goodwill (2010) found a similar complex relationship between denial and recidivism, reporting that for the high-risk offenders in their sample group, denial was consistently associated with decreased recidivism. For low-risk offenders, they found little difference in the recidivism rates for admitters versus deniers. Looking at the low-risk offenders' perceptions of their own risk, they found that those who denied they were at risk for reoffending were less likely to reoffend than those reporting they were at high risk for reoffending.

Treatment Variables

Evidencing poor progress in treatment was not associated with increased risk for sexual recidivism. Likewise, length of treatment was unrelated to recidivism. However, failure to complete treatment was a significant predictor in the 1996

Table 8 Select treatment variables

[a]Denotes significant Q statistic (high variability)

meta-analysis, and this finding has since been replicated in several other studies. Given that attrition rates in sex offender treatment programs have been found to be quite high (from 30 to 50 %; Beyko & Wong, 2005), this relationship is important. As noted in Table 8, Hanson and Bussière (1998) found a significant correlation between treatment noncompleters and recidivism ($r_+ = .17$; $n = 806$; $k = 6$). This can be translated into a 17 % difference between the recidivism rates of treatment completers and those who drop out of treatment. There was a significant degree of variability across the six studies examined; however, the weighted r and median r were very similar (Mdn = .18), suggesting the results were reliable. In another meta-analytic review of the effectiveness of treatment, Hanson et al. (2002) found that those offenders who dropped out of treatment had consistently higher sexual recidivism rates than treatment completers ($Q = 21$, $p > .10$; $k = 18$). The effect was so consistent that the authors identified failure to complete treatment as a "reliable and robust predictor" of sexual recidivism (Hanson et al., 2002, p. 187). The authors speculated that noncompleters may be at higher risk due to preexisting characteristics associated with higher recidivism (e.g., youth and impulsivity). They also noted that factors associated with a lack of treatment motivation are often correlated with recidivism (e.g., hostility toward authority, noncompliance). Similarly, it was suggested that interrupted treatment may make offenders worse in that they are exposed to novel deviant sexual fantasies and behaviors, deviant role models, and cognitive distortions from the other offenders with whom they are in treatment.

The Hanson and Morton-Bourgon (2004) meta-analysis did not look at treatment completers versus noncompleters. The authors did look at poor progress in treatment and low motivation for treatment but found that neither were significantly related to sexual recidivism. Losel and Schmucker (2005) in their meta-analysis found that dropping out of treatment doubled the odds of reoffending and that this effect was consistent across the 13 studies that contained this variable ($Q = 11.52$, $p = 0.57$). Langton, Barbaree, Hansen, Harkins, and Peacock (2007) also found that treatment dropouts showed the fastest failure rates when compared to treatment completers, who showed the slowest rates of sexual offense recidivism by comparison. In one of the few randomized studies using longitudinal data, Marques (1999) also noted a high reoffense rate for noncompleters, though the number of subjects in this group was small (noncompleters = 34). Approximately half of the noncompleters in that study were dropped from the treatment program due to creating serious management problems, suggesting that preexisting conditions such as impulsivity and poor self-control were factors in their dropping out. Further, Marques noted that early treatment dropouts, defined as those who terminated the program within the first year, had the highest rates of sexually reoffending (21 %). In a follow-up article analyzing this same data set (Marques, Wiederanders, Day, Nelson, & Ommeren, 2005), comparisons between treatment completers ($n = 167$) and dropouts ($n = 37$) found they did not differ significantly on measures of static risk, treatment need, or demographic variables other than age (dropouts were significantly younger than completers).

With regard to factors that might influence treatment completion and non-completion, Langevin (2006) looked at 778 sex offenders assessed from 1960 through 2000. Approximately 35 % of the sample completed treatment. He found no significant differences in age, education, or marital status for treatment completers versus noncompleters and no differences by offender subtype or by degree of sexual deviance. More offenders without a substance abuse problem completed treatment, fewer cases with antisocial personality disorder completed treatment, and treatment completers had significantly lower mean PCL-R scores than noncompleters. Langton, Barbaree, Hansen, Harkins, and Peacock (2006) also found noncompleters had significantly higher PCL-R scores ($M = 19.47$) than offenders who completed the same treatment program ($M = 16.40$). Nunes and Cortoni (2008) examined the Static-99 scores of treatment noncompleters ($n = 52$) compared to program completers ($n = 48$) and found, consistent with Langevin (2006), that dropping out was significantly associated with the general criminality items on the instrument but not the sexual deviance items. Beyko and Wong (2005) also examined factors leading to treatment attrition. They found two sets of variables predicted attrition: disruptive, rule-violating behaviors and poor treatment engagement (e.g., poor attitude toward treatment, denial,

lack of motivation, etc.). Dropouts were more likely to act aggressively, to be noncompliant with institutional rules, and to have histories of rules violations. They also had longer offense histories and were generally more criminalized. More rapists than pedophiles dropped out of treatment, which would be consistent with the study's findings as rapists are, in general, more aggressive and violence-prone than pedophiles. The Static-99 did not predict attrition, indicating risk level (as defined by that instrument) was not a factor. Also not predictive of attrition were sexual deviance, past employment history, education, intellectual ability, cultural background, and marital status.

Developmental History and Family Variables

Other than those variables associated with criminality and an antisocial lifestyle (i.e., childhood behavior problems and juvenile delinquency), none of the developmental/family variables have been consistently related to sexual recidivism. Notably, being a victim of sexual abuse as a child was not predictive of sexual recidivism, though it is often associated with onset of sexual offending (e.g., offender groups tend to report a higher-frequency of child sexual abuse than normative samples). As for the significant finding for separation from parents in the Hanson and Morton-Bourgon (2004) meta-analysis, the effect was small, but reliable, and based on a large sample size ($N=4{,}145$; $k=13$) (Table 9).

General Mental Health Problems

Relative to major mental illness (defined as severe disorders involving psychotic symptoms), Mann et al. (2010) classified this as a factor "unsupported overall with interesting exceptions." They pointed out that while the meta-analytic findings from 2004 didn't support this being linked to recidivism, a large unselected sample from Sweden had found a robust relationship. Depression was identified as a variable generally unrelated to sexual recidivism, which is consistent with the general correctional literature. Substance abuse was not found to be a consistent or generalized predictor of sexual recidivism in the first meta-analysis. However, it was considered to be an indicator of lifestyle impulsiveness by Mann et al., with impulsivity in turn showing a small but significant relationship to sexual recidivism. Of note, while just one study, Looman and Abracen (2011) recently demonstrated that substance abuse, particularly alcohol abuse, was an important predictor in their sample of 250 sex offenders, a group considered to be preselected for high risk/need (Table 10).

Comments About Individual "Risk Factor" Research to Date

Kraemer et al. (1997) offered some important cautions about the nature of risk and the potential meaning of risk factors. They noted that statistical significance often indicates only that the sample sizes were sufficiently large and the research design and measurement adequate to document nonrandom association between some characteristics of an individual and an outcome of interest. Further, they point out that with large enough combined sample sizes, many factors can be demonstrated to be associated with a particular outcome. Regarding the meta-analyses for sex offender recidivism, it is known that the identified risk factors are more than correlates since they precede the measured outcome in temporal terms. However, per Kraemer et al., it remains unknown if a static risk factor is a "fixed marker" (e.g., year of birth) or if a static risk factor can change (e.g., deviant sexual interest or antisocial orientation). If it can change, then it can be viewed as a "variable risk factor" (a potential dynamic risk factor). Yet that "variable risk factor" can be considered a *causal* risk factor only if the "variable risk factor" can actually be manipulated or modified in such a way that such *change* is demonstrated to be associated with a change in outcome.

At this point in time, it remains unclear which, if any of the static risk factors, can be changed either as a result of situation (e.g., incarceration), the passage of time, or directed intervention (e.g., treatment). There is little existing evidence that indicates that either deviant sexual preferences or antisocial dimensions of personality—the two primary groups of static risk factors—can be modified per se. In addition, with regard to directed intervention, Hanson et al. (2009) noted, "Many of the factors targeted in contemporary treatment programs do not [target risk factors empirically associated with recidivism]. Offence responsibility, social skills training, and victim empathy are targets in more than 80 % of sexual offender treatment programs… yet none of these have been found to predict sexual recidivism." Thus, to date, there is little scientific basis for concluding that any of the static risk factors are "variable risk factors," let alone "causal" risk factors. Per Kraemer et al. "We suggest that labeling a factor with the generic term risk factor with no further effort to delineate its roles as fixed marker, variable marker, or causal risk factor is a limited finding…" (p. 342). Nonetheless, they pointed to the relative value of targeting interventions toward fixed or static risk factors, while scientific study continues to investigate the possibility of identifying those or other conditions as true causal risk factors.

Risk Factor Combinations

As noted earlier, none of the specific risk factors listed above was considered of such magnitude that it could be used in isolation to reliably predict sexual recidivism in that such factors by themselves account for a small amount of variance in sexual offense recidivism. Consequently, it is important to examine the contribution of combinations of variables or risk factors in identifying risk for sexual offense recidivism. Although the meta-analytic studies identified which variables (as studied to date) are most related to sexual recidivism, which is a substantial improvement over previous unguided clinical judgment, the studies did not identify which combination of variables (and what their relative weight) best predict who is most likely to reoffend. Consequently, researchers began looking at ways to best combine the known risk factor variables into assessment instruments that could be scored and interpreted. As a group, these assessment tools are known as "actuarial" instruments because they define which specific variables will be rated and how to weight them (according to their relative importance to prediction) in advance. Optimally combining risk factors, then, is essentially the goal of an actuarial instrument, and there are currently a number of scales to choose from. Hanson and Morton-Bourgon (2009) published a meta-analytic study that focused on the accuracy of these actuarial risk assessment instrument (ARAI) and other multifactorial methods for sexual offense recidivism. The mean *d* for the most commonly used instruments in North America (McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2010) and the Risk Matrix 2000 (Thornton et al., 2003), which is a widely used instrument in the United Kingdom, are listed in Table 11.

Relative to these ARAI, it's noted the number of studies on the Static-99 far exceeds the number of studies conducted on the other instruments. Further, each of the scales listed above was a moderate predictor of sexual offense recidivism,

Table 11 Accuracy of actuarial risk assessment instruments

Actuarial risk assessment instrument	Hanson and Morton-Bourgon (2009) *d*	*k*	*n*
Static-99	.67[a]	63	20,100
RRASOR	.60[a]	34	11,031
MnSOST-R	.76[a]	12	4,672
SORAG	.62	12	3,058
Risk Matrix 2000, sexual	.67	10	2,755
SVR-20 (numerically summing the items)	.68[a]	10	1,699
Static-2002	.70	8	3,330

K number of studies
[a]Denotes significant *Q* statistic (high variability)

but none of the scales clearly outperformed the others and could be seen as the superior choice of instruments. Hanson and Morton-Bourgon (2009) cautioned, however, that equivalency should not be presumed based upon this meta-analytic study alone. Instead, it was recommended the best way to determine which scale is best would be to test each ARAI on the same sample. Thus far, no single scale has consistently outperformed the others in different samples (Harris & Rice, 2003; Knight & Thornton, 2007; Langton et al., 2007).

Further, in a small study, Seto (2005) used four actuarial risk scales (Static-99, RRASOR, SORAG, VRAG) on a sample of 215 adult male sex offenders to determine how effective the four scales could be used in combination. Although he concluded that no combination method provided a statistically significant or consistent advantage over the predictive accuracy of the single best actuarial scale, studies with larger samples have contradicted those findings. For example, Babchishin, Hanson, and Helmus (2012) tested the Static-99R, Static-2002R, and RRASOR on a much larger combined sample of more than 7,000 offenders. In that study, both the Static-99R and Static-2002R outperformed the RRASOR in predicting any form of recidivism (e.g., sexual, nonsexual violent, and any). No differences in the predictive accuracy between the Static-99R and Static-2002R were found, which was different from a prior study comparing the Static-99 and Static 2002 by Hanson, Helmus, and Thornton (2010) on the same samples. It was opined the modification to the age item on both instruments resulted in the updated finding. More importantly, it was noted that both the Static-99R and Static-2002R showed incremental predictive accuracy to each other even though they measured seemingly similar constructs. Specifically, when the findings of the individual instruments were discordant, the observed recidivism rate was intermediate between the findings suggested by the individual scale. As a result of this finding, one suggestion was that an averaging approach may be an optimal method of combining the findings of multiple scales (at least when using the Static-99R and Static-2002R).

Further, the use of multiple actuarial measures has been endorsed by multiple individuals (e.g., Hanson and Morton-Bourgon, 2009; Barbaree et al., 2006) based on several considerations. Scientifically, there is no "best" instrument, and they possess equivalent degrees of predictive accuracy from a measurement perspective. In addition, since the different actuarial instruments contain unique as well as overlapping variables, they each measure recidivism using different sets of risk factors. The relative ranking of risk by the different actuarial instruments may be different for different individuals. Issues in scoring of the different measures will make less of a difference when multiple measures are utilized; multiple actuarial instruments lead to increased reliability in identifying the relative risk of a particular offender. Finally, to the degree that a "set" of (multiple) actuarial measures converge in identifying that an offender is at higher risk, then there can be increased confidence in concluding that sex offender is at higher risk for sexual reoffending.

In an effort to improve actuarial risk prediction and to develop a strategy to produce a scale that outperforms those listed above, a number of factor analytic studies have been done on several of these instruments [Roberts, Doren, & Thornton, 2002 (reporting on two samples); Barbaree, Langton, & Peacock, 2006; Knight & Thornton, 2007]. Results from each study found consistent support for factors of sexual deviance and general antisociality. Three of the four studies also identified a factor related to being young and single. Two of the larger studies also found support for a factor related to having a stranger victim and another factor related to having a male victim (see Doren, 2010 for a review). More recently, it was reported that further analysis of the Static-2002 supported prior research documenting three primary factors that contribute to the prediction of sexual recidivism (Thornton & Phenix, 2010). These were listed as "sexually criminal behavior," "generally criminal behavior," and age (with younger offenders being at higher risk for reoffending than older offenders).

Further, Knight and Thornton (2007) performed a taxometric analysis of 503 adult sexual offenders. Using three independent methods, they concluded that sexual violence risk is dimensional and not taxonic or categorically different. Stated more clearly, they wrote, "sexual violence risk in persons referred for evaluation at a sex offender clinic is a quantitative rather than a qualitative distinction or a difference of degree rather than a difference in kind." Thus, at present, sexual offense recidivism appears to be a function of different accumulations of varied risk factors. It was noted this finding was similar to recent studies about psychopathy, asserting the construct is dimensional rather than categorical. These results supporting the dimensionality of sexual offense recidivism are important because it suggests that cut scores on actuarial instruments can be chosen pragmatically, depending upon the reason for the assessment (i.e., choosing who to refer to treatment, supervision intensity, or restrictive detention).

In summary, a number of actuarial instruments composed of a variety of static risk factors have been developed. The instruments most commonly used all have moderate predictive accuracy, and no single instrument has consistently been found to be superior to the others. Further, research suggests the various risk factors from these instruments are primarily related to sexual deviance, general criminality, and age. This is important because it can help refine risk assessment development by optimizing the variables that measure these underlying constructs. Finally, at least one study has shown sexual violence risk is dimensional rather than categorical, which means cut scores on risk assessment instruments can be chosen in a manner that is responsive to the referral ques-

tion. Put more simply, higher scores are associated with higher risk for sexual recidivism. So, if the referral question is related to whether an individual is a good candidate for probation, then the lower end of the scale would be most relevant. On the other hand, if the referral question is related to whether the person meets criteria for civil commitment, then the higher end of the scale would have more import.

Recent Developments and Future Directions

As noted, actuarial risk assessment instruments are developed by combining select risk factors. As a result, these measures contain only a limited number of identified risk factors and exclude other variables. Often, particular risk factors are included simply because they are easy to measure or the information is more commonly available in the types of records kept on offenders. Consequently, there will always be variables not included in an ARAI (e.g., external to the ARAI). This raises several related issues. First, does the consideration of a limited number of static risk factors in one or more ARAIs place a "ceiling" on the estimate of sex offender recidivism provided by those measures? Second, a related question exists as to whether the results of an ARAI, or conclusions drawn from those results, should be "adjusted" based on the presence or absence of risk factors that were not included in the particular ARAI or ARAIs. Quinsey et al. (2006) have typically advocated a "pure actuarial approach," arguing that adjustments will only degrade the results and conclusions derived from the actuarial instrument. In contrast, Hanson and colleagues (e.g., 2009) have typically acknowledged the need to consider factors external to an ARAI but recommended caution and making adjustments judiciously.

Recently, the need to consider external factors to ARAIs has come to the forefront. Specifically, as part of an attempt to re-norm the risk estimates associated with the various cut scores on the Static-99, Helmus (2009) discovered significant variability in those estimates when 29 studies including 9,261 offenders were combined. After testing several variables that could potentially account for this finding, she determined the variance related to the different cut scores was accounted for by age and sample preselection effects (i.e., effects due to factors inherent or characteristic in samples, such as whether it was a relatively lower-risk "routine" prison sample or whether it was a relatively "high-risk" sample where the subjects had been referred to some judicial or quasi-judicial process (e.g., to determine if they met the criteria to be a "sexually dangerous person"). As mentioned earlier, the age item on the Static-99 (and the Static-2002) was subsequently modified, and, after doing so, age was no longer a significant predictor within that large data set. Relative to the other source of variance (preselection effects), stratification of the score-wise risk estimate by sample type substantially reduced the variability for the 5-year estimates and was no more than would be expected by chance for the 10-year estimates for each sample type (Helmus, 2009, Table 23). The difference in sexual offense recidivism risk estimates for different Static-99R scores by sample type is illustrated in Table 12. It should be pointed out that the 5-year estimates are listed because 10-year sexual recidivism rates are not currently available for the "routine" correctional samples. Indeed, as noted in the beginning of this chapter, sexual recidivism continues to increase with time at risk in the community as documented by Prentky et al. (1997) and Harris and Hanson (2004); consequently, sexual offense recidivism rates would be greater for longer follow-up periods.

Table 12 Static-99R 5-year risk estimates according to sample type

Score[a]	Routine correctional	Preselected for treatment	Preselected for risk/need
0	2.8	4.1	7.2
1	3.8	5.5	9.4
2	5.0	7.2	12.2
3	6.6	9.5	15.8
4	8.7	12.3	20.1
5	11.4	15.9	25.2
6	14.7	20.2	31.2
7	18.8	25.4	37.9
8	23.7	31.4	45.0
9	29.5	38.1	52.4

[a]Most, but not all, cut scores are illustrated

In applied risk assessment, the variation in these risk estimates can clearly impact whether an offender is deemed to meet threshold criteria for civil commitment when a statue requires a finding that a person is "more likely than not" to reoffend. Until recently, methods to determine which sample type is most appropriate to apply to a specific case have not been clearly articulated. Initially, it was recommended evaluators take into consideration the extent to which an individual had been preselected in a manner that was consistent with the sample types illustrated above. Then, Thornton, Hanson, and Helmus (2010) illustrated how the integration of "dynamic" risk factors or what might be referred to as criminogenic needs into an assessment essentially replicated the differences between sample types. This is illustrated in Table 13, where it is shown that depending upon one's rating on the Stable 2007 (an instrument that rates potentially changeable or "dynamic" factors; Hanson, Harris, Scott, & Helmus, 2007), the resulting recidivism rate is proportional to the difference in recidivism rates for two different sample types (it should be noted the Stable 2007 study only provided 3-year estimates, so the follow-up times are not equal with the previous table).

Table 13 Static-99R risk estimates with either low or high external risk factors in two samples

Static-99R Score	Three-Year Recidivism		Five-Year Recidivism	
	Stable = 5	Stable = 14	Routine	Selected for Risk/Need
2	3 %	7 %	5 %	12 %
5	7 %	18 %	11 %	25 %
7	14 %	32 %	19 %	38 %

More recently, Thornton (2010) has introduced a modified version of the Structured Risk Assessment (SRA, Thornton, 2002), which rates dynamic risk factors or criminogenic needs on four domains (sexual interests, attitudes, relationship style, and self-management). This modified instrument, called the SRA-Forensic Version (SRA-FV), uses three of the four domains (the attitudes domain was not included due to the difficulty in accurately measuring attitudes in forensic settings). As illustrated in Fig. 1, the cross-validation of the SRA-FV produced a similar, if not more robust, effect as the Stable 2007. That is, persons with higher ARAI scores in combination of higher degrees of criminogenic needs demonstrate higher rates of sexual offense recidivism.

The recent findings of significant incremental validity to the Static-99R when combined with instruments designed to assess "dynamic" risk variables is mentioned because this directly addresses the earlier debate about adjusting estimates derived from ARAIs. Clearly this is an emerging area of refinement in sexual offender recidivism research and suggests that improvements in risk assessment methods are not only possible, but potentially convergent and robust.

Adding structured assessment of "dynamic" risk factors [which Mann et al. (2010) proposed would be more aptly conceptualized as "psychological meaningful risk factors"] not only has the potential to improve the predictive validity of existing instruments. Such findings are also important because they provide the basis to improve treatment targets and management of sexual offenders under community supervision. These "dynamic" risk factor scales also have the potential to guide treatment in a more meaningful way. Put differently, one of the drawbacks to using static risk factors alone is that they typically only tell us about a person's risk for recidivism based on likely unchangeable characteristics (e.g., sexual offending history). Evaluation of "dynamic" risk factors, on the other hand, potentially provides treatment targets (e.g., relational style and self-management strategies can be directly addressed) that, if addressed in treatment and/or modified, may reduce a person's risk for sexual recidivism. Hopefully, the emerging research on the incremental predictive validity of the SRA-FV, Stable 2007, and Violence Risk Scale: Sexual Offender Version (VRS:SO; Olver, Wong, Nicholaichuk, & Gordon, 2007) may not only improve prediction; these instruments may also help guide interventions. Whether or not changes to "dynamic" risk factors targeted in treatment will be found to reliably reduce sexual offender recidivism, however, remains an empirical question (c.f., Rice & Harris, 2015).

A final area in need of refinement is related to optimizing combinations of variables to the type of sexual risk posed by a particular individual. To date, ARAIs have not been shown to work differently for child molesters and rapists; thus, the risk estimates are typically combined for offender types. On the other hand, Knight and Thornton (2007) noted a trend for the predictability (from ARAIs) between rapists and child molesters to be somewhat different. Though the sexual recidivism rates between the two groups were similar, it was noted that the predictability of rapist sexual recidivism decreased with time (e.g., best at 3 years, lower at 10 years, and maintained same level at 15 years), while the predictability of child molester recidivism improved from 3 years to 10 years and did not change at 15 years. Therefore, there was a trend for the predictability of sexual recidivism for rapists to decrease with time and for the predictability of child molester recidivism to improve over time. This suggests it may be possible to improve risk assessment by further researching how ARAIs work differently for the two groups of sexual offenders.

On a related note, very little recidivism research has systematically evaluated "mixed offenders" as a separate offender type. These individuals, who have a history of perpetrating sexual crimes against both children and adults, were recently shown to have a relatively higher recidivism rate than either rapists or child molesters (Harris, Knight, Smallbone, & Dennison, 2010). Indeed, past research looking at the differences in recidivism between child molesters and rapists often excludes the "mixed" offender group during such analyses in order to compare the other two groups. The recent study by Harris et al. concluded by asserting that more attention should be paid to this mixed offender subgroup in the interests of public safety. Specifically, it was reported that while the sexual recidivism rate for rapists was 21.4 % and for child molesters was 28.4 %, mixed offenders sexually reoffended at a rate of 43.8 % during the same time frame. Mixed sexual offenders represent another area in need of further research. Given the very large samples being combined for study, such investigations may be more readily attempted in the near future.

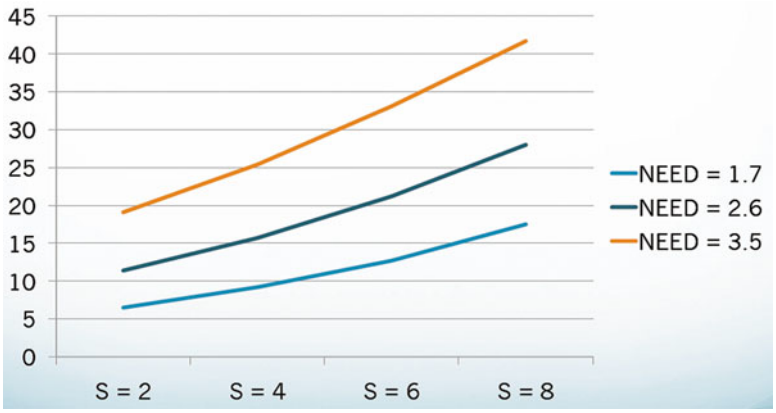

Fig. 1 Illustrates the difference in recidivism rates for the same Static-99R scores when the SRA-FV need levels are considered

Summary/Conclusions

Studying risk factors for sexual offense recidivism is an especially challenging area of research because many sexual crimes are never reported and, even when they are, the offenders are not always arrested and prosecuted. Therefore, finding relationships between predictors and sexual reoffense is often minimized or obfuscated. Although many risk factor studies were conducted prior to the meta-analysis by Hanson and Bussière in 1996, the reliability and magnitude of relationships between predictor variables and sexual recidivism were never really clear because the possibility existed that findings could be unique to a given sample or a relationship may have been too weak to be detected. Meta-analytic research in this area has helped to overcome these limitations. Though there are clearly limitations associated with this technique (i.e., more complex relationships related to moderating variables may be missed), these studies have made a significant contribution to the development of actuarial risk scales and sexual offender risk assessment in general. Future improvements can be made by combining static and dynamic factors in structured ways, optimizing combinations (and weights) of these variables, and focusing on the unique attributes of sexual offender subtypes. As noted in the beginning of this chapter, sexual offender evaluations have enormous consequences for the various stakeholders, and it is critical that such evaluations be as precise and reliable as possible.

The views expressed are those of the authors and not necessarily those of the California Department of State Hospitals, Forensic Services Division.

Overview of the Development, Reliability, Validity, Scoring, and Uses of the Static-99, Static-99R, Static-2002, and Static-2002R

Amy Phenix and Douglas L. Epperson

This chapter will provide a high-level overview of the Static-99, Static-99R, Static-2002, and Static-2002R. Each of these instruments is an empirically derived, actuarial, risk assessment tool for use with sexual offenders. As actuarial tools, they provide increased accuracy in assessing risk of sexual re-offense relative to clinical judgment and structured clinical judgment (Hanson & Morton-Bourgon, 2009). The increased accuracy of this class of risk assessment tools is necessary to implement programs that enhance management of sexual offenders and promote greater community safety.

These risk assessment tools, which are designed to provide measures of relative and absolute risk of sexual re-offense (Hanson & Thornton, 2000), are commonly incorporated into risk assessment evaluations of sexual offenders that are used to inform a wide range of processes and decisions. Examples include civil commitment hearings (Jackson & Hess, 2007), level and intensity of supervision for offenders on probation and parole (Interstate Commission for Adult Offender Supervision, 2007), sentencing hearings, determination of community notification levels, and treatment (Jackson & Hess, 2007).

The Static-99 has, for many years, been the most commonly used actuarial risk assessment tool for sexual offenders in Canada and the United States (Interstate Commission for Adult Offender Supervision, 2007; Jackson & Hess, 2007; McGrath, Burchard, Zeoli, & Ellerby, 2010) and Australia (Doyle, Ogloff, & Thomas, 2011). Thus, this chapter appropriately begins with a discussion of the Static-99, followed by a discussion of the Static-99R, which is markedly similar in structure and scoring but has separate norms. Next, the Static-2002 and the Static-2002R sexual offender risk assessment tools are presented in tandem. Although these two tools are conceptually distinct from the Static-99 and Static-99R, they are very similar to each other. In addition, the revision of the Static-2002 to produce the Static-2002R used parallel processes for the Static-99 revision. The chapter concludes with a discussion of training requirements and potential uses for the Static tools, along with some observations regarding the use of multiple risk assessment tools.

Static-99

The original Static-99 was developed by Karl Hanson, Ph.D. and David Thornton, Ph.D. (2000) to assess risk of sexual and violent recidivism with sexual offenders. The Static-99 is the combination of static, historical risk factors that were initially included in two earlier tools, the Rapid Risk Assessment for Sex Offender Recidivism (RRASOR) and the Structured Anchored Clinical Judgment (SACJ-Min).

The RRASOR was developed by Karl Hanson as an outgrowth of seminal research that empirically identified the most robust static risk factors for sexual re-offense (Hanson & Bussiere, 1998). Four of the strongest predictors of sexual re-offense, identified through stepwise regression, comprise the items of the RRASOR. The four items are number of prior sexual offenses, any unrelated victims in sexual offenses, any male victims in sexual offenses, and age less than 25 years at time of release (Hanson, 1997). The last three items were scored 1 if the characteristic was present and 0 if it was absent. The scoring for number of prior sexual offenses ranged from 0 to 3. Thus, the total score on RRASOR could range from 0 to 6 risk points. The RRASOR was widely used in the United States and Canada prior to the release of Static-99 (Jackson & Hess, 2007).

The SACJ, developed by David Thornton, contained items related to sexual deviance and criminality (Grubin,

1998; Hanson & Thornton, 2000). It was scored in a stepwise approach, initially considering any current sexual offenses, any prior sex offenses, any current nonsexual violent offenses, any prior nonsexual violent offenses, and four or more prior sentencing occasions. The total score on the first group of items determined the risk level. The second step considered the following eight items: any stranger victims, any male victims, never married, convictions for noncontact sex offenses, substance abuse, placement in residential care as a child, deviant sexual arousal, and psychopathy. The presence of two or more risk factors in the second step would raise the risk level by one category. The third stage of the SACJ-Min included consideration of variables related to current behavior and treatment completion. Only the items in the first two steps that were subject to cross-validation were included in the development of Static-99. The items in these first two steps are the minimum necessary items to assess risk. Hereafter, they are collectively referred to as SACJ-Min. A detailed description of the development of the RRASOR and the SACJ-Min is referenced in Hanson and Thornton (2000).

Static-99 Items and Scoring

Based on preliminary analyses, Hanson and Thornton (2000) recognized that the two tools assessed related, but not identical, constructs and appeared to have incremental validity. Therefore, they recognized the possibility that a single tool that included the combined, nonredundant items of the two tools might have superior accuracy. This produced the 10-item Static-99 with the following variables: number of prior sexual offenses, four or more prior sentencing occasions, any conviction for a noncontact sexual offense, any nonsexual violent conviction in conjunctions with the index sexual offense, any prior conviction for a nonsexual violent offense, any male victim in a sexual offense, any unrelated victim in a sexual offense, any stranger victim in a sexual offense, young age at release (under 25), and never lived with an intimate partner for at least 2 years. As indicated in Table 1, the scoring for the number of prior sexual offenses ranged from 0 to 3, and the scoring of the other nine, dichotomous items was scored 1 if the characteristic was present and 0 if it was absent.

An advantage of the Static-99 items is that they generally are easy to score from correctional and forensic records, and scoring does not require an interview. In addition, the Static-99 can be scored by law enforcement, mental health workers, and essentially anyone sufficiently trained in coding the instrument (Harris, Phenix, Hanson, & Thornton, 2003a, 2003b).

The total score on the Static-99 is the simple sum of the 10 item scores, with a resulting possible range of 0 to 12. The score can be converted into a measure of relative risk (e.g., nominal risk categories and percentiles). Nominal risk categories and percentiles from Hanson, Lloyd, Helmus, and Thornton (2012) are provided in Table 2.

Table 1 Static-99 items and scoring

Item #	Item description	Scoring categories		Score
1	Young age at release	Age 25 or older		0
		Age 18–24.99		1
2	Ever lived with lover for at least 2 years?	Yes		0
		No		1
3	Any conviction for index nonsexual violence?	No		0
		Yes		1
4	Any convictions for prior nonsexual violence?	No		0
		Yes		1
5	Number of prior sexual offenses (score whichever is higher for charges or convictions)	*Charges*	*Convictions*	
		None	None	0
		1–2	1	1
		3–5	2–3	2
		6+	4+	3
6	Number of prior sentencing occasions	3 or less		0
		4 or more		1
7	Any convictions for noncontact sexual offenses?	No		0
		Yes		1
8	Any unrelated victims in sexual offenses?	No		0
		Yes		1
9	Any stranger victims in sexual offenses?	No		0
		Yes		1
10	Any male victims?	No		0
		Yes		1
		Total score (simple sum)		0–12

The scoring of Static-99 (along with the Static-99R and the Static-2002R—both discussed later in this chapter) is contained in a comprehensive coding manual available on www.static99.org. This website is dedicated to providing resources for the instrument, including training, research, and other documents related to the use of various Static tools. The static99.org website also allows for submitting questions on the coding of the Static-99 and receiving responses from the website manager.

The Static-99 measures the risk of sexual or violent reconviction. Because many offenses go undetected, particularly sexual offenses, the resulting risk estimates should be considered an underestimate of the true risk of recidivism (Bonta & Hanson, 1994).

Static-99 Development Sample and Results

The assumptions leading to the construction of the Static-99 were assessed in the Static-99 development sample, which

Table 2 Static-99 indices of relative risk

Suggested nominal risk categories		
Category	Score	
Low	0–1	
Moderate-low	2–3	
Moderate–high	4–5	
High	6 or higher	
Percentiles		
Score	***Percentile***	***95 % CI***
0	6.3	0.3–12.6
1	21.9	12.8–31.3
2	42.3	31.5–53.1
3	63.3	53.3–73.3
4	78.7	73.1–84.2
5	87.5	83.6–91.3
6	93.7	90.7–96.5
7	97.3	96.0–98.6
8	98.9	98.0–99.6
9	99.7	99.3–100
10	99.99	99.8–100

Source Hanson et al. (2012)
Note Percentiles are midpoint averages based on an adjusted, reweighted average of 4 Canadian samples (n = 2,011) (Helmus, Thornton et al., 2012b)

consisted of four subsamples, three from Canada and one from England. The three Canadian samples largely formed the basis for the earlier construction of the RRASOR. One sample was drawn from the Institut Philippe-Pinel, a maximum security psychiatric facility located in Montreal that included 344 offenders treated between 1978 and 1993 (Proulx, Pellerin, McKibben, Aubut, & Quimet, 1997). A second sample, drawn from the Millbrook maximum security correctional institute in Ontario, consisted of 191 child molesters released between 1958 and 1974 (Hanson, Steffy, & Gauthier, 1992, 1993a, 1993b; Hanson, Scott, & Steffy, 1995). The third sample was drawn from the Oak Ridge Division of the Penetanguishene Mental Health Centre in Ontario and consisted of 142 sexual offenders referred for treatment and/or assessment between 1978 and 1993 (Rice & Harris, 1996, 1997 ; see also Quinsey, Rice, & Harris, 1995).The English sample (Thornton, 1997) included 563 sexual offenders released from Her Majesty's Prison Service in 1979. This latter sample was not used in the construction of RRASOR or the SACJ-Min.

Because the recidivism rates for all four samples were so similar, Hanson and Thornton (2000) combined them into a single sample (n = 1,208) for further analyses. Area under the Receiver Operator Curve (AUC) was used to test the predictive accuracy of each of the tools. The Static-99 (AUC=0.71), RRASOR (AUC=0.69), and SACJ-Min (AUC=0.67) each predicted sexual recidivism significantly better than chance levels (Hanson & Thornton, 2000). Generally, these levels of accuracy would be considered to be in the moderate to large range.

Additional analyses (Hanson & Thornton, 2000) demonstrated that the predictive accuracy of the Static-99 was greater than either the RRASOR ($Z = 2.38$, $p < 0.05$) or the SACJ-Min ($Z = 2.84$, $p < 0.01$). Consequently, further analyses focused exclusively on the Static-99. Those analyses demonstrated the increasing spread of recidivism rates over time as a function of relative risk level. For example, at 5 years after release, about 6 % of low-risk offenders had sexually recidivated compared to about 39 % of high-risk offenders, a 24-point difference. By year 15, about 9 % of low-risk offenders had sexually recidivated compared to 52 % of the high-risk offenders, a 43-point difference. These analyses also identified the absolute risk estimates (probabilities) for both sexual and violent recidivism associated with each score. However, since these absolute risk estimates are outdated and have been replaced with new norms for the Static-99R, they are not reported here.

Static-99 Reliability

Typically, studies have shown excellent levels of reliability for Static-99 scores in both research and applied settings (Hanson & Morton-Bourgon, 2009). Across 11 studies reporting inter-rater reliability, Helmus (2009) found consistently high reliability, with correlations ranging from 0.86 to 0.92 and intra-class correlations (*ICC*s) coefficients ranging from 0.84 to 0.95.

A number of inter-rater reliability studies have been conducted in the field for sexually violent predator (SVP) evaluators. An early unpublished study by Hanson (2001) examined 55 cases from SVP evaluations in California and found an *ICC* of 0.87. Levenson (2004) conducted a larger field reliability study in Florida and also found strong rater agreement in Static-99 total scores for 281 offenders evaluated for SVP commitment in Florida (*ICC* = 0.85).

Murrie et al. (2009) examined inter-rater agreement for Texas SVP evaluators with a relatively smaller sample. Reliability of Static-99 scores was high when comparing scores of experts on the same side of a case (*ICC* = 0.84 for petitioners' experts and *ICC* = 0.95 for respondents' experts). However, when comparing scores of petitioners' experts with respondents' experts, the *ICC*s dropped into the 0.60 range, suggesting the possibility of adversarial allegiance effects.

Field studies on inter-rater reliability have also been conducted in community supervision and treatment settings. In a Canadian study, the Dynamic Supervision Project, Static-99 scores across 88 cases produced an *ICC* = 0.91 (Hanson, Harris, Scott, & Helmus, 2007). Storey, Watt, Jackson, and Hart (2012) compared the ratings of clinicians in the field to those of researchers for 100 adult males who completed an outpatient sexual offender treatment program. Clinicians and

researchers showed excellent agreement for total scores on Static-99 (*ICC* = 0.92) and for most of the individual items.

Quesada, Calkins, and Jeglic (2014) examined the consistency of clinicians' item and total scores with those from researchers using a sample of 1,973 case files. Total scores showed a high degree of consistency, as reflected by an *ICC* = 0.924 for the combined sample of researchers and clinicians. There was exact agreement in total scores on 1,255 (63.6 %) of the cases, though a small number of cases (*n* = 90) achieved the same score despite some disagreements at the item level. An additional 557 (28.2 %) cases yielded total scores that were within 1 point of each other. Overall, then, total scores from clinicians and researchers were identical or within one point of each other in 1,812 (91.8 %) of the cases. Item-level agreement was also strong. Two of ten items produced outstanding agreement (*K* = 0.81 to 1.00 range), and the remaining eight items yielded substantial agreement (*K* = 0.61 to 0.80).

In a large study of field reliability with the Static-99, Boccaccini et al. (2012) reviewed the Static-99 scores for 600 sexual offenders in Texas and 135 sexual offenders in New Jersey. The Static-99 scores were generated by correctional officers in Texas and by doctoral-level evaluators in New Jersey. Texas evaluators produced an *ICC* = 0.79 and New Jersey evaluators produced an *ICC* = 0.88. In both state samples, about 55 % of cases had identical scores from raters, and an additional 33 % had scores within 1 point of each other. So, 88 % of the time scores were the same or within one point of each other, consistent with many studies of inter-rater agreement on Static-99 scores.

Cross-Validations of Static-99

The Static-99 has been validated on large and diverse samples from all over the world. There were 63 validations on Static-99 in Hanson and Morton-Bourgon's (2009) meta-analysis, substantially more than any other actuarial instrument that measures risk for sexual recidivism, and a number that continues to grow. Collectively, approximately 20,000 sexual offenders have been sampled in these studies. As noted by Hanson and Morton-Bourgon, the weighted average AUC across those studies was 0.67 (*95 % CI* of 0.62–0.72) and the median AUC was 0.74.

AUC values indicating moderate to strong predictive accuracy for sexual recidivism with the Static-99 have been very robust across nations, settings, and populations. Overall, the Static-99 shows moderate to strong predictive accuracy in Canada, the United States, the United Kingdom, Europe, Australia, and New Zealand, with the largest effect sizes in the United Kingdom, Australia, New Zealand, and California (Helmus, Hanson, & Morton-Bourgon, 2011; Hanson, Lunetta, Phenix, Neely, & Epperson, 2014)

Similarly, the Static-99 has shown moderate to large effect sizes for sexual offenders released from prisons (Beggs & Grace, 2010; Brown, 2003; Craig, Beech, & Browne, 2006, Epperson, 2003; Friendship, Mann, & Beech, 2003; Hood, Shute, Feilzer, & Wilcox, 2002; McGrath, Hoke, Livingston, & Cumming, 2001; Levenson, 2004; Ternowski, 2004; Thornton, 2002; Hood et al., 2002; Skelton, Riley, Wales, & Vess, 2006; Hanson et al., 2014) and for sexual offenders in community samples (Craissati, Webb, & Keen, 2005; Epperson, 2003; Hanson et al., 2007; Beech, Friendship, Erikson, & Hanson, 2002; Endrass, Urbaniok, Held, Vetter, & Rossegger, 2009; Stalans, Seng, & Yarnold, 2002).

Moderate predictive accuracy has been demonstrated for sexual offenders from forensic hospitals (de Vogel, de Ruiter, van Beek, & Mead, 2004; Ducro & Pham, 2006; Harris, Phenix et al., 2003a, 2003b; Nunes, Wexler, Firestone, & Bradford, 2003; Bengtson & Långström, 2007; Harris et al., 2003). Varying levels of predictive accuracy, from small to large, have been documented in validations with more specialized groups of sexual offenders, such as developmentally delayed sexual offenders (Tough, 2001; Hanson, Sheahan, & VanZuylen, 2013), juvenile offenders (Beech, 2005; Poole, Liedecke, & Marbibi, 2000; Ralston & Epperson, 2013), subtypes of sexual offenders (rape, child molest) (Bartosh, Garby, Lewis, & Gray, 2003; Brouillette-Alarie & Proulx, 2013; Ducro & Pham, 2006), treated offenders (Allan, Grace, Rutherford, & Hudson, 2007; Friendship et al., 2003; McGrath, Lasher, & Cumming, 2012; Seager, Jellicoe, & Dhaliwal, 2004; Thornton, 2002), and offenders who committed sexually motivated homicides (Hill, Habermann, Klusmann, Berner, & Briken, 2008).

A recent meta-analysis involving 43 studies and 31,426 sexual offenders from 11 countries examined the predictive accuracy of 15 risk assessment tools for sexual offenders. The total sample for analyses of the Static-99 was comprised of 20,727 sexual offenders from 30 studies. All of the reviewed tools produced at least a moderate effect size in predicting sexual re-offense, including Static-99 (*AUC* = 0.69) (Tully, Chou, & Browne, 2013).

There are mixed results of replications of Static-99 in the field versus research settings. An actuarial instrument may work well in a research setting, where there is quality control over fidelity to scoring rules, but not in an applied context where there is more opportunity for "coder drift." The field validity of Static-99 was tested for 1,928 sexual offenders screened for possible civil commitment as sexually violent predators in Texas. Sexual offenders in this study were either subject to discharge, mandatory supervision, or civil commitment (outpatient intensive supervision in Texas). The results demonstrated modest predictive accuracy (*AUC* = 0.55 for sexually violent predators and *AUC* = 0.57 for sex offenders who were not determined to be sexually violent

predators) (Boccaccini, Murrie, Caperton, & Hawes, 2009). Potential problems with this study included a very low sexual recidivism base rate, relatively short follow-up time, lower inter-rater reliability, and the level of supervision received by higher scoring sexual offenders, with each of these contributing to decreased variance in the outcome measure. This was likely most true for higher scoring offenders given the increased supervision that they received.

In contrast, very positive results emerged in a recent field study in California (Hanson et al., 2014). This study examined the predictive accuracy of Static-99 and Static-99R in a prospective study of 475 randomly selected adult males released in 2006 and 2007 and followed for 5 years. The California study revealed strong predictive accuracy for Static-99 (*AUC* = 0.82). This study demonstrated that the higher levels of predictive accuracy obtained in research setting can also be achieved in the field. While the reasons for the relatively higher AUCs are not fully understood, it is likely that California's comprehensive and structured training program for scoring Static-99R for probation and parole officers in California was a contributing factor. This program requires certification and recertification of scorers every 2 years, resulting in scoring that demonstrated very broad-based reliability *and* consistency with scoring rules.

Although the majority of Static-99 validation studies were conducted with retrospective samples, the study just described used a prospective design. In addition to the study just described, there have been other prospective validation studies. The Dynamic Supervision Project (Hanson et al., 2007) followed over 997 Canadian probationers for 3 years, and the Static-99 showed high predictive accuracy in this sample (*AUC* = 0.74) in this large contemporary sample (Hanson et al., 2007). An Austrian prospective study was conducted on 1,142 sexual offenders released from Austrian prisons and yielded statistically significant indices of predictive accuracy for the total sample (*AUC* = 0.73) and separately for child abusers (*AUC* = 0.77) and rapists (*AUC* = 0.69) (Eher, Schilling, Haubner-MacLean, Jahn, & Rettenberger, 2012).

Until 2004, little was known about the predictive accuracy of Static-99 for particular ethnic or racial groups. Subsequent research has demonstrated that predictive accuracy may vary depending on ethnicity. Långström (2004) examined the predictive accuracy of the Static-99 for Nordic (*AUC* = 0.76) and non-Nordic European (*AUC* = 0.79) sexual offenders in Sweden. The predictive accuracy for these two groups was similar to or higher than what was reported in other studies, but the Static-99 did not predict sexual recidivism for the smaller subsamples of African and Asian sexual offenders in Sweden (*AUC* = 0.50).

More recently Babchishin, Blais, and Helmus (2012a) found that both the Static-99 and Static-99R predicted equally well for Canadian and Aboriginal sexual offenders. Across five samples of Canadian Aboriginal sexual offenders, the AUC ranged from 0.60 to 0.81. This compared to a range from 0.61 to 0.78 for the five comparable samples of Canadian non-Aboriginal sexual offenders. The AUC values were statistically significant in four of the five non-Aboriginal samples and in three of the five much smaller Aboriginal samples.

In a study of Australian indigenous or nonindigenous sexual offenders (Smallbone & Rallings, 2013), Static-99 scores predicted sexual recidivism well with both indigenous (*AUC* = 0.76) and nonindigenous (0.82) sexual offenders. In a large sample from Texas (Varela, Boccaccini, Murrie, Caperton, & Gonzalez, 2013), the predictive accuracy of the Static-99 was assessed. Within this context, in which the Static-99 did not do well with any group, the relative predictive accuracy of the tool for sexual recidivism, the outcome of greatest interest, was comparable for White (*AUC* = 0.62), Black (*AUC* = 0.63), and Latino (*AUC* = 0.58). None of these values were statistically significant.

Overall, a clear pattern based on ethnicity does not emerge. This variability of results should be a consideration in applied risk assessments with sexual offenders identified with an ethnic minority.

Static-99R

The Static-99 Revised (Static-99R) was released for clinical use in 2009 (Hanson, Phenix, & Helmus, 2009; Helmus, Thornton, Hanson, & Babchishin, 2012b). The reasons for revising Static-99 were twofold. First, it was discovered that Static-99 did not adequately account for reductions in recidivism with advancing age at release (Hanson, 2002; Helmus, Thornton et al., 2012b). Second, more contemporary samples showed substantial reductions in sexual recidivism base rates relative to those in the Static-99 development samples. Although the reason for the reduction in base rates of sexual recidivism is not fully understood, Helmus (2009) reported a roughly 60 % decrease in sexual recidivism rates samples across 29 more contemporary samples relative to the original Static-99 normative samples. In addition, considerable variability in sexual recidivism base rates across samples was documented (Helmus, 2009; Helmus, Hanson, Thornton, Babchishin, & Harris, 2012a).

Static-99R Development and Validation Samples

Of the 29 samples used to document the lower sexual recidivism rates in more contemporary samples, 23 contained information on age. The Static-99R (Helmus, Thornton et al., 2012b) was developed and validated with these 23

samples, which were drawn from eight different countries. Eleven samples were from Canada, six were from the United States, two were from the United Kingdom, and one each was drawn from Austria, Denmark, Germany, Sweden, and New Zealand. A total of 8,390 sexual offenders were included in the 23 samples.

The majority of samples were drawn from correctional settings. All but one had an average follow-up period of at least 5 years, and 13 samples had average follow-up periods of at least 10 years. Most offenders (81 %) were released in 1990 or later, and the mean age at release was about 40. The criterion for sexual recidivism was a new sexual offense charge in nine of the studies and convictions in the other studies. Across all samples, the observed sexual recidivism base rate was 12.4 %.

For analyses to recode age at release, the sample was divided into construction and validation subsamples. All offenders with a follow-up period less than 10 years were included in the construction sample (n = 5,714) and all offenders with a longer follow-up period were included in the validation sample (n = 2,392). The entire sample was used to re-norm the Static-99R and to address the issue of variability of sexual recidivism base rates across the samples. More details on the samples are available in Helmus et al. (2012b).

Age at Release Item

Examining the Need for Recoding In Static-99, age at release (following the last sexual offense) was classified and scored using two categories, under age 25 (1 risk point) or age 25 and older (0 risk points). Analyses on the full sample were performed to determine if recoding of the age item was required. Analyses demonstrated that age at release was negatively correlated with Static-99 scores and negatively associated with sexual recidivism. Cox regression analyses documented significant incremental validity for age at release after controlling for Static-99 scores. Finally, additional analyses indicated that the association of between age at release and sexual recidivism was nonlinear (Helmus, Thornton et al., 2012b). These results confirmed the desirability of recoding the age at release item.

Recoding the Age at Release Item Additional analyses by those authors, using only the *construction* subsample, indicated that the optimal scoring for the age item required four age categories and associated scores as follows: 18 to 34.9 (1 point), 35 to 39.9 (0 points), 40 to 59.9 (−1 point), and 60 and older (−3 points) (Helmus, Thornton et al., 2012b). This new scoring reflects increased risk for younger offenders and decreased risk with advancing age. All other Static-99R scoring is identical to that of the Static-99, as listed in Table 1.

It is important to note that the age item must be scored based on age at release for the last *sexual* offense because that is how it was scored in all the study samples. It is possible that an offender had a sexual offense early in his life and subsequent incarcerations were for nonsexual crimes. In this case, age at release would be the offender's age when he was released from his sexual offense many years ago. His aging post-release from the index sex offense would not be captured by the Static-99R age item, so risk reductions associated with aging would have to be considered outside the instrument in such instances.

Validity of the Static-99R

Relative Risk Static-99R total scores, with the new scoring of the age at release item, were expected to produce only modest improvements in predictions of relative risk from Static-99R total scores, as reflected in slightly higher AUC values. This was tested with the *validation* subsample using a 10-year follow-up period. Although the difference was not statistically significant, the Static-99R (AUC = 0.720) was nominally more accurate than the Static-99 (AUC = 0.713). In addition, Cox regression analyses indicated the age at release failed to add incremental validity to predictions of sexual recidivism after controlling for Static-99R scores. Finally, additional analyses indicated that the Static-99R worked equally well with rapists and child molesters.

Although total scores, and not individual items, are used as the index of risk for sexual recidivism, Helmus and Thornton (2014) examined whether the individual items themselves significantly predicted sexual recidivism. Combining data on 8,053 offenders from the 22 samples described earlier, they determined that only one item (nonsexual violence as part of the index offense) was not significantly associated with sexual recidivism. All other items were significant predictors for Static-99R, and each added incremental validity (either with statistical significance or approaching significance). Static-99R indices of relative risk are presented in Table 3.

Absolute Risk Predicted probabilities of sexual recidivism based on Static-99 and Static-99R scores were compared to each other and to observed rates of sexual recidivism by age group (Helmus, Hanson et al. 2012a; Helmus, Thornton et al. 2012b). As expected, the probabilities of sexual recidivism predicted by Static-99R scores were significantly different than those of the Static-99. The Static-99 predicted probabilities also were significantly different from the observed rates of sexual recidivism. Although there was

10 and higher	99.99	99.8–100	

Source Phenix et al. (2012)

Note Percentiles are midpoint averages based on an adjusted, reweighted average of 4 Canadian samples (n = 2,011) (Hanson et al., 2012). Risk ratios were calculated from hazard ratios based on Cox regression coefficients derived from entering the continuous (i.e., unclumped) Static-99R scores (β = 0.322; SE = 0.022), with sample as strata (k = 8, n = 4,037) (Hanson, Babchishin, Helmus, & Thornton, 2013)

[a]Due to small sample size, risk ratios are not presented for Static-99R scores greater than 8 (the risk ratio given is for 8 and higher). The analyses were based on routine (i.e., relatively unselected) correctional samples

good congruence at younger ages, the Static-99 overpredicted risk for older sexual offenders. In contrast, Static-99R predicted probabilities were congruent with observed rates of sexual recidivism across the full range of ages, demonstrating good calibration overall with the new scoring of the age at release item.

Variable Base Rates: Multiple Norm Groups As noted earlier, sexual recidivism rates of more contemporary samples were approximately 60 % of the rate observed in the original Static-99 samples, with the greatest reductions occurring at higher scores (4 and higher) (Helmus, 2009). These findings pointed to a need for updated norms for absolute risk estimates (predicted probabilities of sexual recidivism) associated with each score and/or risk category.

A related finding in the new data was that sexual recidivism base rates varied significantly across samples, which contrasted with the homogeneity of sexual recidivism base rates in the Static-99 development samples. Helmus (2009) noted the problems of such variability in constructing norms for absolute risk (see also Helmus, Hanson et al. 2012a). Helmus examined a number of variables that might moderate the observed variability, including use of charges versus convictions to define sexual recidivism, number of recidivism sources searched, utilization of national criminal records, incorporation of "street time," adherence to Static-99 coding rules, and variation in jurisdiction, offender type, country, age at release, release year, race, treatment, and sample type. Of these potential moderator variables, only sample type warranted further consideration.

This finding, and further analyses, led to the adoption of new contemporary norms for four separate groups based on the level of preselection: routine correctional samples, preselected for treatment samples, preselected for high-risk/high-need samples, and other nonroutine correctional samples. The *routine norms* are based on correctional samples comprised of sexual offenders included in relatively random and unselected ways. This group has the lowest recidivism rates for each cutoff score.

The *preselected for treatment norms* are based on sexual offenders who, through formal or informal processes, were judged as requiring treatment. The *high-risk/high-need norms* are based on sexual offenders selected (on the basis of perceived risk) for relatively "rare or infrequent measures or interventions or sanctions, such as psychiatric commitments and being held past their release date" (Hanson et al., 2009; Phenix, Helmus, & Hanson, 2012). The nonroutine norms are based on sexual offenders who were not routine because of some degree of preselection, making the use of *routine norms* inappropriate. However, the degree and purpose of the preselection was not sufficiently clear to be classified into the previous two preselected groups. The risk estimates for this group are simply a weighted average of the samples in the other two preselected groups and other preselected samples that did not match either definition.

The classifications of Static-99R normative samples into these four groups, as well as a summary of the defining characteristics of each of the groups, were first presented by Hanson et al. (2009). More detailed descriptions of the defining characteristics of each normative group, as well as a listing of the risk estimates for each group, are provided in the *Evaluator's Handbook* (Phenix et al., 2012). This handbook can be accessed at the static99.org website.

However, just as this chapter was going to press, the authors of the Static-99R and their associates completed a study that included additional contemporary samples (Hanson, Thornton, Helmus, & Bachishin, 2015). This broader study supported the use of separate norms for two groups: *routine* and *high-risk/high-need* samples. Overall, the *preselected for treatment* samples did not significantly differ from the *routine* samples. As a result, the authors recommend using only two sets of norms. The *high-risk/high-need norms*

are appropriate for sexual offenders preselected on these dimensions, as discussed above, and the *routine norms* are recommended for other sexual offenders. Consistent with the author's recommendation, only the absolute risk estimates for these two groups are reported in Tables 4 and 5.

Scoring the Static-99R and Using the Static-99R Norms

As noted earlier, the scoring of the Static-99 and Static-99R differ only on the age at release item, a variable that is easily scored from records. Thus, like the Static-99, the Static-99R is an instrument that is easy to score from correctional and forensic records. Scoring Static-99R does not require an interview and it can be scored by law enforcement, mental health workers, and essentially anyone sufficiently trained in coding the instrument (Harris, Phenix et al., 2003a, 2003b). Again, the new scoring for the age at release item on the Static-99R is as follows: 1 = age 18–34.9, 0 = age 35–39.9, −1 = age 40–59.9, and −3 = age 60 or older.

Relative Risk Norms The total score on Static-99R can be translated into measures of relative risk and absolute risk. Measures of relative risk reflect an offender's risk relative to a generally unbiased and representative group of sexual offenders given the offenders Static-99R score. The comparison of a single score to this group can be reflected by placement into one of the four nominal risk categories, for which the cutoffs remain unchanged, by specification of a percentile (based on four relatively unbiased Canadian samples), or by relative risk ratios (level of risk relative to the average offender in the *routine* sample). The methods and tables to translate relative risk from the total score on Static-99R are contained in the *Evaluator's Handbook* (Phenix et al., 2012) and presented here in Table 3.

Absolute Risk Norms Prior to Static-99R, only one set of norms was used to determine the absolute risk of sexual re-offense for 5, 10, and 15 years. Using a Static-99 score of 6, for example, the 5-year risk estimate was 39 %, the 10-year risk estimate was 45 %, and the 15-year risk estimate was 52 % (Harris, Phenix et al., 2003a, 2003b). However, because of the significant base rate variability of the 23 samples used to develop and validate Static-99R, it became necessary to use one of two sets of norms to determine absolute risk estimates for Static-99R (see Tables 4 and 5 and the Evaluator's Workbook for the sets of norms).

Choosing Static-99R Absolute Risk Norms for an Individual Case Because there is no longer a single probability of re-offense associated with any cutoff score on Static-99R, evaluators are tasked with the job of determining which absolute risk norms (predicted probability of sexual recidivism) are most appropriate for the offender they are evaluating. In theory, this could be done by comparing the degree of preselection for high-risk/high-need interventions; however, this involved a degree of subjectivity and sometimes proved problematic in court.

More recent research has helped resolve these issues. Increasingly, research evidence confirms that the variability in sexual recidivism base rates in the Static-99R samples is due to differences in the presence of unmeasured risk factors external to Static-99R (Hanson & Thornton, 2012). These external risk factors are often referred to as psychological needs or dynamic risk factors. Many such enduring psychological/dynamic needs or long-term vulnerabilities were identified meta-analytically by Mann, Hanson, and Thornton (2010).

For example, Looman and Abracen (2012) examined 348 high-risk sexual offenders who were divided into two groups based on the level of preselection (detained and not detained past release date). The detained (preselected) group evidenced greater levels of hostility, cognitive distortions supportive of offending, sexual obsessions, and sexually deviant behaviors. They also showed less assertiveness and greater psychiatric histories. These results supported the findings by Hanson and Thornton (2012) that preselection is associated with greater levels of dynamic needs.

Importantly, these dynamic needs add incremental validity to Static-99R (Hanson & Thornton, 2012). Offenders with low dynamic needs are most similar to offenders in the routine norms, offenders with moderate dynamic needs have re-offense rates most similar to the preselected for treatment norms, and offenders with high dynamic needs are most similar to offenders in the high-risk/high-need norms. Similarly, sexual offenders with identical scores on the Static-99R have different rates of sexual recidivism based on the density of psychological/dynamic needs, with higher-need sexual offenders exhibiting higher rates of sexual recidivism than lower-need sexual offenders with the same score (Hanson & Thornton, 2012; Thornton & Knight, 2013).

Concurrent with research documenting the additional explanatory power of psychological/dynamic needs external to the Static-99, empirically derived and validated tools measuring the density of such needs emerged. Examples of such tools include the Stable-2007 (Fernandez, Harris, Hanson, & Sparks, 2012; Helmus, Hanson et al., 2012a; Hanson et al., 2007), Structured Risk Assessment-Forensic Version (SRA-FV) (Thornton, 2012; Thornton & Knight, 2013), the Violence Risk Scale-Sex Offender Version (VRS-SO) (Olver, Wong, Nicholaichuk, & Gordon, 2007), and the Sex Offender Treatment Intervention and Progress Scale (SOTIPS) (McGrath et al., 2012). These tools provide methods for reliably quantifying the density of psychological/dynamic needs and informing the selection of an appropriate Static-99R norm group. For example, the SRA-FV manual contains a Level of Need Inventory (LONI) that gives specific cutoff scores to select the appropriate Static-99R norm group. Similarly, the Stable-2007 provides recidivism rates depending on the score on Static-99R and Stable-2007 combined.

As additional research accumulates, it is possible that the Static-99R group may further modify absolute risk norms. Any such changes would be published on the static-99 website at the appropriate time.

Reliability of the Static-99R

Given that the scoring for the Static-99R differs from the Static-99 on only one of ten items, it can draw from the vast research confirming the ability to reliably score the Static-99. Still, it is technically a different tool, so it was important to independently document the reliability of scores using the Static-99R. McGrath et al. (2012) reported very high reliability for the Static-99R (*ICC* = 0.89).

Noting the importance of assessing reliability of scores produced by fieldworkers, Hanson et al. (2014) assessed the reliability of Static-99R scores from 55 corrections and probation officers in California scoring a common set of 14 cases. Overall rater reliability was acceptable (*ICC* = 0.78). There was a substantial difference in the reliability of scores from experienced scorers (*ICC* = 0.85) and less experienced scorers (*ICC* = 0.71), pointing to the importance of recent practice. Experienced scorers were those who had scored 26 or more sexual offenders on the Static-99R in the previous 12 months.

Cross-Validations of the Static-99R

Validity of the Static-99R was well established through the use of separate construction and validation samples. As noted earlier, the AUC = 0.720 in the validation sample (n = 2,392) was statistically significant and nominally higher than that for the Static-99 (AUC = 0.713) (Helmus, Thornton et al., 2012b). Because the Static-99 and Static-99R are identical except for the age item, Static-99 cross-validations can be informative about the predictive accuracy for both Static-99 and Static-99R.

In a separate cross-validation of the Static-99R in California, Hanson et al. (2014) reported high relative risk validity (discrimination) and good absolute risk validity (calibration). This was a prospective, field study of 475 randomly selected, adult males released from California prisons in 2006–2007 and followed for 5 years. The resulting *AUC* = 0.817 (95 % CI 0.716, 0.919) demonstrated strong relative predictive accuracy.

The level of calibration was calculated through *E/O* ratios, using norms from other routine samples (Hanson et al., 2012). Analyses demonstrated overall fit between expected and observed rates of sexual recidivism across nominal risk categories as well as across scores. Relative to the normative

routine samples and consistent with the high AUC in this study, this sample produced a significantly lower adjusted base rate ($\beta 0_2 = -3.778$ vs. -2.941) and significantly higher discrimination index (change in relative risk per score increase) ($\beta 1 = 0.548$ vs. 0.331). As a result, the range of predicted probabilities for sexual recidivism in this sample ranged from approximately 0 for a score of −3 to just slightly over 0.50 for a score of 9. This contrasted to a range of predicted probabilities in the normative samples from approximately 0.01 to just less than 0.30 for the same range of scores.

Hanson et al. (2014) also looked at the predictive accuracy of the Static-99R for 5-year sexual recidivism separately for Black (*AUC* = 0.765), Hispanic (*AUC* = 0.734), and White (*AUC* = 0.850) sexual offenders. The levels of predictive accuracy were statistically significant ($p < 0.05$) for Blacks and Whites, but not for Hispanics. That latter nonsignificant finding resulted from a very wide 95 % confidence interval, which was at least in part due to the small sample size of Hispanic sexual recidivists ($n = 5$). Logistic regression equations for Black, Hispanic, and White sexual offenders revealed no significant differences in the adjusted base rate (predicted value for a Static-99R score of 2) or in the rate of change in relative risk for a one-unit increase in Static-99R score. In other words, discrimination and calibration were not different based on ethnicity.

Performance of the Static-99R with Black, Latino, and White sexual offenders was also examined in the large Texas study described earlier (Varela et al., 2013). The Static-99R did not perform well overall in this study, but its sexual recidivism predictive accuracy for relative risk was roughly equivalent with Blacks (*AUC* = 0.65), Latinos (*AUC* = 0.57), and Whites (*AUC* = 0.59). Only the AUC for Blacks was statistically significant.

In a sample of 319 Canadian Aboriginals and 1,269 Canadian non-Aboriginals across five independent samples, Babchishin, Blais, and Helmus (2012a) found similar, statistically significant levels of predictive accuracy for the Static-99R with both groups, *AUC* = 0.698 and *AUC* = 0.726, respectively. Predictive accuracy at the item level was also similar for the two groups of sexual offenders. In contrast, with a smaller sample of Australian Aboriginals ($n = 67$) and non-Aboriginals ($n = 399$) with a relatively short follow-up period ($M = 29$ months), Smallbone and Rallings (2013) reported statistically significant sexual recidivism predictive accuracy for the Static-99R with Australian non-Aboriginal sexual offenders (*AUC* = 0.79) but not for Australian Aboriginal sexual offenders (*AUC* = 0.61).

As with the Static-99, a clear pattern based on race/ethnicity does not emerge. This variability of results should be a consideration in applied risk assessments with sexual offenders identified with a racial/ethnic minority

Static-2002 and Static-2002R

Development and Initial Validation

Static-2002 The Static-2002 was developed by Hanson and Thornton (2003) with the intent of creating a risk assessment tool with improved reliability and predictive accuracy, as well as increased conceptual clarity and coherence. Like Static-99, the Static-2002 was designed to be a brief actuarial measure of relative and absolute risk for sexual recidivism that could be scored from commonly available information in correctional files.

Potential items were identified through a review of existing research literature at the time, as well as a review of items in some other validated actuarial tools. This review produced 22 variables that were considered for inclusion on the Static-2002. Items were selected, weighted, and combined in some cases based on meta-analyses of 10 samples, including three of the four samples to develop the Static-99 (Institut Philippe-Pinel, Millbrook, and Her Majesty's Prison Service in the UK) (Hanson & Thornton, 2003). Two federal Canadian samples were also utilized, and other Canadian samples were from Edmonton, British Columbia, and Manitoba. Two samples were included from the United States, one from California and one from Washington. In all, 4,596 sexual offenders were included in the development sample with an average follow-up period of 7 years.

Of the 22 variables, 17 had statistically significant associations with sexual recidivism. Using 6 of the 10 samples that included information on all 17 variables, the 17 variables were combined into 14 items and weighted based on empirical relationships and observing the principle of simplicity when considering options that were essentially equivalent from an empirical perspective.

The resulting14 items on Static-2002 are organized into five meaningful subscales of risk: age, persistence of sexual offending, deviant sexual interests, relationship to victims, and general criminality. Age at release consisted of a single item and the other four categories consisted of two to five items (see Table 6). For the age, deviant sexual interests, and relationship to victim(s) category, the category score is simply the sum of the item scores within the category. For the persistence of sexual offending category and the general criminality category, the raw total score summed across items within a single category is converted to a category score, as summarized in Table 6. The converted score is used for these two categories so that unit increases in risk are similar in each of the five categories.

Organization of the 14 items into 5 subcategories was intended to provide greater conceptual clarity and potentially enable treatment providers to identify specific areas of risk to

Table 6 Static-2002 items and scoring

Item #	Item description	Item scoring categories		Item score	Category score
Age at release risk group (item 1)					***0–3***
1	Young age at release	Age 50 or older		0	
		Age 35 to 49.99		1	
		Age 25 to 34.99		2	
		Age 18 to 24.99		3	
Persistence of sexual offending group (items 2–4)					***0–3***
Raw score total		*Risk factor score*			
0		*0*			
1		*1*			
2 or 3		*2*			
4 or 5		*3*			
2	Number of prior sexual offenses (score whichever is higher for charges or convictions)	*Charges*	*Convictions*		
		None	None	0	
		1–2	1	1	
		3–5	2–3	2	
		6+	4+	3	
3	Any juvenile arrest for a sexual offense and convicted as an adult for a separate sexual offense?	No		0	
		Yes		1	
4	More than one sexual offense sentencing occasion every 15 years?	No		0	
		Yes		1	
Deviant sexual interests group (items 5–7)					***0–3***
5	Any sentencing occasions for noncontact sexual offenses?	No		0	
		Yes		1	
6	Any male victims?	No		0	
		Yes		1	
7	Has two or more victims under age 12, with at least on victim being unrelated?	No		0	
		Yes		1	
Relationship to victims group (items 8–9)					***0–2***
8	Any unrelated victims in sexual offenses?	No		0	
		Yes		1	
9	Any stranger victims in sexual offenses?	No		0	
		Yes		1	
General criminality group (items 10–14)					***0–3***
Raw score total		*Risk factor score*			
0		*0*			
1 or 2		*1*			
3 or 4		*2*			
5 or 6		*3*			
10	Any prior involvement with the criminal justice system?	No		0	
		Yes		1	
11	Number of prior sentencing occasions for anything	0 to 2		0	
		3 to 13		1	
		14 or more		2	
12	Any community supervision violations?	No		0	
		Yes		1	
13	Free more than 36 months prior to the index sexual offense date AND more than 48 months prior to index sexual offense conviction?	Yes for both conditions		0	
		No for at least one		1	
14	Any prior nonsexual offense sentencing occasion?				
		Total score (sum of GROUP scores)			***0–14***

Table 7 Static-2002 indices of relative risk

Suggested nominal risk categories		
Category	Score	
Low	0 to 2	
Moderate-low	3 to 4	
Moderate	5 to 6	
Moderate–high	7 to 8	
High	9 or higher	
Percentiles		
Score	***Percentile***	***95 % CI***
0	2.3	0.1–4.8
1	10.0	4.7–15.6
2	23.0	15.5–30.6
3	39.1	20.5 -47.8
4	56.5	47.6–65.3
5	72.6	65.1–79.9
6	84.4	79.6–89.0
7	91.2	88.4–93.7
8	95.1	93.0–96.9
9	97.7	96.3–98.8
10	99.3	98.4–99.9
11	99.9	99.7–100
12+	99.99	99.8–100

Note Percentiles are midpoint averages based on an adjusted, reweighted average of 4 Canadian samples (n = 2,011) (Hanson et al., 2012)

better develop treatment plans and interventions. Using the scoring just described, the range of category scores is 0–3 for each category except relationship to victims, which has a range of 0–2. The Static-2002 total score is the sum of the category scores rather than the sum of the item scores, so the range of total scores is 0–14. Indices of relative risk for the Static-2002 are presented in Table 7.

To estimate the predictive accuracy, Hanson and Thornton (2003) compared the performance of the Static-2002 to the Static-99 and the RRASOR using eight of the ten samples. However, because of extensive missing data when trying to compare the three instruments, these were truly only estimates even though none of the tools appears to have been disadvantaged by the common rules for how to handle missing data. The performance of the three tools in predicting sexual recidivism across the eight samples was comparable, as reflected in unweighted average *AUCs* of 0.678 for the RRASOR, 0.688 for the Static-99, and 0.716 for the Static-2002. There was also little difference in the performance of the three tools separately for child molesters (respective *AUCs* of 0.671, 0.700, 0.687) and rapists (respective *AUCs* of 0.693, 0.671, 0.734). One advantage of the Static-2002 is that it had less variability across samples. Although absolute risk estimates were generated for the Static-2002, they are not reported here because they have been deemed outdated by the developers and replaced with new absolute risk estimates in conjunction with the development of the Static-2002R.

Static-2002R The Static-2002 Revised (Static-2002R) was developed for the same reasons as the Static-99R, to better reflect decreasing risk with advancing age and to adjust for decreasing base rates of sexual recidivism and variability in those base rates in generating absolute risk estimates. The analyses and results were parallel to those described earlier for the Static-99R, and both sets of analyses are provided by Helmus et al. (2012a) and Helmus, Thornton et al. (2012b), so only the differences between the Static-99R and Static-2002R analyses and results are described here.

One important difference is that there were only 7 Static-2002 samples (n = 2,609) available. Analyses to determine the need for new scoring of the age at release item utilized the samples from these studies. Overall, analyses revealed a pattern of decreasing sexual recidivism across increasing age bands, similar to that for the Static-99. After controlling for Static-2002 scores in Cox regression analyses, the quadratic effect for age significantly added to the prediction of sexual recidivism, though the linear and cubic effects did not. The same weights as those used to recode the age at release item on the Static-99R were used to recode the age at release item on the Static-2002R. The one difference was that a constant of 1 was added to the weights to maintain consistency with the previously established risk categories.

The age at release item on the original Static-2002 is scored as 3 for age 18 to 24.9, 2 for age 25 to 34.9, 1 for age 35 to 49.9, and 0 for age 50 and older, as reflected in Table 6. Based on the procedures just described, the Static-2002R age at release item is scored: 2 for age 18–34.9, 1 for age 35–39.9, 0 for age 40–59.9, and −2 for age 60 and older. With the new scoring, age at release produced no incremental validity after controlling for Static-2002R scores, and absolute risk estimates by age group were better calibrated with observed rates of sexual recidivism.

With these seven samples, the relative predictive validity for 5-year sexual recidivism was nominally higher on Static-2002R (*AUC* = 0.713) than the Static-2002 (*AUC* = 0.709). As with other actuarial tools, relative risk can be reported as nominal risk categories, percentiles, or relative risk ratios. Static-2002R nominal risk categories, percentiles (based on four relatively unbiased Canadian samples), and relative risk ratios (relative to the average offender in the *routine* correctional samples) are available at the static99.org website and presented in Table 8.

Absolute risk estimates have changed substantially for the Static-2002R relative to the Static-2002. Because of the significant variability in sexual recidivism base rates across the seven samples used to develop and initially validate Static-2002R (Helmus, 2009; Helmus, Hanson et al., 2012a), it was necessary to generate three sets of norms for Static-2002R absolute risk estimates.

Table 8 Static-2002R indices of relative risk

Suggested nominal risk categories			
Category	Static-2002R score		
Low	−2 to 2		
Moderate-low	3–4		
Moderate	5–6		
Moderate–high	7–8		
High	9 or higher		
Percentiles and relative risk ratios			
Score	**Percentile**	**95 % CI**	**Relative risk ratio**
−2	1.4	0–3.0	0.20
−1	4.2	2.6–6.1	0.28
0	9.0	5.5–12.8	0.38
1	17.3	12.3–22.5	0.52
2	30.1	22.2–38.3	0.72
3	47.1	38.1–56.1	1.00
4	63.7	55.9–71.4	1.38
5	78.0	71.1–84.7	1.90
6	88.3	84.3–92.1	2.63
7	93.3	91.3–95.1	3.62
8	95.9	94.2–97.4	5.00
9	98.3	96.9–99.5	6.90[a]
10	99.7	99.3–100	
11	99.97	99.8–100	
12 and higher	99.99	99.8–100	

Source Phenix et al. (2015)

Note. Percentiles are midpoint averages based on an adjusted, reweighted average of 4 Canadian samples (n = 2,011) (Hanson et al., 2012). Risk ratios were calculated from hazard ratios based on Cox regression coefficients derived from entering the continuous (i.e., unclumped) Static-99R scores (β = 0.322; SE = 0.022), with sample as strata (k = 8, n = 4,037) (Hanson, Babchishin et al., 2013)

[a]Due to small sample size, risk ratios are not presented for Static-99R scores greater than 9 (the risk ratio given is for 9 and higher). The analyses were based on routine (i.e., relatively unselected) correctional samples

These norm groups, first presented by Hanson et al. (2009), reflect level of preselection, similar to the Static-99R norm groups. The Static-2002R norm groups are *routine norms* (based on routine and representative correctional samples), *high-risk/high-need norms* (based on samples of sexual offenders selected based on perceived risk for significant but relatively infrequent interventions or sanctions, such as psychiatric commitments and being held past their release date), and *nonroutine norms* (based on samples of sexual offenders that are not routine or representative of sexual offenders broadly because of some degree of preselection, but the preselection is not clearly for high risk/high need). There is not a "preselected for treatment" group for the Static-2002R because of a lack of sufficient samples in this category.

Hanson et al. (2015) investigated support for the three sets of norms using a broader sample that included additional contemporary samples. As with the Static-99R, they found broad support for the use of only two sets of norms, *routine* and *high risk/high need*. As a result, the authors recommend using only these two sets of norms. The *high-risk/high-need norms* are appropriate for sexual offenders preselected on these dimensions, as discussed earlier, and the *routine norms* are recommended for other sexual offenders. Consistent with the author's recommendation, only the absolute risk estimates for these two groups are reported in Tables 9 and 10.

Table 9 Static-2002R 5-year sexual recidivism risk estimates for routine samples

Reliability

Five studies reporting inter-rater reliability for the Static-2002 scores were identified, and all reported high indices of reliability. In a comparative study of risk assessment tools, Langton et al. (2007) reported high reliability (*ICC* = 0.91) for the Static-2002. Similarly, Knight and Thornton (2007) reported an inter-rater r = 0.89, and Haag (2005) reported an inter-rater r = 0.92. Finally, Bengtson (2008) found very high reliability (*ICC* = 0.96), as did Helmus and Hanson (2007) (*ICC* = 0.98). The latter authors explicitly acknowledged that their process was not typical of the coding complexities that occur in the field because of the simplified nature of the records used in the study. The other reliability indices reported should also be considered as estimates of reliability achieved in a research setting. Given that research and field reliability were comparable for the Static-99/R tools, strong reliability in the field for the Static-2002/R tools would be expected, but a robust assessment of field reliability would be beneficial.

Published reports of reliability for the Static-2002R could not be found. However, the latter tool differs from the Static-2002 only in the scoring of one item. Given that there were no meaningful differences in the reliability achieved with the Static-99R versus the Static-99, one would not expect reliability with the Static-2002R to differ from that of the Static-2002. This should be confirmed through appropriate lab and field assessments.

Cross-Validations

Hanson, Helmus, and Thornton (2010) reviewed and performed meta-analyses on samples from eight studies (n = 3,034), published and unpublished, to assess the predictive accuracy of the Static-2002 on independent samples in comparison to the Static-99. Across the eight studies, the *AUCs* for sexual recidivism ranged from 0.64 to 0.79, and all 95 % CIs excluded 0.50, reflecting statistically significant predictive accuracy in each of the studies. A similar pattern was also evident for violent recidivism (*AUCs* ranged from 0.64 to 0.77 and all were statistically significant).

Across all eight studies, the weighted average predictive accuracy for sexual recidivism was slightly higher for the Static-2002 (*AUC* = 0.685) and the Static-99 (*AUC* = 0.665). Predictive accuracy for violent recidivism exhibited a similar pattern, with the Static-2002 (*AUC* = 0.702) being slightly higher than the Static-99 (*AUC* = 0.662). The differences between the two instruments were statistically significant in both cases, with the predictive accuracy of the Static-2002 superior to that of the Static-99. Although there was significant variability in AUC's across studies, the difference between the Static-2002 and the Static-99 was stable.

Babchishin, Hanson, and Helmus (2012b) compared the predictive accuracy of the Rapid Risk Assessment of Sex Offender Recidivism (RRASOR), Static-99R, and Static-2002R for 7,491 (20 samples from the Static-99R re-norming project) offenders primarily from Canada and the United States, but also offenders from Austria, Denmark, Germany, New Zealand, Sweden, and the United Kingdom. Total scores of Static-2002R (*AUC* = 0.686) predicted sexual recidivism. This level of predictive accuracy was similar to that for the Static-99R (*AUC* = 0.684) in these analyses.

Another recent meta-analysis (Tully, Chou, & Browne, 2013) of 43 studies and 31,426 sexual offenders from 11 countries examined the predictive accuracy of 15 risk assessment tools for sexual offenders (the number of studies and sexual offenders varied for each instrument). All of the reviewed tools produced at least a moderate effect size in predicting sexual re-offense including the Static-2002 (*AUC* = 0.70). The Static-99 performed similarly (*AUC* = 0.69).

Babchishin, Blais, and Helmus (2012a) examined the predictive accuracy of the Static-2002 and the Static-2002R with three samples of Canadian Aboriginals (n = 209) and non-Aboriginals (n = 955). Predictive accuracy for sexual recidivism was statistically significant in the total sample for the Static-2002 (*AUC* = 0.740) and the Static-2002R (*AUC* = 0.733) and in the non-Aboriginal sample for the Static-2002 (*AUC* = 0.763) and the Static-2002R (*AUC* = 0.759). In contrast to the Static-99 and Static-99R, there was a substantial drop in predictive accuracy in the Aboriginal sample for both the Static-2002 (*AUC* = 0.617) and the Static-2002R (*AUC* = 0.608), though the accuracy for the Static-2002 remained statistically significant.

Uses and Training Requirements for the Static Tools

Over the last 20 years or so, lawmakers have passed a number of statutes intended to produce more restrictive policies and procedures with sexual offenders. Examples include the Jacob Wetterling Act in 1994, Megan's Law in 1996, and the Adam Walsh Child Protection and Safety Act in 2006. Additional statutes have been passed in a number of states that impose even more restrictions on sexual offenders and how they are managed.

Earlier statutes largely left defining and assessing risk to leaders in relevant state divisions and departments. In response, a number of states developed tiered risk-management systems, generally based on relative risk estimates. Over time, jurisdictions increasingly turned to actuarial instruments for establishing risk and implementing policies and systems for the management of sexual offenders in the community (Zgoba, Miner, Knight, Letourneau, Levenson, & Thornton, 2012). Through this empirical approach to risk management, scores on actuarial instruments are used to inform many aspects of risk management, including level of supervision, intensity of treatments, level of community notification, use of Global Positioning Systems (GPS), sentencing decisions, and civil commitment referrals.

Because of the extensive research confirming the predictive validity of the Static-99, Static-99R, Static-2002, and Static-2002R, these are increasingly the instruments of choice by administrators responsible for risk-management policy implementation. The development team for these two tools recommends that the Static-99R, rather than the Static-99, and the Static-2002R, rather than the Static-2002, be used to inform the implementation of such policies (Helmus, Thornton et al., 2012b). The reasons are that the revised tools better incorporate the association of advancing age with reduced risk for sexual recidivism and use absolute risk norms (predicted probabilities) that provide better calibration with observed rates of sexual recidivism for the respective norm groups.

The Adam Walsh Child Protection and Safety Act was significant because it created more stringent registration requirements and established a standardized, offense-based classification system. In other words, legislators defined risk levels themselves largely based on history of prior offenses. Zgoba et al. (2012) investigated whether the classification system outlined by the Adam Walsh Act accurately represented the risk of sexual recidivism, which is necessary to create more effective sex offender management. Specifically, they compared the Adam Walsh classification system tiers to the use of the actuarial risk instruments to identify high-risk sexual offenders and recidivists. The Static-99R, Static-2002R, and existing state tier systems (often based on actuarial tools) were superior to the Adam Walsh Act tiers. In fact, the Adam Walsh Act tiers were unrelated or inversely related to sexual recidivism across the four states in the sample (Zgoba et al., 2012).

The validity of the Static tools is well established, particularly the Static-99/R tool, with the Static-99R and Static-2002R now being the risk assessment tools recommended by the developers. To have the full weight of this research bear on particular cases, people scoring the Static-99R or Static-2002R must be appropriately knowledgeable about and faithful to the scoring guidelines. Accordingly, the developers of these tools recommend that professionals complete training, ideally from a certified trainer, before using the tools. It is also desirable for certified scorers to periodically code the same case and compare scores to help prevent "coder drift" over time. With this goal in mind, the state of California requires scorers to be recertified every 2 years.

Certified trainers are listed on static99.org website and are generally available in multiple jurisdictions in the United States, Canada, and other countries. The criteria to become a certified trainer, also outlined on the static99.org website, include completing a workshop with a certified trainer, regular use of the instrument, being observed by a certified trainer while giving a training, and passing a test of knowledge on Static-99R and/or Static-2002R.

Online training is available for Static-99R at http://www.jibc.ca/course/soap105. This 21-h online course is designed to be completed part-time over 5 weeks. All materials and resources are provided electronically. Evaluative components for this training include completion of case studies, participation in online discussions, and a final graded exam. The domestic (Canadian) fee for this course is $504.59 and the international fee is $605.51. Online training is not available for the Static-2002R. Training workshops by certified trainers are occasionally available at conferences (e.g., the Association for the Treatment of Sexual Abusers).

The Evaluator Workbook for the Static-99R and Static-2002R (Phenix et al., 2012, 2015) is available at the static99.org website. Finally, scoring questions may also be submitted to the static99.org website.

The Use of Multiple Actuarial Instruments

Evaluators in the field have to determine which actuarial instruments they will use to evaluate a sexual offender's risk to sexually reoffend. Evaluators should consider aspects of the development of the instrument, predictive accuracy, reliability, and replications of the instrument, among other things, in choosing an actuarial instrument. Incremental validity of risk instruments is a helpful gauge in deciding what combination of instruments to use. Incremental validity is the extent to which new information improves the accuracy

of a prediction above and beyond that of the previous instrument(s) used.

Seto (2005) examined the incremental validity of several routinely used scales (i.e., RRASOR, Static-99, SORAG, and VRAG) and found the scales did not add incrementally to each other in the prediction of sexual recidivism. Seto advised evaluators to choose the "best" instrument, which was identified as the RRASOR in his sample. However, this study was limited by a small sample size, and subsequent studies did not support the RRASOR as having superior predictive accuracy relative to other instruments. However, as a result of this study, many evaluators followed Seto's advice and used only one scale.

The use of multiple actuarial instruments was revisited more recently by Babchishin, Hanson, and Helmus (2012b). This study examined potential incremental validity of the RRASOR, Static-99R, and Static-2002R in a large cohort of 7,491 sex offenders from 20 samples in the re-norming project. Contrary to Seto's (2005) prior findings, all three scales provided incremental validity to the prediction of sexual recidivism in the Babchishin, Hanson, and Helmus (2012b) study. This robust finding confirmed clear potential improvements by considering multiple scales. Even though the Static-99R and Static-2002R are highly correlated scales, the incremental validity of each indicates that there is better coverage of relevant static risk factors by using both. This finding may generalize to other scales when samples are large enough to have sufficient statistical power.

Decision rules for combining static, actuarial risk instruments for sexual offenders in the overall evaluation of risk were examined by Lehmann et al. (2013). In this study, the RRASOR, Static-99R, and Static-2002R all predicted sexual recidivism (*AUCs* of 0.69–0.71) and provided incremental validity to each other. In regard to using multiple risk instruments, the authors examined whether choosing the highest, the lowest, or averaging absolute risk estimates (probabilities) optimized accuracy. Their findings supported averaging the probabilities obtained on Static-99R and Static-2002R for the follow-up period of interest (5 or 10 years).

McGrath et al. (2012) developed SOTIPS, a new rating scale to assess dynamic risk among adult male sex offenders. SOTIPS predicted sexual, violent, and any criminal recidivism, as well as returns to prison, across time. However, combined SOTIPS and Static-99R scores predicted all recidivism types better than either instrument alone. These results bolster previous sexual offender studies documenting the incremental validity of layering assessments of dynamic risk factors onto assessments of static risk factors (Beggs & Grace, 2010; Hanson et al., 2007; Knight & Thornton, 2007; Olver et al., 2007; Thornton & Knight, 2013). These findings collectively confirm that a comprehensive risk assessment should include multiple actuarial instruments, including measures of both static and dynamic risk factors. As discussed earlier, this practice can also make the selection of Static-99R and Static-2002R norms more empirically based.

Summary and Conclusions

By empirically generating a suite of actuarial static risk assessment tools, Karl Hanson, David Thornton, and their associates have provided tremendous benefit to professionals responsible for risk assessment and the implementation of a host of sexual offender policies. Through the consistent use of research best practices, they have established a high standard for the discipline and an excellent model for other developers of risk assessment tools.

The research establishing the reliability and validity of the Static-99 and Static-99R is voluminous and overwhelmingly positive. As newer instruments, the Static-2002 and Static-2002R have not generated a comparable quantity of research. However, that research is promising and supports the use of these tools in a variety of settings.

The developers strongly recommend use of the revised tools, Static-99R and Static-2002R, over their respective predecessors because of their better incorporation of age as a risk factor and their more contemporary and accurate norms for absolute risk estimates. The Static-99R offers a greater research base and the Static-2002R provides greater organizational coherence and potentially greater relevance to sexual offender treatment. In light of recent research on the use of multiple instruments, it is not necessary to choose between them, unless time or resources limit options to one or the other, because risk estimates may be more accurate if they are averaged across the two tools.

Regardless of which tool(s) is used, a number of best practices have emerged from the work of Hanson, Thornton, and their associates. The first is that relative risk should always be reported because relative risk has been far more stable over time, as reflected in various temporal cohorts in samples. Relative risk should be presented in multiples ways, including nominal relative risk categories, percentiles, and relative risk ratios. The static99.org website and the Evaluator's Workbook provide relative risk indices based on large samples available to the developers. If local norms are available, those should be reported as well.

If absolute risk estimates are needed, they should be based on contemporary local norms, if available, and/or the appropriate contemporary norm group estimates provided on the static99.org website and in the Evaluator's Workbook. Historically, some degree of clinical judgment was required in determining which norm group is most appropriate for an individual offender based on the degree of preselection for treatment and/or high-risk/high-need interventions. More recent research has begun to provide cutoffs on measures of dynamic risk factors/needs (e.g., SRA-FV, Stable-2007) to

inform the selection of norm group. In cases where the appropriate norm group is undetermined or when a narrow risk estimate is not required, evaluators should provide the range in risk estimates from the routine norms (low estimate) to the high-risk/high-need norms (high estimate) for the sexual offender's specific score. Finally, template language is provided on the static99.org website and in the Evaluator's Workbook for reporting relative and absolute risk estimates. The purpose of the language is to increase the clarity and accuracy of evaluator's communication of risk.

Research on the Static-99R and Static-2002R is ongoing, so normative information and recommendations may change. Thus, people using these tools should periodically check the static99.org website to ensure that current normative information and language are being used and that they are using the most appropriate methods for selecting absolute risk norm groups.

Base Rates of Sexual Recidivism After Controlling for Static-99/R

L. Maaike Helmus, R. Karl Hanson,
and Kelly M. Babchishin

One of the most frequently asked questions about sex offenders is how often they reoffend. Given the adverse consequences to victims of sexual offences (Paolucci, Genuis, & Violato, 2001; Resick, 1993), politicians, clinicians, researchers, and the general public have an understandable interest in reducing sexual recidivism. The rate of sexual recidivism among sex offenders is referred to as a *base rate* and can be discussed generally (e.g., the recidivism rate for all convicted sex offenders), or for a specific subgroup (e.g., the recidivism rate for incest offenders), which are sometimes called base rates "adjusted" for a factor. We will use the term "base rate" to refer to recidivism rates for an entire sample of sex offenders and will specify when we make subgroup distinctions (e.g., the base rate for rapists). Recidivism rates for a particular score on an actuarial scale will be referred to as scorewise base rates.

Base rate information is essential for understanding and contextualizing risk. For example, interpreting the phrase "moderate risk sex offender" requires knowledge of the risk posed by all sex offenders. If the base rate for sexual recidivism is 70 %, then the release of a "moderate" risk sex offender invokes concern. If the base rate is 5 %, however, then the release of a "moderate" risk sex offender invokes much less concern.

The views expressed are those of the authors and not necessarily those of Public Safety Canada. We would also like to acknowledge the Social Science and Humanities Research Council of Canada and the Ontario Graduate Scholarship Program for providing funding for this research.

Many non-forensic contexts involving the prediction of an event also rely heavily on base rate information. Insurance is the most common example, where base rate statistics (e.g., frequency of car accidents among young males, average life expectancy) are commonly used to determine insurance premiums. Weather forecasts are another example of predictions that rely on base rates (e.g., 40 % chance of rain). If asked whether it would snow in Toronto on Canada Day (July 1st), the forecaster can confidently say "no" (it has never snowed in Toronto in July). If asked, in June, whether it would snow on Christmas Eve, the best response would be a probabilistic estimate based on historical frequencies and current global conditions. Largely due to the extensive statistical base rate data informing these predictions and the availability of rapid and objectively measured feedback, weather predictions have achieved remarkable accuracy (National Research Council, 1989).

Actuarial Risk Assessment and Base Rates

In the context of predicting criminal behavior, risk assessment is a method of combining multiple factors into an overall assessment of the likelihood of recidivism (Hanson & Morton-Bourgon, 2009). Actuarial methods of risk assessment involve explicit rules to combine prespecified items (risk factors) into total scores, which are then linked to empirically derived estimates of recidivism probability (Hanson & Morton-Bourgon, 2009). Actuarial methods of risk assessment are generally more accurate than other methods, such as structured or unstructured clinical judgement (Bonta, Law, & Hanson, 1998; Hanson & Morton-Bourgon, 2009; Mossman, 1994; for a review, see Quinsey, Harris, Rice, & Cormier, 2006). There are over a dozen actuarial risk scales designed for sex offenders, such as Static-99 (Hanson & Thornton, 2000), the Sex Offender Risk Appraisal Guide (SORAG; Quinsey et al., 2006), and the Risk Matrix 2000 (Thornton et al., 2003), and these actuarial scales show comparable levels of predictive accuracy (Hanson & Morton-Bourgon, 2009).

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_20

Actuarial risk scales assess two properties of risk: relative and absolute. Relative risk provides information about a particular offender's level of risk compared to other offenders and can be reported in numerous ways, including percentiles (e.g., "95 % of offenders score higher than this individual") or relative risk ratios (e.g., "the risk of recidivism for this offender is about ½ the risk of a typical sex offender"). The accuracy of a risk assessment scale in predicting relative risk can be reported using correlation coefficients, areas under the receiver operating characteristic curve (AUC for ROC), standardized mean differences (Cohen's *d*), or regression coefficients (B_1), and the pros and cons of these statistics have been described elsewhere (Hanson, 2008; Quinsey et al., 2006; Rice & Harris, 2005). Although relative risk provides no information about base rates, this property is useful because it remains fairly consistent across samples (Hanson, Helmus, & Thornton, 2010).

Absolute risk, however, refers to the expected rate of recidivism (i.e., scorewise base rates). Although relative risk information is sufficient for most decisions involving the allocation of scarce resources (i.e., treatment and supervision decisions), absolute risk information is required in certain high-stakes evaluations, notably sex offender civil commitment statutes in the USA. Some of these laws require a determination of whether the offender is more likely than not to reoffend, which has been operationalized as a recidivism estimate of 51 % or higher (Doren, 2002).

Effective risk communication should incorporate both absolute and relative risk information (Babchishin & Hanson, 2009). Nominal risk categories (e.g., low/moderate/high) are interpreted inconsistently (Hilton, Carter, Harris, & Sharpe, 2008; Monahan & Silver, 2003) and with more errors than numerical information (Karelitz & Budescu, 2004). A common error in risk interpretation is base rate neglect, which occurs when base rate information is overlooked or not fully considered, leading to inaccurate interpretation of relative risk information (Elmore & Gigerenzer, 2005). For example, "high risk" is often interpreted to mean that recidivism is nearly certain, although the base rate for high-risk offenders may be relatively low (e.g., 20 %). Generally, people tend to overestimate improbable risk and underestimate more common risks (St. Evans, Handley, Perham, Over, & Thompson, 2000; Moore, Derry, McQuay, & Paling, 2008). According to the representativeness heuristic, base rate neglect can also occur based on the similarity between the individual being assessed and the referent group (Tversky & Kahneman, 1974). In risk assessment, for example, if an offender appears similar to offenders from which the recidivism estimates were derived, those estimates are interpreted as plausible. If an offender appears different from the referent group, base rate information (even for high-risk offenders) may be overlooked and can result in substantial overestimation of risk. Optimal risk assessments should therefore communicate relative risk in the context of absolute risk (i.e., base rates).

Although base rates are a central part of risk assessment and are routinely reported, relatively little research has examined the stability of base rates for actuarial risk tools for sex offenders (see Doren, 2004, for an exception). Conventions have yet to be developed concerning the best ways to report this information. This chapter will discuss sexual recidivism base rates and identify possible factors that may affect them. We will also briefly summarize our recent research on this topic. The findings will be discussed in terms of their implications for actuarial risk evaluations.

What Is the Base Rate of Sexual Recidivism?

Sexual recidivism base rates for sex offenders have been difficult to establish due to considerable variability across studies. One of the earliest reviews (Furby, Weinrott, & Blackshaw, 1989) concluded that there was too much variability across studies (in description of sample selection, in recidivism definition, and in follow-up) to adequately aggregate the results into an overall base rate estimate.

More recent meta-analyses and multisite studies have found base rates of roughly 10–15 % after about 5 years of follow-up. Hanson and Bussière (1998) found a sexual recidivism rate of 13 % among 23,393 offenders ($k=61$), with an average follow-up period between 4 and 5 years. Combining 10 samples ($n=4{,}724$), Harris and Hanson (2004) found sexual recidivism rates of 14, 20, and 24 % at 5, 10, and 15 years, respectively. Additionally, Hanson and Morton-Bourgon (2005) found a sexual recidivism rate of 14 % among 19,267 offenders after an average follow-up of 5–6 years ($k=73$).

Despite the similarity in these aggregate findings, the variability across individual studies is substantial. Figure 1 displays sexual recidivism rates from 52 studies in the Hanson and Bussière (1998) meta-analysis, as well as a random sample of 20 newer studies drawn from Hanson and Morton-Bourgon (2009). The recidivism rates are plotted as a function of the follow-up length for the study, with larger bubbles representing larger studies ($N=35{,}522$). As expected, the recidivism rates appear a bit higher in samples with a longer follow-up, but this pattern is fairly weak, indicating considerable variability across studies with similar lengths of follow-up.

Interpreting the variability across studies in Fig. 1 is difficult because the samples come from different time periods and settings and may contain a mix of offenders in terms of their individual risk for recidivism. Base rates tend to be lowest in large, contemporary samples of sex offenders. For example, examining 9,691 sex offenders released from 15 US states in 1994, Langan, Schmitt, and Durose (2003)

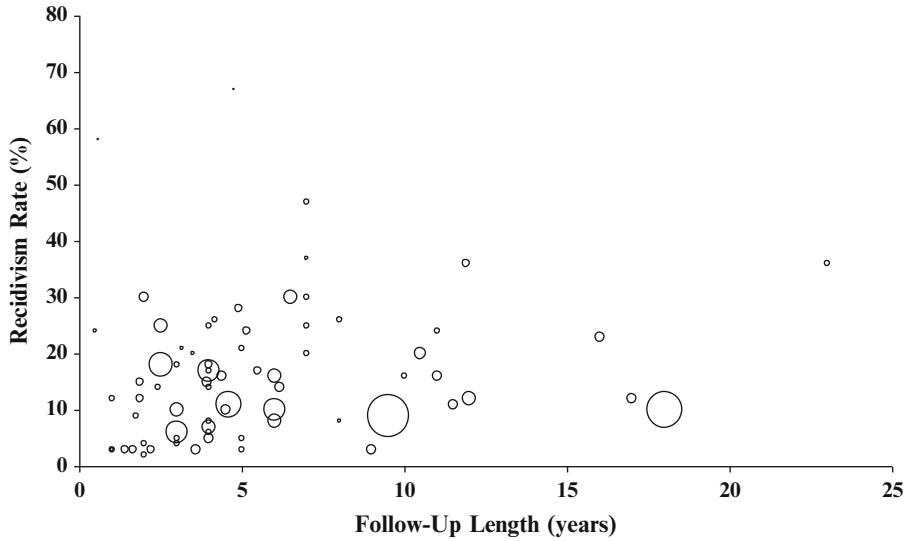

Fig. 1 Sexual recidivism rates ($k = 72$; $N = 35{,}522$)

found an overall sexual rearrest rate of 5.3 % after 3 years. In another US study, Boccaccini, Murrie, Caperton, and Hawes (2009) found a 3.2 % sexual recidivism rate for 1,983 sex offenders in Texas followed up for an average of nearly 5 years. These US findings are similar to some large European studies. For example, a cohort of all sex offenders released from Swedish prisons between 1993 and 1997 ($n = 1{,}303$) had a 5.8 % sexual recidivism rate after an average follow-up of 5.7 years (Långström, 2004). Recent UK studies have found similarly low sexual reconviction rates, such as 5.4 % after 3 years ($n = 3{,}402$ sex offenders who completed community treatment; Barnett, Wakeling, Mandeville-Norden, & Rakestrow, 2010) and 3.6 % after an average of 4.2 years ($n = 3{,}773$ sex offenders who participated in prison treatment; Wakeling, Beech, & Freemantle, 2010).

In contrast to these recent large studies, base rates have been considerably higher for smaller samples preselected for rare sanctions or measures, such as civil commitment. For example, Milloy (2007) found a 23 % sexual recidivism rate after an average follow-up of 6 years for 135 offenders referred for civil commitment between 1996 and 1999 but who were not subsequently committed. A frequently cited long-term recidivism study of 265 civilly committed offenders released between 1959 and 1985 found that 25-year sexual recidivism rates (defined as new charges) estimated from survival analysis were as high as 39 % for rapists and 52 % for child molesters (Prentky, Lee, Knight, & Cerce, 1997).

In his review of long-term recidivism studies, Doren (1998) concluded that the findings of Prentky et al. (1997) were reasonable estimates of recidivism base rates, but he relied heavily on outdated studies (offenders released prior to 1980) and did not take into account that sex offenders civilly committed (or nearly committed) appear to be an unusually small and high-risk subset of sex offenders. Their base rates are, therefore, unlikely to generalize to most sex offender samples. For example, between 1999 and 2004, only 43 offenders were civilly committed in Texas, which represented a small subset (2.2 %) of an original pool of sex offenders in prison who were screened as possible repeat offenders (Boccaccini et al., 2009). Factoring in sex offenders not screened as possible repeaters, as well as those serving community sentences, civilly committed offenders may represent even less than 2 % of all sex offenders. In California, 199 offenders were civilly committed between 2001 and 2005 (California Department of Mental Health, personal communication, June 20, 2011), which represents only 0.5 % of the 38,363 adults arrested for sex offences in that same time period (California Department of Justice, n.d.).

The studies reviewed above highlight that groups of sex offenders vary widely in their risk for recidivism. Although it is possible to identify some subgroups with high recidivism rates, most large samples suggest recidivism rates are fairly low. Nonetheless, the variability in base rates raises questions about which subgroups are higher risk. This requires examining individual risk factors for recidivism. For example, Harris and Hanson (2004) found that incest offenders have the lowest recidivism rates after 10 years (9 %), with the highest rates found among child molesters with male victims (28 %), and intermediate rates for rapists (21 %) and child molesters with female victims (13 %). Considerable research has explored other factors related to sexual recidivism, with a particular focus on static (historical) factors. For example, Harris and Hanson (2004) also found large differences in base rates for offenders with a previous conviction for sex offences (32 %) compared to offenders without (15 %) after 10 years. Similarly, 10-year

recidivism rates were approximately doubled for offenders less than 50 years old (21 %) compared to offenders over 50 (11 %). Other known risk factors for sex offenders include deviant sexual interests, antisocial orientation, sexual preoccupations, intimacy deficits, and emotional congruence with children (Hanson & Morton-Bourgon, 2005; Mann, Hanson, & Thornton, 2010).

Many of these risk factors are incorporated into actuarial scales. Differences in actuarial risk scores should, therefore, explain some of the base rate variability across samples. Variability that persists after controlling for actuarial risk would suggest that there are additional factors not already considered in the actuarial scale that influence the base rates. To the extent that variability persists after controlling for actuarial scores, this variability should be noted when reporting estimated scorewise recidivism rates. In other words, the recidivism base rates reported with actuarial scores can be viewed as a function of the factors included in the actuarial scale, as well as factors not measured by the scale (as well as random error). In the next section, we will discuss some of the external factors that may moderate the relationship between actuarial risk and recidivism rates. Our discussion of potential moderator variables is divided into three categories:

1. Methodological factors—These factors are part of the design of a study and are typically controlled by the researcher (e.g., how recidivism is measured)
2. Individual-level factors—These factors refer to individual characteristics of the offender. They may or may not be under the control of the offender (e.g., age is a risk factor, but not one that the offender can control)
3. Systems-level factors—These are features of the sample and are typically not under control of either the researcher or the offender (e.g., the country from which the sample is obtained)

Methodological Factors

Methodological factors are design features of a study, which are typically under the control of the researcher. Broadly, they relate to the nature of the outcome measure (recidivism) and the quality of the actuarial assessment. The outcome should ideally be measured with a fixed and lengthy follow-up period using street time to assess an inclusive definition of recidivism gleaned from at least one (but preferably more) reliable recidivism source.

Length of Follow-up

Longer follow-up periods increase base rates because recidivists accumulate over time. This increase, however, is nonlinear. Most recidivism occurs within the first few years after release and the longer an offender remains offence-free in the community, the lower their individual probability of recidivism becomes (Harris & Hanson, 2004; Harris, Phenix, Hanson, & Thornton, 2003). Survival curves in Figs. 2 and 3 depict the cumulative and nonlinear increase in sexual recidivism rates over time (these curves display overall survival rates, as well as survival rates broken down by Static-99 risk category). Survival curves depict recidivism rates as a function of time, with offenders starting out with a 100 % survival rate at the moment they are released (no one has reoffended yet), which gradually descends as recidivism accumulates. Given the relatively low base rate of sexual recidivism, optimal follow-up should be at least 5 years (Collaborative Outcome Data Committee, 2007b).

Fixed Versus Variable Follow-up

Given that the relationship between recidivism and length of follow-up is nonlinear (see above), this complicates analysis of

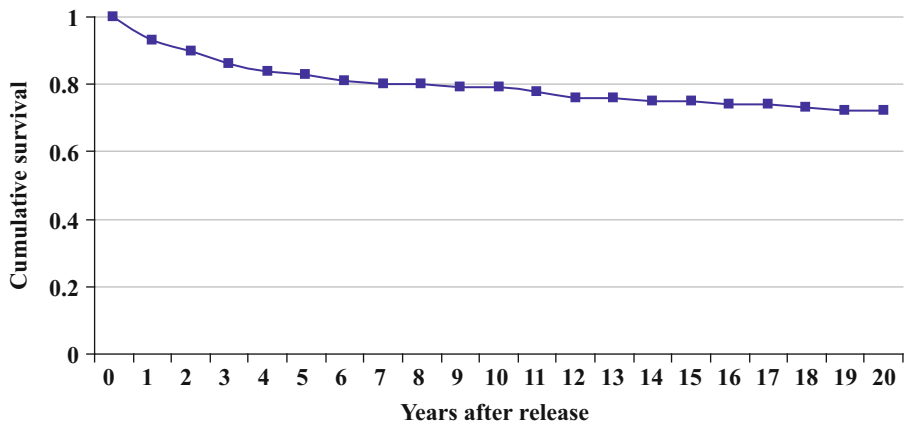

Fig. 2 Survival curve for sexual recidivism ($n = 1{,}086$) [*Note* Data are from the development samples of Static-99 (Hanson & Thornton, 2000)]

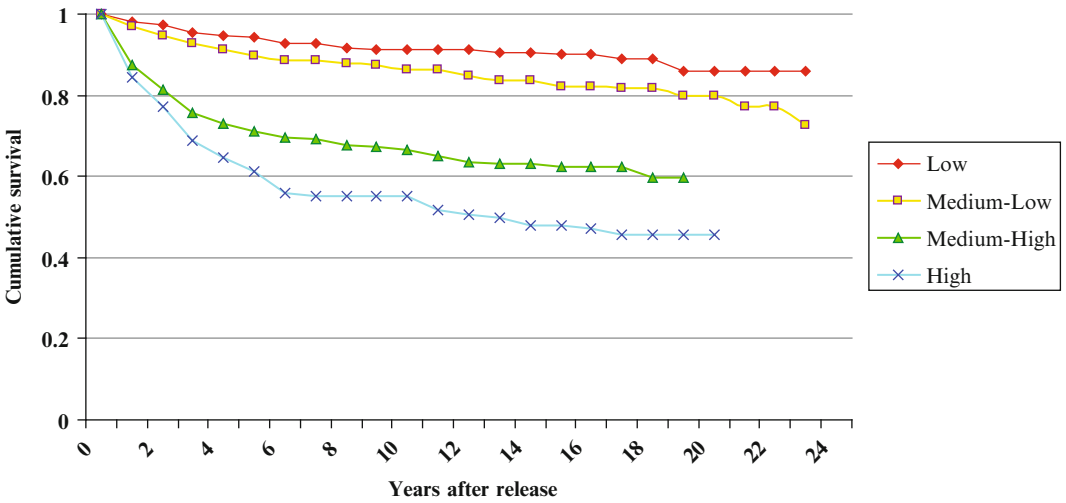

Fig. 3 Survival curve for sexual recidivism by Static-99 risk level ($n = 1{,}086$) [*Note* Data are from the development samples of Static-99 (Hanson & Thornton, 2000)]

data where the offenders have been followed for varying lengths of time. It is common to present a recidivism rate for an "average" follow-up length. When the relationship is nonlinear, however, averaging different time points to estimate recidivism at some midpoint will produce different results than examining that specific time point. The difference increases as the variability in follow-up increases. For example, if all offenders have been followed up between 9 and 11 years, then to assume the overall recidivism rate applies to 10 years is reasonable. However, if the follow-up period ranges from 1 to 15 years, with an average of 8 years, then the overall recidivism rate may not be a good estimate of 8-year recidivism rates.

Ideally, all offenders should have the same length of follow-up. This is rarely achieved. As an alternative, life table survival analysis (Soothill & Gibbens, 1978) provides a reliable method of correcting for variations in follow-up by examining recidivism patterns over time and estimating the expected recidivism rate of the sample for any specified time period. In other words, for a specific follow-up period, it estimates what the recidivism rate for the sample would be if everyone had been followed up to that point. Estimates from survival analysis are generally reliable provided that there are a sufficient number of cases with follow-up data for the time period being estimated. When predicting scorewise base rates for an actuarial risk scale, however, logistic regression provides some advantages over survival analysis (Hanson et al., 2010), but it does require using data with a fixed follow-up.

Street Time

Additionally, using real time or street time in the follow-up calculation can also affect base rates. Real time refers to the actual calendar time that passes between the offender's release from the index offence and when the recidivism information is collected. In contrast, street time deducts time that the offender does not spend in the community. For example, consider a high-risk sex offender who is released from their index sex offence and for whom recidivism information is collected 10 years later. One year into the follow-up period, the offender is arrested for impaired driving causing death and serves 8 years in prison. In real time, the sexual recidivism follow-up period is 10 years, whereas in street time, the follow-up period is 2 years. The use of street time therefore gives a more realistic picture of reoffending because it takes into consideration opportunity to reoffend.

Inclusiveness of Recidivism Definition

More inclusive definitions of sexual recidivism will also logically increase base rates. Examples include using charges as opposed to convictions or counting any sexually motivated offence (e.g., first-degree murder with a sexual component) as opposed to counting only offences with a sexual component in the title (e.g., sexual assault; Harris & Rice, 2007). Although Harris and Hanson (2004) did not find higher sexual recidivism rates in samples using charges compared to samples using convictions, studies directly comparing the rate of charges versus convictions within a single sample do find differences (Epperson, 2003; Johansen, 2007; Langan et al., 2003; Minnesota Department of Corrections, 2007). For example, of 9,691 sex offenders from 15 U.S. states, 5.3 % were charged with a new sex offence within 3 years, whereas only 3.5 % were convicted, suggesting a small but nonetheless meaningful difference (Langan et al., 2003). A similar difference was found in a smaller study ($n = 280$) with a longer follow-up (average of 7 years), where 6.8 % of

offenders were rearrested and only 3.9 % were reconvicted (Johansen, 2007). In short, definition of sexual recidivism seems to account for some variability in base rates.

Number of Recidivism Sources

Using multiple sources of recidivism information would result in more accurate data and could also raise the base rate of reoffending. Previous research on two centralized criminal record sources in the United Kingdom (Offenders Index and the Police National Computer) indicated that both sources contributed unique data on recidivism (Friendship, Thornton, Erikson, & Beech, 2001). Another example comes from the Dynamic Supervision Project (raw data from Hanson, Harris, Scott, & Helmus, 2007), where two recidivism sources (probation/parole officer reports and official national criminal records) revealed a sexual recidivism rate of 6.2 %. Additional information obtained from selected provincial criminal records (British Columbia, Manitoba, and Ontario), informal police contacts, and semi-regular perusal of newspapers increased the known recidivism rate to 7.4 %.

Quality of the Assessment

Methodological factors relating to the quality of the risk assessment can also affect base rates for actuarial scores. Better quality assessments should result in less measurement error, which can affect base rates (in either direction) and reduce the variability in findings. For example, an evaluator who codes an actuarial scale incorrectly or without access to complete information may provide predicted base rates for a given score that contains offenders whose "true" score should be higher or lower.

Greater confidence in the assessment is expected when scales are scored correctly by conscientious properly trained evaluators and who have access to complete data. To the extent that any of these elements are missing, base rates may be affected and the relative predictive accuracy may also decrease. For example, Hanson and colleagues (2007) found that conscientious officers (defined as officers who submitted all the data that were requested of them) showed greater predictive accuracy in their Static-99 and STABLE-2007 scores (ROCs of 0.81 and 0.77, respectively) compared to the complete sample of all officers (ROCs of 0.74 and 0.67, respectively). There is also some evidence that studies with greater interrater reliability show significantly larger effect sizes (Hanson & Morton-Bourgon, 2009). Additionally, training by certified trainers increases the validity of risk assessments (Flores, Lowenkamp, Holsinger, & Latessa, 2006) and ongoing training and support are critical for appropriate scoring of actuarial scales (Bonta, Bogue, Crowley, & Motiuk, 2001).

Individual-Level Factors

The second category of factors that may affect scorewise base rates are individual-level factors not already included in the actuarial scale. It is worth noting that not all external risk factors will add incremental predictive accuracy to an actuarial scale because they may be correlated with other factors already included in the scale.

Dynamic Risk Factors

Many of the commonly used actuarial risk assessment instruments for sex offenders focus on static risk factors (i.e., historical and unchanging factors). Dynamic risk factors are features related to recidivism which can change, and when changed, should alter the likelihood of recidivism (Andrews & Bonta, 2006). Some potential dynamic risk factors for sex offenders identified through meta-analysis include deviant sexual interests, sexual preoccupations, antisocial personality, general self-regulation problems, employment instability, hostility (Hanson & Morton-Bourgon, 2005), intimacy deficits, and emotional congruence with children (Mann et al., 2010). Such risk factors have been found to add incremental predictive validity to static risk factors (Allan, Grace, Rutherford, & Hudson, 2007; Beech, Friendship, Erikson, & Hanson, 2002; Dempster & Hart, 2002; Hanson et al., 2007; Olver, Wong, Nicholaichuk, & Gordon, 2007; Thornton, 2002), and more recent risk assessment scales have incorporated these factors. Some of the more well-known dynamic risk assessment scales include the Violence Risk Scale—Sex Offender version (VRS-SO; Olver et al., 2007), the STABLE-2007 (Hanson et al., 2007), and the Structured Risk Assessment (SRA; Thornton, 2002), all of which have been found to add incremental predictive validity to static actuarial scales.

Treatment

Participation in sex offender treatment may also contribute to base rates. Several meta-analytic reviews have concluded that sex offender treatment is effective in reducing recidivism (Gallagher, Wilson, Hirschfield, Coggeshall, & MacKenzie, 1999; Hall, 1995; Hanson et al., 2002; Hanson, Bourgon, Helmus, & Hodgson, 2009; Lösel & Schmucker, 2005), although some have argued that there is insufficient evidence to establish treatment effectiveness (Furby et al., 1989; Harris, Rice, & Quinsey, 1998; Kenworthy, Adams, Brooks-Gordon, & Fenton, 2004; Rice & Harris, 2003). One of the largest reviews (Lösel & Schmucker, 2005; Schmucker & Lösel, 2008) examined 69 studies ($n = 22{,}181$) and found that the recidivism rate of treated sex offenders was, on

average, 6.4 percentage points lower than untreated sex offenders. More recently, we conducted a meta-analysis (Hanson et al., 2009) using only studies identified as acceptable study quality according to the Collaborative Outcome Data Committee guidelines for evaluating study quality (CODC, 2007a, 2007b). Among 22 studies, the unweighted average sexual recidivism rate for treated sex offenders was 10.9 %, compared to 19.2 % for the comparison group.

Although the more recent meta-analytic reviews suggest significant base rate differences among treated versus untreated offenders, an important limitation of current treatment outcome research is that most studies have poor methodological study quality. Of 127 eligible treatment studies in the Hanson et al. (2009) meta-analysis, only 23 met minimal standards for study quality. Of these, most were rated as "weak" ($k = 18$), with only 5 rated as "good." No studies were considered "strong." Another limitation is that the current research does not answer the question of whether treatment information adds incremental predictive validity to actuarial scores. Evidence for the incremental predictive validity of treatment performance over static actuarial scores has been found in some studies (Beggs & Grace, 2011; Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005; Olver et al., 2007), although further research is needed in this area.

Age at Release

Age is already considered to some extent in many actuarial scales (e.g., SORAG, Static-99), but age at release has been found to add incremental predictive validity above Static-99, with older offenders showing less sexual recidivism (Hanson, 2006). Additionally, Barbaree, Langton, and Blanchard (2007) found that SORAG scores were correlated with age at release, and once the shared variance was removed, age added significantly to the prediction of recidivism.

Systems-Level Factors

Systems-level factors are features which may affect recidivism base rates but are typically not under the control of either the offender or the researcher. The most obvious examples of systems-level factors are the jurisdiction and setting of a sample.

Country

International variability in official crime rates has been routinely documented (Krohn, 2001; Maffei & Merzagora Betsos, 2007; Rushton, 1995; United Nations, 2007), including differences in the official rates of sexual offences (Kutchinsky, 1991; United Nations, 2007). Crime rates are higher in countries with greater urbanization and industrialization (Krohn, 2001). Some of this variation could be due to differences in laws as well as prosecution practices; crime rates could be higher when the number of activities defined as illegal increases and when there are more resources (e.g., financial, political) to prosecute certain offences. For example, in the early 1980s in Canada, drastic broadening of the legislation defining sexual offences was accompanied by large increases in officially reported sexual crimes (Brennan & Taylor-Butts, 2008).

Religiosity may also play a part in the variability of international crime rates. Data from 13 industrial nations found an inverse relationship between overall criminality and religiosity, but a reverse trend was found for sexual offences, with higher rates in countries reporting greater levels of religiosity (Ellis & Peterson, 1996). One possible mediator of this relationship could be the emphasis on the subservience of women common in traditional cultures (Raj, Silverman, Wingood, & Diclemente, 1999).

Jurisdictional base rate differences could also reflect differences in the quality of criminal record-keeping (Marenin, 1997), with poor or unreliable record-keeping resulting in artificially lower base rates. Both Canada and the UK contain centralized national criminal records. In Canada, these records are maintained by the Royal Canadian Mounted Police in the Canadian Police Information Center (CPIC). CPIC records have certain disadvantages, however, because charges not resulting in convictions are inconsistently recorded, and information is submitted only after a disposition is made (e.g., conviction, dismissal, acquittal, stay of proceedings), which can result in substantial delays between the commission of an offence and its appearance on the CPIC. Additionally, records are purged over time due to pardons and inactivity, further reducing their reliability (Hanson & Nicholaichuk, 2000). The UK has two centralized criminal record sources: the Offenders Index (OI) and the Police National Computer (PNC). The disadvantage of these sources is that they exclude Scotland and Northern Ireland, and the OI includes only standard list offences, which tend to be the more serious types of offences (Friendship et al., 2001).

Although criminal records in Canada and the UK are far from perfect, they are nonetheless centralized and relatively comprehensive, whereas the US lacks a comprehensive and centralized criminal record database. Each state maintains its own criminal records and the FBI maintains a separate database, but both sources are sometimes known to have incomplete, inaccurate, and ambiguous data (Laudon, 1986).

Setting

In addition to differences across countries, there may be differences across settings and sample types. Most studies of sex offenders do not use a complete (i.e., random) sample of

offenders. Instead, samples are often preselected based on certain characteristics. For example, some studies are from a particular treatment setting, or a setting where offenders are referred for assessment or other services (e.g., psychiatric assessment), or from a particular institution (e.g., a maximum security prison). In other studies, the sample is defined by certain conditions the offender meets (e.g., their sentence type or other special measures they are subject to). An important empirical question involves the extent to which offenders preselected under some of these conditions would be expected to vary in their risk for recidivism from truly random, unselected samples of offenders.

It is likely that some of the selection processes described above would select offenders on the basis of factors already included, at least to some extent, in the actuarial scales (e.g., prior sex offences). It is also likely that factors external to actuarial scales would affect these preselection processes. Some of these external factors would presumably be related to risk for reoffending (e.g., treatment need, institutional behavior, treatment performance), while others may not be (e.g., offence severity, treatment availability, publicity surrounding a case). Normative data have found that general offenders from institutional samples have consistently higher actuarial risk scores than offenders serving community sentences (Andrews, Bonta, & Wormith, 2004), showing that even crude forms of preselection (sentence type) do seem to distinguish offenders with different risk profiles.

It is plausible that studies of sex offenders over-sample from settings where offenders are preselected to be higher risk. This could be an issue of convenience; good research requires comprehensive information, which is more readily available for offenders serving long sentences or subject to special measures (e.g., high intensity treatment, civil commitment). For example, in Canada, specialized psychological assessments are more common for offenders being considered for a Dangerous Offender or Long-Term Offender designation. Examining different ways offenders are preselected and the extent to which this preselection contributes to recidivism rates may increase our understanding of the extent to which some variables external to actuarials are influencing base rates.

Time Period

Cohort effects can also contribute to base rate variability across samples. Crime rates peaked in the early 1990s and have been generally declining since then. This trend has been found for both violent and property offences in Canada (Mishra & Lalumière, 2009b; Public Safety Canada, 2008) and the USA (Federal Bureau of Investigation, 2007; Mishra & Lalumière, 2009b), using both official crime data as well as victimization surveys (Bureau of Justice Statistics, 2006). Sexual offences appear to be no exception (for a review, see Mishra & Lalumière, 2009a). Declines have been observed in the rates of forcible rape in the USA (Federal Bureau of Investigation, 2007), sexual assault in Canada (Mishra & Lalumière, 2009a), clergy sexual abuse (Terry, 2008), and child sexual abuse measured both by substantiated cases as well as victimization surveys (for a summary, see Finkelhor & Jones, 2006; Jones & Finkelhor, 2003). Recent data from Minnesota ($n = 1{,}782$; Minnesota Department of Corrections, 2007) show a dramatic decline in 3-year rates of sexual rearrest, reconviction, and reincarceration. More broadly, surveys also tend to show that between 2003 and 2011, children's exposure (as victims and as perpetrators) to violence, crime, and abuse have decreased (Finkelhor, Shattuck, Turner, & Hamby, 2014). In addition, risky behaviors typically correlated with criminal behavior (e.g., accidents, suicide, risky sexual behavior such as unprotected sex, dropping out of school), have also shown similar declines (Mishra & Lalumière, 2009b). Given these overall trends and their apparent universality in both Canada and the USA, it is expected that recidivism base rates will show similar changes over time.

Detection Rates

Recidivism rates can also be affected by detection rates because reporting an offence is a necessary precondition for counting an offender as a recidivist. Sexual offences typically have the highest levels of non-reporting (Besserer & Trainor, 2000), with estimated rates between 78 and 84 % (Besserer & Trainor, 2000; Kilpatrick, Edwards, & Seymour, 1992). These startlingly high levels of underreporting, however, do not necessarily mean that the majority of sexual recidivists are not caught. If an offender reoffends with multiple victims (which is not uncommon), it is sufficient for one victim to report the offence for the offender to be counted as a recidivist. It is also possible that offenders previously charged with sexual offences are more likely to be caught in the future, as more supervision may be in place (e.g., monitoring by police or probation officers) and potential victims may be more inclined to report a new offence. Underreporting will, therefore, have some effect on recidivism base rates, but the exact relationship is difficult to estimate.

Correctional Philosophy and Policies

Another factor that could affect recidivism base rates includes features inherent in the correctional system from which the sample is obtained. Considerable research among

general offenders has demonstrated that treatment adhering to the principles of effective correctional practice (matching treatment intensity to risk, targeting criminogenic factors, and delivering treatment appropriate to the abilities and learning style of offenders) produces significant reductions in recidivism (Andrews & Bonta, 2006). Similar results have also been obtained with sex offender treatment studies (Hanson et al., 2009). Additionally, considerable research has found that punitive approaches (e.g., longer sentences) and poor quality treatment do not reduce reoffending and may be associated with slight increases in reoffending (Andrews & Bonta, 2006; Smith, Goggin, & Gendreau, 2002). Given this body of research, we expect that jurisdictions with more punitive correctional systems (e.g., longer and harsher sentences, less treatment) would show higher base rates than systems with more rehabilitative approaches.

Recidivism rates may also be affected by sentencing policies. Specifically, the rise of civil commitment and longer sentences for sex offenders in the USA could remove the highest risk offenders from recidivism studies (because they are not released), thereby lowering the observed base rates in current studies. This is unlikely to have more than a trivial impact on base rates given that civilly committed offenders represent a very small portion of sex offender samples (e.g., 0.5 % to 2 %) and that distributions of risk scores are largely similar across samples from countries with profound differences in sentencing policies (Hanson, Lloyd, Helmus, & Thornton, 2012).

Community Supervision

The existence and restrictiveness of community supervision is another feature of correctional systems that may have some impact on base rates. Previous meta-analytic research on community supervision found a significant reduction in general recidivism, although the magnitude of this difference was trivial (Bonta, Rugge, Scott, Bourgon, & Yessine, 2008). Further analyses of these studies, however, revealed that community supervision that was delivered in adherence to the principles of effective correctional treatment showed meaningful reductions in recidivism (Bourgon, 2011).

Although community supervision delivered with appropriate treatment may reduce reoffending, highly restrictive supervision may have the opposite effect. There is some evidence that more intensive supervision with home visits results in higher detection rates for new offences (Stalans, Seng, Yarnold, Lavery, & Swartz, 2001). Additionally, intensive supervision programs with high revocation rates for technical breaches may artificially suppress recidivism in the short term by reducing the opportunity to commit new offences. This effect can be mitigated somewhat by analyses using street time as opposed to real time.

Summary

Table 1 presents a summary of the factors discussed above. Though not an exhaustive list, it highlights the number and diversity of factors that could affect recidivism base rates, although assessing their impact is likely to be complicated by their intercorrelations. For example, cohort differences may be caused by a variety of other factors, including an aging population, as well as changes in correctional environments over time (e.g., providing better quality treatment). Another example is that differences across countries could be related to differing correctional philosophies as well as the quality of criminal records.

Given the large number of factors external to actuarial scales for which direct or indirect evidence suggests they might affect base rates, it may be naïve to expect consistency across samples in the recidivism rates estimated for each actuarial score. Our increasing knowledge of some of these factors led us to question whether the recidivism norms for one commonly used actuarial risk assessment scale, Static-99 (described below), remain stable across time and samples. Our research has focused on Static-99 because it has considerably more validation studies than any other actuarial scale used for sex offenders (Hanson & Morton-Bourgon, 2009), thereby providing a rich source of data for cross-sample comparisons.

In the next section, we will briefly summarize our recent research assessing the variability in recidivism base rates across samples (after controlling for Static-99R scores) and exploring factors external to the scale which may influence the recidivism rates.

Table 1 Summary of factors that may affect recidivism base rates per actuarial score

Methodological factors	Individual-level factors	Systems-level factors
Length of follow-up	Dynamic risk factors	Country
Fixed vs. variable follow-up	Treatment	Setting
Street time	Age at release	Time period
Inclusiveness of recidivism definition		Detection rates
Number of recidivism sources		Correctional philosophy
Quality of the risk assessment		Community supervision

Recent Research Results

Age: Developing Static-99/R

In a recent study, we (Helmus, Thornton, Hanson, & Babchishin, 2012) examined age at release, sexual recidivism, and Static-99 scores in 23 samples (N=8,106). Even though Static-99 already contained a dichotomous item for age at release, age still added incremental accuracy for the prediction of sexual recidivism after controlling for Static-99 scores. This indicated that age was not sufficiently addressed in the scale.

To develop new age weights, the overall sample was divided into a development sample (5,714 offenders from 23 samples) and a validation sample (2,392 cases from 15 samples). The new age item was scored on a 4-point scale, where offenders less than 35 received 1 point, offenders 35 to 39.9 received 0 points, offenders 40 to 59.9 received −1 point, and offenders age 60 and above received −3 points. With the new age weights, the resulting scale was called Static-99R.

After creating Static-99R, analyses in the validation sample indicated that age no longer added incrementally to the prediction of sexual recidivism, meaning that age does not need to be considered further after using Static-99R. The new age weights did not meaningfully improve the relative predictive accuracy of the scale, but it did improve the absolute predictive accuracy. Specifically, observed recidivism rates were not significantly different from predicted recidivism rates for offenders in various age groups (for comparison, Static-99 significantly overestimated recidivism for offenders age 50 and above). Development of the revised age item, therefore, improved the absolute recidivism estimates of the scale, and analyses suggested that age no longer contributed to variability in scorewise base rates. In other words, after scoring Static-99R, age at release does not need to be considered further.

Variability in Absolute Recidivism Rates for Static-99R

Although the creation of Static-99R improved the recidivism estimates by better incorporating age at release information, significant variability in Static-99R recidivism estimates persists. Examining 8,106 offenders from 23 samples, we (Helmus, Hanson, Thornton, Babchishin, & Harris, 2012) found that relative predictive accuracy for Static-99R was fairly consistent across samples, but absolute predictive accuracy was not. Predicted recidivism rates were examined for three scores on the Static-99R (scores of 0, 2, and 5). The expected 5-year recidivism rate for offenders with the median score on Static-99R (a score of 2) was 7 %. However, meta-analysis indicated that the predicted rates for the same risk scores were significantly different across studies, demonstrating moderate to large amounts of variability. For example, the predicted 10-year sexual recidivism rate for a Static-99R score of 2 was as low as 3 % in some samples and as high as 20 % in other samples. A visual representation of this variability is presented in Fig. 4. This finding of scorewise base rate variability has also been found for Static-2002R (Helmus, Hanson et al., 2012) and the MATS-1 risk scale (Helmus & Thornton, 2014).

Possible Moderators of the Base Rate Variability

Attempts to understand which factors are contributing to the variability in recidivism rates for Static-99R are ongoing. Preliminary analyses indicated that relatively small amounts (if any) of the base rate variability are convincingly explained by factors such as the recidivism definition (charges versus convictions), the number of recidivism sources, use of street time (versus calendar time), offender race, offender type (rapist versus child molester), and year of release (see Helmus, 2009, for review). Although analyses did find a significant and meaningful effect for the country of the sample, with higher scorewise recidivism estimates generally found in the United States, this effect became nonsignificant after controlling for the amount of preselection in the sample (Helmus, 2009). Sample preselection generally had the most substantial influence on the recidivism estimates, explaining over half of the variability across samples. The lowest recidivism rates were found among routine (i.e., relatively unselected) correctional samples, and the highest rates were found among samples of offenders selected for some kind of sanction, measure, or intervention that was generally reserved only for the highest risk cases (Helmus, 2009).

Further analyses of the preselection effect have demonstrated that it is likely related to the density of external risk factors in the samples (e.g., dynamic risk factors; Hanson & Thornton, 2012). Consequently, recidivism estimates for the Static-99R are currently presented for different normative groups (see www.static99.org)

Conclusion

Previous meta-analyses have suggested that the base rate of sexual recidivism is close to 15 % after about 5 years (Hanson & Bussière, 1998; Hanson & Morton-Bourgon, 2005; A. J. R. Harris & Hanson, 2004), but there is substantial variability in base rates across studies. That variability is partially due to differences in follow-up and because most studies do not take into account actuarial risk. In a recent study, we found that most sex offenders would be expected to have

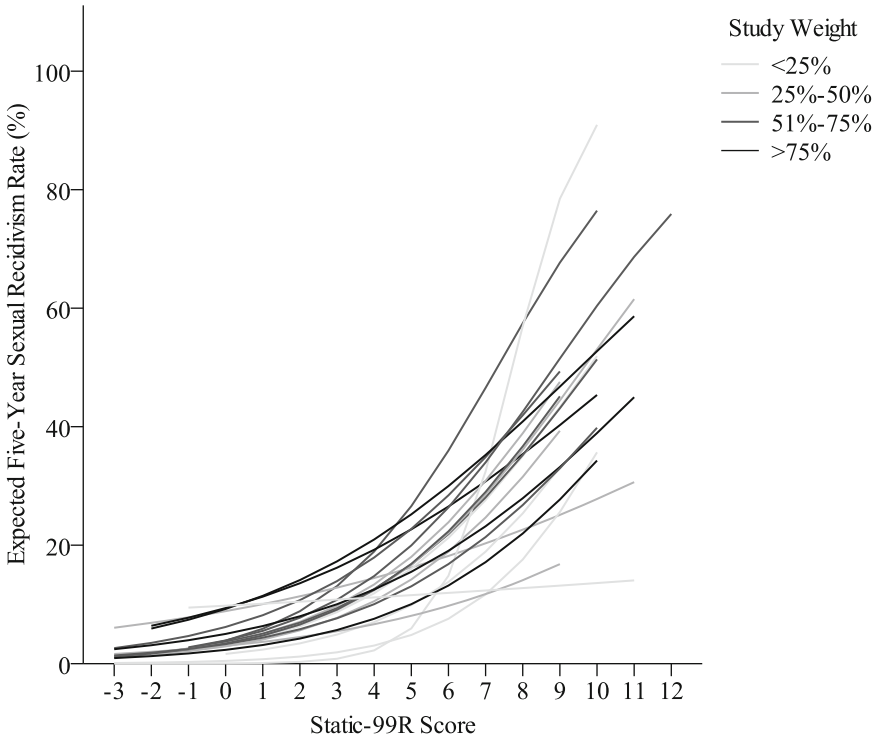

Fig. 4 Predicted recidivism rates (from logistic regression) per Static-99R score across diverse samples [*Note* This is reproduced from Helmus, Hanson et al. (2012). Sample weight was computed using the inverse of the variance of the slope coefficient from logistic regression and divided into four categories: (1) studies with lowest weight (*bottom* 25 %), (2) studies with low average weights (25–50 %), (3) studies with higher weight (51–75 %), and (4) studies with the largest amount of weight (*top* 75 %)]

recidivism rates of 7 % or less (Helmus, Hanson et al., 2012), which is meaningfully lower than the estimates from previous meta-analyses (Hanson & Bussière, 1998; Hanson & Morton-Bourgon, 2005; A. J. R. Harris & Hanson, 2004) and is also much lower than the public generally believes (Levenson, Brannon, Fortney, & Baker, 2007).

A plausible explanation for the higher estimates in previous meta-analyses is that research oversamples from higher risk settings. This could be an issue of convenience; good research requires comprehensive information, which is more readily available for offenders serving long sentences or subject to special measures (e.g., high intensity treatment, civil commitment).

Although recidivism rates for most offenders are lower than previous research suggests, there is also significant variability in scorewise recidivism estimates across samples. Many factors that were discussed may have an impact on scorewise recidivism estimates, but our research suggests that the most meaningful influence on the recidivism rates may be the density of risk factors external to Static-99R, which is likely indicated by the amount of preselection in the sample (Hanson & Thornton, 2012; Helmus, 2009).

Where does this leave evaluators? Well, it leaves them in a challenging position. These findings indicate that predicting scorewise base rates is not as simple as we once thought it was. When reporting recidivism norms for a given actuarial scale, evaluators must acknowledge that there is notable variability in recidivism rates across samples, and that the source of that variability is not fully understood.

How to best account for this variability in applied risk assessments is not clear. Current recommendations have focused on sample preselection (Phenix, Helmus, & Hanson, 2012). Other options could be to develop local norms based on large samples. It is possible that future research will be able to provide estimates that better account for the variability across studies and settings. Until the variability is fully understood, however, evaluators will need to use their judgement to determine the applicability of recidivism estimates to the offender they are evaluating.

Given the variability in absolute risk, evaluators should also explore options for reporting relative risk (e.g., percentiles, risk ratios), which has been found to be more stable across samples and settings (Helmus, Hanson et al., 2012). For Static-99R and Static-2002R, we have developed both percentiles (Hanson et al., 2012) and risk ratios (Babchishin, Hanson, & Helmus, 2012; Hanson, Babchishin, Helmus, & Thornton, 2013). Other recommendations for reporting absolute and relative risk can be found in Babchishin and Hanson (2009). For many decisions involving allocation of limited resources (e.g., determining how often an offender must report to a probation officer), relative risk is a highly stable and useful property of actuarial risk scales.

The Sex Offender Risk Appraisal Guide

Marnie E. Rice and Grant T. Harris*

Background

In this chapter, we describe the development, validation, replication, and recommended forensic application of the actuarial *Sex Offender Risk Appraisal Guide* (SORAG). We specifically address its application in the United States which is the main focus of this volume. Among psychologists, the fundamental rationale for actuarial violence risk assessment owes its origin more than a half century ago to the recognition that actuarial techniques are more accurate than clinical judgment, experience, and intuition (Meehl, 1954; see also Ægisdóttir et al., 2006; Grove & Meehl, 1996). This is especially true for violence risk (Hanson & Morton-Bourgon, 2009; Hilton, Harris, & Rice, 2006; Campbell, French, & Gendreau, 2009). The general empirical superiority of comprehensive forensic actuarial tools over unaided clinical judgment is now beyond responsible debate (see also Monahan, 2006; Skeem & Monahan, 2011). The SORAG is actuarial inasmuch as the items were selected based on their measured relationships with outcomes in specific development samples, and scores are accompanied by tables of measured recidivism rates (experience tables) and percentiles also based on large samples. In this context, the meaning of "actuarial" excludes certain other mechanical or formulaic ways of yielding numerical scores that are not based on measured relationships in development samples and that do not provide experience/outcome tables and percentile norms. Before we discuss the system specifically, we address one forensic issue that arises when an actuarial tool such as the SORAG is used in the United States.

The Appropriate Outcome for Sex Offenders

What is the outcome relevant to legislation and policy? In several US states, various statutes pertaining to the preventive detention of sexually violent persons (SVP) specify a concern about subsequent sexually motivated violent crime. We understand "violence" in this context to involve at least some specific risk of physical harm (as in attempting to commit a rape by threatening a victim with a firearm) or physical contact between perpetrator and victim. In general, such statutes do not specify the time frame of concern. Some SVP statutes refer to "predatory" sexual violence, but this term is also not defined. Preventive detention statutes exist in other countries, but we are not aware of any that limit application to sex offenders' sexual recidivism specifically. In Canada, for example, legislation permits the prosecution to apply for designation as a "dangerous offender" at the time of sentencing. The Canadian statute refers to the risk of "causing death or injury to other persons, or inflicting severe psychological damage," and permits indefinite incarceration. By far the majority of those designated as dangerous offenders are sex offenders, but the outcome of legislative concern is clearly subsequent violent crime in general.

Outside the execution of SVP preventive detention statutes in the United States and elsewhere, criminal justice officials and forensic clinicians everywhere make decisions about sentencing, probation, and parole of sex offenders. Indeed, even in the United States, non-SVP-related decisions about sex offenders occur much more often than SVP-related decisions. Professionals also make decisions about treatment, conditions of release, and the intensity of community supervision. When making these decisions about known sex offenders, what outcome is (and should be) of primary concern to such clinicians and officials? What outcome is of concern to the public? We accept that there might be some division of opinion here, but we believe that violent crime in general is the principal concern for the public and for most criminal justice applications. That is, just as a rape by a released sex offender constitutes failure, no sentencing

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_21

judge, parole board, probation officer, forensic psychologist, or taxpayer regards it as success when a discretionarily released sex offender kills a store clerk during a robbery.

What is the outcome for which assessments are designed? In addition to the SORAG and VRAG, there are several other actuarial systems intended for use in evaluating sex offenders' risk of recidivism, and these rank sex offenders differently than do the VRAG and SORAG (Barbaree, Langton, & Peacock, 2006). The most commonly researched are the various versions of the Static-99/Static-99R, the MnSOST/MnSOST-R, and the various forms of the Risk Matrix 2000 (Hanson & Morton-Bourgon, 2009). Generally, these latter assessments were constructed using *sexual recidivism*. But what is sexual recidivism in this context? Sexual recidivism has been operationalized as the subsequent appearance of a crime labeled as sexual on releasees' criminal justice system records. Sexual crimes include those called rape, sexual assault or battery, indecent assault, and so on. It is often unclear whether such crimes as sodomy, incest, gross indecency, sexual interference, and so on would have been counted as sexual recidivism. Another complication is that criminal codes use different terms to refer to the same criminal act (e.g., "rape" is called "sexual assault" in the Canadian code) and the same terms to refer to different acts (e.g., "sexual assault" almost always involves physical contact in the application of the Canadian code, while in some US jurisdictions "sexual assault" would rarely involve physical contact). The best research method to clarify such things would, of course, entail examining detailed offense descriptions, but this is very rarely done. Typically, developers of actuarial systems for "sexual" recidivism use only the evident sexual content of the offenses named in the records, and many procedural details pertaining to how ambiguities are addressed have simply been omitted from the published reports (e.g., Hanson & Morton-Bourgon, 2009). Where it is specified, it is often the case that both contact and noncontact offenses are included in the definition of sexual recidivism (e.g., Kingston, Seto, Firestone, & Bradford, 2010; Ducro & Pham, 2006). Moreover, in the relatively rare cases where "sexual recidivism" has been divided into "violent" sexual recidivism (usually defined as involving physical contact of a sexual nature), versus "nonviolent" sexual offenses, nonviolent sexual offenses are found to be nearly as frequent, or even more frequent, than violent sexual offenses, suggesting that "sexual recidivism" as usually operationalized in research on the development and validation of actuarial systems for its prediction captures a considerable number of noncontact offenses. For example, Rettenberger, Matthes, Boer, and Eher (2010) reported a sexual recidivism rate of 4.3 % compared to a sexually violent (i.e., hands-on) recidivism rate of 1.8 %. Ducro and Pham (2006) reported a violent (including hands-on sexual) recidivism rate of 17 %, whereas the sexual recidivism rate was 25 % in the same time period. We (Rice, Harris, Lang, & Cormier, 2006) observed that of 195 offenses labeled as sexual on criminal rapsheets, 21 % were nonviolent according to the label, and 63 % of those were actually nonviolent upon reading more detailed information. Thus, counting all rapsheet sexual offenses as sexual recidivism increases the base rate of sexual offenses to a proportion closer to the probably true rate, but does so at the expense of including a sizeable proportion of hands-off (i.e., nonviolent), sexually motivated offenses. In addition, it is likely that many crimes lacking any sexual connotation in their names (e.g., battery, assault, kidnapping, murder) are actually sexually motivated criminal acts when committed by sex offenders. Although most published reports about the development of actuarial systems for assessing the risk of sexual recidivism also lack satisfactory details about how these crimes / offenses are addressed, it is safe to conclude that most research in this area does not count such offenses as sexual, even when perpetrated by known sex offenders.

In sum, although there are several actuarial risk assessments for sex offenders, the outcome for which most were designed is not that of primary forensic concern in almost every jurisdiction—subsequent violent crime. Even in the minority case where the narrower outcome of sexually violent recidivism is the forensic issue (i.e., SVP statutes in the United States), the operationalization of "sexual" recidivism upon which these actuarials are based appears to be different than that legislatively mandated. Also, as discussed later, the experience tables for all actuarial tools are based entirely on officially detected recidivism, which is known to be a subset of the actual outcomes of forensic concern—subsequent criminality, detection by the criminal justice system notwithstanding.

In an attempt to address the issue pertaining to officially detected sexually motivated violence and classification from police records, we examined such records in conjunction with detailed offense descriptions (Rice et al., 2006). It was evident that research that measures sexual recidivism based only on police "rapsheets" misses sex offenders' most serious sexually violent reoffenses (homicide especially), and needlessly underestimates the base rate of officially detected sexually violent recidivism (by inappropriately assuming that all charges for assault, battery, kidnapping, abduction, and so on are nonsexual). In our study, research assistants read all information available about the referral and all past offenses of 177 men referred to our sex offender program. Then, research assistants used a definition of sexually motivated that was consistent with the U.S. legal understanding of the term in order to rate offenders' referral and past offenses as "clearly," "probably," "possibly," "probably not," or "clearly not" sexually motivated. Omitting the "possibly" sexually motivated offenses, we found that 31 % of the offenders had committed referral offenses that were probably or clearly sexually motivated and violent but for which

the rapsheets gave no indication the offense was sexual. For past offenses, 33 % of those labeled as violent but nonsexual on the rapsheet were rated as probably or clearly sexually motivated based on all information available. In addition, a small proportion of the offenses labeled as nonsexual and nonviolent on the offenders' criminal rapsheets were also rated probably or clearly sexually motivated and violent according to all information available. We concluded that one would have to multiply the number of rapsheet sexual offenses by between 1.4 and 1.7 in order to get a more accurate number of the actually sexually motivated violent offenses committed. We then used our results to develop a more fully informed measure of violent sexual recidivism that included homicides, kidnappings, forcible confinements, and a proportion of nonsexual assaults. Overall, the more fully informed measure of violent sexual recidivism was more closely related to rapsheet violent recidivism than to rapsheet sexual recidivism. Furthermore, rapsheet sexual recidivism was better predicted by apparently nonsexual past rapsheet violent offenses (including those that, given full information, were coded as violent sex offenses) than it was by past rapsheet sex offenses. That is, among sex offenders released from secure custody, officially detected violent recidivism was a better index of officially detected sexually motivated violence than sexual recidivism recorded on rapsheets (Rice et al., 2006). Thus, even when the public policy concern is only the risk of sexually motivated violent reoffending, actuarial assessment based on officially detected violent recidivism was a closer approximation to the outcome of most legislative and public policy concern than was sexual recidivism as usually operationalized.

The Development of the SORAG

The SORAG is a modification of the *Violence Risk Appraisal Guide* (VRAG), the first and most thoroughly researched actuarial assessment for the risk of violent criminal recidivism among men who have committed at least one violent offense (Harris, Rice, & Quinsey, 1993). Elsewhere, we have described the derivation of the VRAG in detail (Quinsey, Harris, Rice, & Cormier, 2006), but some introduction to the VRAG is required for understanding the provenance of the SORAG. Each possible VRAG score has been associated with 1 of 9 categories, each in turn bearing a known estimated rate of violent recidivism in 7 years, increasing linearly from 0 to 100 %. There are also tables for 10 years of opportunity, and each VRAG score is associated with a percentile whereby the risk represented by an individual may also be determined according to his standing relative to violent offenders in general.

Development of the VRAG was based on follow-up research where the outcome was any new criminal charge for a violent offense (coded blind to independent variables). Violence included homicide, attempted homicide, kidnapping, forcible confinement, wounding, assault, armed robbery, and rape. Although some sexual assaults rely on guile or abuse of trust rather than physical force, we counted all sexual assaults involving physical contact as violent. Such noncontact sex offenses as exhibitionism and voyeurism were not counted as violent recidivism. Criminal charges and convictions are imperfect measures of actual violent conduct. Wrongful arrest and conviction occur while some violent crimes go unreported to the authorities; some police investigations fail to identify a perpetrator; some identified perpetrators avoid apprehension and arrest; and some guilty perpetrators are not convicted. Our research has indicated, however, that charges entail less measurement error than do convictions. Although charges appear to be optimal, studies have shown that criminal convictions, institutional records of aggression, and self-reported violence are generally predicted by the same variables, especially VRAG scores (Harris et al., 2015). For the purposes of construction, the outcome was dichotomous such that the dependent variable in analyses was at least one occurrence of violent recidivism. Opportunity was operationalized as release to the community, minimum-security hospital, or a halfway house. The VRAG development sample had a mean of 81.5 ($SD = 60.6$) months of opportunity for recidivism and time institutionalized for nonviolent offenses (or other reasons) was subtracted in calculating opportunity.

Approximately 50 potential predictor variables were considered as possible VRAG items, including those related to psychiatric history, distress and diagnosis, expressions of remorse, volunteering for treatment, whether the offender was regarded by clinicians as having "insight," and so on. In developing the VRAG, the tested variables reflected childhood history (e.g., conduct disorder, school maladjustment, education), adult adjustment (e.g., criminal history, unemployment, marital status, socioeconomic status), index offense (e.g., number and sex of victims, victim injuries), and assessment results that could be obtained shortly after the index offense (e.g., IQ, MMPI, PCL-R score, phallometric assessment), all coded (blind to outcome) to a high standard of inter-rater reliability from records including thorough psychosocial histories.

The VRAG was constructed to be an actuarial instrument for serious offenders for whom the courts, clinicians, and criminal justice officials need to make predictive decisions—those who have already committed at least one serious antisocial act. Thus, offenders with only minor offenses and men without offenses were not included in our heterogeneous sample of serious offenders from two previous studies (Rice, Harris, Lang, & Bell, 1990; Rice, Harris, & Cormier, 1992). Of these 695 cases, 618 had an opportunity to recidivate and there were few differences between those who did or did not

have an opportunity. Potential items without a bivariate relationship with violent recidivism were not considered further. Additionally, from highly collinear pairs (e.g., prior criminal charges and prior convictions for violent offenses), the variable with the higher association with violent recidivism was retained. Multiple regression identified variables with independent and incremental contributions to predicting violent recidivism. Only variables selected by the regression analyses in subsidiary analyses were eligible in a final regression using the entire sample of cases, yielding the 12 VRAG items. Logistic regression and Cox proportional hazards regression were shown to have selected substantially the same items as would ordinal measures of recidivism—number, severity, and rapidity of violent reoffenses (Quinsey, Harris et al., 2006).

Unitary item weights would have performed well (Harris et al., 1993; see also Grove & Meehl, 1996), but the small improvement afforded by differential weights was potentially worthwhile. Thus, a method described by Nuffield (1982) was used where weights are computed actuarially using the item's base rate relationship with the outcome. This meant that a score of zero was recommended for missing items because that added the score for the base rate. Now, we recommend prorating (Harris et al., 2015, pp. 323–324; Quinsey, Harris et al., 2006, pp. 164). Elsewhere (Appendices of Quinsey, Harris et al., 2006), we provided an extensive manual for the VRAG including scoring instructions, norms, frequently asked questions, how to compile suitable psychosocial histories, practice material, and recommended report format. Whether intended for research or individual assessment, the appropriate basis for scoring the VRAG is a psychosocial history (see Quinsey, Harris et al., 2006) that addresses childhood conduct, family background, antisocial and criminal behavior, psychological problems, and details of all offenses. Adequate psychosocial histories rely on collateral information (i.e., from friends, family, schools, correctional facilities, police, and the courts). VRAG scoring is not a typical clinical task because it requires no contact between assessor and assessee. But compiling appropriate psychosocial histories clearly necessitates considerable clinical expertise.

The VRAG is properly used for men (prisoners or forensic patients) who have committed a serious offense (e.g., Harris, Rice, & Cormier, 2002; Pham, Ducro, Marghem, & Réveillère, 2005; Snowden, Gray, Taylor, & MacCulloch, 2007; Thomson, 2005; Urbaniok, Noll, Grunewald, Steinbach, & Endrass, 2006; Yessine & Bonta, 2006) including sex offenders (e.g., Dempster, 1998; Harris et al., 2003; Rettenberger & Eher, 2007) in that it has been reported to predict violent recidivism, and its severity and rapidity, all with large effect sizes (Harris, Rice, & Quinsey, 2010; Rice & Harris, 2005). It has also predicted violence (where criminal charges have not necessarily been laid) for male and female civil psychiatric patients (e.g., Doyle, Dolan, & McGovern, 2002; Gray, Fitzgerald, Taylor, MacCulloch, & Snowden, 2007; Harris, Rice, & Camilleri, 2004). In development and subsequent evaluations, VRAG scoring has yielded very high inter-rater reliability (Rice, Harris, & Hilton, 2010). The mean VRAG score for the development sample was 0.91 ($SD = 12.9$) and the standard error of measurement was 4.1, roughly half a VRAG category. The 95 % confidence intervals for categories increase slightly as scores increase (Harris et al., 1993), but the standard error of measurement and observed rates of violent recidivism are such that any "true" score is expected to differ from an obtained score by more than one category less than five percent of the time (Harris et al., 1993).

The VRAG has been shown to generalize across violent outcomes (number of violent reoffenses, institutional violence, very serious violence, self-reported violence, general recidivism, overall severity of violent recidivism, rapidity of violent failure); follow-up times (12 weeks to 20 years); countries (eight in North America and Europe); populations (mentally disordered offenders, sexual aggressors, violent felons, developmentally delayed sex offenders, emergency psychiatric patients, wife assaulters, and juvenile offenders), all extensively reviewed elsewhere (Harris et al., 2010; Quinsey, Harris et al., 2006; Harris et al., 2015). Replications generally report that obtained rates of violent recidivism match the predicted rates; if the average score of the sample is similar, the follow-up duration is approximately the same as for the norms, and the outcome is similar (Harris & Rice, 2007a; Harris et al., 2015).

Rationale for the SORAG

The foregoing notwithstanding, sex offenders' rates of violent recidivism were higher than expected based on VRAG scores (Harris & Rice, 2007a; Rice & Harris, 1997), suggesting different norms might be necessary for men institutionalized for sex offenses against minors and sexual assaults against women than for other offenders. Contrary to the claims of those who claim sex offenders are of lower risk than other offenders, every study we are aware of that has included VRAG scores for their sample of sex offenders (Dempster, 1998; Harris et al., 2003; Langton et al., 2007; Rice & Harris, 1997) has obtained a mean VRAG score for sex offenders that is considerably higher than that obtained in the development sample for the VRAG. Specifically, the weighted VRAG score in the three studies cited above was 5.03 vs. 0.90 in the development sample, further supporting the view that among offenders scored on actuarial instruments, sex offenders present a higher risk than other offenders. Variables associated with violent recidivism among such

sex offenders were slightly different from those shown to be related for violent offenders without histories of sexual offending (Quinsey, Rice, & Harris, 1995; Rice, Harris, & Quinsey, 1990; Rice, Quinsey, & Harris, 1991). For example, phallometric measurement of sexual deviance has only been reported to predict recidivism among sex offenders. An index offense of homicide is associated with lower-than-average risk only among non-sex offenders, and the relationships among recidivism and victims' age and sex differ for sex offenders compared to other violent offenders.

Consequently, the VRAG was modified to assess the risk of violent criminal recidivism among sex offenders by eliminating two items (female index victim and index victim injury, both inverse scored) that afforded no incremental value among sex offenders, and adding four that did (in decreasing order of weights: prior history of violent offending, prior sexual convictions, adult female or male child victims, and deviant sexual preferences assessed phallometrically). Norms were derived as in the VRAG based on a sample of 288 sex offenders (Rice, Harris, Lang et al., 1990, 1991) where the outcome was that used in developing the VRAG—at least one subsequent charge for a violent offense. Weights for all new items used the same Nuffield (1982) method as in the VRAG and the 10 VRAG items retained their VRAG weights. The result was the 14-item Sex Offender Risk Appraisal Guide (SORAG). The items, ranges of scores, and bivariate correlations with violent recidivism are shown in Table 1. As with the VRAG, SORAG scores are associated with one of nine categories, each with a measured rate of violent recidivism in 7 years, increasing linearly from 7 to 100 %. There are norms for both 7 and 10 years of opportunity, and each SORAG score is also associated with a percentile rank. The base rate of violent recidivism in the developmental sample was 42 % in 7 years, which increased to 58 % in 10 years (Rice & Harris, 1995). Elsewhere (Quinsey, Harris et al., 2006, Appendices), there is an extensive manual for the SORAG including detailed scoring instructions, norms for the standard SORAG categories, frequently asked questions, instructions for compiling a suitable psychosocial history, practice material, and recommended report format. As for the VRAG, up to four missing SORAG items may be prorated or substituted (see Quinsey, Harris et al., 2006 for details regarding acceptable substitutions).

The inter-rater reliability of the SORAG was 0.90 in construction (Quinsey, Harris et al., 2006) and similar high reliability coefficients have been reported in replication studies (see Table 2). In development, SORAG scores had a mean of 8.90 (SD = 11.33) and a standard error of measurement of 3.58, with a mean of 9.99 (SD = 10.8) and a standard error of measurement of 0.012 in a subsequent replication (Harris et al., 2003). That replication reported very close correspondence between observed rates of violent recidivism for SORAG categories and those expected on the basis of the norms. In the development sample, SORAG scores yielded an ROC area of 0.75 in predicting violent recidivism that was replicated (0.73) in the independent evaluation (Harris et al., 2003), which also reported that SORAG scores significantly predicted the severity and rapidity of violent recidivism. Of the 11 nonoverlapping samples of released sex offenders (see Table 2), 9 reported predictive accuracy for violence (including contact sexual recidivism), and SORAG scores have yielded a mean ROC area of 0.74 (see also "Replications

Table 1 Sex offender risk appraisal guide items, ranges indicating relative weights and correlations with violent recidivism in the construction sample (see Harris et al, 2015; Quinsey, Harris et al., 2006 for definitions, instructions, norms, and practice materials)

[b]Defined as being known or suspected of having had a prepubescent or early pubescent victim
[c]% of child molesters with at least one intrafamilial (biological or step) victim

of the Violence Risk Appraisal Guide"). The SORAG has obtained mean ROC areas for the prediction of violent recidivism of 0.70 or greater among rapists (Bartosh et al., 2003; Ducro & Pham, 2006; Harris et al., 2003; Rettenberger & Eher, 2007), 0.75 among extrafamilial child molesters (e.g., Bartosh et al., 2003; Ducro & Pham, 2006; Rettenberger & Eher, 2007; Rice & Harris, 2002), and 0.75 or over among intrafamilial child molesters (e.g., Bartosh et al., 2003; Ducro & Pham, 2006; Rettenberger & Eher, 2007; Rice & Harris, 2002). As with the VRAG, accuracy is enhanced by neither dropping nor replacing SORAG items, and by ensuring high reliability and fixed duration of follow-up (Harris & Rice, 2003; Harris et al., 2003; Langton et al., 2007). The accuracy of SORAG scores for violent recidivism has been shown to be enhanced neither by adding other actuarials (Seto, 2005) nor by adding "structured" clinical intuition (Johansen, 2007; see also Hanson & Morton-Bourgon, 2009). Although (as we outlined earlier in this chapter) we believe that violent recidivism is the most appropriate outcome measure, we realize that there are many who want to know how well the SORAG predicts rapsheet sexual recidivism. As may be seen from Table 2, of the 10 nonoverlapping studies that reported sexual recidivism (measured mostly from rapsheets only), SORAG scores have yielded a mean ROC area of 0.68.

Data from a Long-term Follow-up of Sex Offenders

We have gathered new follow-up data on 750 sex offenders included in one or more of our earlier follow-up studies (Harris et al., 1993; Harris et al., 2003; Rice & Harris, 1995; Rice & Harris, 1997). These offenders included 464 men assessed while they were inpatients in our institution, 94 assessed as outpatients and referred from local probation, parole, and child welfare agencies, and 192 assessed while they were serving federal sentences in one of two Canadian penitentiaries. Detailed information about the childhoods and criminal and psychiatric backgrounds of these men can be found in the original studies. In Table 3, we report only a few characteristics of the sample that will be of most interest to those wanting to apply the SORAG to their clientele. All the men were subjects in earlier follow-up studies, but new follow-up data for as many men as possible were gathered in 2004 or 2007. In addition, we were able to determine that 52 of the men had died. Data were gathered about all criminal offenses committed following time first at risk, but only the first violent recidivism is reported here. Time at risk was calculated (as in our earlier studies) by subtracting time spent incarcerated for nonviolent offenses from time since first at risk.

All of the men had spent at least 6 months at risk before the end of the last follow-up or had committed a violent offense despite having had no time at risk (n = 19). The mean time at risk for successes was 18.4 years, $SD = 9.91$ years (with a range from 0.50 to 48.2), and the mean time at risk until first violent failure for those who failed was 4.37 years ($SD = 4.05$), with a range of 0 to 27.6. Considering only those 742 men who either failed violently or had at least 2 years at risk, the overall rate of violent failure was 59 % and the ROC area for the prediction of violent recidivism using the SORAG was 0.729 (95 % CI = 0.691–0.766).

We also examined the accuracy of the SORAG over various fixed values for time at risk varying from 6 months to 40 years. To conduct these analyses, we counted all those who failed after the fixed time at risk as successes for that period. We also counted each offender who died without committing a new violent offense as a success regardless of how long they were at risk. The results of these analyses are shown in Table 4. It may be seen that the ROC area appears to be highest for a follow-up of 6 months and lowest at 10 years. In fact, the accuracy at 6 months is significantly higher than at follow-ups at 10, 12, and 15 years (i.e., the confidence

Table 4 Time at risk and predictive accuracy of SORAG

Time at risk	ROC area	95 % CI	Base rate (%)	N
6 months	0.773	0.700–0.846	7.2	704
1 year	0.760	0.703–0.817	13	701

8	+26 to +31	0.89	18	0.69	68
9	≥ +32	1.00	5	0.93	61
Total Sample		0.58	288	0.56	678

interval of those follow-ups does not include the ROC area for the 6-month follow-up). It may be seen that the base rate of violent recidivism climbs from 7 % at 6 months to 92 % at 40 years. However, we caution that the base rates may be inflated at follow-ups beyond 12–15 years because after that time we lose track of significant numbers of men who we know did not fail up until the time we lost track. A Kaplan–Maier survival curve levels off at 37 % survival after 28 years at risk. The curve falls steeply until about 12 years and then falls only very slightly after that. Fewer than 5 % of failures occurred after more than 12 years at risk.

We also examined the rates of violent recidivism in each of the 9 categories of the SORAG for the 10-year fixed follow-up to compare to the norms presented in Quinsey, Harris et al. (2006) based on the development sample of 288 (all of whom were also subjects in the new follow-up) (Table 5). The base rates of violent recidivism were nearly identical in the two samples (58 % in the original sample and 56 % in the new follow-up). Table 5 shows that there was more recidivism in the lower risk categories in the new follow-up than in the construction sample, and less in the higher categories. This is, partly, what would be expected based on the lower overall predictive accuracy (ROC area of 0.73 versus 0.77 in the construction sample). However, the rates in categories 1 and 2 are higher, and the rates in categories 6 and 8 are lower than expected even when the reduced accuracy is taken into account. Based on our results, however, we can be quite confident that the 10-year expected recidivism rates as described in Quinsey, Harris et al. (2006) are not gross overestimates and that the 10-year recidivism rates in at least categories 6–9 are all greater than 50 %.

In order to examine whether recidivism rates have declined over time, we divided the men into three cohorts based upon their date first at risk. Those men whose date first at risk was on or after January 1, 1988, had a 10-year violent recidivism rate of 40 % compared to 54 % for those whose date first at risk was between January 1, 1981, and December 31, 1987, and 57 % for those whose date first at risk was before that. Thus, it appears that the violent recidivism rate of the most recent cohort is lower than that of earlier cohorts. This is contrary to results reported by Prentky, Lee, Knight, and Cerce (1997), who found no evidence of cohort effects

when they divided their sample into three cohorts based on year of release. However, it is important to note that the risk scores of our most recent cohort were also significantly lower than those of our earlier cohorts. The mean SORAG score for the most recent cohort was 8.58 (95 % C.I. 6.38–10.78) compared to 12.20 (95 % C.I. 10.28–14.12) for the middle cohort and 10.90 (95 % C.I. 9.2–12.60) for the earliest cohort. Therefore, we suspect that this trend in our own data reflects a change in referral patterns rather than a more general reduction in the risk represented by sex offenders overall.

Because we are often asked about the use of the SORAG with adolescent offenders, we examined adolescent offenders separately. There were 71 offenders who were under age 18 at the time of their index offense and for whom we had 10-year outcome data. Most were adults when they first had an opportunity to reoffend. Of the 71, 59 % failed violently within 10 years of opportunity. The ROC area for the 10-year outcome was 0.80. Thus, although the sample was quite small, the SORAG worked just as well with adolescent offenders as it did with adults.

Now, we turn to a few remaining issues regarding the use of actuarial risk assessment tools, especially the SORAG.

Dynamic Risk Assessment and Post-actuarial Adjustments for Sex Offenders

The SORAG does not include items labeled "dynamic." Unfortunately, this term lacks consensual meaning and experts in the field seem unlikely to arrive at one in the near future. For example, one-time measurements of identical constructs are called static in some assessments (e.g., sexual deviance in the SORAG) but dynamic in others (e.g., sexual deviance in the VRS-SO) (Olver, Stockdale, & Wormith, 2009). In our opinion, progress will be hampered until the general adoption of a definition which understands that a dynamic risk factor is one that can be shown to change and that alters risk when changed (Hanson & Harris, 2000; Quinsey, Coleman, Jones, & Altrows, 1997; Quinsey, Book, & Skilling, 2004; Rice, 2008; see also Douglas & Skeem, 2005's "causal" dynamic risk factor). Until then, however, we note that if the association between the change in the putative dynamic factor and the corresponding change in the risk of recidivism is entirely subsumed by a static variable, then the potentially dynamic factor is not *usefully* dynamic.

This fact first became apparent to us when we evaluated the effects of a treatment program for child molesters that targeted their deviant sexual preferences (Rice et al., 1991). Deviant preferences were found to yield the highest correlations with recidivism of all variables examined in meta-analyses of the predictors of sexual recidivism among sex offenders (Hanson & Bussière, 1998; see also Hanson & Morton-Bourgon, 2005) and thus are considered to be an important criminogenic need among sex offenders. In our study, we examined whether pre-post treatment changes in deviant sexual preferences measured using phallometry would be related to lower recidivism upon release. Although we were able to demonstrate significant changes in deviant preferences as a result of therapy, we found that the pretreatment preferences predicted subsequent sexual recidivism better than did posttreatment preferences. We concluded that there was no evidence that our behavioral program reduced risk of sexual recidivism, and we would now conclude that there is, as yet, no evidence that deviant sexual preferences are usefully dynamic.

Although various risk assessment schemes for "dynamic" assessment among sex offenders have been promulgated, evidence is lacking to support the conclusion that any usefully dynamic factors have been identified. Consider, for example, a study of the VRS:SO (Olver, Wong, Nicholaichuk, & Gordon, 2007; see also Olver, 2003), with which we disagree, and in which the authors concluded there was evidence for dynamic risk factors in their sample of sex offenders. Inspection of Table 3 in Olver et al. (2007, page 324) shows that for sexual recidivism, the AUC for just the static items of the VRS-SO was 0.74 (95 % CI = 0.68–0.80). The AUCs for the pre- and posttreatment dynamic scales were 0.66 (95 % CI = 0.59–0.73) and 0.67 (95 % CI = 0.60–0.74), respectively, and the AUCs for the pre- and posttreatment total (static plus dynamic) scores were 0.71 (95 % CI = 0.64–0.77) and 0.72 (95 % CI = 0.66–0.78), respectively. Thus, the highest predictive accuracy was obtained for the static scale alone. Changes on putative dynamic variables did not add to the predictive accuracy of static variables, nor did the posttreatment dynamic scale predict significantly better than their pretreatment dynamic scale. The same pattern of results was found for their other outcome measure: nonsexual violent recidivism. Similarly, Beggs and Grace (2010) discussed having demonstrated a role for "dynamic" factors in sex offender risk assessment. However, inspection of their Table 3 (pg. 244) reveals that the combination of static items and posttreatment scores on putatively dynamic items performed no better for the prediction of sexual recidivism (AUC = 0.80, 95 % CI = 0.71–0.89) than static items and pretreatment scores (AUC = 0.79, 95 % CI = 0.69–0.88) on the same items. The same was true for their other outcome measures (violent and general recidivism). Thus, there was in fact no demonstration that the evaluation of putatively clinically relevant change improved predictive accuracy. Hanson, Harris, Scott, and Helmus (2007) reported the results of the "Dynamic Supervision Project," which examined the contributions of two so-called "dynamic" risk scales, the Stable-2007 and the Acute-2007, in the prediction of sexual recidivism among 997 sex offenders across 16 North American jurisdictions. They found (as did Beggs & Grace,

2010) that the scales did add to the predictive accuracy of the Static-99. However, they also found that there was "little evidence that changes on these [dynamic] factors were related to recidivism risk. Offenders changed little on the stable factors during the 6-month retest period, and the change was unrelated to recidivism" (pg. 25). In fact, as of 2010 there have been no empirical demonstrations that prerelease changes in any risk factors are usefully dynamic.

Therapists' impressions of treatment progress are unrelated or positively (perversely) related to sex offenders' recidivism (Looman, Abracen, Serin, & Marquis, 2005; Quinsey, Khanna, & Malcolm, 1998; Seto & Barbaree, 1999). More generally, clinicians' application of putatively dynamic factors (Daffern et al., 2009; Desmarais, Nicholls, Read, & Brink, 2010; Philipse, Koeter, van der Staak, & van den Brink, 2006) shows negligible utility. Although dynamic aspects of sex offenders and their environments must be among the causes of recidivism, there is little evidence yet that these have been identified and incorporated into forensic clinical practice.

An especially important prerelease static variable (sometimes inaccurately called dynamic) is whether some form of treatment has been provided prior to release. Some studies have reported that this dichotomous variable is related to recidivism and this, in turn, has occasionally been interpreted as a treatment effect. Unfortunately, more comprehensive research shows that relatively high-risk sex offenders are less likely to begin treatment, and even less likely to complete it. This raises the possibility that sex offenders who receive treatment are systematically different from those who do not, and that this difference may be/is relevant to their risk of recidivism. Thus, it remains possible that what has appeared to be a specific effect of therapy can be more accurately understood as a selection effect (Rice & Harris, 2003, 2013b), and the field of sex offender treatment has been insufficiently rigorous to shed light on this. The best way to resolve this issue is through the use of strong inference evaluation designs (Seto et al., 2008).

We anticipate that effective treatments for sex offenders will eventually be clearly demonstrated. Presently, however, we suggest that the unpersuasive evidence in this regard is primarily due to current therapies being based on incorrect or very incomplete explanations of sexual aggression in combination with weak treatment evaluation research. In the meantime, we suggest that, from a practical perspective, worthwhile multivariate analyses would examine the incremental effect of a provision-of-treatment variable in predicting recidivism after statistical consideration of historical variables known before the beginning of treatment (i.e., criminal records, psychopathy, sexual deviance, substance abuse history, childhood aggression and antisociality, family background, etc.). If the provisiona of treatment (or response to it) is subsumed by such historical items, optimal risk assessment need not incorporate treatment items.

In contrast, within-subject changes in various states (e.g., attitudes, moods, intoxication) have been shown to indicate the imminence of violence, especially among those whose statically determined risk is already high (Mulvey et al., 2006; Quinsey et al., 1997; Quinsey, Harris et al., 2006; Skeem et al., 2006). Thus, there is some evidence that fluctuating variables aid in anticipating when a high-risk offender might recidivate, although work on incorporating these findings into formal assessment has not been completed. Actuarial systems incorporating fluctuating factors, when developed, will be useful for short-term, post-release community management aimed at forestalling violent recidivism, but cannot, as yet, improve long-term risk assessment decisions about who is likely to be violent.

As previously discussed, the SORAG relies on clinical skill to evaluate its items, but permits no modification of the score based on clinical judgment. Supplementary clinical discretion has been recommended by developers of some non-actuarial schemes to lower user resistance, incorporate idiosyncratic risk factors, permit application to new populations, adjust for offender age, give credit for perceived treatment progress, recalibrate for differences in base rates, accommodate anxiety about errors, and accede to the notion that inserting clinical judgment is a professional responsibility. No evidence supports claims that alteration of actuarial scores based on clinical judgment results in better accuracy than actuarial scores alone. In fact, there is good reason to believe such revision generally results in decreased accuracy, partly by lowering measurement reliability (see Gore, 2007; Grove & Meehl, 1996; Hanson & Morton-Bourgon, 2009; Harris & Rice, 2007a; Hilton & Simmons, 2001; Janus & Meehl, 1997; Quinsey, Harris et al., 2006).

The Base Rates of Recidivism

What is the actual base rate of violent reoffending (or sexually motivated violence) in the one of the most relevant offender populations: sex offenders released from secure custody? We also note here the obvious point that it is all subsequent criminal activity that is of legislative and public policy concern, not just crime detected by the police. Legislation and public policy are clearly aimed at minimizing or reducing crime per se, but it is well-established that crimes reported to the police represent only a subset of those actually committed, especially by sex offenders (Harris & Rice, 2007a), and that the police actually apprehend and arrest only a subset of the perpetrators of the crimes reported. Only a fraction of sexually violent offenses are reported to authorities (Bonta & Hanson, 1994; Gannon & Mihorean, 2004; Rennison, 2002), and only a fraction of these are attributed to any perpetrator via criminal charges or convictions (Du Mont, McGreggor, Myhr, & Miller, 2000;

Parkinson, Shrimpton, Swanston, O'Toole, & Oates, 2002). In addition, sex offenders admit to more offenses than those for which they have been apprehended (Abel et al., 1987; Baker, Tabacoff, Tornusciolo, & Eisenstadt, 2001; Groth, Longo, & McFadin, 1982; Weinrott & Saylor, 1991; Zolondek, Abel, Northey, & Jordan, 2001).

The best available data about the base rate of officially detected sexually violent recidivism come from long-term follow-up research on sex offenders released from secure custody. Studies with 20 years or more of follow-up (e.g., Hanson, Steffy, & Gauthier, 1993; Harris et al., 2003; Langevin et al., 2004; Prentky et al., 1997, discussed above) generally show that about 30 % of such sex offenders have subsequent offenses noted to be sexual on police rapsheets and over 40 % have subsequent violent offenses. Hanson (2002) reported a sexual recidivism rate of 22 % in a mean duration of 8 years based on 4,673 sex offenders released from secure facilities in three countries; the correlation between duration and recidivism was 0.81, such that, if all follow-ups were of more than 15 years, "sexual" recidivism would exceed 30 %. Follow-up studies reporting survival analyses (Broadhurst & Loh, 2003; Craig, Beech, & Browne, 2006; Greenberg, Bradford, Firestone, & Curry, 2000; Gretton, McBride, Hare, Shaughnessy, & Kumka, 2001; Hanson et al., 1993; Hanson & Thornton, 2000; Hildebrand, deRuiter, & deVogel, 2004; Langstrom, 2002; Looman et al., 2005; Marques, Day, Nelson, & West, 1994; Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005; Nicholaichuk, Gordon, Gu, & Wong, 2000; Prentky et al., 1995, 1997; Rice & Harris, 1997; Worling & Curwen, 2000) report a mean longest duration of 14 years and a mean final rate of "sexual" recidivism of 31 % (with a correlation of 0.70 between duration and recidivism rate). If all sex offenders released from secure custody were followed for 15 years, the rate of recidivism recorded as sexual on rapsheets would exceed 30 %. The examination discussed in the previous section (Rice et al., 2006) indicated that a correction of approximately 1.4 ought to be applied to estimate the actual rate of officially detected sexually motivated violence by released sex offenders, suggesting that the appropriate overall base rate of such "sexually violent" recidivism is over 40 %.

Because the public policy concern is actual repeated crime, not just crime detected by the criminal justice system, it is scientifically uncontroversial to conclude that police rapsheets underestimate rates of sexually violent offending among sex offenders. Among unselected samples of sex offenders released from secure custody, rates of officially detected general violent recidivism exceed rates of "sexual" recidivism by, on average, at least double (e.g., Bartosh et al., 2003; Ducro & Pham, 2006; Harris et al., 2003; Kingston et al., 2008; Kingston et al., 2010; Langton et al., 2007; Looman, 2006; Rettenberger & Eher, 2007; Rettenberger et al., 2010). Thus, it is safe to conclude that the long-term rates of officially detected violent recidivism among mixed samples of sex offenders released from secure custody approach 60 %. This, of course, is the outcome the SORAG was designed to predict and is very near the 63 % final recidivism rate suggested by the survival analysis in Rice and Harris (2013a) discussed earlier. Inspection of the studies reported in Table 2 and Rice and Harris (2013a) support the conclusion that those offenders who have had at least one adult victim are at considerably higher risk for violent (including sexual) recidivism than are those offenders with exclusively child victims. In addition, the underreporting of violent crime is likely to be similar to that observed for the subset of violent crime that is sexually motivated, but the degree of this underestimation is not fully known; nevertheless, actuarial estimates associated with the SORAG norms are certainly underestimates of actual violent recidivism and may not be overestimates of actual sexually violent recidivism.

Other Formal Sex Offender Risk Assessments

Clearly, the research strategy underlying all actuarial tools for assessing sex offenders imperfectly captures the outcomes of legislative and public policy concern. Most tools were designed to assess the risk of sexual recidivism labeled as such on police rapsheets even though this is a minority concern. In addition, this research operationalization of sexual recidivism is a poor match to the sexually violent recidivism that is actually of forensic concern in relevant statutes. Even in the minority of decisions in the United States. that pertain only to the risk of subsequent predatory sexually motivated violence (those pertaining to SVP designation), the role of predatory offending is undefined. The rates of detected recidivism for various scores on actuarial systems for any operationalization of recidivism are based on average time frames of 5–15 years post-release. Whether these encompass the entire period of concern is unclear. The rates of detected recidivism over these time frames must be underestimates of the actual behavior of concern over the same time period, but the degree of underestimation is unclear. In our judgment, officially detected violent recidivism by sex offenders comes closest (among all available imperfect alternatives) to the outcome of primary concern in all jurisdictions, including those in which sexually violent recidivism is a legislatively mandated issue.

Because of this imperfect match between research methods and legislation and public policy concerns, one might be tempted to eschew actuarial methods in favor of some scheme to incorporate intuition to compensate for the mismatch. Thus, as discussed earlier, some non-actuarial schemes and, unfortunately, much advice for forensic clinicians encourages the use of unaided clinical judgment to

ascertain not only base rates in their own jurisdictions, but also the relevance and direction of additional risk factors (e.g., psychopathy, response to treatment, etc.), the advanced age of an assessee, and so on. These schemes and all this advice provide no procedure to accomplish these ends. While others disagree, based on all the available evidence, we regard it as scientifically and ethically unjustified to use unstructured clinical opinion for these purposes (Harris & Rice, 2007b), a matter we address further below.

Age and Sex Offender Recidivism

There is a well-established relationship between age and recidivism among offenders in general, and many investigators report a similar association among sex offenders in particular (Hanson, 2002), although this finding is far from universal (Craig, 2011; Doren, 2006; Thornton, 2006). Some commentators have concluded that, when observed, this association reflects "maturational" effects associated with decreasing testosterone (e.g., Barbaree, Blanchard, & Langton, 2003) such that the resultant decreased sex drive causes a lowering of recidivism among sex offenders, although it is unclear how lowered sex drive reduces non-sexually motivated reoffending among sex offenders (or any others). In addition, these correlations between age and recidivism come almost entirely from cross-sectional studies comparing the rates of recidivism for offenders of varying ages at release. Very few studies follow a cohort of offenders as they age and examine the rates of violence (or sexual violence) over time. This methodological problem carries the risk that offenders released at young ages are different in relevant ways (in addition to or instead of being younger) from offenders released at older ages (i.e., cohort differences). In fact, this often appears to be the case. For example, we (Harris & Rice, 2007a) and others (Barbaree, Langton, & Blanchard, 2007) have shown that sex offenders high in psychopathy were released younger than those scoring low in this trait, reflecting enduring antisociality.

Two hypothetical causal possibilities emerge about this association between enduring antisociality or psychopathy and age at release: either high psychopathy causes offenders to be released younger, or being released older causes a reduction in psychopathy. We believe the former is more likely in the sense that offenders high in psychopathy, by definition, begin their criminal careers at younger ages so that in any cohort of offenders, those high in psychopathy will have been incarcerated younger and are, therefore, younger at release. We regard it as unlikely for a sex offender's age at release (on average over 30) to have any effect on his level of psychopathy (a trait that emerges in childhood) measured beforehand. Some commentators assert that psychopathy, and its resultant risk of violent recidivism, does decrease as offenders get older (e.g., Barbaree et al., 2007, 2009), although, again, these findings are based on cross-sectional studies (e.g., Harpur & Hare, 1994) and not on remeasuring psychopathy and violence as offenders get older. With respect to violent crime, however, there is evidence that offenders with high PCL-R scores do not exhibit much age-related desistence even at advanced ages (Harris, Rice, & Cormier, 1991; Hare, Forth, & Strachan, 1992; Porter, Birt, & Boer, 2001) as long as differential opportunity is included in the analyses.

Hypotheses aside, the practical issue here is whether optimum risk assessment for sex offenders must incorporate age at release. Table 6 illustrates the situation in a sample of sex offenders (Harris et al., 2003). The table shows violent recidivism for each quartile of age at first offense, and then recidivism as a function of the subdivision of each of those quartiles into further quartiles based on age at release. The top of the table shows a strong, clear relationship between the four age-at-first-offense quartiles and outcome ($rho = -1.0$, $p < 0.05$). In the lower half, there is no clear, consistent relationship between the age-at-release quartiles and recidivism; the overall association is much smaller and not significant. Because the two age variables remain correlated, the apparent incremental predictive power of the age at release quartiles shown in Table 6 remains an overestimate. Nevertheless, the point is obvious: in this sample, once one knows age at first offense, little or no *additional* predictive information is afforded by knowing age at release (while the converse cannot be concluded).

More importantly, in the context of this chapter, studies by us (Harris & Rice, 2007b) and others (Barbaree et al., 2007; Barbaree, Langton, Blanchard, & Cantor, 2009; Knight & Thornton, 2007) suggest that the addition of age at

Table 6 Probability of violent recidivism as a function of quartiles for two age variables

Quartiles for age at first offense															
First (youngest)				Second				Third				Fourth (oldest)			
0.56				0.36				0.35				0.19			
				Quartiles for				Age at Release							
1	2	3	4	1	2	3	4	1	2	3	4	1	2	3	4
0.63	0.55	0.80	0.18	0.37	0.67	0.21	0.25	0.25	0.42	0.43	0.30	0.13	0.24	0.19	0.16

release to SORAG scores affords no additional predictive value over SORAG scores alone. In addition, we reported above that when the base rates of recidivism were equalized for opportunity in 14 samples from Table 2, the mean SORAG score was strongly associated with the sample base rate, $r=0.59$, $p<0.05$. As might be expected, there was a small inverse association between mean sample age at release and sample base rate, $r=-0.19$, *ns*, but mean age at release afforded no significant incremental value in accounting for sample base rates. Thus, age at release, at both the individual and aggregate levels, appears to add little to the prediction of recidivism after the items of the SORAG are known (Harris & Rice, 2007b, Barbaree et al., 2007, 2009). Knight and Thornton (2007) state, based on their study, "we would not recommend adjusting actuarial risk estimates on the basis of offenders' aging in prison…inmates do not age out of risk, at least until after the age of 60" (p. 85). Statistical and theoretical complaints to the contrary (e.g., Barbaree et al., 2007, 2009) do not and cannot gainsay this empirical result.

Of course, age at release might validly index both enduring antisociality/psychopathy (perhaps through age at first offense) and maturational change. The question is, with respect to risk assessment for sex offenders specifically, which does age at release better reflect? In attempting to answer this question, we replaced age at release with age at first offense in two actuarial risk assessments for sex offenders (Harris & Rice, 2007b). If age at release mostly reflected maturational changes, then such a replacement has to have resulted in a decrease in predictive accuracy (because age at release has to be a better index of maturational change than age at first offense). The result was the opposite; replacing age at release with age at first offense improved predictive accuracy (which, incidentally, was then never improved by the re-introduction of age at release). Certainly, maturational changes occur, but among sex offenders released from secure custody, age at release appears to be a poor index of any risk-relevant maturational changes. For these reasons, we continue to regard it as scientifically unjustified to "correct" actuarial estimates using various post hoc intuitive or statistical procedures (e.g., Barbaree et al., 2009; Donaldson & Wollert, 2006; Wollert, Cramer, Waggoner, Skelton, & Vess, 2009) because such adjustments ignore known cohort-related differences in recidivism risk and are based on the invalid assumption that age at release reflects only hypothetical intra-individual changes.

The SORAG in US Commitment Proceedings

We searched a publicly available archive of legal opinions (leagle.com) for all instances in which the SORAG was mentioned in connection with SVP (or equivalent) determinations. This search yielded a total of 54 distinct documents from 12 states written between 2000 and 2011 in which the SORAG was mentioned. The party presenting testimony based on the SORAG usually prevailed, but not always. Sometimes, the most central legal issue was something other than risk of recidivism (e.g., effective representation, due process, etc.). In no instance we could find, however, was the SORAG declared inadmissible, rejected, or even criticized on grounds that it "only predicts interpersonal violence," or the like. The single exception was a 2008 case in Hawaii of a man whose only convictions were for indecent exposure and possession and distribution of pornography. The court opined that his lack of any violent history made the SORAG not applicable, a decision we support. Thus, consistent with the data on actuarial risk assessment tools in general (Monahan, 2006), the courts, even when executing U.S. statutes pertaining to SVP designation, seem receptive to the use of the SORAG. Some clinicians, attorneys, and courts might not make use of the SORAG due to the notion that its outcome is over-inclusive (overestimates sexually motivated violent reoffending). As discussed at length earlier, our considered judgment is that this belief is mistaken. It would appear that courts are willing to consider SORAG scores presented in evidence.

Limitations, Conclusions, and Future Directions

Compared to tools such as the RRASOR or the Static-99, the SORAG requires more time and more training to score (largely because it contains the PCL-R). The SORAG was developed exclusively on male offenders and there are no data to support (or refute) its use for female offenders. Existing data also suggest it is equally valid for young offenders as for older offenders, although data are only available for offenders over the age of 18 at the time of release. These are obvious directions for future research.

A statistical argument against the SORAG (or any actuarial tool) can be paraphrased as, "We can accurately predict the recidivism of a group of sex offenders defined by their obtaining the same score on the SORAG, but that tells us nothing about what any one of them will do." (Hart, Michie, & Cooke, 2007). Elsewhere, we and others have addressed the conceptual and statistical errors upon which this complaint was based (Grove & Meehl, 1996; Hanson & Howard, 2010; Harris, Rice, & Quinsey, 2007, 2008; Mossman & Sellke, 2007; Skeem & Monahan, 2011). Briefly, the complaint foundered on invalid use of a statistical approximation, inappropriate conflation of test reliability and validity, misunderstanding the technical nature of the outcome, and confusion about the meaning of "risk."

Actuarial (and mechanical) methods are not as widely used by psychologists as the evidence suggests they ought to

be (Hilton & Simmons, 2001; McKee, Harris, & Rice, 2007; Vrieze & Grove, 2009; see also Elbogen, Huss, Tomkins, & Scalora, 2005; Elbogen, Tomkins, Pothuloori, & Scalora, 2003). Some clinicians appear to simply reject actuarial methods outright, while others mistakenly believe, based on fallacious professional advice (e.g., Hart & Boer, 2010), that the intuitive combination of actuarial scores and clinical judgment is something other than clinical judgment:

[C]linical integration of MC [i.e., mechanical combination] with other information is a subtype of clinical combination. This mistake involves confusion on a critical point stated earlier, to wit: it is not the type of data combined but the way in which they are combined that matters in the clinical-mechanical prediction controversy. The clinical integration of MC and other information is a clinical combination in which the MC output, be it an MMPI profile, the outcome of Burgess's (1925) checklist, or any other MC output, has been given to the clinician and somehow combined "in their head" with other clinical impressions to arrive at a final prediction. It is this subjective, clinical combination that is important, not the MC output antecedent to the final clinical integration (Vrieze & Grove, 2009, p. 530).

Simply put, the fundamental problem appears to be empirical and professional ignorance; Vrieze and Grove (2009) documented several factual errors in their respondents' reasons for failing to rely on actuarial methods. As well, the best single predictor of use was whether such methods were discussed during graduate training (Vrieze & Grove, 2009). Such problems in evidence-based clinical training have led to renewed calls for science-based accreditation for graduate training in clinical psychology (Baker, McFall, & Shoham, 2009).

We also suggest that actuarial methods sometimes fail to garner support from clinicians for additional reasons. For example, reliance on clinical judgment allows users to bend to powerful but empirically irrelevant implicit interpersonal personal values and prejudices (probably not deliberately) such as granting release to attractive assessees (e.g., Hilton & Simmons, 2001). In addition, the predictive utility of some actuarial items and, more to the point, the lack of incremental predictive validity for others (e.g., assignment to therapy, low self-esteem, loneliness, childhood abuse) (Hanson & Morton-Bourgon, 2005) clearly imply that some practitioners' private explanations for sexual offending must be incorrect (or at least very incomplete). An actuarial tool such as the SORAG is not a "theory" of sexual aggression, but its replicated accuracy in predicting recidivism means that it is consilient with the correct explanation. Thus, substance abuse, sexual deviance, and psychopathy could be general causes of sexual aggression while loneliness (as currently conceived) could not be.

The predictive value of measures of psychopathy has some special practical and theoretical implications. From a practical perspective, it is likely that even actuarial assessments that fail to incorporate psychopathy will be suboptimal, leaving developers in the odd (and empirically unsupported) position of recommending the post-actuarial application of some form of clinical judgment in order to account for missing but relevant characteristics (e.g., Thornton, Hanson, & Helmus, 2010). From a theoretical perspective, these findings imply that psychopathy is an important cause of sexual offending. But how does psychopathy, a substantially heritable neurophysiologically based phenomenon (Lalumière, Mishra, & Harris, 2008; Rice & Harris, 2013a), cause the various kinds of sexual offending behavior? Clearly, psychopathy can be regarded as an enduring psychological predilection that, independent of such specific aspects of sexuality as pedophilia, increases many forms of antisocial conduct (Lalumière, Harris, Quinsey, & Rice, 2005). These considerations raise the question as to whether psychopathy is best conceptualized as a set of affective and emotional personality traits or whether it is best conceived of as a suite of behavioral tactics (including early-starting sexual coercion) that comprise a life history strategy (Rice & Harris, 2013a; Barr & Quinsey, 2004). In fact, both are simultaneous possibilities, the former explicating proximal mechanisms, while the latter provides ultimate explanation (Lalumière et al., 2008). Regarding proximate explanation, however, it remains unclear as to the scientific value of attributing psychopathy to an underlying personality as opposed to more direct attribution to neurophysiology and neuroanatomy.

In conclusion, we regard the SORAG as the formal risk tool of choice for the prediction of violent (including hands-on sexual) recidivism for adult sex offenders considered in secure custody. Its established high reliability, known replicated effect sizes, comprehensiveness, complete manualization, and detailed information about application make it the optimal method for making decisions about the long-term risk of recidivism among sex offenders. We also regard rap-sheet violent recidivism as the outcome closest to subsequent sexually violent behavior as specified in U.S. civil commitment laws for sex offenders. Furthermore, users are not instructed that there are additional unspecified considerations to be included, and there is evidence that the SORAG is not improved by the addition of alternative actuarial assessment information (Seto, 2005). We expect that the SORAG will eventually be improved or replaced and we are evaluating some ways of accomplishing that, such as better phallometric measurement, improved assessment of psychopathy, and the incorporation of statistical interactions in actuarial scoring. As well, we predict that functional brain imaging represents the best long-term prospect for eventually increasing the accuracy of actuarial sex offender risk assessment.

The Minnesota Sex Offender Screening Tool-3.1 (MnSOST-3.1)

Grant Duwe and Pamela Freske

Introduction

More than 20 years ago, Epperson and colleagues began to work on developing the Minnesota Sex Offender Screening Tool (MnSOST) (Epperson, Kaul, Huot, Goldman, & Alexander, 2003). In 1996, they initiated efforts to revise the MnSOST, eventually resulting in the Minnesota Sex Offender Screening Tool-Revised (MnSOST-R). Most recently, we updated the MnSOST-R by developing the MnSOST-3 (Duwe & Freske, 2012).

The MnSOST-3 is different in a number of ways from its MnSOST predecessors. The MnSOST-R, for example, was developed on a sample of 256 sex offenders released from Minnesota prisons during the late 1980s and early 1990s. Using sex offense rearrest within 6 years as the outcome measure, Epperson et al. (2003) employed a modified Nuffield (1982) weighting scheme by first cross-tabulating potential individual items with recidivism rates and then comparing those rates with the baseline rate. Weights were assigned to items based on the magnitude of difference between the recidivism rates for individual items and the baseline rate. Individual items were retained in the MnSOST-R if: (a) the assigned value was different from 0, (b) the item was consistent with existing theory and/or practice, (c) the association with sexual recidivism was $p < 0.10$, and (d) the items significantly improved the prediction of sexual reoffending in a hierarchical logistic regression model at the $p \leq 0.20$ level (Epperson et al., 2003). Altogether, the MnSOST-R contains 16 items and is scored in a pencil-and-paper format, with scores ranging from a low of −12 to a high of 31.

In developing the MnSOST-3, we used a sample of 2,535 sex offenders released from Minnesota prisons. The 2,535 offenders were drawn from two separate samples: the MnSOST-R cross-validation sample and a contemporary sample of released sex offenders. The MnSOST-R cross-validation sample contained 220 offenders released from Minnesota prisons during the early 1990s, whereas the contemporary sample included 2,315 sex offenders released from Minnesota prisons between 2003 and 2006. Using sex offense reconviction within 4 years as the outcome measure, we relied on multiple logistic regression to create the instrument. Moreover, we employed bootstrap resampling to not only select items to be included in the instrument but also to internally validate the model. The MnSOST-3 contains 11 predictors—nine main effects and two interaction effects. Of the nine main effects, only three were items derived from the MnSOST-R (public place, completion of chemical dependency and sex offender treatment, and age at release).

The MnSOST-3, which is scored in a Microsoft Excel application, provides several measures of sexual recidivism risk. The MnSOST-3 value an offender receives represents his predicted probability of sexual recidivism within 4 years, which varies from a low of 0 % to a high of 100 %. To provide a range in which the true risk of sexual recidivism likely falls, we calculated 95 % confidence intervals (CIs) around MnSOST-3 estimates. While the MnSOST-3 value and the accompanying 95 % CIs offer measures of absolute sexual recidivism risk, we also included percentile ranking to provide a measure of relative risk.

To illustrate, an offender with a MnSOST-3 value (i.e., predicted probability) of 10 % would fall into the 92nd percentile. Moreover, this offender would have a lower CI of 5 % and an upper CI of 16 %. Therefore, the MnSOST-3 output for this offender suggests that his likelihood of reconviction for a new sex offense within 4 years is 10 %. The CIs, meanwhile, imply that we can be 95 % confident that his true likelihood for a new sex crime reconviction falls between 5 and 16 %, and the percentile ranking indicates that only 8 %

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_22

of the Minnesota sex offenders we examined had a MnSOST-3 value higher than 10 %.

After we completed the development of the MnSOST-3, the Minnesota Department of Corrections (MnDOC) began using it in place of the MnSOST-R in early January 2012. By the end of January 2012, the MnDOC's Risk Assessment and Community Notification (RACN) Unit had scored more than 200 cases on the MnSOST-3. Upon reviewing these cases, we identified several potential issues with the MnSOST-3, particularly involving the two interaction terms in the model.

First, in the MnSOST-3, both the effects of violations of orders for protection (VOFPs) and recent disorderly conduct convictions on sexual recidivism risk vary according to the age of the offender at the time of release. Whereas VOFPs increase the risk for younger offenders, they decrease the risk for older offenders. Conversely, recent disorderly conduct convictions increase the risk for older offenders, while they decrease the risk for younger offenders. The interaction effects may appear counterintuitive because VOFP and disorderly conduct convictions decrease an offender's risk in some instances. Moreover, given that the VOFP and disorderly conduct convictions are relatively new findings in the sex offender literature, prior research offers little guidance.

Second, although VOFPs and disorderly conduct convictions will reduce the MnSOST-3 score for certain offenders, it does not necessarily mean that these offenders would pose less of a risk for violent recidivism. We are currently analyzing additional data related to the ability to assess risk for different types of recidivism, including nonsexual violence, nonsexual, felony, and first-time sexual offending. Preliminary findings from these analyses suggest that VOFPs and disorderly conduct convictions increase the risk of nonsexual violent recidivism. This finding suggests the possibility that the risk for sexual recidivism may drop because the risk for other types of recidivism (nonsexual violence) increases. For example, the increased likelihood for nonsexual violent recidivism may shorten the at-risk period for sexual recidivism, especially if that recidivism leads to reincarceration (resulting in a more limited opportunity to sexually reoffend).

Finally, we observed that approximately 20 % of the offenders had a prior VOFP among the cases scored by the RACN Unit, which is more than three times the percentage observed (6 %) in the MnSOST-3 development sample. Given the lack of certainty in explaining the VOFP-age interaction, the higher percentage of offenders with VOFP convictions raised concerns regarding this item's interaction with age at release. Therefore, in an effort to produce an instrument that is simpler and easier to interpret, we assessed the model's performance without the two interaction terms. As shown later, removing the two interaction terms did not have a detrimental effect on predictive validity. As a result, in February 2012 the MnDOC began using the main effects-only model—the MnSOST-3.1

Present Study

In this study, we update our work on the MnSOST-3 by presenting findings from the development of the MnSOST-3.1. The development of the MnSOST-3.1 is, of course, similar to that of the MnSOST-3, and our discussion of the MnSOST-3.1's development will likely be familiar to those who have reviewed our work on the MnSOST-3 (Duwe and Freske, 2012). Where relevant, however, we will identify the ways in which the MnSOST-3.1 differs from the MnSOST-3. In addition to presenting the MnSOST-3.1 results, we also include those from the MnSOST-3 for purposes of comparison. Our concluding remarks will focus mainly on practical use of the instrument.

MnSOST-3 and MnSOST-3.1 Sample

As noted above, we examined 2,535 sex offenders who were drawn from two separate samples: the MnSOST-R cross-validation sample and a contemporary sample of released sex offenders. Included among the 2,535 sex offenders were 99 offenders whose only sex offense conviction(s) occurred as a juvenile, 53 "intrafamilial fondlers" (a group of incest-only offenders whose only sex offenses consisted exclusively of non-penetration sexual contact for whom the MnSOST-R has had limited predictive accuracy), and 12 offenders whose only sex-related offense(s) involved possession of child pornography. We included these groups of offenders in the development sample because they have at least one prior sex or sex-related offense, which triggers the need to assess their risk for sexual recidivism, as evidenced by the fact that MnSOST-R assessments were administered to these offenders while they were in prison.

The MnSOST-R cross-validation sample contains 220 offenders released from Minnesota prisons during the early 1990s, whereas the contemporary sample includes 2,315 sex offenders released from Minnesota prisons between 2003 and 2006. During this 4-year period, there were 134 sex offenders who were released from prison but were not at risk to reoffend because they were civilly committed. Due to the absence of an at-risk period, we excluded the 134 civilly committed offenders. Yet, as discussed later, we completed assessments from both versions of the MnSOST-3 on these offenders to further assess the validity of the instrument.

We used the contemporary and MnSOST-R cross-validation samples to develop both versions of the MnSOST-3 for a few reasons. First, due to the recent decline in sexual recidivism rates and to concerns raised about the inflated baseline rate for the MnSOST-R development sample (Vrieze & Grove, 2008; Wollert, 2002), it was necessary to select a group of sex offenders who had recently been released from prison. Second, as noted above, the MnSOST-R development

and cross-validation samples contained sex offenders released from Minnesota prisons during the late 1980s and early 1990s. Since that time, however, sex offenders released from Minnesota prisons have been more likely to be civilly committed, subjected to broad community notification, intensively supervised, have their parole revoked for a technical violation, and incarcerated for longer periods of time. The growing use of these external constraints has likely been responsible, at least to some extent, for the declining sexual recidivism rates observed in Minnesota since the early 1990s (Minnesota Department of Corrections, 2007). To ensure that both versions of the MnSOST-3 predict sexual recidivism risk without constraints as accurately as the MnSOST-R, it was also necessary to include the MnSOST-R cross-validation sample. Although data were available on the sample used to develop the MnSOST-R, we did not use this sample to develop either version of the MnSOST-3 because it oversampled for recidivists. As shown later, however, we use the MnSOST-R development sample to help cross-check the predictive validity of the MnSOST-3.1.

All 2,535 sex offenders in this study were scored at least once on the MnSOST-R. In some instances, offenders received more than one MnSOST-R assessment during the same sentence. For the offenders in the contemporary sample who had more than one MnSOST-R assessment during their confinement, we selected the most recent score prior to their release date. Minnesota prisoners receive a MnSOST-R assessment if they have at least one sex offense in their history for which documentation is available. Of the 2,535 offenders, 67 % were incarcerated for a sex offense while the remaining 33 % had a nonsexual index offense.

MnSOST-3 and MnSOST-3.1 Items

To recalibrate the weights assigned to the 16 items on the MnSOST-R, we created binary measures for the dichotomous items (e.g., under any form of supervision, sex offense committed in a public place, force used, multiple acts, offended against a 13- to 15-year-old victim). For example, on the MnSOST-R, offenders who have committed a sex offense in a public location are given a value of "2," whereas those who have not committed a sex offense in public are assigned a value of "0." We modified the scoring of these items in the multiple logistic regression analyses by giving them values of either "0" or "1." For the categorical measures on the MnSOST-R (e.g., length of sexual offending history, different age groups, stranger victims, adolescent antisocial behavior, pattern of recent alcohol or drug abuse, employment history, chemical dependency treatment, and sex offender treatment), we transformed these into dichotomous dummy variables. For example, on the MnSOST-R, offenders whose history of sexual offending is less than 1 year receive a value of "−1," and offenders with a history between one and 6 years are given a value of "3," while those with a history in excess of 6 years are assigned a value of "0." For the multiple logistic regression analyses, the following three variables were created for length of sexual offending history: less than 1 year (Yes = 1; No = 0), 1–6 years (Yes = 1; No = 0), and more than 6 years (Yes = 1; No = 0). Less than 1 year was the reference in the statistical analysis. Finally, we transformed three of the MnSOST-R items—number of sex offenses, discipline convictions, and age at release—into continuous variables.

To identify whether there are, in addition to the 16 MnSOST-R items, other factors predictive of sexual recidivism, we gathered all of the data collected by the MnDOC and maintained in COMS on the 2,535 offenders. The data included information relating to demographics, prior criminal history (e.g., total number of convictions, age at first conviction, type of offense, etc.), educational level (e.g., presence or absence of high school degree or general equivalency diploma at admission and release from prison), institutional misconduct (e.g., whether the offender received any disciplinary sanctions, the total number of disciplinary convictions, the type of institutional misconduct, etc.), gang membership (i.e., security threat group), involvement in institutional programming (e.g., anger management classes, critical thinking courses, etc.), prison visitation (e.g., whether offenders were visited in prison, the number of times they were visited in prison, number of prison visits divided by length of stay, etc.), length of stay in prison during the most recent incarceration period prior to release, total prison time served during the current sentence, type of offense (e.g., sex offense, assault, robbery, failure to register as a predatory offender, etc.), type of prison admission (e.g., new court commitment, probation violator, and supervised release violator), and whether they were released to supervision and, if so, what type of supervision (e.g., regular supervision and intensive supervised release) (a full list of the variables used can be obtained from the authors upon request). To facilitate valid and reliable scoring of both versions of the MnSOST-3, we focused on identifying items that significantly predicted sexual recidivism, were consistent with existing theory and/or research, and were relatively objective measures that are consistently available in COMS.

A difference between MnSOST-3 and MnSOST-3.1 items is that, in order to avoid inflated risk estimates resulting from extreme values among the five continuous items on the instrument, the values for some items on the MnSOST-3.1 are capped based on the highest value observed in the MnSOST-3/MnSOST-3.1 development sample. Therefore, the largest value an offender can receive for the sentences with male victim item is four. Predatory offense sentences are capped at 25, felony offense sentences as 20, VOFP convictions at 5, and recent disorderly conduct convictions at 2.

Measuring Sexual Recidivism

We collected sex offense reconviction data on the 2,535 sex offenders through the end of December 31, 2010. For the offenders in the contemporary sample released toward the end of 2006, 4 years was the maximum follow-up period. Because logistic regression assumes that each offender has the same amount of time in which to reoffend, we limited the follow-up period to 4 years for all 2,535 offenders in this study.

We defined sexual recidivism as a reconviction for a new sex crime within 4 years of release. In operationalizing sex crimes, we included only hands-on sex offenses. In doing so, we excluded noncontact, sex-related offenses such as possession of child pornography or indecent exposure. We used reconviction as the recidivism measure because it reduces the likelihood of including false positives (i.e., cases that are not truly instances of sexual recidivism). Although rearrest is arguably a more sensitive measure of recidivism and, thus, increases the chances of identifying more true positives (i.e., actual sex reoffenses), it also increases the odds of including more false positives. In addition, information on the date(s) when the reoffense occurred was seldom available in the rearrest data but was consistently present in the conviction data. Offense date information was necessary to exclude cases of "pseudo-recidivism," as there were a handful of offenders who returned to prison for a "new" sex offense that had been committed prior to the beginning of their previous prison term, e.g., an offender who was incarcerated from 2002 to 2005 is reconvicted in 2008 for an offense committed in 1998. In these instances, we did not consider the reconviction to be a recidivism event.

We obtained reconviction data from both the Minnesota Bureau of Criminal Apprehension (BCA) and the Federal Bureau of Investigation (FBI). Whereas the BCA data include only convictions that occur in Minnesota, the FBI criminal history data contain information on convictions that took place outside Minnesota. As with any recidivism study, official criminal history data will likely underestimate the actual extent to which the sex offenders examined here recidivated.

The recidivism data revealed that 102 (4.0 %) of the 2,535 offenders had been reconvicted of a new sex offense within 4 years of their release from prison. The 4-year sexual reconviction rate was 12.3 % in the MnSOST-R validation sample and 3.3 % in the contemporary sample.

Developing the MnSOST-3 and MnSOST-3.1

Existing research has identified three types of validity important for predictive regression modeling: apparent, internal, and external (Harrell, Lee, & Marks, 1996). Apparent validity refers to performance on the sample used to develop the prediction model. In examining the performance of the model on the population underlying the sample, internal validity is concerned with whether the model can be reproduced. External validity, meanwhile, focuses on the generalizability of the model by looking at how well it performs on a related, but slightly different, population. Applied to the present study, apparent validity addresses the performance of the MnSOST-3 on the sample used to develop it. While internal validity tells us how well the MnSOST-3 would likely perform on other samples of Minnesota sex offenders, external validity would assess MnSOST-3 performance on non-Minnesota sex offender populations. In this study, we focus on apparent and internal validity.

To assess apparent validity, statistics such as ROC curves may be estimated on the development sample to determine the predictive accuracy of the model. As for internal validity, three main methods have been developed to determine the reproducibility of a prediction model. The split-population, or data splitting, method has been the most popular approach in the development of sexual recidivism risk assessment tools. With this method, a portion (e.g., one-half or two-thirds) of the sample is used to develop the prediction model. The developed model is then applied to the remaining portion in order to test the internal validity of the model. Despite its popularity, this approach wastes data (Harrell et al., 1996).

Cross-validation, or k-fold validation, is more efficient than the split-population approach because it involves repeated data splitting. Research has demonstrated, however, that bootstrap resampling is the most efficient internal validation technique (Steyerberg et al., 2001; Steyerberg, Bleeker, Moll, Grobbee, & Moons, 2003). Developed by Efron (1979), bootstrap resampling involves pulling many smaller samples from the overall sample in order to generate estimates of error. In doing so, it makes full use of the data set for developing and validating models while also providing error estimates that have relatively low variability and minimal bias (Harrell, 2001; Steyerberg et al., 2001). As discussed shortly, we used bootstrap resampling to not only refine our selection of items for the MnSOST-3/MnSOST-3.1 but also to calculate estimates of optimism due to overfitting for both versions of the MnSOST-3.

Selection of Predictors

Stepwise variable selection procedures are frequently used in the development of prediction models. Although there are a variety of stepwise methods available, the two main approaches are forward selection and backward selection. Under forward selection, a variable does not enter the model unless it is statistically significant at a predetermined level

Table 1 Multiple logistic regression model for MnSOST-3.1

	MnSOST-3.1		MnSOST-3	
Predictors	*B*	*p*	*B*	*p*
Predatory offenses	0.289	0.001	0.292	0.001
Male victims	0.905	0.000	0.874	0.000
Public place	0.653	0.009	0.747	0.003
Felony offenses	0.126	0.000	0.129	0.000
VOFP/stalking/harassment	0.436	0.009	3.271	0.001
Disorderly conduct (last 3 years)	0.936	0.000	−1.742	0.057
Complete SO/CD treatment	−1.491	0.017	−1.557	0.013
Age at release (years)	−0.044	0.000	−0.044	0.001
Unsupervised release	1.726	0.000	1.783	0.000
VOFP X age			−0.099	0.010
Recent disorderly conduct X age			0.074	0.008
Constant	−3.254	0.000	−3.247	0.000
N	2,535		2,535	
Log-likelihood	699.107		686.075	
Nagelkerke R^2	0.209		0.225	

(e.g., alpha = 0.05). With backward selection, a variable is removed from the model if its level of statistical significance exceeds the established alpha level. Stepwise routines have been criticized on a number of grounds, especially for producing biased regression coefficients (Tibshirani, 1996) and for capitalizing on chance features of the data (Judd, McClelland, & Ryan, 2008). Still, because backward selection is generally preferable to forward selection (Harrell et al., 1996), it is the approach we used here.

We conducted multiple logistic regression analyses on the offenders in the development sample to identify significant predictors of sexual recidivism. In addition to including the 16 items from the MnSOST-R, we examined a host of variables derived from COMS data. Using an alpha of 0.10, we examined more than 100 potential predictors. Following Efron and Gong (1983), we added predictors one at a time until no further single addition achieved the significance level a = 0.10. The main effects model showed there were 10 predictors that had a significant effect ($p < 0.10$) on sexual recidivism (see "main effects" model Table 1). Among the 10 significant predictors, there were 45 possible two-way interaction effects for which we tested. Using an alpha of 0.05, we found six interaction effects that were statistically significant.

In an effort to develop a more parsimonious prediction model, we used bootstrap resampling to refine the selection of predictors included in the MnSOST-3/MnSOST-3.1. More specifically, we retained only the predictors that were consistently significant in the bootstrap samples. Although the bootstrap variable selection method has been discussed in the literature (Efron & Gong, 1983), there is no widely accepted "rule-of-thumb" threshold for retaining or removing predictors. Zhao (1998) recommended using at least a 40 % cutoff (i.e., predictors are retained in at least 40 % of the bootstrap samples), whereas Cooke and colleagues (2009) used a 60 % threshold. Here we used a relatively high threshold (70 %) to determine whether predictors should be included in the model.

After estimating 1,000 bootstrap samples from our 16-predictor model, there were five predictors (one main effect and four interaction terms) that were statistically significant at the 0.05 level in less than 70 % of the samples. After removing these five predictors, we estimated another 1,000 bootstrap samples. The results showed that 11 predictors (nine main effects and two interaction effects) were statistically significant at the 0.05 level in at least 70 % of the bootstrap samples. For the MnSOST-3.1, we removed the two interaction terms, which left nine main effects in the model. The results for the main effects model are presented in Table 1.

Discussion of Multiple Logistic Regression Results

Of the nine main effects in the model, three are items derived from the MnSOST-R (public place, completion of chemical dependency and sex offender treatment, and age at release). Although the predatory offense sentences item is somewhat similar to the number of sex/sex-related convictions item on the MnSOST-R, it is arguably a much broader measure of sexual offending history. Moreover, even among the three items derived directly from the MnSOST-R, it is worth noting that they are measured differently for both versions of the MnSOST-3. For example, public place is a dichotomous measure (as opposed to a categorical item), and completion

of both chemical dependency and sex offender treatment is a dichotomous measure that merges these two categorical items on the MnSOST-R, while age at release is a continuous, rather than a dichotomous, measure. Although a visual inspection of the residuals did not reveal any signs of nonlinearity for either age at release or number of predatory offenses, we tested for nonlinearity by estimating a model with a logarithmic transformation of both predictors. Neither coefficient, however, was statistically significant at the 0.10 level, which suggests that recidivism or, more specifically, the logit of the recidivism measure used here is linearly related to age at release and number of predatory offenses.

The results presented in Table 1 are generally consistent with existing research. We found, for example, that the risk of sexual recidivism was significantly less for offenders who completed both chemical dependency and sex offender treatment in prison, a finding that dovetails with prior research on offenders from Minnesota (Duwe, 2010; Duwe and Goldman, 2009) and in general (Lösel & Schmucker, 2005; Mitchell, Wilson, & MacKenzie, 2007). Similar to prior research on sex offenders (Hanson & Morton-Bourgon, 2004) and, more narrowly, those from Minnesota (Epperson et al., 2003), the risk was significantly greater for younger sex offenders and those with more prior predatory offenses, more predatory offenses that involved male victims, and a history of committing a sex-related offense in a public location.

The number of felony sentences of a sex offender had significantly increased the odds of reoffending sexually. We also found that the risk of sexual recidivism was significantly greater for offenders with convictions for violations of orders for protection (VOFP), stalking, or harassment. In addition to measuring impulsivity, this measure may tap into rule noncompliance and intimacy deficits, which have been found to be salient predictors in previous research (Hanson & Morton-Bourgon, 2004). The results showed that offenders with disorderly conduct convictions in the 3 years preceding their commitment to prison had a significantly elevated risk of recidivism.

We found that offenders who were released to no supervision (because their sentence had expired) were significantly more likely to reoffend sexually than those who were released to some form of post-prison supervision. Offenders were typically released to no supervision if they had multiple stays in prison as a release violator or had accumulated substantial extended incarceration disciplinary time stemming from institutional misconduct or failure to complete a sex offender treatment directive. The finding regarding the absence of post-release supervision is consistent with recent research on offenders in general, which has shown that prisoners who "max out" are significantly more likely to reoffend (Ostermann, 2009; Schlager & Robbins, 2008). Moreover, in their validation study of the MnSOST-R and Static-99, Boccaccini, Murrie, Caperton, and Hawes (2009) found that the risk of sexual recidivism was significantly greater for sex offenders who were discharged (i.e., released to no supervision).

Assessing Predictive Accuracy

The validity, or accuracy, of a prediction model is often assessed by examining its predictive discrimination and calibration (Harrell et al., 1996; Steyerberg, 2009). With the MnSOST-3.1, predictive discrimination looks at how well it separates recidivists from non-recidivists. Calibration, on the other hand, examines the extent to which there is agreement between the predicted probabilities of recidivism and the actual rates of reoffending. In light of the recent decline in sexual recidivism, one of the concerns raised about tools such as the MnSOST-R is that, despite having good predictive discrimination, it overestimates the risk of sexual recidivism (Wollert, 2006). With a well-calibrated model, however, the predicted probabilities closely correspond with the observed recidivism rates. In the ensuing sections, we examine predictive discrimination of the MnSOST-3.1 before moving on to an assessment of its calibration with actual rates of sexual recidivism.

Predictive Discrimination

We first analyzed the apparent predictive discrimination for the MnSOST-3.1 by estimating a ROC curve for the predicted probabilities derived from the main effects model shown in Table 1. The apparent AUC value for the main effects model is 0.818, which is slightly lower than the apparent AUC obtained for the MnSOST-3 interaction model (0.821). To determine the extent to which this value overestimates predictive discrimination due to overfitting, we estimated an optimism value based on the method described by Efron and Tibshirani (1993).

First, as shown above, we obtained an upwardly biased (i.e., overly optimistic) AUC estimate of apparent predictive discrimination based on the full sex offender sample (N=2,535) examined here. Second, we drew a bootstrap sample from the full offender sample and then obtained maximum likelihood estimates of beta weights based on the bootstrap sample. Third, we calculated an AUC value for that bootstrap sample. Fourth, we applied the beta weights developed from the bootstrap model to the full offender sample and obtained AUC values for these results. Fifth, we generated optimism estimates by calculating the differences in AUC values obtained during the third and fourth steps. Sixth, we repeated steps two through five 200 times, keeping track of the differences obtained at each iteration. Seventh, we used the average of the 200 differences generated during step

six as our "bootstrap estimate" of optimism for each model. Finally, we calculated an optimism-corrected AUC estimate by subtracting the optimism average obtained during the seventh step from the apparent AUC value produced during the first step.

The optimism value for the main effects model (MnSOST-3.1) was 0.022, which is slightly lower than that observed for the MnSOST-3 interaction model (0.025). As a result, the optimism-corrected AUC values are 0.796 for both the interaction (MnSOST-3) and main effects (MnSOST-3.1) models. The results suggest that removing the interaction terms produced a more stable model. The optimism-corrected AUC value of 0.796 for the MnSOST-3.1 provides an unbiased estimate that adjusts for overfitting. It may also represent an upper-level estimate as to what may be expected in validation studies on non-Minnesota sex offenders.

In examining the predictive discrimination of the MnSOST-3.1, it is worth comparing its performance not only among several different samples but also with the MnSOST-R. For the offenders released from prison between 2003 and 2006 (contemporary sample), the AUC was 0.824 compared to 0.550 for the MnSOST-R. For the cross-validation sample, the MnSOST-3.1 had an AUC value of 0.789 in comparison to 0.758 for the MnSOST-R. As noted by Epperson et al. (2003), the MnSOST-R development sample contained 256 sex offenders released from prison during the late 1980s and early 1990s. Yet, because the data needed to fully score the MnSOST-3.1 were unavailable for 13 offenders in the MnSOST-R development sample, we limited our analyses to the remaining 243 offenders. The AUC value for the MnSOST-R was 0.758 compared to 0.749 for the MnSOST-3.1, a difference that was not statistically significant ($p=0.817$) using the DeLong, DeLong, and Clarke-Pearson (1988) method for ROC curve comparison. The AUC values for the MnSOST-R development and cross-validation samples are not the same as those reported by Epperson and colleagues (2003) due to the different definitions of sexual recidivism we used here; i.e., Epperson et al. (2003) defined sexual recidivism as a new sex offense rearrest within 6 years. Overall, the findings suggest that while the MnSOST-3.1 has higher predictive accuracy for offenders recently released from prison who are subject to significant external constraints, it does not perform significantly worse than the MnSOST-R for offenders released from prison more than 20 years ago who were exposed to relatively few external constraints.

In Table 2, we take a closer look at the predictive discrimination of the MnSOST-3.1 on the MnSOST-R development sample. Epperson and colleagues (2003) distinguished the offenders in the MnSOST-R development sample on the basis of whether they were rapists or molesters. Of the 243 offenders from the MnSOST-R development sample who were examined in this study, 140 had been classified as rapists and the other 103 as molesters. The AUC values for the MnSOST-3.1 were lower for rapists (0.726) but higher for child molesters (0.781).

In Table 3, we present additional performance measures for the MnSOST-3.1. We see that the top one percent of offenders had a MnSOST-3.1 value of 40 % or higher. In other words, only 25 of the 2,535 offenders (i.e., the top one percent) had a predicted probability of sexual recidivism (within 4 years) of 40 % or higher. The top five percent had a value of 14 % or higher, the top 10 % had a value of 8 % or higher, and the top 15 % had a value of 5.8 % or higher. Among the 262 offenders with a MnSOST-3.1 value of 8 % or higher (the top 10 %), there were 53 who were recidivists, which amounts to a reconviction rate of 20 %. Considering the sexual recidivism rate was 4 % for the sample, the reconviction rate for the top 10 % is five times greater than the overall rate. For every true positive (i.e., recidivist) identified

Table 2 MnSOST-3.1 and MnSOST-3 predictive discrimination across samples

≥5.5 % (top 15 %)	380	65	17.1	4.3	4.8	63.7
≥2.5 % and <5.5 % (16–40 %)	637	17	2.7	0.7	36.5	9.7
<2.5 % (bottom 59 %)	1,518	20	1.3	0.3	74.9	11.4

at the 8 % cut point, there were nearly four false positives (non-recidivists). Because there were a total of 102 recidivists, the 53 recidivists with MnSOST-3.1 values of 8 % or higher accounted for 52 % (capture rate) of the total recidivists.

As noted earlier, we did not examine 134 sex offenders released from Minnesota prisons between 2003 and 2006 because they were civilly committed. Still, to further test the validity of the MnSOST-3.1, we generated MnSOST-3.1 values for these offenders. The average MnSOST-3.1 value for the 134 civilly committed offenders was 10.1 %, which is 2.5 times higher than the overall average. One of the criteria for civil commitment or sexually violent predator (SVP) decisions is the determination that the offender is either "substantially likely" or "more likely than not" to reoffend sexually, which roughly translates into a probability of 51 % or higher. Only four of the offenders (three percent), however, had a MnSOST-3.1 value greater than 50 %, and only nine (seven percent) had an upper 95 % confidence interval (CI) that exceeded 50 %. Moreover, as noted above, less than one percent of the 2,535 offenders had a MnSOST-3.1 value that exceeded 50 %, which is substantially lower than the rate (seven percent) at which Minnesota sex offenders have been civilly committed over the last few decades. These findings should not be considered too surprising, however, given that a recent report on Minnesota's civil commitment program found that county of commitment, which is unrelated to sexual recidivism risk, was a significant factor in determining whether sex offenders were civilly committed (civil commitment decisions are finalized at the county level in Minnesota) (Minnesota Office of the Legislative Auditor, 2011).

Calibration

In Table 4, we present data on the distribution of MnSOST-3.1 values and the corresponding 95 % CIs. Although the predicted probabilities from a logistic regression model can vary from 0 to 100 %, the MnSOST-3.1 values for the 2,535 offenders ranged from a low of 0 % to a high of 98 %. Only 0.5 % of the sample, or 13 offenders, had a MnSOST-3.1 value of 50 % or higher, whereas a little more than one percent ($N=33$) had an upper CI at or above 50 %. Two percent of the sample had a MnSOST-3.1 value of 25 % or higher, while nearly eight percent had a value of 10 % or higher. Nearly half of the sample (46 %) had a MnSOST-3.1 value below 2 %, while roughly one-fifth (19 %) had a value below 1 %. Overall, 77 % had a value below four percent, which was the sexual recidivism rate observed among the 2,535 sex offenders.

We first assessed the calibration of the MnSOST-3.1 by estimating a Hosmer–Lemeshow test in which MnSOST-3.1 values were regressed on sexual recidivism. The test was statistically significant at the 0.05 level, which suggests that the MnSOST-3.1 is not well calibrated with the observed rates of sexual reoffending in the sample. Yet, because the Hosmer–Lemeshow test is sensitive to sample size, a statistically significant test does not necessarily mean the MnSOST-3.1 model is not well calibrated due to the large sample size used here.

To better understand the results from the Hosmer–Lemeshow test, we present data in Table 5 that compare average MnSOST-3.1 values and observed sexual recidivism rates among the offenders in the sample according to 13 discrete

Table 4 Distribution of MnSOST-3/MnSOST-3.1 values and 95 % confidence intervals

2.0–2.9 %	2.3	2.4	567
1.0–1.9 %	1.2	1.5	640
Less than 1 %	0.6	0.6	521
Total	4.0	4.0	2,535

categories of MnSOST-3.1 values. Given that the average MnSOST-3.1 values are higher than the observed sexual recidivism rates for offenders with a score of 40 % or higher, the results suggest that the MnSOST-3.1 may overestimate risk for the highest-risk offenders.

The calibration patterns depicted in Table 5 are further illustrated in the Lowess plot, which is shown in Fig. 1. Whereas the dotted line represents actual rates of sexual reoffending among the 2,535 sex offenders, the solid line denotes the predicted probabilities (i.e., MnSOST-3.1 values) derived from the logistic regression model. The plot indicates a relatively tight correspondence between actual recidivism rates and predicted probabilities for offenders with MnSOST-3.1 values less than 40 %, which suggests that the MnSOST-3.1 appears to be well calibrated with actual sexual recidivism rates for roughly 99 % of the sample. The two lines begin to diverge, however, when we reach the 40 % mark. Because the solid line is below the dotted line for MnSOST-3.1 values greater than 40 %, the plot indicates that the MnSOST-3.1 overestimates sexual recidivism risk for the top 1 % of offenders in the sample.

We further assessed the calibration by estimating a Brier score, which is a quadratic scoring rule that calculates the squared differences between observed and predicted values. The results indicate a Brier score that was close to zero (0.0339) and a Spiegelhalter's z-score (0.3480) that was not statistically significant (p=0.3639). Therefore, despite the lack of calibration at the top end of the model, the results suggest sufficient overall calibration between predicted and observed outcomes.

Reliability

In our MnSOST-3 study (Duwe and Freske, 2012), we examined the reliability of scoring the instrument by conducting an inter-rater reliability assessment. Given that the nine main effects are the same in both models, the results are identical to those presented in the MnSOST-3 study except

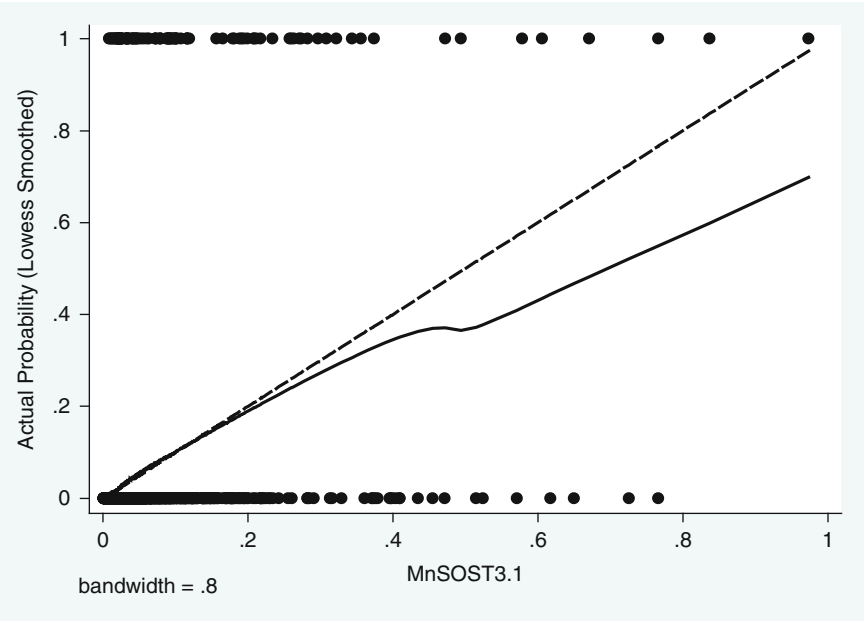

Fig. 1 Lowess plot for MnSOST-3.1 values and observed sexual recidivism

Table 6 MnSOST-3/MnSOST-3.1 inter-rater reliability assessment

	Consistency			Absolute agreement		
MnSOST-3/MnSOST-3.1 items	ICC	Lower bound	Upper bound	ICC	Lower bound	Upper bound
MnSOST-3.1 score	0.810	0.694	0.905	0.811	0.696	0.905
MnSOST-3 score	0.826	0.718	0.914	0.826	0.718	0.914
Predatory offense sentences	0.826	0.718	0.914	0.826	0.718	0.914

Unsupervised release	0.869	0.781	0.936	0.860	0.766	0.932

ICC Intraclass correlation coefficient
All coefficients were statistically significant at the 0.01 level

for the total score. For the inter-rater reliability assessment, we randomly selected 20 sex offenders who were released from Minnesota prisons between January 1 and June 30, 2010, on whom a MnSOST-R had been scored. Following a 4-h training session, eight assessors in the MnDOC's Risk Assessment and Community Notification (RACN) Unit each scored the selected cases on the Microsoft Excel application of the MnSOST-3 over a 5-day period. We created an age at release calculator on the Excel spreadsheet so as to facilitate the valid and reliable scoring of data for this item. The eight raters in this study had, on average, 7 years of experience in scoring sex offender risk assessment instruments. We analyzed the degree of inter-rater reliability among the eight assessors for these 20 cases by estimating intraclass correlation coefficients (ICC) using a two-way random effects model.

The results showed that the singular ICC for the eight raters was 0.810 and 0.811 for consistency and absolute agreement of ratings, respectively, for the 20 cases (see Table 6). These values are slightly lower than the ICC values observed for the MnSOST-3 (0.826 for both consistency and absolute agreement). The item-level data show that ratings were most consistent for age at release, which may be due in part to the creation of a calculator for this item. The ratings were least consistent, however, for VOFP/stalking/harassment sentences. Although most (6) of the items on both versions of

the MnSOST-3 are continuous (as opposed to binary or dichotomous) measures, which presumably increases the margin for error in scoring items, the items on both instruments are largely objective measures. Overall, the findings suggest that both versions of the MnSOST-3 have an adequate degree of reliability.

Discussion

In February 2012, the MnDOC began using the MnSOST-3.1 because, compared to the MnSOST-3, it is simpler, is easier to interpret, and does not have an adverse impact on predictive accuracy. Yet, due to the same optimism-corrected AUC values, both versions of the MnSOST-3 will still be available to the public on the MnDOC website (http://www.doc.state.mn.us/publications/MnSOST3/default.htm). Use of the MnSOST-3.1, however, will result in several modest changes relating to cut scores and scoring the instrument.

In Minnesota, one of the main purposes for using the MnSOST-3.1 is to assess sexual recidivism risk for community notification. Since the inception of the Community Notification Act in 1997, Minnesota has used a tiered risk management system in which the level of community notification is based on the offender's predicted risk of sexual recidivism. Sex offenders with a high predicted risk of sexual recidivism are given the most extensive level (Level 3) of notification (i.e., community meetings held by law enforcement, publication of the offender's photograph and offense description on the Minnesota Department of Corrections' website, etc.), whereas those with lower risk (Levels 1 and 2) are given more limited forms of notification. Because the MnSOST-3.1 is used by end-of-confinement review committees (ECRC) within the MnDOC to determine risk levels for offenders, it anchors Minnesota's tiered risk management system. Yet, because the ECRC considers additional factors that may either increase or decrease the risk of reoffense (e.g., an offender's stated intention to reoffend following release or a debilitating illness or physical condition that mitigates the risk of reoffense), the ECRC may override the risk level suggested by the MnSOST-3.1. As a result, the risk levels implied by either version of the MnSOST-3 are considered presumptive.

Historically, the MnDOC has given Level 3 assignments to approximately 15 % of released sex offenders, Level 2 assignments to about 30 % of offenders, and Level 1 assignments to the remaining 55 %. Cut scores for presumptive risk levels within Minnesota are therefore based on this distribution. Under the MnSOST-3, the cut scores for presumptive risk levels are:

Level 3 = 5.50 % or higher
Level 2 = 2.30–5.49 %
Level 1 = 2.29 % or lower

The 5.5 % MnSOST-3 value was selected as the cut score for a presumptive Level 3 assignment because this threshold represented the 85th percentile. In other words, sex offenders with MnSOST-3 values of 5.5 % or higher constitute the top 15 % with respect to predicted likelihood of sexual recidivism in 4 years. The values of 2.30 and 5.49 % were selected as the cut scores for the presumptive Level 2 assignment range because they represent the 55th and 84th percentiles, respectively. And the value of 2.29 % was the presumptive Level 1 cut score selected because MnSOST-3 values below 2.30 % comprise the bottom 55 % in terms of sexual recidivism risk.

Under the MnSOST-3.1, the Level 1 cut score remains the same, although there is a slight modification for the Level 2 and 3 cut scores. The MnSOST-3.1 cut scores for presumptive risk levels are:

Level 3 = 5.80 % or higher
Level 2 = 2.30–5.79 %
Level 1 = 2.29 % or lower

For offenders without VOFP and/or disorderly conduct convictions, scores from the two versions of the MnSOST-3 will vary only slightly. The major differences in scores for the two instruments will be observed among offenders who have VOFP and/or disorderly conduct convictions. Under the MnSOST-3.1, VOFP and disorderly conduct convictions will increase risk regardless of the offender's age at the time of release.

Even though the MnDOC will be using the MnSOST-3.1, we will continue efforts to better understand the interaction findings from the MnSOST-3 and further assess the impact these interactions have on assessments of risk. In particular, by estimating the impact of items such as VOFP and disorderly conduct convictions on other types of recidivism besides sexual reoffending, we anticipate that work on the global risk assessment tool may help decrease the extent to which the interaction findings appear to be counterintuitive.

We will also be collecting data on offenders who scored on the MnSOST-3.1 to determine what their scores would have been on the MnSOST-3. We expect that analyzing data on a larger number of cases, especially those scored recently, will enable us to more fully comprehend the behavior of the interaction terms in the MnSOST-3, and we plan on sharing the results of these analyses with the broader corrections and forensic communities when they become available.

Although we believe the MnSOST-3.1 offers a modest improvement in several ways over the MnSOST-3, the caveats raised about using the MnSOST-3 on non-Minnesota sex offender populations also apply to the MnSOST-3.1. For example, with either version of the MnSOST-3, we did not attempt to specifically develop a widely applicable instrument. As a result, the relatively high predictive accuracy of

either version of the MnSOST-3 may not generalize to sex offender populations in other jurisdictions. After all, Minnesota is, in several potentially important ways, different from the rest of the United States. Even though Minnesota is, compared to the other 49 states, generally in the middle of the pack for population size and crime rate, it has the second lowest incarceration rate in the nation. Because Minnesota relies more heavily on local sanctions (e.g., jail and community supervision), prison beds are generally reserved for offenders who have committed very serious offenses and/or have lengthy criminal histories. Further, unless offenders receive extended incarceration disciplinary time, prisoners in Minnesota are typically released after serving two-thirds of their sentence. This may make release at expiration of sentence less common in Minnesota relative to some other jurisdictions.

Use of either version of the MnSOST-3 outside of Minnesota may also be limited by the level of data needed to accurately score the instrument. In particular, given that six of the nine items relate, in some form or another, to criminal history (both sexual and nonsexual), access to complete and accurate criminal history data is imperative. The instrument would therefore have diminished value for agencies that have limited access to these data or in jurisdictions where the criminal history data are less than complete. In addition, although we anticipate the items included on the instrument would likely be significant predictors of sexual recidivism for populations of non-Minnesota sex offenders, the weights (i.e., coefficient values) applied to these items are less likely to generalize to other populations.

These limitations notwithstanding the relatively high optimism-corrected AUC for either version of the MnSOST-3 suggest it still may be among the better risk scales even if there is reduction in its predictive accuracy for other sex offender populations. Nevertheless, determining the extent to which the instrument is generalizable to non-Minnesota sex offender populations ultimately depends on the completion of validation studies. Accordingly, we suggest that jurisdictions outside Minnesota consider using either version of the MnSOST-3 alongside externally validated risk assessment instruments (e.g., Static-99/Static-99R, Static-2002/Static-2002R, SORAG, MnSOST-R, etc.) until results from validation studies are available.

Given that our sample contains prisoners whose index offenses included both sexual and nonsexual crimes, the instrument can be used to assess post-release sexual recidivism risk for offenders who have at least one documented sex offense in their history regardless of whether their index offense is a sex crime. The sample also included 53 intrafamilial fondlers, 99 offenders whose only sex offense conviction(s) occurred as a juvenile, and 12 child pornography offenders—a group that has expanded in size over the last decade (Wolak, Finkelhor, & Mitchell, 2011). Due to these relatively small numbers, we recommend exercising a great deal of caution in using the instrument on sex offenders who fall into one of these three groups. Again, we anticipate that external validation studies will help reveal the extent to which the instrument has predictive validity for these groups of offenders.

In an effort to facilitate the completion of validation studies and the use of the instrument in other jurisdictions, we have provided descriptions of how the nine individual items were coded in the Appendix. Moreover, we have prepared a more detailed coding manual and have developed the instrument so that it can be scored in a Microsoft Excel spreadsheet. Both the coding manual and the Microsoft Excel applications of the MnSOST-3 and MnSOST-3.1 can be found at: http://www.doc.state.mn.us/publications/MnSOST3/default.htm.

Appendix

The following lists the nine items on the MnSOST-3.1 and describes how they were measured. The coding manual for the MnSOST-3.1, which provides a more complete description of these items, can be downloaded here: http://www.doc.state.mn.us/publications/MnSOST3/default.htm.

Predatory Offenses: this item, which closely corresponds with the offenses that trigger predatory offense registration in Minnesota, measures the number of predatory offense sentences for which an offender has been convicted, including the index offense(s), up to a maximum of 25. Predatory offenses include all criminal sexual conduct crimes (1st–6th degree), murder in the first degree committed while the offender was committing (or attempting to commit) a criminal sexual conduct offense, kidnapping, false imprisonment (if the victim was not the minor dependent of the offender), indecent exposure, soliciting a minor to engage in prostitution, soliciting a minor to engage in sexual conduct, using a minor in a sexual performance, possession of child pornography, and incest.

Male Victims: this item measures the number of predatory offense sentences, as defined above, committed in which a male was the victim or one of the victims, up to a maximum of four sentences.

Public Place: similar to the MnSOST-R, this item measures whether any sexual activity with any sex offense was committed in a public place, which is defined as an area maintained for, or used by, the people or community or an area open to the scrutiny of others (Epperson et al., 2003). Offenders who have committed a sex offense, charged or convicted, in a public place received a value of "1," whereas those who did not received a value of "0."

Felony Offenses: this item measures the total number of felony-level offense sentences for which an offender has been convicted, including the index offense(s). The value entered for felony sentences is the total number of felony sentences, whether juvenile or adult, index or prior, predatory or non-predatory, up to a maximum of 20.

VOFP/Stalking/Harassment: this item measures the total number of sentences (adult or juvenile, index or prior, petty misdemeanor, misdemeanor, gross misdemeanor, or felony) an offender has for stalking, harassment, or violations of orders for protection, up to a maximum of five sentences.

Recent Disorderly Conduct: this item measures the number of sentences (adult or juvenile, index or prior, petty misdemeanor, misdemeanor, gross misdemeanor, or felony) an offender has for disorderly conduct convictions in the 3 years preceding his most recent commitment to prison, up to a maximum of two.

Completion of Sex Offender and Chemical Dependency Treatment: this item measures whether offenders have completed both sex offender and chemical dependency treatment while in prison for the index offense. Treatment completions are not included here if they occurred during a prior prison sentence or if the offender has received a new treatment directive. Offenders who complete prison-based sex offender and chemical dependency treatment while incarcerated for the index offense(s) receive a value of "1," whereas those who do not complete both types of treatment are given a value of "0."

Age at Release: the age of the offender in years at the time of release based on the date of birth and release date.

Unsupervised Release: this item measures whether offenders are released to correctional supervision. Offenders who are released to no supervision (i.e., discharged) receive a value of "1," whereas offenders released to some form of correctional supervision receive a value of "0."

Structured Risk Assessment

David Thornton

Introduction

Over the last decade, a number of structured schemes have been designed to assist professionals in assessing the risk for future sexual or violent offending presented by men convicted of sexual offenses (see Knight & Thornton, 2007). The most common of these structured schemes are composed of items that capture simple facts from offenders' histories that are statistically known to indicate a raised risk of recidivism. These predictive facts are largely aspects of past sexual offending or of more general criminal behavior. Essentially a problem behavior (sexual recidivism) is being predicted on the basis of prior observations of the same or similar problem behaviors.

A contrasting approach to prediction is to build the predictive classification out of psychologically meaningful factors that are presumed to predispose toward the problem behavior. These psychologically meaningful predictors are sometimes referred to as Criminogenic Needs since it is believed that targeting them in treatment will reduce recidivism (Andrews & Bonta, 2006). As a kind of shorthand the first kind of assessment is sometimes referred to as risk assessment while the second is called need assessment. Evaluation protocols that combine both kinds of assessment are commonly called Risk/Need instruments.

Andrews, Bonta, and Wormith (2006) distinguish four generations of risk assessment instruments. The first generation consisted of unstructured professional judgments. Second-generation instruments are empirically based, but atheoretical, and largely composed of static items. Third-generation instruments, while also being empirically based, include a wider sampling of Criminogenic Needs and are more theoretically based. Fourth-generation instruments are more specifically tailored to support decision-making in specific risk management contexts.

e-mail: david17thornton@aol.com

Within the sexual offender field most risk assessment tools would be categorized as second-generation instruments, but third-generation Risk/Need instruments are beginning to become available.

The focus of this chapter is on the Structured Risk Assessment (SRA) framework. This is a conceptual framework that enables the construction of risk/need instruments relevant to sexual offenders. This chapter has five purposes:

1. An overall description of the SRA framework is provided
2. The Need Assessment portion of the framework is described in detail so that the reader can use it in constructing or assessing a Risk/Needs instrument
3. The available research relevant to the empirical claims made by the Need Assessment portion of the SRA framework is described
4. The strengths and weaknesses of three instruments that are consistent with the SRA Need framework are described
5. Suggestions are made for future developments

Overall Description of the SRA Framework

The SRA framework proposes four steps in a comprehensive assessment. A risk assessment protocol that operationalized all four steps would arguably be a fourth-generation risk assessment since these steps were designed to guide decision-making at different points in the management of an offender as different kinds of information become available and different decisions have to be made.

SRA Step One: Static Actuarial Assessment

Step one is a static actuarial assessment. The SRA framework specifies that these instruments should be an appropriately weighted combination of items chosen to reflect the three underlying risk dimensions of Youth, Generally

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_23

Criminal Behavior, and Sexually Criminal Behavior. Here Youth refers to lower ages within the adult age range. Generally Criminal Behavior refers to the range and persistence of criminal/delinquent behavior, and Sexually Criminal behavior refers to range and persistence of illegal sexual behavior. Support for these three dimensions can be found in the factor analysis reported by Roberts, Doren, and Thornton (2002). Subsequent factor analyses (e.g., Barbaree, Langton, & Peacock, 2006; Knight & Thornton, 2007) have identified more specific dimensions, but these are considered to be components of the three broader dimensions. For example, Sexual Persistence, Male Victim choice, and Relationship to the Victim factors (in Knight & Thornton, 2007) can all be thought of as aspects of the range and persistence of sexually criminal behavior.

In implementing SRA, Step One instruments should be chosen according to how well they measure these underlying dimensions and how appropriately they are weighted so as to predict sexual recidivism. In the past the instruments most commonly used for Step One have been Static-99 (Hanson & Thornton, 2000) and Risk Matrix 2000 (Thornton et al., 2003). However, the better weighting of age in Static-99R (Helmus, Thornton, Hanson, & Babchishin, 2011) gives a basis within SRA for preferring it to Static-99.

In selecting a static actuarial instrument for SRA's Step One preference should also be given to instruments that more explicitly provide scores for the three underlying dimensions over those that do not. This potential feature of static actuarial instruments has not been well developed to date with the exception of Static-2002 (Hanson & Thornton, 2003) and Barbaree's proposed new instrument (Barbaree et al., 2009).

An important advantage of Step One is that it does not require a cooperative offender, does not require treatment participation, and, in fact, can be completed on the basis of the kind of slim information that is often available at the time of sentencing. Step One is therefore an appropriate way to begin making decisions earlier in sentence or before more in-depth information has become available. It is particularly suited to initial resource-prioritization decisions.

An important weakness of Step One assessment is that its risk categories are only based on a limited set of underlying risk indicators. We know that there are important risk factors that are at least partially independent of this kind of static actuarial assessment. As a consequence, members of a risk group defined by Step One procedures may actually differ substantially in the level of risk they present, depending on which external risk factors apply. For example, offenders falling in a high-risk category according to Step One type assessment actually have quite low recidivism rates if dynamic psychological risk factors are largely absent (e.g., Thornton, 2002; Beech, Friendship, Erikson, & Hanson, 2002; Allan, Grace, Rutherford, & Hudson, 2007; Olver, Wong, Nicholaichuk, & Gordon, 2007; Beggs & Grace, 2010).

Recent research has highlighted the importance of this limitation (e.g., Hanson, Helmus, & Thornton, 2010). The expected recidivism rate associated with a static actuarial score is a function of both the factors directly implied by that score (a given level of general and sexual criminality and a certain age) together with the average level of external risk factors that accompany that score. Where selection processes shift the average level of external risk factors associated with static actuarial scores, the recidivism rates associated with those specific static actuarial score will also shift (Thornton, Hanson, & Helmus, 2010). For example, where selection to take part in sexual offender treatment increases the average level of psychological risk factors across all levels of criminal history, the risk presented by these "preselected" individuals will come both from the criminal history and from elevated levels of psychological risk factors found as a result of the selection process. In effect, the selection process is acting as a proxy variable indicating the presence of higher levels of external risk factors.

SRA Step Two: Need Assessment

Step Two has been referred to variably as Initial Deviance Assessment and as Need Assessment. The former phrase is a reference to its origins in the work of Beech and his colleagues (e.g., Beech, 1998); the latter phrase connects to Andrews and Bonta's use of the term Criminogenic Need. Need Assessment is now generally preferred since this language is thought to be helpful in engaging the cooperation of the offender being assessed. As a consequence, the implementation of SRA used by correctional services in England and Wales is termed Structured Assessment of Risk and Need (SARN: Webster et al., 2006; Mann, 2010).

Step Two involves the assessment of potential long-term vulnerabilities or propensities (Mann, Hanson, & Thornton, 2010) that may predispose toward future sexual offending. The focus of treatment then can be to help the offender to manage his long-term vulnerabilities, and where possible to develop healthy prosocial ways of functioning that he can use in circumstances which would in the past have triggered his long-term vulnerabilities. These long-term vulnerabilities are also sometimes referred to as dynamic psychological risk factors.

The SRA Need Assessment framework proposes that these long-term vulnerabilities can be classified into four domains: sexual interests, distorted attitudes, relational style, and self-management (see Thornton, 2002 where the relational style domain was referred to as the socio-affective domain). Within each domain broad groups of long-term vulnerabilities are defined. These are referred to as sub-domains. Specific long-term vulnerabilities are proposed that fall within each sub-domain. Thus Sexual Interests is a

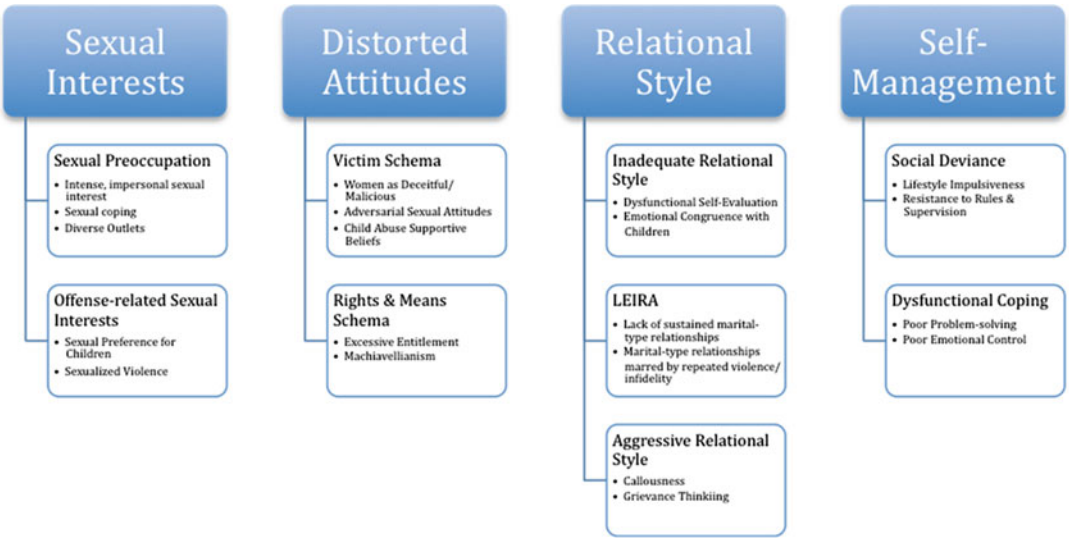

Fig. 1 Structure of long-term vulnerabilities defined by SRA

domain. Offense-Related Sexual Interests is a sub-domain. Sexual Interest in Children and Sexualized Violence are factors within this sub-domain.

In implementing SRA Step Two, Need Assessment protocols should be chosen that include psychological risk factors that fall within at least three of the four domains. Preference should be given to protocols according to how well they represent the main sub-domains within these domains. Of course in addition to this issue of balanced coverage of the domains, preference should also be given to protocols that assess the specified factors with greater reliability and validity in the intended operational context.

To assist the reader in making judgments about how well a particular instrument provides balanced coverage of the domains, Fig. 1 depicts the main sub-domains of long-term vulnerabilities within each domain and lists particular long-term vulnerabilities falling within each sub-domain.

It is important to note that since its inception in the late 1990s, SRA has been seen as an organic framework, intended to grow and incorporate new psychological risk factors within each of the domains. The principles guiding this are as follows.

1. There should be a coherent theoretical rationale for believing that the proposed new factor predisposes toward repeated offending
2. There should be empirical evidence that the factor is correlated with repeated sexual offending. Three kinds of evidence have been regarded as relevant:
   (a) Is the factor more common in those offenders with both current and prior convictions for sexual offenses and less common in those with only a current conviction for a sexual offense?
   (b) Is the factor recurrently found in the sequences of events leading to offenses?
   (c) Is the factor predictive of future convictions for sexual offenses?

This last consideration (prediction of future convictions) is given most weight. It requires that the factor be measured based on data that were created prior to the follow-up period in which recidivism was assessed.

Despite this organic openness to future research data, the main factors falling in the different domains are largely unchanged since 1999. The main development since that time is that the evidence for the relevance of the different factors has become more credible. When SRA Need factors were first proposed, it was primarily on the basis of the first two kinds of evidence. Now most of them are supported by the third, and weightier, kind of evidence (see Mann et al., 2010 for a meta-analysis of relevant studies).

The elements of the SRA Need Framework depicted in Fig. 1 are described below in sufficient detail for the reader to develop a thorough conceptual understanding of the framework.

Domain 1: Sexual Interests

This domain incorporates long-term vulnerabilities that have to do with the direction, form and strength of sexual interests.

Two sub-domains have been conceptualized within the Sexual Interests domain: offense-related sexual interests and sexual preoccupation. The better studied long-term vulnerabilities from the Sexual Interests sub-domains are described below.

1a. The Offense-Related Sexual Interests Sub-domain

Within the ***Offense-Related Sexual Interests Sub-domain***, two specific long-term vulnerabilities have been identified: sexual preference for children and sexualized violence.

Sexual Interest in Children

This refers to an intense interest in or preference for sexual activity with children. Children are defined as prepubescent or pubescent children: females aged 0–12 and males aged 0–14. Biologically, a prepubescent child would be expected not to show the physical cues typically indicative of the biological ability to mate and reproduce while a pubescent child would show them to a much lesser degree than adults.

Relevant ways in which children's bodies differ from adults' bodies include in skin texture, degree of body and pubic hair, smell, body shape, musculature, and breast and genital development.

Note that this definition is *not* equivalent to legal concepts of age at which someone can consent to sex.

Sexualized Violence

Sexualized Violence has two aspects. The factor is regarded as being present if either of these aspects is present. They are

1. An intense interest in or preference for sexual activity that involves forcing sex upon an unwilling recipient (coercive rather than consensual sexual activity). The coercive element must be a source of sexual arousal, not merely a means to overcome victim resistance
2. Sexual arousal to the idea of inflicting violence, pain, terror, humiliation, destruction, or exercising abusive control over another person

It is important to note that this factor refers to "violence" having become a source of sexual arousal, not just to its failing to inhibit sexual arousal.

1b. The Sexual Preoccupation Sub-domain

The ***Sexual Preoccupation Sub-domain*** has not generally been differentiated into more specific long-term vulnerabilities though it would be possible to conceptually distinguish some of the elements within sexual preoccupation (sexualized coping; sex disproportionately valued relative to other motivations; diversity of sexual outlets; impersonal sexuality).

Sexual Preoccupation

Sexual preoccupation involves an intense interest in sex that tends to dominate psychological functioning. Sex tends to be engaged in for its own sake, or as a way of defining the self, or as a way of self-medicating negative mood, rather than as an expression of a loving relationship. Sex is a highly salient feature of life. It is felt as an urgent need so that it is hard to stop thinking about it. Consequently large amounts of time are spent thinking about sex or engaging in sexually motivated behavior. Sexual aspects of situations are highly salient, easily becoming the focus of attention. Sexual dissatisfaction is a common feature among sexually preoccupied men; no amount of sex is felt to be "enough." A wide range of sexual outlets may be tried.

Domain 2: Distorted Attitudes

This domain incorporates long-term vulnerabilities that involve ***general*** beliefs or attitudes that make it easier for offenders to give themselves permission to commit sexual offenses. Such beliefs are sometimes described as cognitive distortions, but these should be sharply distinguished from denial and minimization which are not included in the SRA construct of distorted attitudes. The force of the phrase "general beliefs" is intended to be that what is involved are implicit theories or schema, not post hoc excuse-making with regard to particular offenses. The beliefs should refer to whole categories of activities or people, not just to specific individuals or events.

For example, when an offender is talking about a 7-year-old child who he had sexually abused says "Mary was different from other girls, she became sexually aware long before her friends," this is probably a distorted interpretation of Mary but it is not a general belief since it relates to just to one child. On the other hand, if the offender had said "Young children these days are much more interested in sex than they were when I grew up. They are flirtatious and know more about sex than I ever did," then this would be expressing a general belief about children.

Two sub-domains have been conceptualized within the Distorted Attitudes domain: schema regarding potential classes of victims (mainly women and children) and schema that relate to more general conceptions of rights and to means of gaining control of victims.

2a. Victim Schema Sub-domain

To date three general beliefs have been identified in the ***Victim Schema Sub-domain***. These are Adversarial Sexual Attitudes, Seeing Woman as Deceitful and Malicious, and Child Abuse Supportive Beliefs.

Adversarial Sexual Attitudes

As defined in SRA, Adversarial Sexual Attitudes involve three closely linked components: believing that men need to be tough and dominating while women should be submissive and accepting; seeing sexual encounters between men and

women as essentially adversarial; and seeing it as natural and appropriate for a man to use sexual activity with women as a way to bolster his sense of male dominance or masculine identity without any empathic concern for the woman's experience.

In essence this involves a linkage between a schema regarding the proper relations between men and women, and the offender's self-schema. So for a man with this belief system, experiencing himself as dominating a woman affirms his sense of his own value and the esteem in which he expects other men to hold him. It also affirms that the world is operating as it should. When such a man experiences himself as having to submit to a woman, or as failing to dominate a woman, then his sense of his own value is called into question, he expects other men to view him with contempt, and the world feels unpredictable, dangerous, and "wrong."

Seeing Women as Deceitful and Malicious

The core of this belief is the idea that women are generally deceptive and malicious towards men. Men with this belief think that women like making fools of men and that if you trust a woman then sooner or later she will let you down. Women are seen as seldom expressing their true feelings directly to men. A man with this representation of women thinks that if a woman appears sexually interested in him this doesn't imply true sexual interest, but probably means that she is trying to manipulate him in some way. Equally, if a woman is apparently cold or hostile this may reflect her really being sexually interested. Or if a woman is apparently kind or respectful to his face, it is likely that she is mocking him behind his back.

Child Abuse Supportive Beliefs

Child Abuse Supportive Beliefs include two main types of belief. One variant is seeing children as "little adults" with an adult-like capacity to enjoy sex and/or to consent to it or, relatedly, seeing children as sexually knowing and sexually provocative, deliberately inviting sexual interest from adults. The other variant is seeing sex with children as harmless for the child, or even positively beneficial, so long as the man is "gentle."

2b. Rights Schema Sub-domain

This involves ***an Excessive Sense of Entitlement.*** This takes two primary forms: a generalized sense of entitlement and a sense of sexual entitlement. A generalized sense of entitlement involves the belief that "my needs are more important than other people's rights"; such as feeling that you can "own" other people and/or feeling that you are special and as such entitled to special treatment.

Where a generalized sense of entitlement operates, it is applied to sexual behavior just as it is in other areas. Sometimes, however, a more narrowly sexual form of entitlement is found. The core element of this more specifically sexual entitlement is the sense of deserving or being owed sex, or the notion that the offender's "need" for sex is more important than other people's rights."

2c. Means Schema Sub-domain

Two Means Schema have been identified as theoretically relevant to sexual recidivism: Machiavellianism and Violent World schemas. The Machiavellianism schema has been empirically related to recidivism.

Machiavellianism

As defined in SRA, the Machiavellian belief system combines the following components: believing that human beings are weak, cowardly, selfish, and easily manipulated and sees taking advantage of this in interpersonal interactions as sensible and appropriate.

The Machiavellian offender sees acting on his view of human nature as the "smart" thing to do; believing that people aren't weak, cowardly, selfish, etc., is simply naïve. Consequently he routinely practices this kind of interpersonal manipulation in his dealings with others and, as a result, feels confident in his ability to influence them effectively. This belief system supports the kind of sexual offending that depends on effective interpersonal manipulation to create the opportunity to offend. However, while Machiavellianism supports manipulative grooming of potential victims and their natural protectors it must be remembered that this behavior can also evolve as a form of "tactical expertise" specific to sexual offending. Thus to infer the presence of the Machiavellian belief system, it is necessary to see this kind of beliefs and behaviors also being employed in nonsexual offending contexts.

Violent World Schema

Violent World schema involve seeing the world as a violent place in which effective physical violence is the natural way to achieve your ends. Persons with this schema expect others to be violent and easily resort to violence themselves. As a consequence of repeated practice, they develop some confidence in being effectively violent. Although Violent World schema haven't yet been studied in relation to sexual recidivism, it is highly probable that such beliefs which make it easier to use physical coercion to gain control of potential victims (Polaschek, Calvert, & Gannon, 2009) also represent long-term vulnerabilities for sexual offending.

Domain 3: Relational Style

As defined in SRA, the Relational Style domain (sometimes referred to as the Socio-Affective Functioning domain) concerns general patterns in the way the offender relates to

others and the feelings that are embedded in these patterns. Of particular concern is the capacity for marital-type relationships, but the manner in which friendships and social relations are conducted is also relevant.

Relationships of various kinds provide both the opportunity to satisfy important human needs (romantic and sexual needs, needs for emotional intimacy and social connection, etc.) and at the same time, seeking involvement in relationships exposes the individual to a number of threats (social aggression from others, rejection, betrayal, etc.). Relational style refers to how people cope with the opportunities and threats posed by relationships. A person's relational style will draw on their core schema about themselves and about other people. The challenges posed by relationships commonly trigger affect-laden cognition and powerful motivations. Managing these challenges consequently depends on a range of interpersonal, affective, and cognitive skills.

A healthy relational style is marked by:

- Forming and sustaining emotionally intimate marital-type relationships
- Forming and sustaining emotionally intimate friendships
- Forming and sustaining friendly and respectful social relationships
- Forming and sustaining polite and respectful casual or work-related interactions

Insecure/dysfunctional relational styles represent different ways of departing from a healthy relational style. Underlying these departures can be unbalanced or negative evaluations of the self in relation to others or overly negative evaluations of others.

If the self is undervalued relative to others then there may be nervousness about engaging in relationships as a result of doubting that the self will be valued by others. The individual may be overly concerned to please or overly quick to see others as discounting or disrespecting him. They may also enter into relationships in which they are exploited or abused by the other person. They may choose to relate to a greater degree with children who they feel will value them if adults don't.

If the self is overvalued relative to others then the individual may enter into relationships essentially for what he can gain from the other person, may treat the other exploitatively or disrespectfully, and may have little stake in sustaining the relationship.

If both the self and others are seen negatively relationships may be particularly difficult since there may an expectation that others won't value the self. At the same time, negative views of others may predispose the individual to attributions of hostility so relationships will be seen as particularly dangerous.

Three sub-domains have been conceptualized within the Relational Style domain: an Inadequate Relational Style; a Lack of Emotionally Intimate Relationships with Adults; and an Aggressive Relational Style.

3a. Inadequate Relational Style Sub-domain

Two related vulnerabilities have been identified in the ***Inadequate Relational Style Sub-domain***: dysfunctional self-evaluation and emotional congruence with children.

More specific vulnerabilities have generally not been distinguished within the ***Lack of Emotionally Intimate Relationships with Adults (LEIRA) Sub-domain***. However, Mann et al. (2010) recently suggested that failing to form any sustained marital-type relationships should be distinguished from a pattern of relationship failure due to repeated violence, infidelity, or lack of emotional intimacy. Both aspects appear to be predictive of sexual recidivism.

Two long-term vulnerabilities have been distinguished within the ***Aggressive Relational Style Sub-domain:*** Callousness and Grievance Thinking.

SRA distinguishes five relational style factors. These are Dysfunctional Self-Evaluation, Emotional Congruence with Children, Lack of Emotionally Intimate Relationships with Adults, Callousness, and Grievance Thinking.

Dysfunctional Self-evaluation

Within the SRA scheme, healthy self-evaluation is seen as involving the following elements:

- The core self is viewed positively; there is a sense of personal worth; the core self is lovable and worthwhile
- The self is seen as effective; able to make decisions and follow them through; the core self is able to make choices that determine how life goes
- The individual's sense of their own value is sufficiently secure that they can hear negative feedback and use it to make constructive changes rather than responding with denial, aggression, or falling into an overwhelming sense of worthlessness
- Self-respect is grounded in prosocial achievements. "Achievements" here can be as mundane as taking pride in working hard and earning enough money to support oneself or taking pride in being a good husband

Dysfunctional self-evaluation can be seen as a departure from the above forms of healthy self-evaluation. Common variations of dysfunctional self-evaluation include a painful sense of the self as inadequate, worthless, and defective; fragile narcissism in which the core self is seen as defective, but this schema is overcompensated for with an over-inflated self-image; and delinquent pride where self-respect is grounded in delinquent traits (pride in how much the

community is scared of him, in how effective he is at manipulating people, etc.).

Emotional Congruence with Children

Emotional congruence with children involves feeling that emotional intimacy is more easily achieved with children than with adults. Thus, children may be experienced as more satisfying companions, intimate friends, or romantic partners than adults. The individual may attribute more adult qualities to children or may see himself as a child among other children. Commonly he will feel that he can be "more himself" with children than with adults. He may well have a child-oriented lifestyle in terms of hobbies, activities, or even employment.

In considering this factor, "child" refers to someone under the age of 14. It should therefore be distinguished from the legal concept of the "age of consent."

3b. Lack of Emotionally Intimate Relationships with Adults (LEIRA) Sub-domain

More specific vulnerabilities have generally not been distinguished within the ***Lack of Emotionally Intimate Relationships with Adults (LEIRA) Sub-domain***. However, Mann et al. (2010) recently suggested that failing to form any sustained marital-type relationships should be distinguished from a pattern of relationship failure due to repeated violence, infidelity, or lack of emotional intimacy. Both aspects appear to be predictive of sexual recidivism.

Lack of Emotionally Intimate Relationships with Adults

This factor refers to a relative absence of emotionally intimate marital-type relationships, either homosexual or heterosexual. It does not refer to the closeness of family relationships or social friendships even though some of the skills needed for an emotionally intimate marital relationship can be practiced or displayed in these other kinds of relationship.

Lack of emotionally intimate marital-type relationships with adults is most obviously displayed by a history that contains no marital-type relationships with adults. Where the offender has had some kind of marital-type relationship with an adult, it is necessary to evaluate the duration for which it involved emotional intimacy and the quality of this relationship. The factor would be regarded as present if all marital-type relationships lasted less than 2 years or if they lasted longer but were marred by repeated conflicts, violence, or infidelity.

3c. Aggressive Relational Style Sub-domain

Two long-term vulnerabilities have been distinguished in the ***Aggressive Relational Style Sub-domain.*** These are Callousness and Grievance Thinking.

Callousness

This is essentially similar to the affective facet in the PCL-R (Hare, 2003). An offender showing this factor demonstrates a callous disregard for the feelings, rights, and welfare of others. He lacks an empathic emotional connection with other people. He may be cynical, disdainful, or contemptuous of others. While to other people this attitude may be expressed in how he talks about others, it is most clearly displayed through his behavior. His behavior is essentially selfish, being impacted by how things affect ***him*** but not by how others are affected. He may express a lack of concern or guilt about how his behavior has affected others or he may claim to be remorseful but has persisted in behavior that he knows hurts others.

Grievance Thinking

Grievance thinking is defined by difficulty seeing other people's point of view, believing that others have wronged you and are likely to do so again, angry rumination over past wrongs, suspiciousness of others, a sense of having a grievance against the world and others, and vengefulness. The key issues seem to be angry rumination, vengefulness, and poor perspective-taking in the sense of denying the legitimacy of other people's point of view. The intensity of this long-term vulnerability can be understood both in terms of the cognitive/affective content of relevant schema and in terms of the degree to which this drives aggressive behavior.

Domain 4: Self-Management

As defined in SRA, the Self-management domain refers to the individual's propensity to manage his immediate urges, impulses, and feelings so as to make choices that serve his longer-term self-interest.

Two sub-domains have been conceptualized within the Self-Management domain: Social Deviance and Dysfunctional Coping.

4a. The Social Deviance Sub-domain

Two related vulnerabilities have been identified in the ***Social Deviance Sub-domain***: Lifestyle Impulsiveness and Resistance to Rules and Supervision. These are both seen as habitual and automatic ways of responding which tend to lead to behaviors that are against the individual's long-term self-interest (not least because of the associated economic and legal consequences).

Lifestyle Impulsiveness

Lifestyle Impulsiveness is essentially similar to the Lifestyle Facet in the PCL-R. It refers to a lifestyle dominated by impulsive irresponsible decisions, often driven by the need for stimulation and not organized by realistic long-term goals. It is best thought of as collection of behavioral habits:

how an individual has habitually dealt with a range of situations in the past and therefore how he would unthinkingly and characteristically deal with them now.

Resistance to Rules and Supervision

Resistance to Rules and Supervision is essentially the Antisocial Facet in the PCL-R. In SRA this factor is conceptualized as a habitual and automatic resistance to rules, laws, supervision, or to any attempt at imposing external control. It is apparent from childhood onwards and manifests itself in terms of resistance to a broad range of rules/external controls, both large and small.

4b. Dysfunctional Coping Sub-domain

Two long-term vulnerabilities have been identified in the ***Dysfunctional Coping Sub-domain:*** Poor Problem-solving and Poor Emotional Control. These are both seen as deficiencies in more active coping processes.

Poor Problem-Solving

Poor problem-solving includes lacking effective cognitive problem-solving skills or using faulty (maladaptive) coping strategies in a way that blocks the deployment of cognitive skills the individual actually possesses. Examples of poor coping might include use of alcohol or drugs to self-medicate; using violence or aggression to force change in a situation; trying to distract himself by engaging in other tasks such as working harder, taking long walks alone, or having one-night stands.

Effective problem-solving requires the integrated deployment of a range of skills so poor problem-solving can result from weaknesses in any of these component skills. Examples of weaknesses in component skills include poor problem recognition or definition; avoiding thinking about stress or problems; believing that problems are too hard to solve; lack of creativity in generating options; lack of consequential thinking; believing that violence or aggression is a good way to solve problems; and making assumptions about things without checking facts. Any of these can lead to repeated selection of unhelpful strategies or solutions.

Poor Emotional Control

Poor emotional control may be episodic or chronic. Chronically poor emotional control involves repeatedly behaving in an emotional, unconstrained manner. Episodic emotional dyscontrol involves generally good control of emotions (sometimes overcontrol) with occasional loss of control involving extreme, emotionally driven behavior.

Poor emotional control often is seen in uncontrolled outbursts of emotional behavior. This differs from poor problem-solving in that persons with poor emotional control may be aware of the consequences of acting on their emotions but can't control what feels to them like an overwhelming tide of emotion. Their emotions are easily triggered and are more intense and long lasting than the situation requires.

SRA Step Three: Progress Assessment

Step Three is Progress Assessment. Step Three is appropriate after the offender has participated in some intervention designed to reduce recidivism. Two aspects of progress should be evaluated: criminal vs. prosocial engagement and manifestation vs. Management of long-term vulnerabilities.

Protocols for implementing SRA Step Three should be judged in terms of how well they provide operationally practical ways of assessing both these aspects of progress. To date there are no protocols in the literature that fully do this. In the absence of standardized protocols, this part of the framework could reasonably be used to structure professional judgment of progress.

Engagement: Criminal versus Prosocial

This aspect of assessment focuses on evidence pointing to the degree to which the offender is deliberately and actively engaged with further offending vs. being deliberately and actively engaged with developing a prosocial life.

Three inter-related aspects of Criminal Engagement are distinguished:

1. ***An Active Offense Process*** — when the individual is scanning the environment for potential opportunities to offend rehearsing tactical plans for offending, actively setting up potential victims, attempting to carry out offenses, etc.
2. ***Antisocial Network/Associates*** — when the individual invests significant time with people who are more likely to support or enable his criminal activity
3. ***Criminal Identity*** — when the individual thinks of himself as an offender and understands his criminality as naturally and inevitably emerging out of enduring aspects of who he is

Three parallel aspects of Prosocial Engagement can be distinguished:

1. ***An Active Change Process*** — when the individual actively avoids potential victims, chooses to participate in and complete meaningful treatment programs, and works to build a prosocial lifestyle
2. ***Prosocial Network/Associates*** — when the individual invests significant time with more prosocial people who discourage offending and support or enable his community reintegration.

3. ***Prosocial Identity***—when the individual thinks of himself as a prosocial person. He believes his criminality resulted from bad influences and made bad choices in the past, but he now has his life under control and is building a decent future for himself

There are several studies that empirically support the relevance of the Active Offense/Change Process. For example, Hanson, Harris, Scott, and Helmus (2007)'s finding that victim access behaviors were a risk factor; Hanson and Thornton (2003)'s finding that recency of past sexual offenses predicts future recidivism; Heil, Harrison, English, and Ahlmeyer (2009)'s finding that sexual offenses committed in prison raise the probability of sexual offenses committed after release; the finding that treatment completion is associated with reduced recidivism (Hanson et al., 2002); and the inclusion of attitude to treatment items in empirically validated risk assessment instruments (the SVR-20; the VRS-SO).

The Associates/Networks factor is empirically supported by the general criminological finding of Associates as one of the Big Four predictors of recidivism (Andrews & Bonta, 2006); from Hanson et al. (2007)'s finding that Associates is predictive of sexual recidivism; and from the more general criminological literature that has implicated the active use of prosocial networks in desistance (e.g., Laub & Sampson, 2003; Giordano, Cernkovich, & Rudolph, 2002).

The identity factor is empirically supported by the work of Maruna (2001). Maruna found that persisting offenders tended to have developed a life-narrative that he characterized as a "condemnation script." This incorporates a number of elements including seeing a deviant criminal self as who they really were; seeing their past bad acts as due to their being this criminal self; and feeling helpless or disinterested in changing this. In contrast, Maruna (2001) found that desisting offenders tended to have developed a "redemption script." This involves their having constructed a prosocial identity with which they increasingly identify. They come to believe their prosocial identity is who they had always really been. To accomplish this they find ways of explaining their *past* bad behavior as due to external factors that in some way repressed their real selves while determinedly asserting self-control of their current and future conduct.

Put a little more broadly, Criminal Engagement might be regarded as the ongoing intentional aspect of the problem behavior (sexual offending itself). Considering the factors indicated above is one way of asking the question, "does this individual intend to reoffend?"

Long-Term Vulnerabilities: Manifestation Versus Management

An offender with (say) three long-term vulnerabilities may allow these to dominate his psychological functioning and to drive his behavior. Alternatively he may recognize this pathological functioning for what it is and actively manage himself so that his vulnerabilities are triggered less often, are internally less intense or prolonged, and have less effect on his behavioral choices. This part of the SRA framework assists the evaluator by (a) telling him what aspects of functioning to focus on (the long-term vulnerabilities identified in Step Two) and (b) providing three questions to use in collecting potentially relevant behavioral information and interpreting the information that has been collected.

For each long-term vulnerability relevant to the individual the following questions are asked:

1. How well does the individual control the expression of this long-term vulnerability in situations where it potentially would be triggered?
2. To what extent has the individual developed healthy alternative strategies/behaviors to use in situations that used to trigger the long-term vulnerability and how reliably are these deployed
3. How consistently does the individual avoid triggers for long-term vulnerabilities and seek out environments conducive to strengthening healthy alternative behaviors?

In relation to each of these questions the critical issue is the consistency with which the long-term vulnerability is managed over time and across settings that challenge it. Similarly one may consider the consistency of healthy alternative behavior over time and across situations.

The evaluation of progress through examining evidence for manifestations versus management of long-term vulnerabilities is supported by a variety of research. Notably supportive are findings from research with the Violence Risk Scale-Sexual Offender Version (VRS:SO—Olver et al., 2007). This instrument incorporates a way of rating change that is based on a modification of the trans-theoretical stages of change. Close examination of the VRS-SO's scoring rules, however, makes it clear that reduced risk is only assigned when the kind of behavior implied by the above three questions is shown in relation to previously identified dynamic risk factors (or what here would be called long-term vulnerabilities). "Change scores," defined in this way, have twice been shown to relate to recidivism in two independent studies (Olver et al., 2007; Beggs & Grace, 2010).

SRA Step Four

Step Four of the SRA conceptual framework is Risk Management. It is applied either when a release plan is being developed or when an offender is being managed in the community. It has two aspects: assessing the form a future offense is most likely to take and assessing acute risk factors.

Making Judgments About the Likely Form of a Reoffense

The first part of SRA Step Four requires the evaluator to make judgments about the likely form of any reoffenses. The SRA approach requires that these judgments be supported by empirical findings. This is guided by two principles.

1. Victim choice is partially predictable based on the age and sex of prior victims. Longitudinal research indicates that the sex of future victims is generally consistent with the sex of prior victims, especially if prior victims were aged at least 13 (Friendship & Thornton, 2002). For those with prior victims aged 13+, future victims were 10 to 40 times more likely to be of the same sex as prior victims. For those with prior victims under age 13, future victims are about 4 times more likely to be of the same sex as prior victims.
2. Modus Operandi in future offenses is partially predictable both from the modus operandi employed in prior offenses and from some more general aspects of criminal history. Specifically, there is generally specialization by the gross level of violence and intrusiveness involved. High degrees of brutal violence and intrusiveness (as in a physically violent rape) are predictable to a degree from repeated prior occurrence of this kind of offense and from the following more general features: youth, general criminality, and a history of nonsexual violence. A simple algorithm for predicting this specific kind of offense is described by Thornton and Travers (1991) and is reproduced in foot note.[1]

The first part of Step Four then involves applying these two principles in judging the kinds of offense that the supervision regime should invest most effort in blocking (or making more difficult). Despite their apparent simplicity, when combined with an overall risk assessment, these two principles have remarkable power. For example, only a very low risk to male children, regardless of his Static-99 risk classification, is presented by a man whose only past offending is against females aged 13 or above. In contrast where the potential victim being considered is of the same sex as past victims, the risk is much higher.

Similarly, offenses that involve lower levels of gross physical violence generally depend on more extended grooming of potential victims and accordingly are easier to block through supervision. In contrast, where the indicators from the Thornton/Travers algorithm (see note) are present, less confidence can be placed in the ability of supervision to block offending.

Acute Risk Management

The level of risk presented by an offender may vary over time. Such variation is of limited significance when the offender is being physically prevented from reoffending (for example by incarceration), but when an offender is returned to the community it becomes far more important. In the community, periods of heightened risk call for an increase in the intensity of rehabilitative or supervisory services. The concept of acute risk monitoring is to use the ongoing contact between the offender and relevant agencies (for example, the containment team in jurisdictions that use that model, often community corrections/probation/parole agents) to generate data that can inform risk management decision-making. The factors that are observed in this monitoring process are sometimes known as "acute risk factors" since they are measured in a way that allows them to change rapidly (for example, compliance with supervision over the last month).

The SRA framework prescribes that acute risk monitoring in the community should be focused in the same manner as progress assessment. That is, it should focus on indicators of criminal vs. prosocial engagement and on indicators of the manifestation vs. management of long-term vulnerabilities.

A key issue here is that potential acute risk indicators are subject to a number of sources of error. There are several reasons for this. The behaviors monitored are chosen to reflect the individual offender's long-term vulnerabilities, but they are also liable to be influenced by a number of unrelated factors. An offender's recent behavior does not occur in a vacuum. In part it will be an expression of long-term vulnerabilities, but it will also be affected by the behavior of others around him (other offenders, non-offenders, supervising staff), by how far the immediate environment affords an opportunity to engage in the behavior, and by immediate events. This suggests that averaging scores on acute risk indicators over time, and preferably over observations made by different staff, will give more valid results than attending exclusively to the most recent observations.

Support for this principle can be found in results obtained with the ACUTE scale from the Dynamic Supervision Project (Hanson et al., 2007). A notable finding from this

[1]Thornton & Travers' algorithm was as follows. To predict general violence (future convictions for rape and non-sexual assault) among sexual offenders sum the following items: Does the current conviction include charges for Rape or Non-sexual assault? Do prior convictions include charges for Rape or Non-sexual assault? Did he have more than three convictions (sentencing occasions) of any kind prior to the current conviction? Was he under 30 at the time he was sentenced for his current conviction? 0 or 1 factors present was categorized as Low; 2 factors present was categorized as medium; and 3 or more factors present was categorized as high. In these researchers analyses each of these factors predicted future rape convictions but had no relation to the probability of less violent kinds of sexual offense. Rape here is as defined by the law in England and Wales (basically forcible penile penetration of the vagina).

study was that averaging ACUTE score over 6 months gave better results than taking the most recent months observations.

Although Hanson et al's ACUTE is a groundbreaking instrument, from an SRA perspective it has a number of limitations. First, ACUTE items were developed in a somewhat ad hoc way rather than being deliberately linked to long-term vulnerabilities. From the perspective of the SRA framework, a better instrument would ground ACUTE items in known long-term vulnerabilities. Second, items were tailored for a particular setting in a particular jurisdiction (parole and probation supervision in Canada). Experience trying to implement ACUTE in other settings has sometimes encountered reliability problems. From the perspective of the SRA framework a better instrument would have items developed that corresponded to what different kinds of staff can observe in particular settings. For example, different behaviors are observed by a hostel warden who supervises offenders in a probation hostel, by a police officer who is checking whether a registration address is still accurate, by a therapist providing outpatient treatment, and by a supervising agent. Third, by focusing exclusively on acute risk factors, ACUTE and similar instruments encourage a rather negative strategy in managing offenders that makes an offender who puts out no interpretable behavior look "safe." A more productive approach is to define protective factors corresponding to each acute risk factor. This inclines offender managers to encourage the development of these positive behaviors and provide the offender with a motive to work towards these accomplishments.

Determining whether an active offense process has been initiated is a more troubling problem than seeking to monitor the ongoing expression of long-term vulnerabilities. Clearly this is something that the offender can be expected to actively hide.

It is plausible to suppose that the item referring to Victim Access Behavior in ACUTE may have this meaning, but it is not known whether this is actually the case. The item may simply be a reflection of a long-term vulnerability (sexual preference for children for example).

The issue has been addressed in a practical way by police forces in England and Wales who were operating in the context of a system informed by SRA and trained by this author. In some circumstances, the combination of high risk and need from Steps One and Two, together with evidence of Criminal Engagement from observations in prison (for example, being overheard discussing possible future offenses, trying to establish contact with potential victims, etc.), has motivated mounting operations to try to observe selected offenders and intervene when they are about to reoffend.

Operations of this kind are expensive and face the difficulty that intervening too early may simply alert the offender to the fact of observation while not providing a legal basis for detaining the offender. Intervening too late of course means that the offense has not been prevented. There are also complicated human rights issues that have to be negotiated. Nevertheless there are striking individual case examples where a mixture of surveillance technology and the use of undercover officers has credibly identified an active offense process, documenting planning and gathering of equipment for intended offenses, and prevented very serious offenses (abduction, torture, murder).

Implementing SRA Need Assessment

SRA Need Assessment is a conceptual framework that can be implemented in a number of different ways. It is not in itself a risk assessment tool. Rather the framework can be thought of as defining a family of risk assessment tools that are alike in important ways. Choosing the best implementation of the SRA Need Assessment framework requires taking into account the purpose of the assessment, the kind of relationship that can be established with the person being assessed, and the quality of available file information.

To implement the SRA Need Assessment framework in a meaningful way an assessment protocol should use contextually valid and reliable measures of a balanced selection of factors from a minimum of at least three of the four domains.

Importantly, self-report measures that are relatively valid and reliable in more collaborative settings are often of little value in adversarial contexts. In such adversarial settings structured ratings of file information may be more valid and reliable especially when richly informative files are available. Yet they may be of little value where file data are thin and unreliable.

The protocol should afford a balanced assessment of the domains based on the structural model laid out in Fig. 1. "Balanced" here means that the protocol affords assessment of all of the sub-domains from within each of at least three domains. Protocols can be judged according to how well they approximate this standard.

Given the above criteria, an assessment protocol does not have to be intentionally designed as an implementation of SRA for it actually to be a valid implementation of the SRA conceptual framework. Indeed any assessment protocol that successfully characterizes long-term vulnerabilities from at least three of the four domains can be considered an implementation of the SRA Need Assessment framework. Instruments can be judged in terms of whether the factors they contain fall into the SRA Need domains in a way that meets the criteria for a balanced implementation. Where this happens without the intent of instrument's designer to deliberately following the SRA Need framework the result is referred to as an emergent implementation of the SRA framework.

Implementations using Questionnaires

There have been a number of deliberate implementations of SRA using questionnaires and at least one emergent implementation.

Thornton (2002) reported results with a questionnaire implementation of SRA Need Assessment designed to be used prior to prisoners' participation in Her Majesty's Prison Service's National Sexual Offender Treatment Programme (Mann & Thornton, 1998). This battery has subsequently been greatly extended and elaborated (Wakeling, Beech, & Freemantle, 2009).

Parallel to this work, a battery of questionnaires was developed for research evaluating community and prison treatment programs in England and Wales (e.g., Beech, 1998). Subsequently, a method of scoring this battery has been developed so as to deliberately implement the SRA framework (Harkins, Beech & Thornton, 2009). Similarly, Craig, Thornton, Beech, and Browne (2007) reported results from implementing the framework with a subset of the questionnaires used by Harkins et al.

Quite independently of this an emergent implementation of the SRA Need framework can be found in the work of Allan et al. (2007). They analyzed data from a battery developed to assess treatment needs in the Kia Marama sexual offender treatment program. Factor analysis of their scales identified four factors: Sexual Interests, Pro-offending Attitudes, Social Inadequacy, and Anger/Hostility. In developing a predictor they weighted the first two factors twice as heavily as they weighted Social Inadequacy and Anger/Hostility. Reference to Fig. 1 indicates that while the first two factors correspond to SRA Sexual Interests and Distorted Attitudes domains, the second two factors actually correspond to two of the sub-domains of vulnerabilities (Inadequate Relational Style and Aggressive Relational Style) within the Relational Style domain. Thus Grace et al's way of weighting the factors creates the equivalent of equally weighting the first three SRA domains.

Implementations Using Ratings

There have been three deliberate implementations of the SRA Need Assessment framework and two emergent implementations that relied on clinical ratings as the main methodology. Two of these are very similar.

The generic scoring guide for SRA and the version developed for Her Majesty's Prison Service (SARN) have been deliberately linked to each other, with refinements in each being used to drive changes in the other. They are both primarily intended to be integrated with a treatment process, typically carried out part way through treatment, and used to focus further treatment activity and risk management planning. SARN is an in-house tool not generally available to professionals working outside the aegis of the National Offender Management Service of England and Wales (Mann, 2010). It is supported by staff training, central quality control, and an ongoing research program.

The initial dynamic score from the Violence Risk Scale—Sexual Offender Version (VRS-SO) is an emergent implementation of the SRA Need Assessment framework. The VRS-SO (Olver et al., 2007) was developed by adapting a more general model of criminogenic needs to apply to sexual offenders. Factor analysis of its items indicates three broad factors (Sexual Deviance, Treatment Responsivity, and Criminality that correspond respectively to the Sexual Interests, Distorted Attitudes, and Self-Management SRA domains. Additionally, there is one item (Intimacy Deficits) that clearly corresponds to the relational style SRA domain. There is some evidence that a four-factor solution may provide a better fit (Beggs & Grace, 2010) for the VRS-SO dynamic items and this gives a picture of factors for the Sexual Interests and Distorted Attitudes SRA domains, plus two factors that correspond to the major sub-domains of vulnerabilities in the Self-Management SRA domain (Social Deviance and Dysfunctional Coping). Table 1 shows the mapping of the VRS-SO items into the four SRA domains.

Table 1 STABLE-2007 and VRS-SO items by SRA domain

SRA domains	STABLE-2007 items	VRS-SO items
Sexual interests	Sex drive Sexual preoccupation Sex as coping Deviant sexual preference	Sexually deviant lifestyle Deviant sexual preference Offense-planning Sexual offending cycle Sexual compulsivity
Distorted attitudes	Hostility toward women	Insight Treatment compliance Cognitive distortions Release to high-risk situations
Relational style	Emotional identification with children General social rejection Capacity for relationship stability Lack of concern for others Negative emotionality (hostility)	Intimacy deficits
Self-management	(Antisocial) social influences impulsive Poor problem-solving skills Cooperation with supervision	Impulsivity Interpersonal aggression Substance abuse Compliance with community supervision (–) Criminal personality Community support (–) Emotional control (–)

STABLE-2007 is a revision of the original version of STABLE based on the analysis of a large community supervision sample of sex offenders (Hanson et al., 2007). STABLE ratings of psychological risk factors are predictions about the next 12-months functioning based largely on functioning in the recent past. This differs in principle from SRA's focus on long-term vulnerabilities. However, the empirical revision of STABLE used to produce STABLE-2007 has shifted the model towards the long-term vulnerability concept, at least for some factors. The other big revision was based on the determination that attitudes could not be accurately assessed in the kind of adversarial context (ratings by supervising agents) that STABLE was intended for. STABLE 2007 is regarded as another emergent implementation of the SRA Need Assessment framework. Table 1 shows the mapping of STABLE 2007 items into the four domains.

Finally, Knight and Thornton (2007) tested a planned implementation of SRA Need Assessment using ratings designed to be applicable to the clinical files generated in relation to sexual offenders being considered for an early version of civil commitment. A modification of this intended for use in forensic settings has also been described (Thornton & Knight, 2009, 2014). This last is referred to as SRA:FV (SRA: Forensic Version) since it is intended to be useful in adversarial evaluations carried out for the courts though it can of course be used in other settings.

Empirical Claims

A number of empirical claims are made for the SRA Need Assessment framework. Specifically it is claimed that:

1. Established psychological risk factors will fall within the four proposed domains
2. Each domain, considered by itself, is predictive of sexual recidivism
3. Overall Need (summed across the domains) is predictive of sexual recidivism
4. Overall Need shows incremental predictive validity relative to the static actuarial predictors considered in SRA Step 1

More generally the claim is that predictions 2, 3, and 4 will generally hold for balanced implementations of the SRA Need Assessment framework (deliberate or emergent).

This section reviews the evidence relevant to these claims.

Established Predictors Fall Within the Domains

Mann et al. (2010) review the results of relevant meta-analyses to create a list of empirically supported psychological risk factors; they also create a list of promising risk factors (those with some empirical support). Table 2 maps these two lists of factors into the SRA domains.

Table 2 Psychologically meaningful risk factors by SRA domain

SRA domains	Empirically supported factors	Promising factors
Sexual interests	Sexual preoccupation Multiple paraphilias Sexual preference for children Sexualized violence	Sexualized coping
Distorted attitudes	Offense-supportive attitudes	Hostility toward women Machiavellianism
Relational style	Emotional congruence with children Lack of emotionally intimate relationships with adults Never married Conflicts in intimate relationships Grievance/hostility	Callousness
Self-management	General self-regulation problems Impulsivity/recklessness Employment instability Childhood behavior problems Noncompliance with supervision Noncompliance with conditional release Negative social influences Poor cognitive problem-solving	Dysfunctional coping (externalizing)

As claimed, the existing empirically supported and promising risk factors fall into the four domains, with each domain having several factors within it.

Each Need Domain Is Predictive

Table 3 shows how well each of the domains predicted sexual recidivism in six different studies using various of the SRA implementations discussed above. Typically, a study will have results for three of the four domains. The table also includes the AUCs for overall level of Need and three additional studies report this but did not report results for different domains. Note that the length of follow-up is given with the study authors' names and that the results from the VRS-SO studies are those for the Initial Dynamic scores.

The results are summarized by the median AUCs which indicate moderate predictive accuracy for any domain considered by itself. The Sexual Interests and Distorted Attitudes domains appear to be a little more predictive than the Relational Style and Self-management domains, perhaps reflecting that they are more specific to sexual offending.

It is also important to note that some of the offenders included in the Craig et al.'s study were also in the Harkins et al.'s study which has a much longer follow-up. However, dropping the Craig et al.'s study from the table would not have materially changed the median results.

Table 3 Prediction of sexual recidivism from SRA domains and overall need

Study	AUC for sexual interest	AUC for distorted attitudes	AUC for relational style	AUC for self-management	AUC for overall need
Thornton (2002) (3–years)					0.78
Hanson et al. (2007) (41 months)					0.67
Craig et al. (2007) (5-years)	0.72	0.64	0.64	0.66	0.69
Knight and Thornton (2007) (10 years)	0.67		0.70	0.64	0.73
Allan et al. (2007) (5.8 years)	0.72	0.70	Inad = 0.62 Host = 0.60		0.76
Olver et al. (2007) (10 years)	0.59	0.58		0.63	0.66
Harkins, Beech, and Thornton (2009) (10 years)	0.76	0.74	0.79	0.64	0.79
Eher, Matthes, Schilling, and Rettenberger (2011) (5.5 years)					0.71
Beggs and Grace (2010) (12.2 years)	0.72	0.73		0.69	0.78
Median AUC	**0.72**	**0.70**	**0.67**	**0.64**	**0.73 (0.76 without STABLE)**

Overall Need Is Predictive

Based on the nine studies, overall Need defined using the SRA framework is consistently predictive. The results appear relatively robust in the sense that the inclusion or exclusion of any particular kind of study does not materially shift the median AUC. The one minor exception to this is that the inclusion of the two STABLE-2007 studies does pull the median AUC down a little and in fact the average AUC for STABLE-2007 is 0.69 as compared to the median AUC for the other implementations being 0.76. It is mainly the Hanson et al. (2007) study that seems to show a lower AUC and it is possible that this reflects considerable variation in how conscientiously the ratings were completed. Hanson et al. report that for a subset of "conscientious" raters the AUC for sexual recidivism rose to 0.77, essentially the same as that for the non-STABLE studies (0.76). Only limited weight can be put on this finding however since the definition of "conscientious" was post hoc, a little idiosyncratic, and has not been applied in other studies.

Overall Need Shows Incremental Predictive

In all of the nine studies summarized in Table 3 the implementation of overall Need showed statistically significant incremental predictive validity over a static actuarial instrument (usually Static-99). The one qualification to this is for Hanson et al. (2007) where the data set was used to empirically revise the original STABLE-2000 items. In fact, in both STABLE studies it was only the 2007 version of STABLE that showed significant incremental validity for sexual recidivism.

Robustness of Empirical Results

In reviewing the above data from Table 3, it is important to note that essentially similar patterns of results are observed in all nine studies. This number of conceptual replications indicates that the basic finding is robust. In addition, the fact that these studies use different measures, involve samples released in different eras, involve multiple jurisdictions, community and prison samples, and both more adversarial and more collaborative settings, and still get similar results implies that the results have remarkable generality.

Strengths and Limitations of Existing Measures

This section considers the potential of a number of existing implementations of the SRA Need Assessment framework from the perspective of a forensic evaluator. Three implementations are considered: the forensic version of SRA, STABLE 2007, and the initial dynamic score from the VRS-SO. These implementations are considered because each is potentially available from its authors with training in its use and because each uses ratings rather than depending

on questionnaires. Questionnaire implementations are considered impractical in the forensic context since there is too great an incentive for the offender to fake good.

Five criteria are considered: relative predictive power; institutional vs. community setting; length of follow-up for which predictive power has been demonstrated; and use in adversarial vs. treatment contexts.

Relative Predictive Power

Thornton & Knight (2009) reported AUCs for the forensic version of SRA of 0.72. The mean AUC for the VRS-SO initial dynamic score was also 0.72. The mean AUC for STABLE-2007 was 0.70. Given the number of studies involved, these AUCs are similar enough that it would be hard to justify choosing one instrument over another on this basis.

Institutional Versus Community Setting

This consideration is important since it impacts the kind of information available to evaluators. In addition, where imprisoned offenders are involved an important consideration is how long they served before being released. An instrument can be used more credibly with offenders from a particular kind of setting if it has been tested with offenders from that kind of setting. For example, if an instrument had only been tested in the community it would not be clear whether the results could be generalized to offenders being assessed in prison. In general there is more information relevant to future community functioning for assessments carried out when the offender is now in the community or was in the community relatively recently.

SRA:FV was tested with a diverse sample of imprisoned sexual offenders being considered for an early version of civil commitment.

STABLE-2007 has been tested with a diverse sample under community supervision (largely in Canada) and with a sample of child-molesters serving, by American standards, relatively short (mean 31 months) prison sentences in Europe.

The VRS-SO was tested in the Canadian federal prison system (Corrections Canada) and with imprisoned child-molesters in New Zealand. In both contexts prison sentences would have been relatively short by American standards.

Adversarial Versus Treatment Context

Treatment normally provides a more collaborative setting while forensic evaluations are usually more adversarial. Information that is available in a treatment setting may therefore not be available in a more adversarial setting.

The forensic versions of SRA and STABLE have both been tested in relatively adversarial settings. This is particularly true of the forensic version of SRA where decisions about possible civil commitment were explicitly part of the context of assessment. In contrast the VRS-SO has only been tested with ratings made in the context of treatment.

Length of Follow-Up

Psychological risk factors, especially when assessed with the philosophy that informs STABLE, might be expected to change over the medium term. This raises a question regarding how well they will predict long-term recidivism rates.

The forensic version of SRA was found to have the same AUC for both 5-year and 10-year sexual recidivism rates. STABLE-2007 has so far been tested with follow-ups of around 3 and 5 years. The VRS-SO has been tested with a 10- and 12-year follow-up.

Recommendations

Taking these factors into account the following recommendations can be made.

1. The forensic version of SRA is suitable for sexual offenders serving longer sentences being assessed under more adversarial circumstances. It is known to be relevant to both short-term and long-term recidivism rates
2. STABLE-2007 is suitable for use with offenders being supervised in the community and with those serving relatively short prison sentences (under 4 years real time). It can be used under adversarial conditions. It is known to be relevant to short-term recidivism rates, but its relevance to long-term recidivism rates is not yet known
3. The VRS-SO is suitable for imprisoned sexual offenders serving moderate length prison sentences assessed under more collaborative conditions. It is known to be relevant to short- and long-term recidivism rates

In high-stakes risk assessment such as SVP hearings there would be some merit in using more than one of these instruments. Where consistent results were obtained the evaluator would have a sounder basis for inferring that they were drawing on the SRA Need Assessment framework as a whole (and hence a larger group of studies). If conflicting results were obtained then this would signal a need for caution and care would have to be taken to identify the reason for the inconsistency and hence the relative validity of the two assessments as applied to the specific case. It will also be important to take into account how similar the offender being

evaluated is to those in the different studies with which the scale has been tested. For example, the VRS-SO will be most relevant for offenders who have participated in treatment but hard to apply if they have not.

Summary of the Purpose of SRA Steps

The preceding in-depth focus on Step Two may well have made it difficult for the reader to discern how the steps fit together. Accordingly Table 4 recaps the main purposes and character of each SRA step. How they fit together in practice is then discussed below prior to making suggestions for future research.

SRA Step One is intended for initial resource prioritization decisions, for example, decisions about the degree of resources that should be used for treatment or risk management. Good practice models (Andrews & Bonta, 2006) make the degree of treatment/management resources proportionate to risk.

In addition it can be used for overall risk assessment in circumstances where more comprehensive assessments are not practical.

SRA Step Two is primarily intended for the identification of treatment needs. However, when combined with the static actuarial assessments from Step One, it also allows a more refined assessment of overall level of risk.

Table 4 Outline of the function and content of the SRA steps

Step	Function	Content
1: Static-actuarial risk	Initial resource prioritization decisions. Risk assessment where only thin information is available	Sexually criminal behavior + Generally criminal behavior + Youth
2: Need assessment	Identification of treatment needs. More refined prioritization decisions. More refined risk assessment	Sexual interests + Distorted attitudes + Relational style + Self-management
3: Progress assessment	Determine need for further treatment. Revision of risk assessment in the light of interventions.	Criminal vs. prosocial engagement + Manifestation vs. management of long-term vulnerabilities
4: Risk management	Release planning Focusing and determining the intensity of community risk management.	Likely form of reoffense + Acute risk

High-stakes risk assessment where both the community and the offender will pay a substantial cost for erroneous risk classification should where possible include at least the first two steps, namely including both a consideration of both static and long-term psychological vulnerabilities or predisposing factors. Although research testing how to integrate these two kinds of factor is still in its early days, the findings are sufficiently clear-cut to support the use of this kind of integration in clinical practice. Evaluators wishing to carry out this kind of integration currently have a limited set of instruments to choose between (largely the three reviewed above). While there is sufficient evidence to justify using these instruments in this way, research guidance on their use can be expected to develop significantly over the next decade and additional instruments can be expected to emerge.

SRA Step Three provides a basis for evaluating response to substantive interventions designed to reduce risk. It should be used in conjunction with the first two steps in making decisions about the need for further intervention and about the appropriate intensity of community risk management.

SRA Step Four provides a basis for planning and moderating community risk management processes.

The reader will have noted that the first two steps are better developed with a number of research-based mechanical assessment tools available. In contrast less development work has been done for the third and fourth steps. Nevertheless the conceptualization of these steps offered here would be of assistance in structuring and supporting the relevant kinds of professional judgment much in the way that other "Structured Professional Judgment" tools are.

Prospects for Future Developments

Research within or consistent with the SRA framework has been going on for a decade now. Unsurprisingly, however, as we have learned more, so additional questions emerge. Suggestions for profitable lines of future research and development projects are organized below in terms of the SRA steps.

Suggestions for Step One

Four developments would improve Step One of the SRA framework.

1. Better Normative Samples—the existing normative data for most actuarial instruments that meet SRA Step One requirements is largely drawn from samples of convenience rather than being true representative samples of defined populations. If populations with different base rates are going to be distinguished then these need to be defined more clearly than is currently possible

2. Instruments should provide scores that place offenders on each of the three underlying dimensions, not solely on level of risk
3. Placement along these underlying dimensions should have a more absolute conceptual meaning rather than simply placing offenders relative to each other
4. Together these developments would allow us to move beyond specific instruments to specifying risk in relation to placement on absolute dimensions defined in an instrument-free way

Suggestions for Step Two

Four developments would improve Step Two of the SRA framework.

1. Specific implementations of the framework should be tested repeatedly in different kinds of sample and in conjunction with static actuarial instruments so that the implications of specific combinations of static risk and need can be determined
2. Specific implementations should be developed that are optimized for particular contexts, for example, for a treatment context, for a forensic evaluation context, etc.
3. Long-term vulnerabilities should be understood in terms of more fundamental processes including socio-biological developmental models
4. Measures of long-term vulnerabilities should be developed that are less reactive to the demand characteristics of the assessment situation and more truly dynamic so that current levels of long-term vulnerabilities can be assessed

Suggestions for Step Three

Three developments would improve Step Three of the SRA Framework.

1. While SRA currently suggests an appropriate focus of progress assessment it does not presently provide a mechanical assessment protocol. Currently the most promising is probably the change rating system from the VRS-SO but a range of protocols should be developed and tested
2. Ways of managing offenders in institutional and community settings should be developed that increase the degree to which long-term vulnerabilities will be tested and the degree to which their activation can be observed
3. Preferably protocols should distinguish changes in the underlying long-term vulnerability, changes in how well the offender manages the vulnerability, and the degree to which competing strengths have been developed

Suggestions for Step Four

Three developments would improve Step Four of the SRA Framework.

1. It should be possible to develop empirically based guidelines for other aspects of reoffense than those considered above
2. Systems for rating Acute risk factors should be developed in ways tailored to the kinds of information available in different settings
3. More cost-effective methodologies than police observation should be developed to detect the onset of the Active Offense Process

Beyond Static Risk Assessments? Assessment of Psychologically Meaningful Risk Factors via STABLE-2007 and the SRA:FV

Harry M. Hoberman

Over the last 15 years, so-called dynamic risk factors have become a popular topic in sexual offender research and practice. The available empirical evidence indicates that most persons in the general population do not commit sexual offenses and that even most identified sexual offenders are not detected again for additional sexual offenses. Presumably something about persons (e.g., predisposing genetic and/or psychosocial characteristics likely in interactions with situations) differs between offenders and non-offenders and between those offenders who appear to cease offending from those who do not. Moreover, while identifying sexual and antisocial domains as broad, general determinants of sexual offending, research to date has also demonstrated that sexual offenders are heterogeneous and that sexual offending appears most likely to be the result of multiple, cumulative factors interacting in context. The heterogeneity of sexual offenders also has implications for potential treatments for such individuals. The concept of providing treatment for identified sexual offenders is premised on the notion that relevant underlying causal or maintaining factors can be identified and that such aspects of those individuals can be modified or managed in some manner to a sufficient degree that their risk of sexual offending might be decreased. Conceptually, then there are psychosocial and/or biological characteristics of persons that predispose them to—increase the likelihood of—sexual offending that differ among persons and that are of a nature that they are potentially "malleable" or changeable from some type of experiences or other influences.

Risk factor is a term from epidemiology that is the scientific study of the patterns, etiology, and effects of "disease" (e.g., physical and mental disorders) in defined populations or groups. Epidemiology assumes that disorders do not occur randomly in a group of individuals and that identifiable subgroups, including those who have certain characteristics or experience particular conditions, are at increased risk of exhibiting some disease or disorder. Of note, as a scientific endeavor, epidemiology focuses on the question of general causation (e.g., is some factor capable of causing disease or disorder?) rather than that of specific causation (e.g., did it cause disease or disorder in a particular individual?). Risk refers to the probability of an outcome within a population of subjects, while the term risk factor is typically used to indicate particular conditions or experiences that affect the probability of such an outcome. In their seminal article, "Coming to Terms With the Terms of Risk," Kraemer et al. (1997) defined a risk factor as "a measurable *characterization* of each *subject* in a specified population that precedes the outcome of interest and which can be used to divide the population into two groups (the high-risk and the low-risk groups that comprise the total population)" (p. 338) The "subject" referred to could be a group, individual, or community. Per Kraemer et al., "We suggest that labeling a factor with the generic term risk factor with no further effort to delineate its roles as fixed marker, variable marker, or causal risk factor is a limited finding…" (p. 342). A key distinction in epidemiological research is that correlation is not causation; some characteristic may be associated with a particular outcome as consequence or result of that outcome/condition. Unless there was evidence that the characteristic preceded the outcome/condition, it would be known as simply a correlate of the outcome. A risk fact, however, is "a special type of correlate that requires documentation of precedence" (p. 340). Kraemer et al. (1997) offered some important cautions about the nature of risk and the potential meaning of risk factors. They noted that statistical significance often indicates only that the sample sizes were sufficiently large and the research design and measurement adequate to document nonrandom association between some characteristics of an individual and an outcome of

interest. Further, they pointed out that with large enough combined sample sizes, many factors could be demonstrated to be associated with a particular outcome. Regarding the meta-analyses for sex offender recidivism, it is known that the identified risk factors are more than correlates since they precede the measured outcome in temporal terms. However, per Kraemer et al., it remains unknown if a static risk factor is a "fixed marker" (e.g., year of birth) or if a static risk factor can change (e.g., deviant sexual interest or antisocial orientation). If it can change, then it can be viewed as a "variable" risk factor (a potential dynamic risk factor). Yet that "variable" risk factor can be considered a *causal* risk factor only if the "variable" risk factor can actually be manipulated or modified in such a way that *change* in the factor is demonstrated to also be associated with a *change* in the relevant outcome of a disease or disorder.

The Brief History of Dynamic Risk Factors for Sexual Offending

The term "dynamic predictors" appears to have emerged from Andrews and Bonta (2006) in their discussion of the Psychology of Criminal Conduct (PCC); it is largely a criminological perspective. They distinguished *static* risk factors (SRF) as relatively fixed aspects of offenders' histories, such as age and the extent of previous offending, which increase the risk of reoffending but do not change and cannot be changed through intervention. As largely fixed, historical characteristics such as SRF are not meaningful targets for intervention. In contrast, Andrews and Bonta (2006) used the term *dynamic risk factors* (DRFs) to describe psychological or behavioral features of the offender that raise the risk of reoffending and that are potentially changeable: "ones on which assessed change is associated with subsequent criminal behavior" (p. 55). They noted some DRFs may be relatively stable for criminal offenders (in that change occurs over weeks, months, or even years), while other DRFs are less stable and "may change almost instantaneously"; they labeled this second group as acute DRFs and "typically reflect immediate situations or immediate circumstances… and/or more immediate emotional states such as anger, resentment, or desire for revenge…" (p. 55). Andrews and Bonta further suggested that DRFs "are often called criminogenic need factors. The term 'need' is used for the practical reason that it carries with it the *hope* that if criminogenic need factors are reduced, the chances of criminal involvement will decrease" (p. 56, emphasis added). From the perspective of social learning theory, when human "needs" (e.g., requirements or desires) are met in an antisocial manner or through antisocial means, an individual's criminality develops and is reinforced; criminogenic needs are then a subset of risk factors that can be demonstrated to be directly related to criminal behavior (including reoffending), some of which may be modifiable so that evidence of a change in the "dynamic" risk factor is associated with evidence of a change in risk of offending or reoffending. As Ogloff and Davis (2004) point out, while offenders may have many needs which may be targeted in some type of treatment, not all are criminogenic (e.g., related specifically but not necessarily uniquely to criminal behavior); however, only focusing on those DRFs or needs associated with offending behavior may lead to a reduction in an individual's risk for offending. Andrews and Bonta (2006) suggested that assessment of DRFs would lead to improved "forecasting" of criminal events and that interventions targeting those DRFs might influence the likelihood of the occurrence of those such criminal events. In particular, they called for the classical experiments (e.g., control groups, random assignment to groups) designed to maintain control over variables that might compete for causal status related to increased or reduced criminal behavior. Empirical work on nonsexual criminal offenders suggested that DRFs predicted recidivism as or better than static, historical variables (e.g., Gendreau, Goggin, and Paparozzi (1996); Zamble & Quinsey (1997)). However, as of 2000, Hanson and Harris (2000) wrote: "When the specific goal is to prevent sexual offense recidivism there is almost no empirical foundation for identifying treatment targets or determining whether interventions have been successful…" (p. 6). They suggested that the development of reliable dynamic risk assessment instruments would therefore greatly assist clinicians: (1) correctly identify dynamic risk factors and (2) measure the effect of treatment in changing such factors.

Several alternative models have been proposed regarding the distinction between so-identified DRFs and other risk-related phenomena. Beech and Ward (2004) suggested that historical and static risk factors function as markers of underlying psychological vulnerabilities to commit a sexual offender and that actuarial risk assessments based on such "fixed" static factors are good predictors of sexual offense recidivism because those static factors "mark" offense-related "proclivities" in certain individuals. Ward and Beech (2004, 2006; this volume) proposed that "clinical factors or symptoms" were clinical risk factors created when stable risk factors transformed into "states" of acute clinical risk in the presence of triggering contextual cognitive, affective, and behavioral triggering factors. Thus, "these clinical or state variables are best viewed as the expression of individuals' underlying vulnerabilities that have been activated by situational events" (p. 47, Ward & Beech, 2006). Those vulnerabilities and/or traits can only be inferred from behavior or overt responses "which are indicative of deeper casual properties of a person's functioning" (p. 47), and "What we are proposing is that the psychological vulnerability factors identified by various theorists in the sexual offending domain

do not pick out in any meaningful sense the underlying causal mechanisms that actually generate sexual abuse. Our suggestion is, rather, that they are simply useful descriptive terms for referring to the surface manifestations of the underlying neuropsychological systems; what we have termed clinical phenomena" (p. 47). Ward and Beech appear to suggest sexual offenders are characterized by long-term, underlying vulnerabilities (risk factors) which in particular situations or contexts "emerge"—"that these clinical risk factors are created when Stable dynamic risk factors become transformed into states of acute clinical risk in the presence of triggering contextual cognitive, affective, and behavioral triggering factors…Therefore these clinical or state variables are best viewed as the expression of individuals' underlying vulnerabilities that have been activated by situational events" (p. 48). Thus, what others regard as "dynamic" risk factors are viewed by Ward and Beech as context-induced "acute" psychological trait-directed "states" that reflect more basic vulnerabilities or psychological predispositions; DRFs are simply the acute mental "states" or surface manifestations that emerge out of or caused by "Stable risk dynamic risk factors" or "underlying traits" which are "activated" in specific contexts. Beech and Ward (2004) suggested that static risk factors are etiologically and predictively significant because they represent *markers* of the past expression or enactment of DRFs as such underlying traits; static or historical risk factors are proxies for such traits or DRFs. Per their "risk-etiology" model of sexual offending, then, "acute" DRFs are simply the manifestation of "stable" DRFs; states are effectively manifestation of more "trait-like" features.

More recently, Mann, Hanson, and Thornton (2010) proposed that "…another way to understand risk factors, instead of classifying them as static or dynamic, is by adopting the concept of *psychologically meaningful risk factors*. Such risk factors can be conceptualized as individual propensities, which may or may not manifest during any particular time period. Like the traditional concept of trait, propensities are enduring characteristics that lead to predictable expressions of thoughts, feelings, or behaviors. Although propensities are characteristics of individuals, these propensities can also be recognized by individuals' transactions with others and the environments in which they live. Through consistency in beliefs, actions, and appearance, offenders can contribute to consistencies of their environment in ways that are relevant to their recidivism risk (e.g., high-crime neighborhoods, criminal associates). The propensity to gravitate toward criminogenic environments would be expected to be a conceptually distinct (and potentially better) indicator of long-term recidivism risk than the criminogenic environments themselves. Although certain circumstances would be expected to contribute to sexual crime (e.g., drinking or using offenders with the propensity to place themselves in such situations would be expected to be at increased long-term recidivism risk compared with offenders whose natural tendencies lead them to safer environments…. We use the term *propensities* to describe psychologically meaningful risk factors in order to emphasize that the problematic behavior of interest arises through interactions with the environment. Aggressive offenders are not aggressive all the time—they become aggressive given certain interpretations of their environment (in the classic cognitive-behavioral sense)" (pp. 194–195). Mann et al. chose not to label these propensities as "traits" because of historical connotations of relatively absolute cross-situational consistency or stability (e.g., Mischel, 1968). Rather, they noted: "Alternate terms that are compatible with our conceptualization are *long-term vulnerabilities* and *if… then…behavioral signature*," (p. 194) citing to Mischel and Shoda (1995). Finally, Mann et al. wrote: "In the context of sexual offender treatment, the most useful propensities are those that are amenable to change. It is not necessary, however, that propensities be amenable to change for them to be psychologically meaningful risk factors or for them to be of interest to treatment providers. For example, the extent to which male sexual interests can be changed through deliberate intervention is debatable. Nevertheless, there is widespread agreement that having deviant sexual interests is a risk-relevant propensity. Even if some criminogenic propensities cannot be changed, it is possible that such propensities can be neutralized through compensatory strengths or prosthetics" (p. 195).

In part as a response to Mann et al. (2010), Ward and Beech (2014) recently elaborated on the distinctions they had made in previous papers. They reiterated: "the following clusters of problems can be reliably discerned in sexual offenders: distorted thinking, social difficulties and intimacy problems, problems with controlling mood, negative mood, inappropriate sexual thoughts and fantasies, substance use problems and difficulty problem solving and goal setting" (p. 7). However, they now made the distinction between the descriptive aspect of identifying DRFs and the explanatory or etiological aspect of causal risk factors. They used the term "exemplar" as the representation of the typical course and symptoms of a disorder, and DRFs should be regarded as descriptive attributes of clinical "exemplars" (a new term). Attributes, descriptively, are linked to the mental state or experiential aspects of the sets of problem clusters related to sexual offending. However, Ward and Beech argued that such exemplars do not necessarily provide a clear explanatory model that is inclusive of interactions among the key psychological, social, and biological constructs and the common trajectories of such constructs and problem clusters. They stressed the importance of an etiological model, which provides "guidance concerning how the causal aspects of dynamic risk factors interact to actually generate observed clinical features and subsequent sexual offending…" (p. 10). Ward and Beech raised concerns that, in effect, lists of iden-

tified correlates or even prospective risk factors do not, in and of themselves, provide causal explanations of the diversity of sexual offending. They conclude:

> In summary, we have argued that in the current state of research dynamic risk factors are really hybrid concepts containing 'symptom' or phenomena aspects and etiological aspects. In our view, the conflation of the descriptive and explanatory elements within a single concept is confusing and runs the danger of derailing research and practice into dead ends. We have argued that viewing the descriptive aspects of dynamic risk factors as attributes of an exemplar(s) and introducing a separate explanatory phase of research that concentrates on developing causal explanations of the exemplar and its associated phenomena and course are ways forward. (p. 12)

Thus, Ward and Beech recommend that after identifying DRFs as clinical phenomena that are effects of causal processes, it is necessary to explain the occurrence of such phenomena (e.g., clinical attributes) and their interrelationships.

The evolution of the conceptualization and attempts at operationalization of DRFs occurred contemporaneously in both the UK and Canada. Following the initial development of static actuarial risk assessment instruments such as the Rapid Risk Assessment for Sexual Offenses (Hanson, 1997) and the Static-99 (Hanson & Thornton, 2000), Hanson in Canada and Thornton in the UK began developing and operationalizing approaches to the conceptualization and measurement of DRFs for sexual offenders.

Following the work of Andrews and Bonta (1998), Hanson and Harris (2000) in Canada began by attempting to empirically identify potential DRFs for sexual offenders. Initially, they studied approximately 400 sexual offenders with different types of target victims, excluding incest offenders. Recidivists had committed a new sexual offense while on community supervision within a 15-month period, whereas a group of informally matched non-recidivists were selected from sexual offenders who had completed comparable supervision for, on average, 24 months. Data was extracted retrospectively from records of relatively brief case notes and 1-h interviews with community supervision officers regarding both groups of individuals; 128 items were reduced into 22 scales. The risk factors identified were assumed to reflect relatively Stable characteristics, and they were rated in terms of whether they changed for the better or worse or showed no change during the study period (identified as acute changes).

Hanson and Harris reported overall, substantial differences between the sexual recidivists and the non-recidivists across a variety of areas. They also noted "supposedly dynamic problems observed during the course of supervision could proxies for enduring (static or highly stable) risk factors" (p. 29). However, even after statistically controlling for the more severe or negative ratings of the sexual recidivists, dynamic variables continued to be strongly associated with sexual offense recidivism: "The recidivists were generally more problematic than the nonrecidivists and their behavior deteriorated just before recidivating" (p. 29). They found that Stable dynamic factors most strongly differentiated recidivists from non-recidivists. Hanson and Harris (2001) organized the DRFs identified in their previous study into a scale they termed the Sex Offender Need Assessment Rating (SONAR) and applied that scale to their previous data set. Based on research-based rationale for the identified constructs, the SONAR items were divided into five Stable factors (intimacy deficits, negative social influences, attitudes tolerant of sexual offending, sexual self-regulation, general self-regulation) and four acute factors (substance abuse, negative mood, anger, and victim access). Inter-rater reliability was consistently high for all sources of data for the 10 % of cases that were coded separately by two raters. The subscores of the recidivists were higher than what the non-recidivists had on the total SONAR score as well as each of the subscales. The ability of the scale to distinguish between groups was moderately high (e.g., $r=0.43$; ROC = 0.74). Even after controlling for preexisting risk factors such as age, IQ, and static actuarial measures, the SONAR continued to distinguish between sexual recidivists and non-recidivists.

In the UK, theoretical and empirical work by several investigators formed the foundation for the development of another approach to the appraisal of DRFs (e.g., Beech, 1998; Thornton, 2002). Utilizing a psychometric battery adjusted by social desirability, Beech (1998) attempted to examine a typology for sexual offenders; he hypothesized that high-deviance group of offenders (those who were socially inadequate with many offense-related problems) would be more likely to have a long history of sexual offending and be at greater risk of reoffending than a low-deviance group of sexual offenders. He found that sexual offenders with more deviant personalities, attitudes, and beliefs were more likely to have a more extensive history of sexual offending, including incest offenders. He concluded: "Deviancy, therefore, may be a used way of defining a baseline in terms of defining treatment need." Based on the cumulative research from a variety of approaches conducted largely in the U.K. correctional system, Thornton (2002) suggested the structured risk assessment (SRA) as a process for evaluating the risk presented by sexual offenders. The full scheme covers static assessment based on unchangeable, statistical risk factors, initial deviance assessment (IDA) based on potentially changeable but relatively Stable psychological risk factors, evaluation of progress based on response to treatment, and risk management based on offense-specialization and acute risk factors. In that article, Thornton described the framework for the IDA and its ability to predict sexual offense recidivism. Per Thornton, deviance was defined in terms of the extent to which the offender's functioning is dominated by the psychological factors that contribute to his offending so that "high deviance" meant that the DRFs

underlying offending are "relatively intense and pervasive" and "low deviance" meant that DRFs were relatively weak in intensity and circumscribed in their effects. He postulated "that the main dynamic risk factors fall into four domains: sexual interests, distorted attitudes, socioaffective functioning and self-management (these domains are discussed in much more detail in Thornton, 2015 this volume). High Deviance is defined as the individual showing problems within at least two domains, Low Deviance is when no marked dynamic risk factors are apparent, and Moderate Deviance is when marked dynamic risk factors are present in just one domain" (p. 140). Thornton (2002) demonstrated that repeat sexual offenders versus one-time sexual offenders were distinguished by greater deviance in the areas of socio-affective dysfunction, self-management, and distorted attitudes as indicated by various psychometric measures (no data was available regarding sexual interests so that domain was not studied at that time). In a separate study reported in the same paper, Thornton found that scores for the three areas of the IDA assessed showed an ROC of 0.78 and that the Static-99 was only moderately correlated with IDA (e.g., $r=0.30$). Of those sexual offenders who were classified in the "high" category on the Static-99 and who scored as "high deviance" on the IDA, 67 % were reconvicted of a later sexual offense (even without information or inference about sexual interests). Thus, these studies suggested that the appraisal of psychological characteristics of sexual offenders was related to but different in terms of the association with sexual offense recidivism as measured by reconviction.

Thornton (2002) identified that the SRA model was intended to be a framework of organizing judgment similar to instruments of structured professional judgment; he queried whether an appraisal of relative deviance might be better accounted for by some weighted combination of the different components within each domain. Subsequently, a version of the SRA was implemented by the correctional services in England and Wales but was termed Structured Assessment of Risk and Need (SARN: Webster et al., 2006). The SARN, like the SRA, considers four domains of DRFs: sexual interests, distorted attitudes, socioaffective functioning, and self-management; 16 DRFs within those four clusters are considered for their relevance to an individual offender. Per Webster et al. (2006), in SARN terminology, DRFs are referred to as "treatment needs" because the SARN is primarily a treatment planning tool. Per Webster et al.: "The SARN utilizes a scoring protocol that examines the relevance of each dynamic risk factor as present both in the proximal lead-up to the sexual offence (the "offence chain"), and/or in the offender's life generally ('generality'). Each risk factor is scored 0 (not present), 1 (present but not a central characteristic) and 2 (a central characteristic). There is a 'not possible to score' option for occasions when information is poor or inconsistent. The basis for scoring each individual dynamic risk factor is set out in a scoring manual that defines each factor, summarizes the research base for its inclusion in the framework, and explains how the scoring system should be applied. This scoring protocol is very similar to that of the SONAR (Hanson & Harris, 2001)…Any factor scored as '2' in both offence chain and generality is defined as a relevant treatment need area for the offender." Webster et al. (2006) reported on the results of two studies (involving three samples) regarding the inter-rater reliability of the SARN. The initial study showed high-inter-rater reliability for a sample of seven expert raters. The second study involved a more diverse group of raters in terms of clinical experience and education (e.g. some with just bachelor's degrees) who had received some training in the use of the SARN; Webster et al. also found support for reliability of the SARN although variability depending on the method of analysis applied. They observed that: "…it may be that in the complicated world of sex offender assessment, where information can be messy and conflicting, and where offenders routinely and intentionally use denial and minimization to confuse their assessors, consistently high levels of inter-rater reliability are not realistically obtainable" (p. 451). Webster et al. concluded that the SARN should be used for guiding clinical assessment of treatment needs.

Of note, Allan, Grace, Rutherford, and Hudson (2007) utilized a psychometric battery to study potential DRFs among approximately 500 sexual offenders who had participated in a prison-based sexual offender treatment program and followed for an average of just under 6 years (p.440). They identified their measures as appraising: sexual interest, anger/hostility, pro-offending attitudes, and social inadequacy. All but anger/hostility had moderate degrees of predictive accuracy. They found that the overall deviance score was correlated to a similar degree compared to an actuarial measure's association with sexual offense recidivism and that the overall score was more strongly related than any of the individual four domains.

The Stable-2007

Background Research

Based on the development of the SONAR, Hanson, Harris, Scott, and Helmus (2007) developed the Stable-2000 and later the Stable-2007. The unique feature of this study was that it was essentially a prospective investigation conducted in the field by actual community supervision officers, and a limitation was that it only followed offenders for 3 years. The most promising Stable and acute DRFs identified by previous work (primarily the SONAR) were organized into a comprehensive assessment package, which was refined through field-testing with experienced supervision (e.g., parole/probation) officers. Next, diverse jurisdictions were

approached with an offer to train officers in the assessment package if they were willing to contribute data for a period of 3 years. Consequently, the data collected for this study represented the combined efforts of community supervision officers from all Canadian provinces and territories, the Correctional Service of Canada, and the states of Alaska and Iowa. Officers participating in the project were asked to collect the following information on new sexual offenders on their case loads: (a) static risk factors upon intake, (b) Stable risk factors every 6 months, and (c) acute risk factors at every offender contact. All offenders were adults starting a period of community supervision (probation or parole) for a recent sexual offense. A sexual offense was defined as an offense with a sexual motivation involving a non-consenting person or persons unable to provide consent.

The measure of Stable risk factors, Stable-2000, was developed for this study. Stable risk factors were defined as offender characteristics that are related to recidivism and capable of changing over months or years. The 16 factors were assessed using three-point ratings scales "0 (no problem)," "1 (some concern/slight problem)," and "2 (present/definite concern)," following a structured scoring manual. The manual instructed evaluators to estimate the offender's typical or baseline level of functioning during the following 6–12 months based on all available information. The minimum information required was a structured interview with the offender and a file review of sufficient depth to score the static information requested above (Static-99 scores, victim information, demographics). When available, evaluators were encouraged to use other sources of information, such as psychological assessments, police reports, specialized testing, previous presentence reports, and collateral contacts. All officers submitting data to the project were required to attend a 2-day training session.

The 16 items were organized into six sections and were scored on a Tally Sheet. The first section, *significant social influences*, identified the "nonprofessional" people in the offender's life who were not paid to be with him or her and then computed a section score based on the number of positive and negative social influences. The *intimacy deficits* sections contained 5 items: (a) stability of the offender's current intimate relationship, (b) emotional identification with children, (c) hostility toward women, (d) general social rejection/loneliness, and (e) lack of concern for others. Three items were included in the *sexual self-regulation* section: (a) high sex drive/sexual preoccupations, (b) use of sex as a coping strategy, and (c) deviant sexual interests. The *attitude* section assessed (a) sexual entitlement, (b) attitudes tolerant of rape, and (c) attitudes tolerant of adult–child sex. The fifth section assessed the officers' assessment of the degree to which the offender was *cooperating with supervision*. Per Hanson et al., this included explicit compliance with the conditions of supervision and a more general evaluation of whether the offender was "working with" or "working against" the officer. The final section, general self-regulation, addressed three items: (a) impulsive acts, (b) poor cognitive problem-solving skills, and (c) negative emotionality/hostility. After scoring all the subsections, for the Stable-2000, the *highest score in each subsection* counted as the section score, resulting in total scores that could range from 0 to 12. The following nominal categories for the degree or "density" of DRFs or sexual offending "needs" were proposed for the Stable-2000: 0–4 was "low" need, 5–8 was "moderate" need, and 9–12 was "high" need.

The Acute-2000 included seven items access to victims, emotional collapse, collapse of social supports, hostility, substance abuse, sexual preoccupations, and rejection of supervision. Each item was rated according to a scoring manual from "0 (no problem)," "1 (maybe/some)," "2 (yes, definite problem)," and "3 (intervene now)". An "intervene now" category was designed to indicate situations in which the officer felt that the risk of new offending was sufficiently high that preventive actions were immediately necessary (e.g., offender making direct threats against a specific victim, realistic suicidal ideation).

Regarding reliability, the agreement was high between the original ratings and the consensus ratings developed through file reviews. The intraclass correlation was 0.89 for Stable-2000 total scores ($k = 87$). The ICCs for the individual Acute items ranged from 0.64 to 0.95, with a median of 0.90 ($k = 75$). The Stable item with the lowest rater reliability was significant social influences (ICC of 0.66) and the acute item with lowest rater reliability was collapse of social supports (0.64). Analyses were conducted on the subgroup of offenders for whom complete data were received to examine the effects of variable data quality on the results. For these offenders, the officers had completed the static assessment, an override rating, and at least one Stable and at least one acute assessment. Hanson et al. assumed that the officers who completed the full assessment package were the most conscientious and committed to the project and, as a result, would produce the most reliable data ; these individuals were subsequently referred to as the "conscientious" evaluators. The only item that had unacceptable levels of rater agreement was the override rating, in which the ICC was not meaningfully above chance levels (ICC = 0.15, $k = 74$).

The outcome variable of recidivism was obtained via various sources. Information concerning new offenses was gathered through reviews of state, provincial, and national (Canadian) criminal history records, as well as from supervising officers and local police jurisdictions. For Canadian offenders, centralized criminal history records maintained by the RCMP were received at two points in time; in addition, provincial/state records were received from the following several provincial jurisdictions. The Offender Management System of the Correctional Service of Canada (CSC) was

also checked in recidivism information of the CSC offenders registered in the project. For the purpose of survival analyses, the start date was the date of the first assessment or the date of release into the community, whichever was latest. The survival end date was the earliest of the following events: sexual recidivism, death, deportation, end of follow-up, or incarceration for a period of time that included the follow-up end date.

Five types of recidivism were available for study. The first category was "sexual crime recidivism," which included all crimes with a sexual motivation, whether or not the name of the offense was explicitly sexual. This included contact and noncontact offenses, as well as sexual offenses involving consenting adults (e.g., prostitution, public sex). The second category, "any sexual recidivism," included sexual crimes as well as sexual breaches, defined as official sanctions for sexually motivated violations of the conditions of community supervision including behavior that was not otherwise illegal (e.g., child molester loitering in a park). "Violent recidivism" was defined as all crimes that involved direct confrontation with the victim and included sexual crime recidivism but not sexual breaches. Given that some of the sexual offenses were not violent (e.g., prostitution), this category could also be called "violent or sexual recidivism." The fourth category was "any criminal recidivism," which included all crimes but excluded breaches. The final category, "any recidivism," included all crimes (sexual, violent, and nonviolent) as well as all breaches (sexually motivated and other). The overall recidivism rates for the 991 male offenders in the sample for the 3-year follow-up were as follows: sexual crime, 7 % (68); any sexual recidivism including sexual breaches, 9 % (90); any violent or sexual recidivism, 14 % (134); any criminal recidivism, 19 % (185); and any recidivism including breaches, 28 % (277). There were significant differences in the recidivism rates across jurisdictions. Such differences would be expected given the differences in the follow-up times and the sources of the recidivism information and that the different jurisdictions were responsible for different offenders (only those with probation sentences, only those with sentences of 2 years or more, all sex offenders sentenced in a state for nonfederal offenses).

Analysis of the collected data leads to the modification of the Stable-2000 such that a new instrument, the Stable-2007, was created. Results showed that 7 of the 16 items were characterized by significant linear relationships to all outcomes: (1) negative social influences, (2) hostility toward women, (3) rejection/loneliness, (4) lack of concern for others, (5) lack of cooperation with supervision, (6) impulsive acts, and (7) poor cognitive problem-solving. An additional three items showed significant, linear relationships with the outcome criteria they were specifically designed to predict: (8) sexual preoccupations and (9) sex as coping were significantly related to sexual recidivism; (10) negative emotion/hostility was related to violent and general recidivism. These 10 items were retained without revision in the Stable-2007.

None of the three attitude items as rated was found to be significantly related to sexual recidivism. Emotional identification with children showed significant, but nonlinear relationships with sexual recidivism in the total sample and among the child molesters (ROC AUC were nonsignificant). For child molesters, there was little difference in the sexual recidivism rates of those who scored zero or one (5 %), but those who scored two showed significantly higher rates of sexual recidivism (16 %).

Deviant sexual interests were only weakly related to sexual reoffending, which was surprising given its strong association with sexual recidivism in previous meta-analyses of static risk factors associated with sexual offense recidivism (Hanson & Bussiere, 1996, 1998; Hanson & Morton-Bourgon, 2004, 2005). The original scoring rules of the Stable-2000 specified that deviant interests could be assessed via self-report, specialized testing, or offense history. However, examination of the obtained data suggested that a significant minority of the corrections officers had given insufficient weight to offense history in their judgment of deviant interests (e.g., an offender with eight boy victims was scored as a "zero"). Consequently, this item was revised for Stable-2007, requiring offense history to be considered in the assessment of deviant sexual interests. Specifically, minimum scores were set based on the total number of prior victims (two to seven victims required a minimum score of "one"; eight or more victims required a minimum score of "two"). Given that requiring scorers to count prior victims makes it methodologically "impossible" for those with eight or more victims to improve, a sub-item was added that addresses whether sexual behavior during the past 2 years indicated nondeviant adjustment. In summary, ten of the original Stable-2000 items predicted recidivism as well or better than expected and were retained in Stable-2007. Of these, three additional items were retained with minor modifications (relationship stability, emotional identification with children, and deviant sexual interests). Since the three attitude items did not meaningfully predict sexual offense recidivism, they were deleted from the Stable-2000 when it was modified to the Stable-2007. Overall, there are three key differences between the Stable-2000 and the Stable-2007. First, the Stable-2007 does not attempt to appraise or utilize information related to attitudes supportive of sexual offending. In addition, the scoring criteria were refined for three times: deviant sexual interests, lovers/intimate partners, and emotional identification with children. Finally, the procedure for calculating the total score was simplified and nominal categories (low, moderate, high) were based on the observed distribution of scores in the DSP sample.

Additionally, the method of combining the Stable items was reevaluated and changed from the Stable-2000 to the Stable-2007. Two main options considered were (a) using the worst score in each subsection (the original method) and (b) summing all items. Neither method was more accurate than the other; the relative superiority of the two approaches changed based on the outcome criteria and subgroup examined, and none of the differences in predictive accuracy was statistically or practically significant. Consequently, for simplicity, in scoring the Stable-2007 Stable items, a sum of item scores is utilized. Given that emotional identification with children is scored only for child molesters, total scores can range from 0 to 24 for sexual offenders without child victims and 0 to 26 for sexual offenders with child victims (e.g., including the possibility of two more points for emotional identification with children). In the DSP study, the average total Stable-2007 score was 7.5 ($SD = 4.9$, range of 0–26, $n = 792$). The internal consistency (alpha) of the 13 Stable-2007 items was 0.80 (for the 16 Stable-2000 items, alpha was 0.83).

Stable assessments were to be completed every 6 months for the duration of community supervision. For the sample of 991 offenders, 799 initial Stables were obtained; in addition, the investigators collected 293 s Stables, 114 third Stables, 46 fourth Stables, and 19 fifth Stables, and for one offender, a sixth Stable was obtained. Given the short follow-up time and low recidivism rates, it was deemed most appropriate to test the relationship to sexual recidivism with the first and second Stable assessments. The Stable-2007 scores were highly consistent between the first and second assessment, ICC of 0.79 (« =292). On average, offenders were assessed as having fewer needs on Stable-2007 at the second assessment ($M = 6.5$; $SD = 4.9$) than at the first assessment ($M = 7.2$; $SD = 4.6$; $t = 3.79$; $df = 291$; $p < 0.001$). The amount of change between the first and second assessments was unrelated to any form of recidivism. To examine whether the second assessment was more accurate than the first assessment, the first Stable-2007 assessment and the second Stable-2007 assessment were used to predict recidivism 12 months and 24 months after the second assessment. The predictive accuracy of both assessments was similar. When both the first and second assessments were entered simultaneously in logistic regression to predict 12 months and 24 months recidivism for the five outcome variables, the overall model was significant in all cases, but neither assessment contributed uniquely in 9 of the 10 analyses. The only exception was that the second Stable assessment significantly contributed beyond the first Stable assessment for the prediction of sexual recidivism during the following 12 months. This finding is consistent with expectations, but should be treated cautiously because it was based on only six sex offense recidivists.

Regarding acute dimensions presumed to function as DRFs, over approximately a 5 ½ year period, 149 officers had submitted 7,050 acute ratings for 744 adult male offenders. The number of acute ratings per offender ranged from 1 to 70, with a median of 7 ($M = 9.5$, $SD = 9.2$). A "unique" acute factor was rated in 75 % of the assessments. However, "unique" acute factors were not significantly related to any form of recidivism. The seven acute factors were all significantly correlated with each other, with a median correlation of $r = 0.24$ (range of 0.13–0.49). A principal component factor analysis generated the following initial eigenvalues: 2.6, 1.0, 0.87, 0.85, and 0.65. The scree plot suggested a single factor, but a two-factor varimax rotation provided a relatively clean second factor composed of sexual preoccupations (0.75), victim access (0.74), rejection of supervision (0.61), and hostility (0.51). The internal consistency of these four items was 0.65 (alpha) and 0.72 for all seven items.

A variety of different analyses were conducted using acute ratings from different time frames to examine the predictive accuracy of acute variables: (a) the most recent rating within 45 days of recidivism, (b) the average rating within 45 days, (c) the average rating within 90 days, and (d) the average rating within 183 days (6 months). The acute ratings for the recidivists were compared to acute ratings for non-recidivists based on a randomly selected date. For these analyses, the recidivists were defined as those offenders who reoffended within the specified time frame, while the non-recidivists were those who never reoffended with the specific type of crime. Offenders who reoffended with the specific type of crime outside of the time frames were considered to be "missing." Each of the five recidivism outcomes was analyzed separately, with different recidivism and non-recidivism dates in each sample.

Regarding the Acute variables, (1) victim access, (2) sexual preoccupation, and (3) rejection of supervision were associated with all types of recidivism in all analyses, and (4) hostility was significantly related to recidivism in 13 of 15 analyses. These are the same four variables that clustered together in the factor analyses. (5) Emotional collapse, (6) collapse of social supports, and (7) substance abuse were significantly associated with any recidivism in all time frames, and with any criminal recidivism in two of the three time frames. These three factors (emotional collapse, collapse of social supports, and substance abuse), however, were not consistently related to sexual or violent recidivism. Consequently, the acute variables were considered to comprise two scales: (a) the total of the seven items as a predictor of general recidivism and (b) a subscale consisting of the four sexual/violence items (victim access, sexual preoccupation, rejection of supervision, and hostility).

For the four sex/violence factors, the recommended cut scores were as follows: none = low, one (maybe/possible problem) = moderate, and two or more = high. For all seven acute factors, the recommended cut scores were as follows:

none = low, one to two = moderate, and three or more = high. The acute scales showed moderate ability to differentiate between the imminent recidivists and the non-recidivists (ROC AUCs of 0.65–0.74). Out of the total collection of 7050 ratings, the average score for the sex/violence factors was 0.99 (*SD* = 1.4, range of 0–12) and 1.68 (*SD* = 2.1, range of 0–18) for all acute factors. Results for the 45 days averages showed essentially the same results as the 90 days averages. Hanson et al. examined whether the correlations with recidivism were higher for the assessment conducted in the most recent time period compared to the assessments conducted in the next previous time period. There was no clear superiority for the most recent assessment for time periods less than 6 months. For the 6 months average, however, the average ratings in the most recent 6 months were generally better predictors of recidivism than the average ratings in the prior 6 months (correlations based on all acute totals: 0.25 vs. 0.24 for sexual crime recidivism, 0.18 vs. 0.26 for any sexual recidivism [*wrong direction*], 0.30 vs. 0.29 for any violent recidivism, 0.31 vs. 0.24 for any criminal recidivism, and 0.38 vs. 0.32 for any recidivism; sample sizes range from 217 to 235). Importantly, however, the differences were not strong even at 6 months, suggesting that the acute variables assessed in this study were more "Stable" than originally conceptualized. A related, important finding was that *averaging* the acute ratings over longer time periods increased their predictive accuracy. For example, for the predictions of sexual offense recidivism, the correlations with victim access increased from 0.12 for the most recent assessment in the last 45 days, to 0.23 for the average of all assessments in the last 45 days, to 0.29 for the average of the last 6 months (all $p < 0.01$). Similar patterns were shown for all other risk factors.

The absolute risk of imminent recidivism was small for all types of recidivism. Out of the total 7050 acute assessments, only 17 immediately preceded a new sexual crime (approximately one in 400). Even for the most frequent types of recidivism (any), the frequency was only one in 75 (93/7050). A series of different analyses was conducted to determine the extent to which change in the acute factors was associated with increased risk, including the most recent and the average scores for 45, 90, and 183 days each compared to the average rating of the next comparable time period. In *none* of the analyses were the difference scores significantly related to any type of recidivism. As well, the officers' global ratings of whether the factors were "getting better," "getting worse," or "staying the same" were *not* related to recidivism. That is, attempts to measure and understand factors or changes related to imminent recidivism were unsuccessful; raters were not able to identify "acute" indicators of such behaviors.

Relative predictive accuracy of the risk scales was measured using the area under curve or the receiver operating characteristic curve (AUC; Swets, Dawes, & Monahan, 2000); for the Stable-2000, the ROC was 0.64, and for the Stable-2007, the ROC was 0.67.[1] However, when only the Stable-2007 ratings completed by the subset of "conscientious" raters (e.g., those who had completed at least one full assessment) were examined, the AUC for sexual recidivism rose to 0.77, suggesting that the overall ROC for the Stable-2007 reflected significant variation in how carefully items were rated by some community officers. Similar to other areas and activities of risk assessment, the degree of carefulness and value placed on instrument scoring lead to a significantly higher degree of predictive accuracy.

An important question for the DSP was the extent to which DRS variables added useful information beyond that captured by Static-99. In the DSP data set, the average Static-99 score was 3 (*SD* = 1.9), and it showed moderate relationships with the recidivism outcomes, with ROC AUC ranging from 0.69 to 0.74. In order to test the incremental validity of Stable-2000 and Stable-2007 over Static-99, Hanson et al. employed Cox regression (with jurisdictions identified as strata) and Static-99 scores as the covariate. They found that Stable-2007 made a significant incremental contribution for all types of recidivism, while Stable-2000 made a significant incremental contribution for all types of recidivism, *except* for sexual offense recidivism. Thus, the Stable-2007 demonstrated statistically significant for sexual crime, any sexual recidivism (including breaches), violent or sexual crime, any crime, and any recidivism (including breaches).

Hanson et al. also explored the optimal method for combining the static and Stable variables into nominal categories using different cut-points and combination rules. The previous categories proposed for Stable-2000 were deemed not optimal. Rather, the predictive accuracy of the need categories was initially found to be improved by using the following categorization: 0 to 2 = low need; 3 to 7 = moderate need; and 8 or greater = high need. The recommended three-group categorization for Stable-2007 is as follows: 0 to 3 = low need, 4 to 11 = moderate need, and 12 or greater = high need. Approximately 20 % of the high-need group reoffended with a sexual crime or sexual breach compared to approximately 8 % in the moderate need group and 3 % in the low-need group. However, in addition, study results indicated that sexual offenders who were classified as high risk on the Static-99

[1] An AUC of 0.56 corresponds to a small effect size, while 0.64 reflects a moderate effect and 0.71 reflects a large effect size (Rice & Harris, 2005). An AUC value is statistically significant if the 95 % confidence interval does not include 0.50. The AUC can vary between 0 and 1, with 0.50 indicating the level of prediction that would be expected by chance, and AUCs above 0.50 demonstrating positive predictive accuracy (i.e., higher risk scores are associated with a higher likelihood of reoffending). AUCs can also be interpreted as the probability that a randomly selected recidivist would have a higher risk score than a randomly selected non-recidivist.

but low or moderate need on Stable-2007 were still classified as high priority cases. Further, a fifth category of "very high priority" was created for individuals who scored high on both Static-99 and the Stable variables. To further reduce variability due to diverse sources of recidivism information, other reliability analyses were restricted to Canadian offenders for whom national criminal history records had been received. In these analyses, the predictive accuracy of the static and Stable variables was high. The median AUC for the Static-99/Stable-2007 categories was 0.80.

Hanson et al. concluded that the DSP demonstrated that community supervision officers were able to assess current social and personal characteristics of sexual offenders that were meaningfully related to sexual, violent, and general recidivism. Previous research has documented that recidivism can be predicted by static, historical variables, such as offense history and victim characteristics; in the current study, such static variables also showed moderate to large associations with recidivism. Nevertheless, it was possible to improve the accuracy of risk assessments by using a structured approach to combine static, Stable, and acute characteristics into an overall evaluation of current risk.

The current results were consistent with previous studies in which Stable dynamic characteristics significantly contributed information to the prediction of recidivism above that given by established, static actuarial measures (Beech, Friendship, Erikson, & Hanson, 2002; Hanson & Harris, 2000; Thornton, 2002). To our knowledge, the current study is unique in that it used a truly prospective design in which officers conducted assessments as part of routine supervision practices. The officers were trained in the risk assessment methods, they assessed new cases, and recidivism information was collected on those cases during an average 3-year follow-up period.

More recently, Helmus and Hanson (2013) provided data, including updated 5-year recidivism tables for the Stable-2007 in combination with the Static-99R (Hanson & Thornton, 2000; Helmus, Thornton, Hanson, & Babchishin, 2012) and the Static-2002-R (Hanson & Thornton, 2003; Helmus, Thornton et al., 2012). They advise that this updated information be utilized in place of that previously provided in the appendices of Fernandez, Harris, Hanson, and Sparks (2012).

Recidivism estimates for the Stable-2007 (when combined with Static-99R, Static-2002R) were calculated using life table survival analysis (Soothill & Gibbens, 1978). By estimating what the recidivism rate for the sample would be if everyone had been followed up to that point (based on information from cases with that length of follow-up), survival analysis corrects for unequal follow-up times. Although the median follow-up period was 8 years, recidivism estimates are presented only up to 5 years. For the overall sample, 5-year recidivism rates (from survival analysis) were 11 % for sexual recidivism, 13 % for sexual recidivism including breaches, 15 % for nonsexually violent recidivism, 20 % for any violent recidivism, 30 % for any new crime, and 36 % for any recidivism. As Helmus and Hanson point out, these rates may be higher than recidivism rates published from other relatively routine samples of sex offenders for several reasons: recidivism information was obtained from multiple diverse sources, attempts were made to identify the circumstances of offenses so that seemingly nonsexual offenses could be classified as sexual offenses if there was a sexual motivation, and analyses used the date of offense, which was often much sooner than the date of charge/conviction that is typically used in other studies.

Relative predictive accuracy of the risk scales for a 5-year follow-up period was again measured using the area under curve or the receiver operating characteristic curve (AUC; Swets et al., 2000). The Stable-2007 significantly predicted all five recidivism outcomes (sexual, sexual including breaches, violent, any crime, and any recidivism). For predicting sexual recidivism, the Stable-2007 demonstrated moderate predictive accuracy for all outcomes. ROCs for the Stable-2007 were sexual recidivism, 0.67; sexual (including breaches), 0.73; violent recidivism, 0.71; any crime, 0.73; and any recidivism, 0.70.

Cox regression analyses were used to examine whether the Stable-2007 added incremental predictive accuracy to the static risk scales (i.e., does it provide unique information?). Cox regression estimates relative risk ratios (hazard rates) associated with one or more predictor variables from survival data with unequal follow-up times (Allison, 1984).[2] Each of the Static-99R and Static-2002R scores was entered first into the regression equation to control for their effects. When examining all cases, the Stable-2007 provided incremental predictive accuracy over Static-99R and Static-2002R for the prediction of any sexual (including breaches) recidivism, violent recidivism, any crime, and any recidivism. For sexual recidivism utilizing available ratings by all participating community supervision officers, the Stable-2007 did not provide incremental predictive accuracy over Static-99R in the overall analyses; the incremental effect of Stable-2007 over Static-2002R, however, approached significance for sexual recidivism ($p = 0.060$). However, when analyses were restricted to conscientious officers (again defined as those who submitted more complete information than was requested of them; see Hanson et al., 2007 for more information), the incremental effects over both Static scales increased and were statistically significant for all outcomes (Static-99R: $p < 0.048$ and Static-2002R: $p < 0.044$). Percentages of sexual offense recidivism are provided below for combina-

[2]For analyses of the incremental effect of Stable-2007 above Static-99R or Static-2002R, the analyses used the offender's jurisdiction (e.g., province or region) as a strata variable, which takes into account different survival rates across the jurisdictions.

Table 1 Stable-2007, SRA-FV, and VRS-SO domains and subdomains

SRA domains	Stable-2007 items	SRA-FV	VRS-SO items
Sexual interests	Deviant sexual preference	Sexual preference for children	Sexually deviant lifestyle
	Sex drive	Sexualized violence	Deviant sexual preference
	Sexual preoccupation	*Sexual preoccupation*	Sexual compulsivity
	Sex as coping	*Rule based/narrow*	Offense planning
		Concept based/broad	Sexual offending cycle
Distorted attitudes	Hostility toward women		
Relational style	Capacity for relationship stability	Lack of emotional intimacy with adults (LEIRA)	Intimacy deficits
	Emotional identification with children	Emotional congruence with children	
	General social rejection or loneliness		
	Lack of concern for others		
	Negative emotionality (hostility)	Callousness	
		Grievance thinking	
		Internal grievance thinking	
		Poorly managed anger	
Self-management	*Social influences (antisocial)*		***Criminality***
			Impulsivity
	Impulsive acts	Lifestyle impulsivity	Interpersonal aggression
	Poor (cognitive) problem-solving skills	Dysfunctional coping	Substance abuse
	Cooperation with supervision	Resistance to rules and supervision	Compliance with community supervision (–)
			Criminal personality

			Emotional control (–)
			Treatment responsivity
			Insight
			Cognitive distortions
			Treatment compliance
			Release to high-risk situations

tions of Static-99R and Static-2002R score levels, respectively, with Stable-2007 score levels (Tables 1 and 2).

Administering the Stable-2007

As an empirical actuarial risk tool purportedly assessing dynamic risk factors among adult male sex offenders, the Stable-2007 is a scale composed of 13 items modified from the Stable-2000. For the Stable-2007, there are no acute factors to be considered. For the item measuring relationship stability, the scoring rules were modified to incorporate relationship history in addition to current relationship situation. The emotional identification with children item was revised so that it is only scored for offenders with at least one victim under 14 years of age. The deviant sexual interest item was revised to provide more detailed scoring guidelines and also to incorporate victim information as indicators of sexual deviance. A particularly detailed and comprehensive structured manual and semi-structured interview were created by Fernandez et al. (2012) to guide the information collection and scoring of Stable-2007 items.

Regarding data to be used to score the Stable-2007, Fernandez et al. recommend utilizing comprehensive information about the offender; it is noted that judgment is involved for all items. As noted, Fernandez provides a detailed semi-structured interview. They state that potentially useful interview questions are suggested with each item. Those potential questions are collated into a sample interview; the interview questions are provided as a guide and experienced interviewers are encouraged to use their judgment regarding the most appropriate phasing of questions to best obtain the necessary information. In addition, "there is no expectation that experienced interviewers will use all of the provided questions or use them in the order they are presented." It is noted that in the areas of sexual self-regulation and general self-regulation, the link between interview questions and scoring is less direct; from a global inquiry and in the context of all available information, the evaluator is expected to make judgment based on their over-

Table 2 Predictive accuracy of Static-99R, Static-2002R, and Stable-2007[a]

		Sexual recidivism			Sexual (including breaches)			Violent recidivism			Any crime			Any recidivism (includes breaches)		
	n	AUC	95 % CI		AUC	95 % CI		AUC	95 % CI		AUC	95 % CI		AUC	95 % CI	
Static-99R	764	0.73	0.67	0.80	0.73	0.67	0.78	0.71	0.67	0.76	0.73	0.69	0.77	0.74	0.70	0.77

Stable-2007	615	0.67	0.60	0.74	0.69	0.62	0.75	0.67	0.62	0.72	0.69	0.64	0.73	0.71	0.67	0.75

[a]Table taken from Helmus and Hanson (2013)

all opinion of the offender's functioning in that area. They noted that it was designed so that it could be completed in a single, 1-h session. However, they note that in practice, most evaluators have reported spending between 90 and 120 min spread over two sessions with offenders in the community. Scoring should consider all available collateral information—both historical and recent and item scores for community subjects are scored both on the basis of interview and collateral information. Ratings represent estimates of a community-located offender's typical or current "baseline" functioning with "the primary task to determine expected functioning over the next 6–12 months." It should be noted that Eher in their application of the Stable-2007 to an incarcerated sample of offenders found that reliable and valid ratings of the times could be based on just archival and/or institutional information. After the findings by Hanson et al. (2007), Fernandez recommends that raters "need to be conscientious (i.e. committed to completing a thorough and quality assessment)" (p. 23).

The manual provides a detailed description of the "basic concept" behind each item, a short description of the research related to the item, issues to consider, special considerations as appropriate, information needed to score each item, other possible sources of information, and detailed description and criteria for scoring. In addition, sample interview questions, cross-references to other subsections or items on the Stable-2007 that may relate to the particular subsections or items, and scoring profiles or exemplars are provided. Each item is rated using a three-point rating system, where 0 refers to "not present" or "no concern" and 2 refers to "definitely present" or "definite concern." A score of "1" is given when there is uncertainty about whether the factor(s) is present, it is somewhat present, or it is present but it is not strong enough to justify a "2." When scoring the items for sexual offenders in the community, evaluators should estimate the offender's typical or baseline level of functioning during the following 6–12 months based on all available information. For scoring offenders who are incarcerated or otherwise institutionalized, evaluators should rate the offender's typical or baseline functioning prior to being detained (e.g., Eher et al., 2012). Training by identified certified trainers is strongly recommended for individuals not already trained in the Static or Stable measures or wishing to improve their scoring acumen.

In the initial DSP report, the best method of combining the Stable-2007 with Static-99 and Static-2002 was explored, and an algorithm was proposed. With the updated findings and revised Static scales, the data were reexamined and did not demonstrate a need to revise these rules. Helmus and Hanson (2013) provided the rules for combining Stable-2007 with Static-99R and Static-2002R, respectively. The result of this combination is named the "overall priority level" or the "overall risk level." The basic rules start with the Static risk categories, and the overall risk/priority category is *increased* one category if the Stable-2007 score is high and *reduced* one category if the Stable-2007 score is low. If the Stable-2007 score is moderate, the offender's overall risk/priority category remains the same as that determined by the Static tool. Helmus and Hanson caution that nominal labels for risk categories refer only to relative risk. That is, offenders in the "high" category would be expected to be more likely to reoffend than offenders in the "moderate" category; however, the category labels are not intended to conform to any absolute recidivism rates or thresholds for specific decisions

Helmus and Hanson identified certain exceptions to the basic rule. Offenders are not assigned to a new category lower than "low," even if the offender's Stable score is low. For Static-2002R, offenders are not assigned to a new category higher than "high," even if the Stable score is high. However, for Static-99R, in contrast, a new "very high" category was created for offenders scoring high (6+) on the Static measure and high on Stable-2007 (this new category means there are 5 overall risk categories regardless of whether an evaluator uses Static-99R or Static-2002R in conjunction with Stable-2007). Further, offenders who receive high scores on Static-99R are not assigned to the next lower category even if they have low Stable scores [in the original DSP analyses, there were only two offenders with a high Static-99R score and low Stable-2007, one of which sexually reoffended (an exhibitionist)] (Tables 3 and 4).

Other Research Regarding the Stable-2000/2007

The Stable-2007 has been studied by a number of independent investigators. Nunes and Babchisin (2011) examined the construct validity of the Stable-2000 and Stable-2007 by

Table 3 Incremental predictive accuracy of Stable-2007 above Static-99R and Static-2002R[a]

examining correlations between selected items and independent self-report measures of relevant constructs in samples of convicted sexual offenders. One group consisted of a convenience sample of 33 adult male child molesters, while another group was a sample of 95 adult male sexual offenders participating in sexual offender treatment. As they reported, the results generally suggested that the Stable items examined were associated with measures of similar constructs. However, the investigators noted that the degree of convergence was lower than expected. Comparing evaluator ratings to offender self-report of offense-supportive attitudes, deviant sexual interests, etc. may, in and of itself, be problematic; as Nunes and Babchisin noted social desirability and/or lack of insight might account for the diminished convergence and that current brief self-report measures may not provide complete and accurate description of the Stable constructs.

Eher, Rettenberger, Matthes, and Schilling (2010) studied a group of contact child molesters ($n=127$) released from prison and followed for approximately an average of 6.4 years. Most of the subjects met criteria for pedophilia and a personality disorder (predominantly from Cluster B). All ICCs were highly significant ($p<0.001$) for the Stable-2007 (ICC = 0.90). The results indicated that ROC of the Stable-2007 was in the moderate high range (e.g., 0.77). In addition, using the coding rules specified in Hanson et al. (2007) or simply adding the scores of the Static-99 and Stable-2007 "yielded the beset predictive accuracy of all risk assessment methods leading to high AUC-values" (e.g., 0.86). In addition, Eher et al. (2010) found that a diagnosis of narcissistic personality disorder demonstrated a unique relationship with sexual offense recidivism, even when static risk and DRFs as measured by the Stable-2007 were controlled for.

Eher et al. (2012) extended the application of the Stable-2007 to adult sexual offenders ($n=263$) who had been released from incarceration (in Austria) and followed for an average of 6 years. Participants were included if they had a sexual offender as their index offense and had been released to the community for a minimum of 50 months prior to August, 2010; they had served a mean sentence of 32 months. Approximately half of the sample was described as rapists, with the other half described as child molesters.

Each offender received a comprehensive forensic assessment involving both static actuarial risk assessment instruments; the assessments were conducted by "experienced forensic psychologists and psychiatrists." Information was originally collected to score the SONAR and then its successors the Stable-2000 and the Stable-2007. With the exception of Item 1 (significant others) on the Stable-2001 and Stable-2007, the 16 and the 10 items (on each measure respectively) were rated. The items for the Stable-2007 regarding lovers/intimate partners and sexual deviance were rated retrospectively by analysis of archival material. The inter-rater reliability of each Stable instrument was assessed on 15 randomly selected cases and evaluated by intraclass correlation coefficients (ICCs). All ICCs were highly significant

($p < 0.001$) for the Stable-2000 (ICC = 0.89) and the Stable 2007 (ICC = 0.90).

In the total sample, the average Stable-2000 score (without Item 1"significant others") was 7.5 ($SD = 1.5$), and the average Stable-2007 score (without Item 1 "significant others") was 10.9 ($SD = 2.9$), compared to a mean of 7.5 from the DSP study. Regarding sexual offense recidivism, the AUCs for the Stable-2000 and Stable-2007 were 0.62 and 0.71, respectively. The Stable-2007 demonstrated a significant and comparable AUC relative to the Static-99 (Hanson & Thornton, 2000) and the Sex Offender Risk Appraisal Guide (SORAG; Quinsey, Harris, Rice, & Cormier, 1998, 2006). Since the Stable-2000 was shown to have relatively weak predictive accuracy for sexual offense recidivism and no association with violent recidivism, the Stable-2000 was excluded from subsequent data analyses. In contrast, regarding validity, the Stable-2007 correlated 0.23 with sexual offense recidivism and 0.25 with violent recidivism.

A comparison between the 4-year predicted sexual offense recidivism rates of the five Static-99/Stable -2007 nominal priority categories showed no differences in absolute risk relative to those rates identified by Hanson et al. (2007). Despite the strong correlations for variables related to sexual interest found in studies on specific static risk factors for sexual offense recidivism, Eher et al. found weak correlations between the Stable-2007 sexual self-regulation domain and sexual offense recidivism. Of particular importance, the Stable-2007 sum score made a significant incremental contribution over both the Static-99 and the SORAG (e.g., when each static risk measure was controlled prior to testing, the predictive validity of the Stable-2007 sum score) for imprisonment (general and violent) and for reoffense in general. The AUC for sexual offense for the combination (sum) of the Static-99 and Stable-2007 scores was 0.76. Relative to the five nominal risk categories identified by Hanson et al. (2007), Eher et al. found that just three risk/need categories (low need, moderate need, and high need) produced better predictive accuracy compared to the cutoffs or categories proposed by Hanson et al. (2007). These Stable-2007 nominal risk categories made a significant incremental contribution over the Static-99 for all reoffense categories except for sexual reoffense, which approached significance ($p = 0.086$). Eher et al. suggested that the predictive accuracy of the Stable-2007 need categories could be improved by using new cutoffs (e.g., three risk/need categories) for their sample.

In summary, applying the Stable-2007 to the follow-up of an incarcerated sample of sexual offenders, Eher et al. confirmed the findings of Hanson et al. that (1) the Stable-2007 clearly outperformed the Stable-2000 for all outcome variables of reoffense/reconviction; (2) the Stable-2007 total or sum score, as a putative measure of DRFs, contributed to predictive accuracy beyond that of just static variables (was a significant predictor even after controlling for static risk factors); predictive reoffense/reconviction; and (3) the Stable-2007 total or sum score did not make a significant incremental contribution to Static-99 scores when predicting sexual offense recidivism, but the Stable-2007 score did for the SORAG. Eher et al. (2010) did find that their modified (three tier) nominal risk system was more effective than the five-tier system utilized by Hanson et al. Eher et al. concluded: "In summary, our study provides further support for the utility of the Stable -2007 in risk prediction of sexual offenders. Stable -2007 scores were not only found to predict sexual reoffense, but also general and violent reoffense. The combination of STATIC-99 and Stable -2007 led to a significant improvement of risk prediction over the STATIC-99 scores alone…. A combination of an actuarial and a dynamic risk-prediction tool, therefore, was demonstrated to lead to an improvement in predictive accuracy in sexual offenders…" (p. 24).

Seto and Fernandez (2011) applied the 6-item Stable-2000 to over 400 sexual offenders referred for assessment between 2000 and 2007; such appraisals occurred at entry to a federal penitentiary. Applying a two-stage cluster analysis, they identified four dynamic risk groups. They described the groups as follows:

> The first group (32 % of the sample) was labeled *low needs* because they scored below the overall sample mean on all of the Stable-2000 items. The second group (32 % of the sample) was labeled *typical* because members of this group tended to have moderate scores close to the overall sample mean scores on many items, including both antisociality and sexual deviance items. The third group (16 % of the sample) was labeled *sexually deviant* because they had the highest scores of the four groups on emotional identification with children, deviant sexual interests, and attitudes tolerant of adult–child sex and tied for the highest average score on sex drive/preoccupation. Post hoc comparisons…found that the sexually deviant offenders did not significantly differ from the typical offenders on 7 of the 16 Stable-2000 items. On the items they did differ, sexually deviant offenders were higher than typical offenders on sex drive/preoccupation, sex as a means of coping, deviant sexual interests, emotional identification with children, and attitudes tolerant of sexual offending against children; they were also higher on general social rejection/loneliness but lower on negative social influences, impulsivity, and hostility toward women. The fourth group (20 % of sample) was labeled *pervasive high needs* because these offenders had scores above the overall sample mean on 13 of the 16 variables and were significantly different from the other groups on 9 of these variables in the post hoc comparisons. Total Stable-2000 score increased across these four groups, with the low-need offenders scoring lowest ($M = 3.13$, $SD = 1.61$), followed by the typical offenders ($M = 6.38$, $SD = 1.46$), sexually deviant offenders ($M = 7.12$, $SD = 1.58$), and, finally, the pervasive high-need offenders ($M = 9.14$, $SD = 1.50$), $F(3, 415) = 289.25$, $p < 0.001$. (p. 499)

A second method of cluster analysis suggested fair agreement with 75 % of the sample matching in across the two methods. Matching was particularly good for low-need offenders and sexually deviant offenders. It was poorest for

pervasive high-need offenders; in the second cluster analysis method, the non-matching pervasive high-need offenders were instead identified as sexually deviant or typical offenders. It was notable that offender types based on victim age and relatedness were distributed across the four dynamic risk groups, but there were apparently few or no differences between the types of offenders on dimensions that might be presumed to be victim specific. That is, incest offenders were not overrepresented in the low-need group and offenders against extrafamilial victims were not overrepresented in the sexually deviant group. Offenders in the four dynamic risk groups did not significantly differ from each other in terms of age, marital status, or number of sexual offense victims; the groups also did not differ on mean Static-99 scores, suggesting that the density of DRFs was independent on static risk levels. Seto and Fernandez commented on the fact that their analyses did not identify a group that was high on antisociality items but low on sexual deviance items. The typical group came closest, showing moderate scores on many antisociality and low-to-moderate scores on sexual deviance items. Seto and Fernandez commented that "the lack of redundancy between dynamic risk groups and offender types was consistent with previous research that has suggested that incest offenders can be as sexually deviant as offenders against unrelated children…and studies that suggest a majority of convicted rapists are sexually deviant by showing relatively greater arousal to depictions of coercive sex compared with other men…" (p. 503).

Structured Risk Assessment: Forensic Version

Background Research

Following the line of thought embodied in the SRA framework and the recent meta-analysis by Mann et al. (2010), Thornton has continued to work on delineating and appraising the significance of more dispositional risk factors or long-term vulnerabilities (LTV) for sexual offending. In somewhat of a distinction from the model of empirically derived DRFs as criminogenic needs, Thornton's approach has been focused on understanding the significance of more enduring predispositions. Per a workshop in 2010, he described LTVs as ways of functioning that become sufficiently persistent and generalized that it is likely to reoccur, regardless of whether it is being currently displayed. He also indicated that once a "way of functioning" has operated for a sufficient period of time and been sufficiently intense and general, it gets established as an LTV, as a persistent way of functioning that may be active or inactive at any particular time depending on situational or contextual influences. Relative to other conceptions of DRFs, LTVs are understood such that any changes occur slowly and likely with difficulty.

Knight and Thornton (2007) conducted a study to evaluate the then extant actuarials in a sample of sexual offenders on whom long-term follow-up were available; this sample was the so-called Bridgewater sample. In prior studies, follow-up investigations had been conducted on 599 offenders who had been referred to the Massachusetts Treatment Center (MTC) for evaluation between 1959 and 1984 (e.g., Prentky, Lee, Knight, & Cerce, 1997). Of these, 266 (Bridgewater Treatment [BT] sample) had been committed to MTC as "sexually dangerous" and subsequently released, and 333 (Bridgewater Observation [BO] sample) had been determined not to be sexually dangerous and returned to finish their sentences. Of the 333 BO offenders, 200 constituted a matched sample (on age at evaluation, marital status, and number of prior crimes) and 200 were randomly sampled from the entire sample BO population evaluated. There was an overlap of 67 offenders selected by both the random and matched process. For all these offenders, we had accessed and integrated four outcome record sources, including the Massachusetts Board of Probation records, the Massachusetts Parole Board records, the Massachusetts Treatment Center Authorized Absence Program records, and the Federal Bureau of Investigation (FBI) records. For the 2007 study, Knight and Thornton accessed the archival clinical files for these offenders and coded those records both on modern empirically derived, mechanical actuarials that have been developed since 1997 for predicting sexual recidivism and on a new measure based on the SRA Need Assessment model (Thornton, 2002). In the 2007 report, the measure was referred to as the SRA Need Assessment. Following early writings and the work developing and implementing the SARN, this version of the SRA had been intended primarily to be utilized for treatment planning and assumed a relatively collaborative relationship with an offender. In addition, this version of the SRA was necessarily written to be scorable based on the kinds of data included in the Bridgewater case files.

Several years later, Thornton and Knight (2014) published data on the SRA-FV as a Need Assessment instrument intended specifically for use under the kind of adversarial conditions that apply during forensic evaluations. Per Thornton (2002), to count as an implementation of the SRA Need Assessment framework, a measure has to have quantitatively assessed items providing a reasonable representation of at least three of the four domains identified as central to the SRA model. SRA-FV items were written so that they could be used under more adversarial conditions where offenders believed that displaying potential risk might have serious negative consequences. Thornton and Knight presumed that it would be particularly difficult to assess the Distorted Attitudes domain in adversarial contexts and so

that domain was excluded from the outset of the construction of the SRA-FV (as it was for the Stable-2007). Consequently, the SRA-FV samples *subdomains* from three of the four possible SRA factors or domains: sexual interests, relational style, and self-management. Most of the items used in SRA-FV Need Assessment were selected and their scoring rules written on the basis of previous research; the scoring rules for the subdomains and factors were initially tested on a subset of approximately 90 members of the Bridgewater sample for whom information was available for less than 5-year follow-up. Specific rating instructions were written for sexual interest in children, sexualized violence, sexual preoccupation, emotional congruence with children, lack of emotional intimacy with adults (LEIRA), internal grievance thinking, and dysfunctional coping. In addition, it was decided in advance that Facets 2, 3, and 4 of the PCL-R (Psychopathy Checklist-Revised; Hare, 2003) would be used to represent the SRA factors of callousness (under aggressive relational style), lifestyle impulsiveness, and resistance to rules and supervision (both under social deviance). Two items were added based on an initial investigation of members of the sample for whom there was less than 5 years of follow-up; concept-based sexual preoccupation and poorly managed anger were added on this basis.

As noted, the SRA Need Assessment "framework" conceptualizes that these long-term vulnerabilities can be classified into four particularly relevant *domains*: sexual interests, distorted attitudes, relational style, and self-management. Within each domain, several subsidiary sets of groups of long-term vulnerabilities are defined; these are referred to as subdomains. Specific long-term vulnerabilities are proposed that fall within each subdomain. For the SRA-FV, sexual interests is the first domain considered. Offense-related sexual interests is a subdomain. Sexual interest in children and sexualized violence are factors within this subdomain. Another subdomain within the domain of sexual interests is sexual preoccupation; this is composed of the average of two factors: rule-based and concept-based sexual preoccupation. The relational style domain has four subdomains: lack of emotionally intimate relationships with adults (abbreviated as LEIRA); emotional congruence with children; callousness (Facet 2 from the PCL-R); and grievance thinking (this is composed of the average of two factors: internal grievance thinking and poorly managed anger). Finally, the self-management domain consists of three subdomains: lifestyle impulsiveness (Facet 3 from the PCL-R), resistance to rules and supervision (Facet 4 from the PCL-R), and dysfunctional coping (Table 5).

In addition, Thornton (2010a, 2010b); Thornton & D'Orazio, (2011) provided an alternative method for scoring the SRA-FV when it may not be practical to complete the PCL-R, either because rating a subject on the PCL-R might be too time-consuming, no one is available who has been properly trained in scoring the PCL-R, or the information required to score the PCL-R may not be available. The SRA-Forensic Version Light (SRA-FVL) is intended for use in circumstances such as these. The SRA-FVL provides a less complete assessment of known long-term vulnerabilities. In trainings, Thornton (2010a, 2010b); Thornton & D'Orazio, (2011) has discussed this approach to the SRA-FV (Light), provided a scoring manual and coding form, and reported that this form of the instrument has been found to add additional predictive information to that provided by Static-99R. However, no specific research on the SRA-FVL has been published or presented.

Table 5 Combining Stable-2007 with Static-2002R[a]

Static-2002R category	Stable-2007 category	Combined Static/Stable priority category
Low (2 or lower)	Low	Low

[a]Table taken from Helmus and Hanson (2013)

As described in Knight and Thornton (2007) and Thornton and Knight (2014), the sample from which the SRA-FV subjects were drawn were 566 sexual offenders who had been (1) evaluated between 1959 and 1984 at the Massachusetts Treatment Center (MTC) for Sexually Dangerous Persons in Bridgewater, Massachusetts, and (2) released from MTC in or before 1984. For the purposes of testing, the predictive accuracy of SRA-FV attention was restricted to the 480 participants who had been released and had at least the opportunity for 5 or more years of street time. Of these 480, a total of 215 had been committed before release, whereas 265 had been found not sexually dangerous and had been returned to prison to serve their sentence. The mean age at release of the participants was 35 years ($SD = 14.8$), and prior to the index incarceration, 61 % of these individuals had incurred charges or convictions for sexual offenses and 31 % for nonsexual violence. The *n*s available for analysis varied slightly depending on the measures included in specific analyses as the amount of missing data differed for specific scales. Static-99R scores were available for only 522 subjects and Need scores were available for 534. In addition, only those

who had the opportunity for 5 or more years of street time were used for the cross-validation analyses; whereas 480 participants had the opportunity for 5 or more years of street time, 391 had the opportunity for 10 or more years of street time. There were a total of 418 participants who had SRA-FV Need Assessment, Static-99R, another actuarial risk measure, and the opportunity for 5 or more years of street time. There were a total of 345 participants who had SRA-FV Need Assessment, Static-99R, another actuarial risk measure, and the opportunity for 10 or more years of street time.

Different coders rated file information for the SRA-FV relative to those who obtained recidivism data. Outcome recidivism data was based on four official sources: the central bureau of the Massachusetts Board of Probation, the Massachusetts Parole Board, the Massachusetts Treatment Center Authorized Absence Program, and the Federal Bureau of Investigation. Recidivism was defined as a record of a new charge for a participant per any of the follow-up sources. The overall sexual recidivism rates were 19 % (92 of 480) at 5-year follow-up and 23 % (91 of 391) at 10-year follow-up.

A total of five trained coders blind to the follow-up data rated the SRA-FV items using the MTC's clinical and criminological files. The coders were trained and supervised and consulted with Dr. Thornton when they had questions about rating items. The MTC files contained all the information collected during the 60-day evaluation period at the MTC. During the observation process, caseworkers routinely solicited institution records, school reports, parole summaries, and probation reports. They also conducted interviews with the offender and often gathered additional information through interviews with the patient's family, teachers, and past employers. In addition, for those committed, there were also data on institutional adaptation and progress in treatment. To evaluate inter-rater agreement, two evaluators independently coded the instruments for approximately one third of the participants. The cases were randomly selected, and evaluators did not know which ones were to be coded twice. If two evaluators coded the participants, the mean score was used for statistical analyses. Inter-rater agreement was calculated using intraclass correlation coefficients (ICCs). For SRA-FV Need Assessment, the ICC for a single rater was 0.64, and for the average of two raters, it was 0.78. It should be noted that the rates were utilizing archival records, much of which were written prior to more contemporary conceptualizations regarding sexual offending and case files that were "thin" relative to persons who were only placed for a 60-day evaluation period.

Cases from the Bridgewater sample with 5 or more years of follow-up were used as a cross-validation sample ($n = 365$–444); none of these cases were used in any part of the construction sample (those under 5-year follow-up).

As with the Stable-2007, predictive accuracy was characterized using the AUC statistic for cases in the validation sample. For the specific domains of the SRA-FV, the AUCs for the three domains were 0.62 for sexual interests, 0.86 for relational style, and 0.66 for self-management. For fixed 5-year sexual recidivism, the AUC for the total or overall SRA-FV Need score was 0.72 ($p < 0.001$). For the subsample of rapists, it was 0.74 ($p < 0.001$), and for the subsample of child molesters, it was 0.72 ($p < 0.001$). For fixed 10-year sexual recidivism, the AUC for the Need score was also 0.72 ($p < 0.001$) for the entire sample, 0.70 for rapists ($p < 0.005$), and 0.76 ($p < 0.001$) for child molesters. Clearly, the discrimination of the SRA-FV "holds up" for longer follow-up period.

Logistic regression equations were calculated to test the incremental validity that the Need score added to Static-99R for 5-year and 10-year sexual recidivism. The sample was 418 subjects with fixed 5-year follow-up, including 88 recidivists. The Need score contributed significant incremental predictive validity ($p < 0.001$) at both 5- and 10-year follow-ups. The AUC of the total Need score of the SRA-FV and Static-99R score was 0.75 relative to 0.68 for the Static-99R alone. In addition, SRA-FV Need Assessment continued to show statistically significant incremental predictive validity relative to sexual offense recidivism even when the designation of being sexually dangerous was controlled for.

Thornton and Knight acknowledged a number of limitations with their study of the SRA-FV. First, the observed inter-rater reliability was lower than desirable. In explanation, the authors stated: "Very thin file information, combined with defensive self-report (or refusing to be interviewed), might make it hard for the instrument to be applied. Similarly, the scale's properties will likely also be affected by the professional competencies of the raters, their participation in sufficient scorer training to learn the scoring rules thoroughly, the time and care given to the task of making the ratings, and so on." Second, because the 2014 results were limited to a particular population, cross-validation of the scale in other populations is essential. Third, given that the offenders in the Bridgewater sample were released some decades ago, Thornton and Knight identified that it would be important to establish both the comparability of this sample to current offenders functioning within the context of general changes in policies and management of sexual offenders. Fourth, they noted that the 2014 study involved retrospective ratings focusing exclusively on clinical files and indicated the potential value of conducting a true prospective study as well as investigating how ratings might be affected by the addition of a standardized clinical interview and other improved assessment methods. Finally, Thornton and Knight noted that the 2014 study does not provide a direct examination of the construct validity of the different factor ratings that are combined to produce the overall Need score.

Administering the SRA-FV

The SRA-FV is intended to be scored based on all available information about a particular sexual offender, inclusive of files

and potentially an interview. Thornton (2010a, 2010b, 2011) recommends that evaluators collect and rely on as much relevant information for scoring each factor, including psychophysiological information such as that from a penile plethysmograph (PPG).

A detailed scoring manual for the SRA-FV was developed in 2010 and subsequently has been modified several times by Thornton (2010a, 2010b); the current version is 1.55. For some subdomains, multiple items are combined into a single factor, and these items are averaged for the subdomain score. Thus, for example, when items from the PCL-R Facet 2 are combined to produce a score for callousness, the scores for each individual item on that facet are averaged, which is different from the standard PCL-R procedure where item scores are summed. As a result of this averaging approach, all factors or subdomains are on a scale that runs from 0 to 2. Factors or subdomains each are averaged to give domain scores. Finally, the three domain scores are summed to give a total SRA-FV or Need score that ranges from 0 to 6. The SRA-FV manual contains a definition of the concept domains with very detailed, carefully anchored scoring criteria for each subdomain. Item scoring rules were developed so that self-report could be taken into account if available but that factors could be coded on the basis of the commonly available historical information found in typical files of individuals. Each subdomain or item in the instrument is rated on a 0, 1, 2 scale per very specific criteria; 0 reflects "Does not apply," 1 reflects "Partially applies," and 2 reflects "Generally applies." A rating of "Does not apply" indicates no evidence exists for the requisite scoring criteria or there is weak evidence for them that is contradicted by strong evidence of contrary functioning.

An evidence-grid is suggested as a means to indicate evidence supportive of the presence of the details of each subdomain as well as evidence that might weigh against a higher score for the subdomain. Raters are cautioned to score one domain at a time, to not score impressionistically, and to assign subdomain scores based upon the conceptual definition and more specific rules delineated for the factor or subdomain. In addition, scores of 2 on the subdomains can be reduced by one point if the only evidence for the factor relates to behavior before the offender was 18 and/or if there is no evidence of the factor during the offender's last 5 total years in the community and during any periods of custody sandwiched within or after those months for a cumulative total of 5 years in the community. Subdomain scores are entered into a specific coding form, and the factor, domain, and total need scores are calculated.

Per the Coding Manual, the SRA-FV is intended to be used by professionals who have a master's or doctoral level qualification in psychology, clinical social work, or related disciplines, who have experience in working with sexual offenders, and who have participated in at least a 1-day training in how to score the instrument including practice with case studies. As research has demonstrated with other risk assessment instruments, scoring accuracy is likely to increase with greater clinical sophistication, experience in using the instrument, and participation in further training.

The offender should be aged at least 18 at the time of assessment and should have committed their most recent sex offense after their 16th birthday. Caution should be used in interpreting the results for those whose most recent sexual offense was when they were 16 or 17 years old. Similarly caution should be used when applying the scale to persons aged 70 or older at the time of assessment.

Thornton (2010a, 2010b) demonstrated that variation in known psychological risk factors, including both DRFs [as measured by the Stable-2007 and Violence Risk Scale-Sex Offender Version] (VRS: SO; Olver, Wong, Nicholaichuk, & Gordon, 2007; Olver, Beggs, Christofferson, Grace, & Wong, 2013)] and long-term vulnerabilities as measured by the SRA, can explain the variation in sexual offense recidivism rates after controlling for static actuarial scores. Thus, persons scoring one standard deviation above or below the mean "need" score showed marked differences in their sexual reoffending. Thornton 2011; Thornton & Knight, 2011; D'Orazio & Thornton, 2012a, 2012b described the application of qualitative norms for differing need levels based on scores for the SRA-FV (and the SRA-FV Light). He distinguished four score bands for the SRA-FV based on qualitative need level: routine (below 1.7), moderate–high (1.7–2.5), high (2.6–3.4), and very high (3.5 and above). On this basis, he identified a level of need index (LONI) that provided a basis for distinguishing sexual offenders with particular risk scores (e.g., on the Static-99, Static-99R, and/or Static-2002R) as having higher or lower absolute recidivism rates relative to other members in preselected groups. Offenders scoring at the routine level of need would likely require no more than "routine" risk management. In contrast, offenders scoring in the very high category of need are suggested to receive intensive and enhanced levels of risk management and prioritization for more intensive treatment programs.

More recent research has attempted to validate the LONI relative to different samples. Thornton and Sachsenmaier (2012) examined the frequency of different needs in a sexually violent predator (SVP) sample. They found that offenders diagnosed with pedophilic disorder and "agonistic" disorders (rape paraphilias and sexual sadism) manifested needs in the expected domains. They also attempted a cluster analysis by identified needs and found that offenders showed diversity in their need profiles. They distinguished between romantic and aggressive pedophiles, as well as agonistic and antisocial offenders. Thornton and Sachsenmaier concluded that based on the nature and range of needs represented in this generally high need sample that treatment should be individualized to a marked degree. D'Orazio and Thornton (2012a,

2012b) examined the degree to which individual needs corresponded to different diagnoses in comparing an SVP and outpatient sample. Utilizing a cluster analytic procedure, they found that sexual offenders in the outpatient sample appeared to fall into four clusters: pedophilic offenders, unstable hostile offenders, lower need offenders, and unstable sexually preoccupied offenders. Again, overall the investigators found that sexual offenders were characterized by a diversity of needs and recommended that sexual offender treatment be individualized on that basis. In addition, they identified a set of needs that appeared to be common across outpatient sexual offenders including dysfunctional coping, difficulty forming emotionally intimate relationships, and sexual preoccupation (including sexual coping).

Other Research Regarding SRA Approaches to Need Assessment

Mann and Wakeling (2006) presented data on two studies of inter-rater reliability of the SARN based on the SRA framework with 16 factors. In the first study, seven expert users rated four cases using realistic files; the % agreement ranged from 75 to 91 % across the four cases, while kappa scores ranged from 0.61 to 0.84. The intra-class correlations among the four domains ranged from 0.91 to 1.0 (sexual interests showed perfect agreement). The investigators concluded that expert raters showed good to excellent inter-rater reliability. In a second study, Mann and Wakeling evaluated two samples of novice raters; approximately half had bachelor's degree and no knowledge of the SARN prior to training. All participants scored two cases and were compared to a "Gold Standard" rating. They found that average percent agreement was good and moderate for the two cases, while kappas showed moderate reliability. They determined that novice users of the SARN were less reliable and that some errors were systematic and could be traced to ambiguities in the case materials or scoring guide. They emphasized the importance of field reliability over research reliability. In a conference presentation, Sachsenmaier, Thornton, and Olson (2011) reported on a study of 15 evaluators who administered the SRA-FV as part of sexually violent predator evaluations. They reported inter-rater agreement of 55 % for 19 psychologists who completed the SRA-FV on 69 persons previously committed to a civil commitment center. However, they found that there was a 91 % chance that one rater's score would fall within one level of another rater's score relative to the total need score and a 90 % chance that one rater's score would fall within two levels of another rater's score relative to the total need score. Sachsenmaier et al. identified that evaluation of lower functioning individuals (e.g., those with cognitive deficits or severe mental illness) may have compromised evaluator's judgments; it was noted that some raters discounted evidence in support of SRA-FV domains by attributing the characteristics to particular conditions (e.g., lower IQ). When low functioning individuals were excluded, the intra-class correlation increased to 0.68, closer to strong agreement among raters. Since all of the subjects were in treatment, it was also noted that raters overweighed recent apparent improvements in functioning rather than considering and rating previous behavior that was indicative of long-term vulnerabilities or in the context of lifetime presence.

How Can DRFs Best Be Understood and Applied?

The consistency of the clusters of DRFs that have repeatedly emerged from varied research efforts and methods of information is striking and thus seems significant. Virtually, all investigations to date have identified remarkably similar sets of primary dimensions of predisposing characteristics: sexual interests and degree of sexual preoccupation, antisocial dimension as indicated by self-regulation or self-management deficits, "distorted" attitudes about self and types of victims, and social/emotional functioning (Table 6).

Clearly, there has been an increasing amount of research regarding putative or alleged DRFs; the empirical evidence is mounting that whatever DRFs represent, they carry some significant degree of weight in predicting sexual offense recidivism. However, what is currently known about likely relevant DRFs is a function of what has been and can be measured. Simply because some condition is difficult to measure and consequently doesn't "show up" in available analyses of risk factors does not mean that there are conditions that are important to understanding sexual offending. It would be a mistake to stop actively conceptualizing and attempting to develop new measures or refine existing ones that might "capture" substantive aspects of persons that are related to sexual offending. Knowledge of DRFs exists and more knowledge of DRFs is possible and likely necessary.

In addition, a related value of the study of DRFs has been to provide some additional perspectives on the nature of sexual offenders and sexual offending. Implicitly suggested in the research and theory related to the Stable-2007 and the SRA-FV is that sexual offenders are heterogeneous and characterized by diverse, even person-specific needs. Further, the combined research literature regarding DRFs seems to increasingly point to the importance of considering sexual offenders dimensionally and not necessarily or at least only categorically. As Seto and Fernandez wrote: "The present finding suggests that designing interventions based on offender victim choice (e.g., rapists versus child molesters) may be less effective than designing treatment based on dynamic risk assessment. These results also suggest that developing typologies of sexual offenders based on dynamic

Table 6 SRA-FV domains

Sexual interests domain (SID): incorporates long-term vulnerabilities that have to do with the direction, form, and strength of sexual interests	
Sexual interest in children factor	Sexual interest in children refers to an intense interest in or preference for sexual activity with children
Sexualized violence factor	An intense interest in or preference for sexual activity that involves forcing sex upon an unwilling recipient (coercive rather than consensual sexual activity) or sexual arousal to the idea of inflicting violence, pain, terror, humiliation, or destruction or exercising abusive coercive control over another person. The coercive element must be a source of sexual arousal, not merely a means to overcome victim resistance
Sexual preoccupation factor	Intense interest in sex; sexual focus dominates psychological functioning; impersonal rather than relational sex; sexualized coping
Rule based/narrow	Atypically or unusually intense interest in sex; much behavior is sexually motivated
Concept based/broad	Global rating of the amount of sexual activity relative to norms; preoccupation with sexual urges or gratifying sexual needs; sexualized coping; impersonal, not relational sex
Relational style domain (RSD): concerns general patterns in the way the offender relates to others and the feelings that are embedded in these relational patterns. It particularly concerns capacity for marital-type relationships and how friendships and social relations are conducted	
Lack of emotionally intimate relationships with adults (LEIRA) factor	This refers to the absence of emotionally intimate marital-type relationships, where a marital-type relationship involves two adults living together as lovers, sharing a household, sharing bills, and making a life together. A marital-type relationship can be seen as lacking emotional intimacy if it is significantly marred by any of the following: frequent fights, domestic violence, repeated infidelity, or emotional distance between the partners
Emotional congruence with children factor	Finding it easier to relate to children than to adults or preferring the company and companionship of children to that of adults to satisfy emotional needs for such things as acceptance, friendship, validation, emotional intimacy, and/or romantic love
Callousness factor	Callous, lack of empathic connection to others, shallow affect, behavior not regulated by feelings of guilt or by empathic distress at harm caused to others
Grievance thinking factor	An easily triggered sense of grievance that results in internal anger which drives poorly regulated aggressive behavior
Internal grievance thinking	Easily feels wronged; suspicious; ruminates angrily; tends not to see or accept other's point of view
Poorly managed anger	Generalized and persistent pattern of poorly managed anger. Includes repeated verbal aggression and angry outbursts, threatening and intimidating behavior, and physical assaults of a nonsexual kind. The key issue here is poorly managed anger being apparent across both persons and situations
Self-management domain (SMD): refers to the individual's propensity to manage his immediate urges, impulses, and feelings so as to make choices that serve his longer-term self-interest	
Lifestyle impulsiveness factor	An impulsive irresponsible lifestyle, driven by sensation-seeking and poor tolerance of boredom, and lacking regulation by realistic long-term goals
Resistance to rules and supervision factor	A generalized and persistent oppositional reaction to rules, supervision, and other attempts by authority figures to control him
Dysfunctional coping factor	Reacts to stress or problems in an impulsive/reckless way

risk factors can shed new light on the understanding of the psychological origins of sexual offending when compared with typologies of sexual offenders based on victim choice, given that victim choice is constrained by opportunity and other situational factors and may therefore be less strongly related to offender motivations" (p. 10). Overall, the studies of DRFs and/or criminogenic needs suggests that sexual offenders are characterized by a diversity and intensity of such needs and that sexual offender assessment and treatment be as comprehensive and individualized as possible.

On the one hand, efforts have been made to identify empirically based risk factors that may be or appear to be causally related to sexual ***re***offending or more persistent sexual victimizations. This conceptualization of DRFs as criminogenic needs suggests that DRFs are capable of changing and consequently can be appropriate targets of psychosocial interventions and/or management strategies. Such a view is supported by the finding of Hanson et al. (2008) that psychosocial sexual offender treatment for sexual offenders may be similar to that for other criminal offenders so that the "more" intervention is directed at empirically defined criminogenic needs, the more likely it is to be effective at reducing recidivism. The notion of DRFs as mutable is a hopeful perspective premised on the possibility that effective interventions exist, that key personal characteristics can change, and that a significant number of sexual offenders might be motivated to commit to personal change.

On the other hand, another perspective of DRFs is reflected in a conceptualization that DRFs, while also causal risk factors, are far more dispositional in nature and reflect

enduring or persisting ("long-term") vulnerabilities (LTV) for sexual offending; such LTVs are viewed as more enduring predispositions than more easily or readily mutable "dynamic" risk factors. As noted above, Thornton has described LTVs as ways of functioning that become sufficiently persistent and generalized that it is likely to reoccur, regardless of whether it is being currently displayed. He also indicated that once a "way of functioning" has operated for a sufficient period of time and been sufficiently intense and general, it gets established as an LTV, as a persistent way of functioning that may be active or inactive at any particular time depending on situational or contextual influences. Relative to other conceptions of DRFs, LTVs are understood such that any changes occur slowly and likely with difficulty. While the constructs of LTVs do not completely mitigate against mechanisms and the potential for personal change, it certainly emphasizes that individual LTV—and particularly an accumulation of interacting LTV—might not respond readily to short-term interventions and show limited plasticity. As Mann et al. (2010) wrote:

> It is quite possible, however, to conceive of causal factors that do not change. Most obviously, many biologically or genetically determined propensities are considered to be lifelong enduring characteristics -present since birth. We expect that most, if not all, of the risk factors we propose here are underpinned by neuropsychological mechanisms (for further information, see Ward & Beech, 2006) as well as social and psychological mechanisms. It is not clear that all of the factors in our list [of psychologically meaningful risk factors] would be expected to be changed by deliberate intervention. For instance, the scientific community has yet to establish consensus concerning the mutability of some deviant sexual preferences, such as pedophilia… (p. 211)

Thus, DRFs as LTVs *may* be causal factors of repeated behavioral enactments of sexual offending, but, in fact, they *may* be quite difficult to modify and manage (e.g., Hoberman, 2015).

Some evidence suggests that sexual offenders may be able to change something that is observable to others as the result of treatment (e.g., McGrath, Lasher, & Cumming, 2012; Olver et al., 2013), such that "change" measures in uncontrolled studies of sexual offenders exposed to treatment show associations with reduced sexual offense recidivism. This should be viewed as a potentially positive finding that at least some sexual offenders may be sufficiently motivated to commit to learning and actually enacting behavioral changes – at least in controlled settings and/or with goals of release present – that such they may have that diminished their likelihood of sexual offense recidivism. However, despite these limited findings, a much more substantial body of evidence would suggest that psychosocial treatments for sexual offending have yet to have been empirically demonstrated to have any small, let alone robust, effect in reducing sexual offense recidivism (e.g., Hoberman, 2015) and that an examination of the specific components of various sexual offender treatment programs do not appear to impact on even the low-moderate risk sexual offenders to any significant degree (Hoberman, 2015).

Other perspectives would strongly suggest that much of what is significant about personality and related conditions reflects a significant genetic and biological basis. Thus, as Hoberman (2015) reviewed, many personality characteristics related to violent and sexual offending (e.g., features of externalizing spectrum disorders) and related executive functioning, self-control, and substance use have been demonstrated to have particularly substantial genetic components, which in turn affect characteristics of environmental selection and exposure that often magnify or exacerbate such biologically based liabilities. Numerous authorities in the field of behavioral genetics speak to the likely development and expression of a self-reinforcing cycle, for example, where impulsivity and antisocial behavior (substance use) lead to increases in disinhibition/novelty seeking and more persistent antisocial behavior and substance use. Further, genetic or evolutionary perspectives suggest that persons who are "competitively disadvantaged" in terms of obtaining resources through socially acceptable means (e.g., agreeableness and higher intelligence) and are characterized by a higher degree of impulsivity and sensation-seeking than others may be particularly likely to engage in antisocial behavior as a means of obtaining those resources.

Consequently, it would appear that DRFs might actually function as more static or at least relatively stable or persisting risk factors; psychologically meaningful risk factors are best viewed as robust, persisting predispositions. Despite the compelling explanatory power of Mischel and Shoda, (1995) "if… then… behavioral signature," highlighting the contextual nature of the expression of select personality dimensions, the research to date on DRFs has revealed little explanatory power of more immediate contexts or "triggering" events. The DSP indicates that acute DRFs explained none of the variability in future sexual offending or criminal behavior; they had no association to recidivism but were highly correlated with one another. Similarly, despite the potential for change in stable DRFs in the DSP, when both the first and second Stable assessments were entered simultaneously in logistic regression to predict 12-month and 24-month recidivism for the five outcome variables, the overall model was significant in all cases, but neither assessment contributed uniquely in 9 of the 10 analyses. The predictive accuracy of both assessments was similar despite a 6-month passage of time while the offender was residing in the community with potential situational opportunities, reduced monitoring of behavior, and opportunities for desired victims. So, acute DRFs have no predictive validity and stable DRFs appear to remain relatively constant over time from the perspective of trained observers whose role is to attend to potential changes in offender presentation.

To date, there is little empirical support for a distinction between stable and acute DRFs.

If DRFs do not represent, to any great degree, characteristics of sexual offenders that are potentially modifiable through intervention (e.g., "change mediators"), then what might explain their incremental predictive validity relative to future sexual offending? It is notable and significant that predictive validity of future outcomes improves when DRFs are combined with static risk factors; clearly DRFs capture some aspects of an offender that specific historical risk factors do not. However, while adding to incremental validity of static risk factors, the relative amount of incremental validity is fairly small relative to the contribution made by the static risk factors. Further, when the statistical process is reversed, with DRFs entered first into a predictive equation (before the static risk factors), the static risk factors continue to carry the lion's share of predictive validity. Thus, those phenomena of the person and environment that are captured by relatively specific features of a limited number of static risk variables represent considerable predictive weight and explanatory power. Yet the more "general" or "global" characteristics of stable DRFs carry some incremental predictive validity. In addition, research indicating that groups of sexual offenders with similar static risk scores manifest different degrees of sexual reoffending also suggests that different rates of sexual offense recidivism likely depends on some unspecified factors external to the actuarial risk items. Thus, Helmus (2009) identified significant variability in risk estimates associated with various cut scores on the Static-99. She determined that this variance was to a large degree accounted for by sample preselection effects [i.e., effects due to factors inherent or characteristic in samples, such as whether it was a relatively lower-risk "routine" prison sample or whether it was a relatively "high-risk" sample where the subjects had been referred to some judicial or quasi-judicial process (e.g., to determine if they met the criteria to be a "sexually dangerous person")]. These findings too suggest that some variables not captured by static or historical factors may also affect the relative and absolute risk of persons with a particular level of static risk factors.

Given the available scientific evidence, it seems most likely that both static and putative stable DRFs represent different perspectives or measurements of constructs of "psychologically meaningful risk factors." As Mann et al. wrote: "Such risk factors can be conceptualized as individual propensities, which may or may not manifest during any particular time period. Like the traditional concept of trait, propensities are enduring characteristics that lead to predictable expressions of thoughts, feelings, or behaviors. Although propensities are characteristics of individuals, these propensities can also be recognized by individuals' transactions with others…" (p. 211). Perhaps individual propensities are best "captured" for purpose of appraisal or measurement by their actual behavioral expression as opposed to a more global characterization as a predisposition or enduring characteristic. Thus, the predisposition of paraphilic sexual interests may account for less variance than the number of times someone has been accused or adjudicated of illegal paraphilic behavior. Similarly, the predisposition toward may account for less variance than the number of times someone has been accused or adjudicated of illegal criminal or violent behavior. Various aspects of social functioning may account for less variance than the "fact" that someone has never had a marital-type relationship of at least 2 years. While static risk factors constitute the "skeleton" of predictive validity in risk assessment, DRFs function as "interstitial" elements both overlapping and entwined with actual historical behavioral markers and carrying their own predictive weight. Thus, while behavioral, historical markers are the best means of demonstrating stable risk factors, some additional explanatory power is provided by the more general identification of predisposing characteristic that does underlie or cause the behavioral marker.

As Quinsey et al. (2006) and Rice, Harris, and Lang (2013) have written, given the high degree of predictive accuracy of actuarial measures of risk based on historical, static factors in an individual's life, such approaches may effectively create a ceiling so that the ability of DRFs to make more substantive contribution than what has been demonstrated to date may not be possible. To this effect, Harris et al. (2003) showed that the predictive accuracy of actuarial instruments increased to as high as 0.84 with standard fixed follow-up periods and the completeness of information in completing those instruments. Similarly, Helmus and Hanson (2013) have noted that overall lack of substantive improvement in actuarial measures despite modifying theoretically presumed relevant variables (e.g., age at release) might indicate that current static actuarial instruments may have reached an "asymptote" or plateau for what can be achieved with currently identified or measured historical predictors. It may also be the case that interaction effects of select stable or static risk factors may add some increased predictive validity to a simple summation of such factors, although such interaction effects are notoriously hard to demonstrate in a robust manner.

A related issue to be noted is the approaches to assessment of DRFs or psychologically meaningful risk factors. Evidence exists that self-report can contribute to the identification of putative DRFs (e.g., Hoberman & Riedel, 2015). However, it is also the case that select types of self-report in particular contexts are not useful measures of change after sexual offender treatment (e.g., Wakeling & Barnett, 2014) but are useful measures of risk assessment, particularly when obtained at initial evaluation or pretreatment (Hanson & Morton-Bourgon, 2004, 2005). In contrast, structured clinical judgment as per the Stable-2007 and SRA-FV appears to provide relatively reliable and valid contributions

to understanding a key dimensions of a particular sexual offender associated with sexual reoffending and informing risk assessment. In this manner, they may represent a means of representing the type of multidimensional risk profile suggested by Doren (2010). However, results to date would also suggest that continued refinement of the means and source of measurement, as well as different methods of combining different sources of information, might improve the utility of DRFs.

Additionally, following Ward and Beech (2014), an important step is to systematically and iteratively, both through etiological theory or model development and empirical research, clarify the nature of putative DRFs as more than "psychological meaningful risk factors" as causal risk factors (e.g., after Kraemer et al., 1997) and the nature of processes by which such casual risk factors work to determine the particular pathways or trajectories by which sexual offending occurs for particular individuals. Thus, there should be continued attempts to describe, define, and refine DRFs and their related experiential states. In addition, addressing these phenomena from a comprehensive and sophisticated perspective, researchers need to articulate and test factors and processes that may or can provide explanatory theories of sexual offending. In turn, Ward and Beech argue, such understanding and clarification will lead to improvements in the ability to provide individual case formulations and treatment plans. However, Ward and Beech's critique of the current status of DRFs raises significant questions about the increasingly common use of DRFs as targets of sexual offender treatment. Per Ward and Beech, it remains unclear if commonly referenced DRFs are, in fact, causally related to sexual offending but are simply attributes or exemplars of other yet unidentified causal predispositions. Consequently, the apparent ineffectiveness of current programs of sexual offender treatment (e.g., Hoberman, 2015a, 2015b, 2015c) may be the result of misdirected programs that are intended to target putative criminogenic needs (e.g., often so-called DRFs) but are not actually addressing, let alone modifying, true underlying predispositions to sexual offending.

In summary, DRFs may be much less "dynamic" and mutable than they were originally conceived to be and, in fact, reflect relatively static and persisting predisposing conditions (in contexts) to offending. As Harris and Hanson (2010) pointed out: "To date, there has been little evidence that changes on STABLE factors are associated with changes in recidivism risk" (p. 11). While they may represent one means of measuring predispositions, a person's actual behavioral history (e.g., static risk factors) appears to capture much more of the predictive validity with regard to sexual offending behavior as opposed to more global psychosocial characteristics. Nonetheless, the available evidence indicates that DRFs do appear to contribute relatively small but statistically significant incremental additions to predictive validity of sexual offense recidivism. In addition, even currently as psychologically meaningful risk factors, they provide some empirically based means of individual case formulation and treatment planning, albeit with the possibility of improvement as Ward and Beech have suggested. However, as Seto and Fernandez (2010) pointed out, the extent to which DRF items assess theoretically meaningful risk factors that can be targeted in treatment and supervision targets is constrained by the extent to which the items accurately—reliably and validly—measure the underlying psychosocial factors. However, increased research investigating the nature, means, and degree to which the convergent domains identified as DRFs can be modified via sexual offender treatment or other forms of management is an effort that continues to be worth pursuing. While limited research indicates that change in DRFs may be associated with some degree of diminished risk of sexual offense recidivism, more robust demonstrations of such temporal variability of DRFs (particularly in response to objectively determined changes in context or action) and improved methods of measuring such DRFs remain to be accomplished. In addition, it seems timely to begin to work more iteratively with the available empirical evidence regarding sexual offending and currently available etiological theories of sexual offending. Available models of these processes remain relatively crude or at least general in nature and would benefit from attempts to consider the interaction static/stable risk factors and/or DRFs/dispositional risk factors over time and in context to attempt to elucidate increasingly refined and comprehensive models of the heterogeneity of sexual offending. Whether DRFs can or do change, certainly it appears that they represent manifestations of long-term vulnerabilities of psychologically meaningful risk factors and that some or many of them are causal in some capacity. A challenge now is to theoretically conceptualize the possible varied and cumulative interactions over time of such multiple predispositions and to systematically and empirically test those processes that best describe the heterogeneity of trajectories of sexual offending and the possibility that those conditions may be changeable and/or changed and through what mechanisms.

Assessing Sexual Violence Risk and Evaluating Change with the Violence Risk Scale-Sexual Offender Version

Mark E. Olver and Stephen C.P. Wong

The assessment of sex offender risk, in particular the identification of those at high risk for sexual reoffending, has important policy, public health, and criminal justice implications. The past 15 years have witnessed a rapid advance of sex offender risk assessment research, the result of which has been translated into improved decision-making on risk management and treatment of sex offenders. Of note is that research has identified salient static and dynamic predictors of sexual offending, and these variables have been formulated into valid and reliable risk assessment instruments and guides that can be used to assess sex offender risk (Hanson, Bourgon, Helmus, & Hodgson, 2009). The development of sexual offending risk assessment technologies has paid some handsome dividends in terms of informing sentencing, treatment planning to reduce risk, making release decisions, and community monitoring of high-risk sex offenders, all with the goal of reducing sex offending and victims of such offending.

While accurate risk prediction is certainly important, if not essential, the overriding purpose of violence risk assessment should be violence prevention (Douglas & Kropp, 2002), that is, identifying high-risk individuals and taking steps through treatment and various risk management strategies to prevent future sexual violence. In addition, policy developments in North America, such as the sexually violent predator (SVP) statute in the USA and dangerous offender (DO) designation in Canada, speak to the need for risk assessment technologies to not only be accurate in the appraisal of risk but also to inform special sentencing provisions such as SVP and release decisions. We argue that one of the key responses to this challenge is to be able to capture changes in risk. The present chapter is a review of a sex offender risk assessment, risk management, and treatment planning tool that is designed to inform treatment planning and to capture possible changes in risk, the violence risk scale-sexual offender version (VRS-SO) (Wong, Olver, Nicholaichuk, & Gordon, 2003).

The chapter begins with a detailed description of the VRS-SO and then proceeds with a discussion about evaluating changes in sexually deviant behaviors, in particular, in custodial settings through paying attention to offense analogue and offense replacement behaviors. We then discuss clinical applications of the VRS-SO and offer guidelines in interpreting and reporting risk-related information gathered from pretreatment and posttreatment assessments. Finally, we discuss possible use of the VRS-SO within the context of DO and SVP evaluations and provide a detailed case examination involving the clinical application of the VRS-SO with an SVP-adjudicated offender.

The Violence Risk Scale-Sexual Offender Version

The VRS-SO was developed to assist service providers who work with high-risk/high-need sexual offenders to integrate risk assessment/prediction/management and treatment (see Olver, Wong, Nicholaichuk, & Gordon, 2007; Wong, Gordon, & Gu, 2007). Results of VRS-SO assessments can inform service providers of *who* to treat by identifying high-risk/high-need treatment candidates, *what* to treat by identifying treatment targets—that is, dynamic factors linked to violence—and *how* to treat by identifying appropriate therapeutic approaches using a modified stages of change model (Prochaska, DiClimente, & Norcross, 1992). The VRS-SO is also designed, using the modified stages of change model, to

measure *how much* changes in risks have occurred as a result of treatment. The theoretical basis of the VRS-SO is predicated on the theory of the Psychology of Criminal Conduct (PCC; see Andrews & Bonta, 2006, 2010), the principles of effective correctional treatment, relapse prevention (RP) theory (Pithers, 1993; Ward & Hudson, 1998), and the transtheoretical model of change (TTM).

The VRS-SO Static and Dynamic Items

The VRS-SO (Wong et al., 2003) was developed to assess sex offender risk using dynamic and static variables linked to sexual recidivism. The VRS-SO has 7 static and 17 dynamic variables (see Table 1 for a listing of items with brief item descriptions), and each variable is rated on a 4-point scale (0, 1, 2, 3). In general, higher ratings indicate that the variable is more closely linked to inappropriate sexual or nonsexual behaviors.

The static items were selected and operationalized through purely statistical procedures. A set of potential static variables were culled from the literature, and then each correlated with outcome; the strongest predictors were retained and rescaled on a 4-point scale. The dynamic items were first identified after a detailed review of the risk literature (e.g., Hanson & Bussière, 1998; Hanson & Harris, 2000; Proulx et al., 1997), including contributions from the relapse prevention theory (Pithers, 1993; Ward & Hudson, 1998) and the PCC model (Andrews & Bonta, 2006). Scale variables were then chosen statistically to maximize the content validity of the scale. A dynamic variable rated 2 means the item is *quite closely* or 3 *very closely* linked to sexual offending; that is, the dynamic variable is criminogenic and hence should be a treatment target. For example, if Offense Planning, one of the dynamic variables, is rated 2 or 3, then Offense Planning has been determined by the assessor, following guidelines given in the VRS-SO manual, to be quite or very closely associated with sexual offending in the person's overall functioning. Dynamic variables identified as treatment targets (i.e., rated 2 or 3) are also rated to determine the stage of change (readiness for treatment) evidenced by the client.

A factor analysis of the dynamic items suggested the presence of three broad factors labeled: Sexual Deviance (*sexually deviant lifestyle, sexual compulsivity, offense planning, sexual offending cycle, deviant sexual preference*), Criminality (*criminal personality, interpersonal aggression, substance abuse, community support, impulsivity, compliance with community supervision*), and Treatment Responsivity (*cognitive distortions, insight, release to high-risk situations, treatment compliance*); two of the items (Emotional Control and Intimacy Deficits) did not load (Olver et al., 2007). The factor structure of the instrument is consistent with the major risk factor domains identified in the literature (i.e., sexual deviance, antisociality, pro-offense attitudes, and cognitions). There is evidence that different types of sex offenders have differential scores on the three factors. For instance, research on the VRS-SO found that

Table 1 VRS-SO static and dynamic items and brief item descriptions

Static items
S1 Age at release: <age 25; 25–34; 35–44; 45 years and up
S2 Age at first sex offense: <age 20; 20–24; 25–34; 35 and up
S3 Sex offender type: mixed offender; child molester; rapist; incest offender
S4 Prior sex offenses: 4 or more prior sexual charges/convictions; 2–3 prior; 1 prior; 0 prior
S5 Unrelated victims: 4 or more unrelated victims; 2–3 unrelated; 1 unrelated; 0 unrelated (all related)
S6 Victim gender: 2+ male victims; 1 male and 1 female/or 2+ female; 1 male victim only; 1 female victim only
S7 Prior sentencing dates: 11+ prior sentencing dates; 5–10 prior; 2–4 prior; 0–1 prior
Dynamic items
D1 Sexually deviant lifestyle: lifestyle hobbies, interests, work, or relationships involve sexually deviant behaviors
D2 Sexual compulsivity: strong sex drive and high frequency of sexual behavior and cognitions
D3 Offense planning: victim grooming and premeditation involved in sexual offending
D4 Criminal personality: interpersonal and emotional attributes conducive to criminal behavior (e.g., lack of remorse)
D5 Cognitive distortions: attitudes and distorted thinking supportive of sexual offending
D6 Interpersonal aggression: physically and/or verbally aggressive behavior in interpersonal interactions
D7 Emotional control: tendency to overcontrol or undercontrol emotions linked to sexual offending
D8 Insight: poor understanding of causes of sexual offending and unwillingness to discuss/explore sexual offending
D9 Substance abuse: substance use problems linked specifically to sexual offending
D10 Community support: lack of positive support people, services, or plans in community (or unwilling to use)
D11 Released to HRS: offender seems likely or has shown pattern of returning to situations linked to sex offending
D12 Sexual offending cycle: pattern of interpersonal, situational, and personal factors linked to sexual offending
D13 Impulsivity: behavior displays tendency to "act first, think later" and lacks reflection or forethought
D14 Compliance with community supervision: poor attitude and/or cooperation with community supervision
D15 Treatment compliance: poor attitude and/or cooperation with sex offender treatment
D16 Deviant sexual preference: interests or preferences for deviant sexual stimuli or behaviors (e.g., children, violence)
D17 Intimacy deficits: incapacity to form or maintain adult romantic relationships

Adapted from Olver et al. (2007) with permission

[a]All items are rated on a four-point (3, 2, 1, 0) scale. Item descriptions are abbreviated examples of the originals and are not intended to be used for clinical or research purposes. Please consult the VRS-SO rating manual (Wong, Olver, Nicholaichuk, & Gordon, 2003) for more detailed item descriptions, stages of change ratings, and scoring instructions

child molesters tended to score higher on Sexual Deviance and lower on Criminality compared to rapists, who had the reverse pattern (higher on Criminality and lower on Sexual Deviance), and mixed offenders, who had quite high scores on both (Olver et al., 2007).

Scores on each of the three factors provide general indications of where the risk of sexual recidivism primarily resides. Further inspection of the items comprising the factors can be used to highlight more specific problem areas for treatment. For instance, some rapists show patterns of deviant arousal (e.g., preference for underage victims or sex involving violence and humiliation) and thus may require arousal modification interventions. However, for those with no such preference, the focus of intervention may be elsewhere, such as aggressiveness, impulsivity, and lack of community support. Assessment and treatment have to be integrated; assessment should inform treatment such that it is focused and prescriptive.

The Theoretical Underpinnings of Measuring Treatment Readiness and Change in the VRS-SO

To assess the individual's readiness for treatment and treatment change, the VRS-SO uses a scheme based on a modified transtheoretical model (TTM) which, as its core construct, is a stage of change (SOC) conceptualization of treatment change (Prochaska & DiClemente, 1984; Prochaska et al., 1992). The model proposed that individuals, in making changes to their behaviors, progress through five stages—Precontemplation, Contemplation, Preparation, Action, and Maintenance—characterized by various levels of motivation and commitment, behavioral engagement, and change. Interventions that are matched to the individual's stage are presumed to be more effective than if they are not (outlined in more detail below). The transtheoretical model's conceptualization of treatment change has been applied to a number of forensic populations, including domestic batterers (Levesque, Gelles, & Velicer, 2000), violent nonsexual offenders (Lewis, 2004; Wong & Gordon, 2006; Wong et al., 2007; Polaschek, Anstiss, & Wilson, 2010), young offenders (Hemphill & Howell, 2000; Willoughby & Perry, 2002), and sexual offenders (Tierney & McCabe, 2005).

The VRS-SO is the first attempt to incorporate the SOC model into a risk/need assessment tool for sexual offenders. The five stages of change used in the VRS-SO are based on the SOC model as identified above. However, the descriptions and meanings of the stages as used in the VRS-SO (and the VRS as well) presented below were modified for use in forensic populations. The two key modifications involve making the forward transition through the stage (i.e., criteria for crediting treatment improvement) more demanding and using an assessor-rated scheme rather than a self-report questionnaire to assess and locate the individual's SOC. Since release and other significant forensic mental health and criminal justice decisions are often made based on whether or not the individual has improved through treatment as a proxy for risk reduction, false positives (i.e., giving treatment improvement credits when none are warranted) obviously could have very serious consequences. Raising the bar for crediting treatment improvement should reduce false positives. Similarly, using an assessor-rated scheme instead of self-report should increase the veracity of the assessment. Briefly, those in the Precontemplation stage have neither insight nor intention to change in the foreseeable future. They are often in denial and externalize blame. Consciousness-raising activities, for example, would be an appropriate approach for those in this stage. Those in the Contemplation stage are fence-sitters; they acknowledge their problems but have shown no relevant behavioral change: all talk, no walk. Cost-benefit analyses approaches, for example, likely would be suitable for those in this stage. Those in the Preparation stage combine intentions to change with relevant behavioral changes to address problems; however, changes tend to be recent and/or quite unstable. Those in the Action stage actively and consistently modify their behaviors, attitudes, and environment to address their problems; overt behavioral changes are made, commitments followed through, and energies expended to change. In the Maintenance stage, relapse prevention techniques are used to consolidate, strengthen, and generalize the gains made in the Action stage. Conceptually and psychometrically, the client can be assessed as having made progress, remaining unchanged, or having deteriorated, that is, transitioning forward or backward or making no movement through the stage.

The SOC model, the central organizing construct of the TTM, has come under a number of criticisms that we first highlight and then discuss based on evidence in the literature and our own research findings. Space limitations preclude us from giving a full discourse of the responses to the various criticisms other than a brief outline of the criticisms and our views on them.

The criticisms of the SOC as applied to forensic populations can be organized into the following five general areas. First, critics of SOC have asserted that the stages of change should be, but often were found not to be, discrete from each other. As well, other than the Precontemplation stage, quite often people can be in more than one stage at a time, can reverse their progression through the stages, or can even skip stages (Bandura, 1998; Burrowes & Needs, 2009; Elder et al., 1990; Sutton, 2001). There continues to be much debate on the level of separation or even the existence of the stages and their utility (see Brug et al., 2004 and also Prochaska & Velicer, 1997). In our view, the stages should best be conceptualized as constructs that can be used to assist in conceptualizing or partitioning one or more underlying dimensions, often referred to generally as the change

process(es). The utilities and predictive validity of these constructs should be subject to empirical verifications. Human problems are seldom simple and unidimensional, despite our often simplistic attempts to label them as such, for example, smoking/tobacco use, weight control, and, among forensic clients, violence or sexual deviance problems. None of these problems are unidimensional, despite their labels; invariably many sub-problems exist within each label. It should come as no surprise that people can progress to different stages in different sub-problem areas and, thus, may appear to be in more than one stage at a time. As well, being in more than one stage at a time can be, in part, a function of the measurement tool. Whether or not people are seen to be reversing their progression may depend on the *width* of the window of observation and measurement. Taking two steps forward and one step back may appear erratic or even as sliding backward in the short term, but can be deemed to be making progress in the longer term. Taking measurements with a blunt measuring tool or taking measurements at inappropriate times may create the impression that stages were skipped.

Second, the tools that have been developed to measure the stages might not have adequately captured the treatment progress of offenders, in particular those in custodial settings. For example, the assessment of the Maintenance stage cannot be undertaken when the individual does not have the opportunity to practice the behavior. Assessment using different scales can produce different results, and, as we indicated above, an individual can be assessed as being in more than one stage at any one time (Burrowes & Needs, 2009, pp. 41–42). There have been several instruments developed over the years to assess stages of change. These have been largely self-report inventories and have been designed to assess an individual's stage of change broadly (e.g., University of Rhode Island Change Assessment, URICA; DiClemente & Hughes, 1990) or with respect to changing specific syndromes or problem behaviors such as alcoholism (e.g., Stages of Change Readiness and Treatment Engagement Scale, SOCRATES; Miller & Tonigan, 1996), chronic pain management (Pain Stages of Change Questionnaire; Kerns, Rosenberg, Jamison, Caudill, & Haythornthwaite, 1997), exercise behavior (Stages of Exercise Change Questionnaire; Dannecker, Hausenblas, Connaughton, & Lovins, 2003), and recovery from anorexia nervosa (Anorexia Nervosa Stages of Change Questionnaire; Reiger, Touyz, & Beumont, 2002), among others. We recognize the limitations of self-report tools when applied to forensic populations, and, as such, we have opted instead to develop a staff-rated metric to assess the stage of change. The VRS-SO SOC rating metric and the corresponding supporting research evidence are discussed in considerable detail in the next section under the heading Measurement of the Stages of Change in the VRS-SO and under point (5) below, respectively. Ultimately, empirical evidence should be the arbiter of the validity of any psychological measurement tool. That it is not possible for offenders to reach the Maintenance stage because of the lack of opportunity to practice the behavior could be due to limitations of the environment rather than deficiencies of the SOC model. While we acknowledge that it would be almost impossible for a child molester to advance to the Maintenance stage in a custodial environment, we would argue that someone with serious problems with authority figures would be severely tested on a daily basis while in custody and could conceivably progress to the Maintenance stage. The VRS-SO SOC metric recognizes and can accommodate these contingencies. The issue of individuals being assessed as being in more than one stage simultaneously was discussed earlier.

Third, the SOC has also been criticized for the lack of explanatory value of why people are at different stages; it can be used merely to identify at what stage an individual is (Drieschner, Lammers, & van Der Staak, 2004). There can be many different reasons why people end up in a different SOC. The value of the SOC model, in our view, is not in trying to explain how people get to a certain stage but, rather, to identify what stage they are at, thus informing what needs to be done to facilitate their progression from that stage. The SOC model authors have suggested various interventions (obviously not an exhaustive list) that may facilitate forward transition through the stages (see Prochaska et al., 1992). No doubt, understanding how people get to a certain stage should also contribute to helping them progress.

Fourth, it has been argued that offending behaviors are too complex and multidimensional to be assessed using the SOC model (McMurran et al., 1998). We agree that offenders' problem behaviors (or for that matter, human problems in general) are often multidimensional, as evidenced by the many dynamic risk factors identified in risk assessment tools such as the Level of Service Inventory-Revised (LSI-R; Andrews & Bonta, 1995) and the Violence Risk Scale (VRS; Wong & Gordon, 1999–2003), which are primarily used with nonsexual offenders, as well as the VRS-SO, the Stable-2000/Stable-2007 (Hanson, Harris, Scott, & Helmus, 2007), and the Sexual Violence Risk-20 (Boer, Hart, Kropp, & Webster, 1997) for sexual offenders. A single SOC may not be adequate to capture the change processes for the individual's many problem areas. For example, willingness to acknowledge and work on a substance abuse problem does not mean similar commitment to work on a sexual deviance problem. Similarly, a Swiss study also concluded that individuals can be in different stages of change depending on whether moderate or vigorous physical activity was the focus (Martin-Diener, Thuring, Melges, & Martin, 2004). The VRS-SO recognizes the multidimensional nature of offender problem areas and thus provides an SOC rating for each identified problem area.

Fifth, one of the key tests of the SOC model is its ability to predict outcome based on the stage rubric; results of

predictive studies of the SOC model, however, seemed to have produced inconsistent results (Littell & Girvin, 2002; Wilson & Schlam, 2004). Taken individually, studies can provide evidence both for and against most theories and propositions and may produce seemingly inconsistent results. Meta-reviews can quantitatively summarize an extant body of research and can provide a more objective assessment of the aggregated evidence. A recent meta-analysis of 47 studies by Webb and Sheeran (2006) examined the *causal* rather than the correlational relationship of behavioral intentions to subsequent behavior change, a much stronger test of the cause-and-effect relationship than correlational or cross-sectional studies. The authors asserted that "behavioural intentions are assumed to capture the motivational factors that influence a behavior" (Webb & Sheeran, 2006, p. 249) and highlighted considerable similarities between increasing intentions and forward transitioning in the SOC, in particular, the first three stages where, according to the TTM, there should be clear increases in motivation and commitment to change in transitioning forward. The authors found "that a medium-to-large change in intention ($d=0.66$) leads to a small-to-medium change in behavior ($d=0.36$)" (p. 249) when a number of different theoretical positions were examined using meta-analyses. The different stage theories, including the TTM (SOC), showed similar associations of intention with behavioral change. The results of this meta-analytic study provide support not only for the validity of the SOC model in predicting expected behavioral changes but also the causal relationship of movement through the stages and subsequent behavioral improvement.

The literature examining the SOC model and behavior changes in offenders is currently too small to be subjected to meta-analysis, but the individual study results are encouraging. Lewis (2004) examined treatment change using the TTM in a treated sample of 191 high-risk violent offenders. While most offenders were assessed, using the VRS, as being in the Contemplation stage at pretreatment, the majority were assessed as being in the Preparation stage (i.e., having forward transitioned one stage) at posttreatment (also see Wong et al., 2007). A follow-up study (Lewis, Olver, & Wong, 2013) on this sample has since found that treatment changes were significantly associated with reductions in violent recidivism. Similar findings have been obtained with the VRS-SO's assessments of change with respect to reductions in sexual recidivism (discussed in greater detail later in this chapter).

In all, the SOC conceptualization of treatment change within the TTM has been widely applied to a variety of health concerns, including entrenched and challenging clinical problems (e.g., chronic pain, eating disorders) and within offender populations. Meta-analytic results provide evidence in support for both the predictive validity of the SOC model and the casual links between stage transition and subsequent behavioral improvements in the general context of health-related changes in community samples. Within the forensic area, results of individual studies using the assessor-rated SOC metric developed for the VRS and VRS-SO also support the predictive validity of the SOC model using both nonsexual and sexual offender samples. Like any theory, challenges to the TTM (SOC) and the need for modifications and adjustments when the theory is applied to the forensic populations are not unexpected, and more research is required without a doubt. However, we would argue that the wider literature supports the validity and applicability of the general TTM (SOC) model, and the results of the smaller but growing literature of the application of the model to forensic populations are also encouraging.

Measurement of the Stages of Change in the VRS-SO

The operationalizations of the stages of change are designed to measure the extent to which the positive coping skills and strategies that the client has learned are stable, sustainable, and generalizable. All treatment targets, that is, dynamic items rated 2 or 3, are given the stages of change baseline rating at pretreatment or Time 1 to assess the individual's motivation and readiness for change. Dynamic items that are not treatment targets, that is, those rated 0 or 1, generally require no stages of change rating. The stages of change are then re-rated at posttreatment or Time 2 on all dynamic items identified as treatment targets. Change is quantified by comparing the stages of change rating for each dynamic item at pretreatment to that at posttreatment. Advancing from one stage of change to the next on a given item is an indication of positive change and, hence, risk reduction. Progression from one stage to the next stage is scored as a 0.5 point reduction in the pretreatment rating of the item, progression in two stages, 1.0 point reduction, and so on with the exception in progressing from precontemplation to contemplation when no change credit is given because the offender only verbalized change without any evidence of behavioral change. This is repeated for each dynamic item identified as a treatment target. The total point deductions for each dynamic item at posttreatment are summed across all 17 dynamic items to arrive at a total change score reflecting the total amount of change. The total change score is subtracted from the total pretreatment dynamic ratings to obtain the total posttreatment dynamic ratings.

For instance, a rapist entering sex offender treatment may receive a 3-point rating on the item *Cognitive Distortions* and be assessed as being in the Contemplation stage of change for this item. Following treatment, during which the offender learns how to challenge and modify various rationalizations for offending and objectifying attitudes toward women, major gains are observed and progress is made to

the Action stage of change. The individual has progressed two stages (i.e., Contemplation to Preparation to Action), resulting in 2 × 0.5 = 1.0 points of change, the change score. The change score is deducted from the pretreatment rating of this item, resulting in a posttreatment rating of 3–1 = 2. The total change score is the sum of the change scores for all the dynamic items. The total VRS-SO pre- and posttreatment scores represent the offender's overall risk level for sexual recidivism at two points in time. Higher scores indicate higher risk.

Assessing the Presence and Change of Sexually Deviant Behaviors in Custodial Settings: Offense Analogue and Offense Replacement Behaviors

Sexually deviant behaviors clearly observable in the community, such as deviant sexual arousal or victim grooming, may not be as easily observable in a custodial setting. Such behaviors may be transformed and assume a different complexion in artificial and highly controlled settings, such as in forensic hospitals or prisons, where there is no easy access to potential victims, close monitoring, and imposition of severe sanctions for these behaviors. In such settings, the *repackaging* of sexually deviant behaviors into some proxies of such behaviors may make them less obvious and may even allow them to remain undetected by less experienced or less observant staff. These offense analogue or proxy behaviors observable within custodial settings are good indications that the root problems underlying such behaviors have remained intact and the individual risks to recidivate likely have not been reduced.

The term *offense analogue behaviors* (OABs) has been used specifically to describe the day-to-day behavioral manifestations of an individual's criminogenic problems in controlled or closely monitored situations wherein the individual does not have the total freedom to engage in their usual activities nor unfettered access to victims and tools to commit crimes (Gordon & Wong, 2010). The underlying deviance may still be alive and well, but the behavioral expressions of such deviance may have been "repackaged" to adapt to the demands of the situation. For example, an incarcerated child molester, whose modus operandi has been to use the Internet to lure and groom victims, may resort to watching children in TV programs and secretly viewing and masturbating to images of children in newspapers and magazines when access to the Internet is not available. Usually, OABs are somewhat more socially acceptable proxies of the individual's criminogenic needs when the open expression of the deviant behaviors will likely attract heavy sanctions. The notion of analyzing analogues of offending behaviors to facilitate risk assessment, treatment, and case formulation has attracted considerable attention recently (see Daffern, Jones, & Shine, 2010). Much research is still required to provide clear support for the reliability and validity of the construct (e.g., see Daffern, Howells, Manion, & Tonkin, 2009). We introduce the notion of offense analogue and offense replacement behavior for sex offenders within the framework of the PCC theory and the RNR principles.

It is important to clearly identify an individual's OABs in custodial settings for a number of reasons (see Gordon & Wong, 2010). First, individuals who repackaged or temporarily redirected their deviant behaviors while in custody are by no means problem-free or have their risk significantly reduced, and they should not be misconstrued by staff as having been rehabilitated. The potential for staff to be manipulated and conned into a false sense of comfort under such conditions by highly psychopathic offenders has been repeatedly documented (e.g., see Wong & Burt, 2007, pp. 477–478). In the community, psychopaths can behave like chameleons, changing their colors to suit the moment, just as much can be expected when they are in custody. Treatment and custodial staff must be trained and experienced in observing, documenting, and reporting these OABs. Some OABs are easier to observe than others. Certain OABs, such as deviant sexual fantasies and urges, can be challenging to measure and document. Ultimately, the treatment staff's knowledge of such OABs is, in part, based on the offenders' self-report. Given the frequent tendency for offenders to downplay personal concerns and attempt to present themselves in a positive light (e.g., denying deviant fantasies and reporting exclusively "healthy" fantasies), for obvious reasons, it is important for treatment staff to be vigilant to other proxies that do not rely exclusively on offender self-report (e.g., television viewing patterns, PPG testing, polygraph).

Second, since OABs are closely linked to the individual's criminogenic needs, they can be considered as the person's here-and-now targets for risk-reduction treatment. Criminogenic needs are the individual's higher-level or *macro* treatment targets, such as deviant sexual arousal, whereas OABs are the individual's idiosyncratic treatment targets, such as "fantasizing about sexual contact with male children" or "masturbating to age-inappropriate images in books and magazines." The OABs are clearly linked to the individual's macro criminogenic needs and are observable and tangible in the here-and-now custodial or treatment environments. As such, staff can work with offenders on their OABs and monitor the frequency of their occurrences. Also, recognizing and addressing OABs swiftly may avert problems from spiraling out of control, thus resulting in improved risk management in custodial settings.

Third, reduction in the intensity and frequency of OABs for those participating in risk-reduction treatment could be considered as important indicators of treatment improvement and risk reduction. Despite having participated or

completed risk-reduction treatment, those who continue to demonstrate significant OABs are likely the ones who have not been responsive to treatment and correspondingly show little or no risk reduction. All too often, in treatment reports and in other communications of treatment performance, references to the participants' improvements or lack thereof are limited to statements such as "successfully completed treatment," "participated in groups and programs," "completed homework assignments," and so forth, which may not have much bearing in assessing if criminogenic needs have been addressed and recidivism risks reduced. The conceptual and practical links between the individual's OABs and criminogenic needs allow for the assessment of relevant risk-related changes in treatment.

From a theoretical standpoint, the concept of OAB is explicitly linked to the principles of effective correctional treatment, that is, the risk, need, and responsivity principles (RNR; Andrews & Bonta, 2006), which are themselves derived from the theory of the psychology of criminal conduct (PCC). In brief, the PCC is based on a combination of social learning, cognitive-behavioral, and social cognition theories. The PCC attributes the cause of antisocial behaviors to a combination of "personal control through antisocial attitudes, interpersonal control through social support for crime provided by antisocial associates, non-mediated control established by a history of reinforcement of criminal behavior, and/or personal predispositions" (Andrews & Bonta, 2003, p. 10). The use of RNR principles in designing and delivering correctional intervention has received considerable empirical support. RNR-based interventions have been found to be more effective in reducing recidivism than those that are not (see Andrews & Bonta, 2003, 2006, 2010; Andrews et al., 1990; Harland, 1996; McGuire, 1995; Motiuk & Serin, 2001). Recent writings, including meta-analytic and other reviews, have identified the "risk-need-responsivity framework (Andrews, Bonta, & Wormith, 2006) [as] … currently the best validated model" (McGuire, 2008, p. 2591) for reducing aggression and violence.

The PCC essentially provides a theoretical basis for the identification of common criminogenic factors that can be targeted for treatment. According to this theoretical framework, effective correctional treatment should lead to positive changes in the criminogenic needs, resulting in risk reduction. Interventions directed at areas unrelated to recidivism (i.e., not criminogenically related) will not reduce the individual's recidivism risk. The validity of the PCC and RNR in the treatment of sexual offenders has received recent support (Hanson et al., 2009).

The OAB concept has the closest link with the risk and need principles. We define OABs as the here-and-now manifestation of the criminogenic needs of the individual in controlled settings. It follows that OABs are the logical theoretical extensions of criminogenic needs, from within the RNR framework. Similarly, the more OABs the person possesses, the higher the risk (risk principle). A key corollary of this conceptual link is that effective treatment directed at OABs, theoretically speaking at least, should result in the reduction of the risk of sexual recidivism for sex offenders. On account of these theoretical and empirical linkages, OABs can be used, in particular, in custodial settings to guide the identification of the sexual offender's treatment targets linked to sexual violence and criminality and to assess treatment changes and risk reduction. As treatment progresses and improvements are made by the participant, the number and frequency of occurrences of OABs are expected to decrease. However, there is an important caveat.

The caveat is that the reduction of OABs is a necessary but not *always* a sufficient condition for assessing risk reduction. For instance, for various reasons, triggers or challenges that usually precipitate the antisocial behaviors may not be present. A rapist who is highly controlling toward women may appear to be quite well behaved in the absence of interactions with female staff. A man who had many problems with his peers may seem to be managing well when left alone or restricted to solitary confinement.

We similarly posit that a more complete depiction of treatment progress should be represented by both an increase in positive or offense replacement behaviors (ORBs) and a decrease in OABs. In short, not doing the wrong things (fewer OABs) is good, but one has to do more of the right things instead (more ORBs). We define ORBs as the appropriate skills, usually newly acquired ones, an individual uses to manage past problems or situations that had culminated in criminality or violence. Observations of ORBs are particularly critical in controlled settings because of the many artificial situations that an individual may be subjected to that may inhibit and reduce problem behaviors.

Like OABs, ORBs should also be linked to the individual's criminogenic need areas, and one size does not fit all. For example, what are often considered by custodial staff to be positive and constructive pursuits while incarcerated (and rightfully so), such as striving to improve one's education and work skills, may be risk reducing for someone whose antisocial behaviors were related to a lack of steady employment because of poor education and job skills, but may be totally irrelevant for someone else who did not have such problems. Similarly, for someone with a passive-aggressive problem who tended to suppress his anger and then act out violently, behaving assertively and standing his ground are his relevant ORBs, but not so for a psychopath who revels in showing off his verbal skills and having the last word. In fact, for the psychopath, the same behavior may be his OAB! For some sex offenders, the lack of interpersonal skills to socially interact with women may be criminogenic, but not for others who may be highly interpersonally skilled in luring unsuspecting women into short-term relationships in order to abuse them.

Since treatment and change take time, we suggest that in most cases the gradual decrease in OABs (negative behaviors), together with a corresponding gradual increase in ORBs (positive behaviors), should indicate positive treatment progress leading to risk reduction. Recent data suggest that an increase in ORBs together with reductions in OABs, as measured by the progression through the stages of change (as in the transtheoretical model of change (Prochaska & DiClemente, 1984; Prochaska et al., 1992), is linked to reductions in violent recidivism (Lewis et al., 2013; Olver & Wong, 2009) also see Mooney and Deffern (2011). A structured guide to assess OABs and ORBs has been developed for non-sexual offenders (see Gordon and Wong, 2015) and a similar one for sexual offenders is under development.

How Real Are the Observed Changes in Treatment?

Meta-analytic reviews have demonstrated the effectiveness of treatment adhering to the principles of RNR for reducing sexual and other forms of recidivism (Hanson et al., 2009), including some support that correctional programs involving some mild to moderate coercion can be effective, albeit smaller compared to voluntary programs (Parhar, Wormith, Derkzen, & Beauregard, 2008). However, one of the major challenges in trying to effect changes through treatment of high-risk offenders is to discriminate real treatment changes that should lead to reductions in risk of recidivism from, for the lack of a better word, faked changes. Talking the talk is often confused with walking the walk, in particular for those with significant psychopathic personality traits. Theoretically speaking at least, real changes are changes linked to the individual's relevant criminogenic factors, and fake changes are changes that are unrelated to their criminogenic factors. Again, by definition, changes in OABs and ORBs should be linked to the individual's relevant criminogenic factors and, therefore, should be indicators of real changes. One has to walk the walk before changes in OABs and ORBs are registered and used to indicate risk reduction. Moreover, the individual has to demonstrate the reduction in OABs and increase in ORBs not just in formal treatment sessions such as groups and individual therapy sessions but in their daily living and in different environments under challenges. In essence, they have to demonstrate the reduction in OABs and increase in ORBs and be able to generalize such positive changes to different high-risk situations.

All too often, treatment staff may assess change by paying attention to inappropriate or potentially irrelevant indicators of changes so much so that putative positive treatment changes are sometimes linked to increases in recidivism (Seto & Barbaree, 1999; but see also Barbaree, 2005, and Langton, Barbaree, Harkins, & Peacock, 2006). Some examples of potentially irrelevant indicators of changes include the following:

1. Attendance of treatment sessions. This may be used as a proxy indicator of engagement in and integration of treatment information, but such links may be tenuous at best. This is one of those "tick box" indicators that require minimal effort to collect and document and are favored by some treatment providers or managers. Such information can be collected but should be supplemented by more relevant and focused indicators of change such as OAB reductions.
2. Successful completion of programs, similar to (1) above. Attending all treatment sessions or complying with group requirements may or may not be a useful indicator of change. Few would disagree that change is better indicated by implementing what has been learned in the treatment sessions, that is, walking the walk. Even then, whether one could generalize what is practiced in an institutional setting to the community is still unknown unless one has been tested under situations that simulate the community.

A related issue is that assessing treatment change has been shown to be easily open to subjectivity and biases when such assessments are carried out by the same treatment provider. Obviously, the treatment provider has many vested interests in the case and that may compromise the objectivity of such assessments (see Weiss, Rabinowitz, & Spiro, 1996). Having an independent third-party carryout, the treatment outcome assessment and obtaining a reliable second opinion are highly desirable. However, such is not always possible due to logistical, financial, or other reasons. We would argue that the subjectivity should be substantially reduced if the change assessments are done with the structured guidance of constructs and tools such as OAB and ORB and the use of the guide discussed below. An analogy can be drawn with respect to risk assessment and prediction. Risk prediction based on the clinical opinion of a health professional alone is much more open to subjectivity and biases compared to similar assessments done with the aid of a structured risk prediction tool such as one of the many so-called second- or third-generation risk tools (Bonta, 1996). Similarly, assessment of treatment change may be less biased when a similar structured tool is used; however, this is very much an empirical question, and research is required to assess such assertions.

Measurement of OABs and ORBs for Sex Offenders

OABs and ORBs may not be immediately obvious and easily observable. As such, we have developed guidelines that we hope could help service providers and assessors to identify and document them. Since OABs and ORBs are derived from criminogenic factors for sex offenders, we start by

using the dynamic (criminogenic) risk factors of the VRS-SO. The following is an example of the steps in identifying OABs and ORBs.

1. Assess the individual using the VRS-SO and identify all his/her dynamic factors rated 2 or 3. These are the individual's risk factors with significant links to sexual deviancy and/or violence and, as such, treatment targets. For illustration, say "Deviant Sexual Preference" is one of them.
2. Assess how Deviant Sexual Preference is manifested by the individual in the community and while he/she is in custody. This will require a fairly in-depth interview and review of collateral information, ideally including third-party information, to focus on the idiosyncrasies of the individual in question. The earlier example (see p. 15) of the child molester who used the Internet to lure victims is a case in point. Since the client's willingness to disclose is often very helpful in identifying OABs, the list of OABs may have to be revised with the progress in treatment when better working and more trusting relationships with staff may prompt further disclosure of OABs.
3. Identify the frequency of occurrence or base rate of each of the OABs. Increases or decreases in the base rate of the OAB are indicative of deterioration or improvement with treatment, respectively
4. ORBs are more easily identifiable when the individual is, at least, in the Contemplation or, better, the Preparation stage of change when he/she acknowledges problems and tries to make changes. Needless to say, staff assistance is necessary to help offenders identify both OABs and ORBs.
5. The information captured by identifying the rates of OABs and ORBs is indicative of progress or lack thereof during treatment and can be used to indicate movement along the stage of change continuum, that is, movement from Precontemplation to Contemplation to Preparation, Action, and Maintenance.

The OAB/ORB Guide that accompanies the VRS-SO provides a structured way of capturing OAB and ORB information. We provide examples of OABs and ORBs from the Sexual Deviance, Criminality, and Treatment Responsivity factor domains. Examples of OABs consistent with Deviant Sexual Preference (Dynamic Item 16) would include deviant masturbatory fantasies (e.g., underage individuals, masturbating to past offenses, rape fantasies), deviant arousal (e.g., as assessed by PPG, self-report, or the VRS-SO sexual deviance factor—see Canales, Olver, & Wong, 2009), and use of materials that can fuel deviant interests (e.g., observing child photos in catalogues, drawing pictures of children, watching inappropriate television shows featuring children, or accessing other triggering stimuli). These OABs, in turn, would be rated by their frequency (i.e., *never, seldom, somewhat frequent, frequent*) and applicability to the client. By contrast, relevant ORBs would include appropriate fantasies (i.e., consenting partner, appropriateness with respect to age, relatedness [i.e., not family, staff member, past victim] to the client), avoidance of triggering stimuli, and capacity to control deviant arousal (e.g., via PPG testing). Relevant ORBs, in turn, would also be assessed in terms of their frequency and appropriately documented.

Examples of OABs consistent with Interpersonal Aggression (Dynamic Item 6) would include verbal aggression (e.g., swearing and shouting) and/or physical aggression directed at others, aggression directed toward things (e.g., slamming doors, throwing, punching, or kicking things), engaging in nonsexually violent fantasies, or using aggression to control or intimidate others. In turn, relevant ORBs for this item would include using problem-solving approaches to deal with interpersonal issues with staff and peers, attempting to see and understand another person's point of view, or using time-outs, perception checking, consequential thinking, and so forth to manage interpersonal problems.

Finally, examples of OABs consistent with Cognitive Distortions (Dynamic Item 5) would include rationalizations, justifications, and minimization of past sexual offenses (or other sexual offending behavior) in treatment, verbalizations, or other behaviors that suggest at least a tacit acceptance of sex offender attitudes (e.g., objectifying statements about women or children) and so forth. By contrast, alternative ORBs for sex offender cognitive distortions would include espousing prosocial sexual attitudes and beliefs and actively rejecting or challenging distorted sex offender cognitions in group, personal, and other circumstances.

Issues in Conceptualizing and Measuring Treatment Changes

There are a number of commonly raised questions regarding the issue of treatment-related changes for sex offenders. First, what constitutes long-term *real* treatment changes, for example, if a treated sex offender with a history of repeat sexual offending appears to be doing well on all counts after treatment was released to the community and did well but recidivated once many years later, has *real* change actually occurred? Second, what program or clinical information does one need to support the assessments of risk-related treatment change? Third, what quantitative research evidence is required to support the dynamic or changeable nature of sexual offender risk?

The answer to the first question pertains to how long-term treatment change should be conceptualized and measured. If one expects that treatment changes should result in the complete desistance of all sexual offending for the treatment

participant, then zero sexual recidivism in the person's lifetime is the only acceptable indication of the expected treatment change. Using this criterion, the offender in the example has not changed. There are valid reasons why such an expectation is unrealistic. Entrenched behavioral patterns, habits for short, such as repeat sexually abusive behaviors, are established over time, and they take time to undo. Treatment, no matter how effective, does not have a 100 % remission rate for all on the completion of formal programming; the treatment outcome literature has repeatedly demonstrated this point. Treatment change conceptualized as harm reduction is probably a more accurate approximation of the research evidence. More recently, in the crime desistance literature, desistance has been viewed as a process of "gradual decline toward zero or a very low rate of offending" (Laub, Nagin, & Sampson, 1998, p. 227). Loeber and Le Blanc (1990) further specified four components of desistance as (1) reduction in the frequency of offending (deceleration), (2) reduction in the variety of offending (less criminal versatility), (3) reduction in the seriousness of offending (de-escalation), or (4) no increase in the seriousness of offending (reaching a ceiling). In all, desistance, when conceptualized as a process of gradual positive change that leads to desistance instead of a step function of moving from no desistance to desistance in a single step, is consistent with the harm reduction approach. Within the context of sex offender treatment, risk management and relapse prevention are also predicated on the notion that treatment is not a cure but a lifetime management or the reduction of the risk of relapse, also a harm reduction model. Taking on board the harm reduction model, the indicators of positive treatment change should be broadened to include reduction in the frequency (number of offenses per unit time) and seriousness of offending (level of harm) as well as the increase in the latency of offending (time to first offense) in addition to complete desistance. We would argue that these three additional measures of recidivism are more realistic and sensitive measures of change and should be used over and above total desistance (yes/no reoffending) as the sole indicator of change. Applying these suggested measures within a harm reduction model shows that the sex offender in the example has made changes.

Still others may argue that treatment change should not be limited to risk-related changes but should entail changes in the underlying personality or other comorbid disorders, interpersonal style, social adjustments, mental and/or physical health status, and so forth. All of the above can be argued as possible objectives for sex offender treatment programs depending on how the treatment program is designed and conceptualized. However, the onus is on the proponent of the treatment program to stipulate and justify the objectives of the treatment based on available scientific evidence and then measure how well the objectives are fulfilled. Given that the overwhelming need to treat sex offenders is to reduce their risk to reoffend, program designers, regardless of their theoretical persuasion, should address the risk-reduction issue nonetheless.

If sexually abusive behaviors are akin to an ingrained habit refractive to change, can a relatively brief, albeit intensive treatment of a few months or even a year serve to undo such habits and produce real and enduring changes? Similar to most psychologically based intervention, treatment programs for sexual offenders should be seen as a period in which changes can be started, supported, and practiced and participants gradually move forward to more enduring changes that are self-supporting: becoming internally rather than externally motivated, building on a good foundation, and gathering momentum as the changes become more firmly rooted. Treatment simply starts people on a trajectory of cognitive and behavioral change. The end of the program should be viewed as the end of a formal and intensive learning period rather the end of the learning and change process. For instance, if an individual is in the Preparation stage at the completion of a treatment program, he or she, with the appropriate support, may continue to progress positively, moving eventually into Action stage and thereafter. Similarly, most do not cease learning when they finish formal education in schools or universities provided that there is sufficient motivation and reward to continue to learn and self-improve. As such, posttreatment support, maintenance, and supervision are essential to sustain any improvement started in formal programming. The SOC rubric in the VRS-SO is simply one approach to conceptualize and measure changes that can occur in treatment programs for sex offenders. Sex offenders with different levels of risk obviously will require treatment with different levels of intensity, that is, the risk principle.

Another question that is often raised related to sex offender treatment is what program or file information can systematically and reliably show that real treatment change has occurred, vis-à-vis our second question. We argued earlier that if risk reduction is the ultimate objective of the treatment program, then changes in proxies of past offending behaviors observable in treatment programs (our so-called OABs and ORBs) should be the appropriate indicator of risk-related treatment changes. Unfortunately, such information is not always captured and documented by treatment staff, in part, because of differences in program objectives and, perhaps, the theoretical or professional orientations of the treatment providers. If changing personality, interpersonal style, and anger control are the objectives of the program, then information pertaining to such objectives will be documented regardless of their relationship to offending behaviors. Valid and reliable change information that can be used to make VRS-SO change ratings can be obtained from records, and providing there is a suitable volume of information upon which to base the changes, staff members are trained to recognize and document OABs and ORBs, and

that participants were exposed to a credible change agent (e.g., risk-reduction treatment). For better information quality, multiple sources of information, including interview and multidisciplinary reports including observations of the offender's day-to-day behaviors to detect any selective or deceptive behaving, should be used. If the individual has not participated in a treatment program (no credible change agent) or if mainly irrelevant and inappropriate pieces of information unrelated to risk change are documented, it will be challenging to rate SOC and detect movement along the stages of change. When staff are trained to recognize relevant OABs and ORBs linked to the individual's criminogenic needs and document this information as part of their routine treatment duties, the files become a much richer source of information from which to code SOC.

Our third question highlights the continued debate on what can be considered a definitive (if there is ever one) indication of the dynamic nature of risk. We refer the readers to the seminal and widely cited paper by Kraemer et al. (1997). Kraemer et al. (1997) provided various definitions of dynamic risk and discussed them at length. In a subsequent paper, Douglas and Skeem (2005) reiterated a similar definition of dynamic risk. In essence, the necessary and sufficient condition for risk to be deemed dynamic is when risk is measured at least at two points in time to assess change, which can then be linked to recidivism changes in the predicted direction; that is, is risk reduction linked to subsequent reductions in recidivism (see also the discussion of causal risk factors in a later section of this chapter)? Linking risk assessment at a single time point to recidivism does not adequately address the question of whether or not risk is changeable. We suggest that a further caveat must be noted and that is the baseline level of risk must be controlled in order to assess change. For example, a higher-risk offender, despite having undergone more change after treatment than a lower-risk offender, may still be at higher risk to reoffend when compared to his lower-risk counterpart since treatment change began at a much higher baseline. When linking risk changes to recidivism, controlling for baseline risk level should eliminate this potential confound. This methodology has been used to assess the hypothesis that risk is dynamic, and an increasing number of publications have reported evidence to support the hypothesis, as will be discussed in more detail below (Olver et al., 2007; Olver & Wong, 2009, 2011; Beggs, 2008; Beggs & Grace, 2010; Lewis et al., 2013, for nonsexual offenders). The methodologies or change measures used to test the dynamic nature of risk should assess risk at two or more time points and control for the baseline measure of risk at a minimum. It is possible that, if not reliably assessed, treatment changes can become a source of noise and may even increase errors in measuring posttreatment risk such that, paradoxically, pretreatment risk measures can be better predictors of outcome than posttreatment risk measures (e.g., Barbaree, Seto, Langton, & Peacock, 2001; Rice, Harris, & Quinsey, 2002).

Guidelines for Interpreting a VRS-SO Assessment

The VRS-SO is designed not only as a risk assessment tool for sex offenders, but it can also guide risk management, identify treatment targets, and measure treatment change. The guidelines for interpreting a VRS-SO assessment are available in detail in a companion technical manual for the tool; a summary of the information is provided here.

Risk Assessment and Prediction

One important issue in risk prediction is the selection of risk cutoffs to designate a level of risk for offenders assessed with the tool. Using Hanson's and Morton-Bourgon's (2009) rubric from their meta-analysis of sex offender risk assessment instruments, the VRS-SO total scores can be arranged into four risk bins with associated cutoff scores and percentage sexual recidivism in a manner similar to research with the Static-99: Low Risk (0–20), Moderate-Low Risk (21–30), Moderate-High Risk (31–40), and High Risk (41–72). The norms for the VRS-SO represent posttreatment total (i.e., combined static and dynamic) scores and were found to be the strongest predictors of subsequent sexual recidivism in our normative sample.

The base rate of sexual recidivism also varies with the length of follow-up and type of outcome (e.g., charges versus convictions). The current norms available and reported here are from the original sample of 321 treated and federally incarcerated sex offenders followed up on an average of 10.0 years post-release. The recidivism rates for the four risk bins are presented in Figs. 1 and 2. Figure 1 presents simple recidivism rates (any new sexual charge or conviction) irrespective of follow-up. Figure 2 reports sexual recidivism rates for the four risk categories at 3-, 5-, and 7-year follow-up. In this figure, a simple cap was placed on the length of follow-up for each time interval while retaining the total offender sample at each follow-up point. As most (71 %) of the sample had at least 7 years of total follow-up time, the sexual recidivism base rates were likely more realistic and stable than the 10-year reconviction rates reported in Olver et al. (2007), although the 3- and 5-year recidivism rates between Olver et al. and Fig. 2 are almost identical. The base rates in Figure 2 also represent any new sexual charge or conviction, a somewhat more liberal criterion that can yield higher base rate estimates (Doren, 1998).

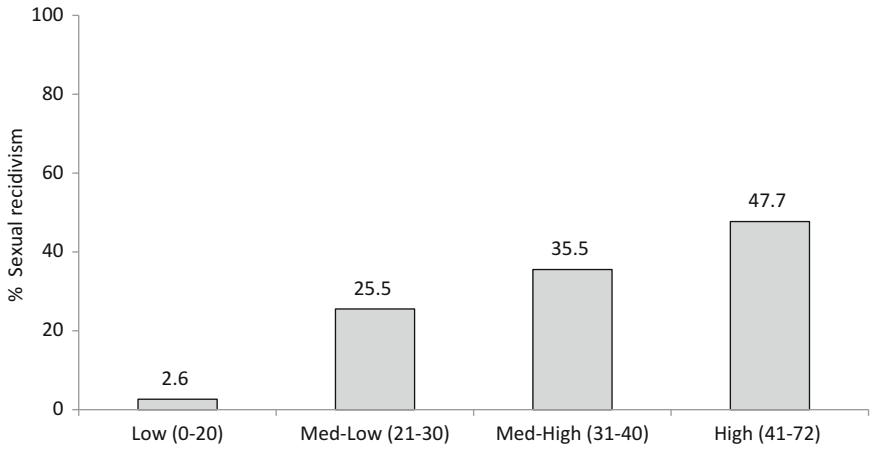

Fig. 1 Rates of sexual offense recidivism for the four VRS-SO risk categories, no cap placed on length of follow-up (mean follow-up = 10 years; *N* = 321)

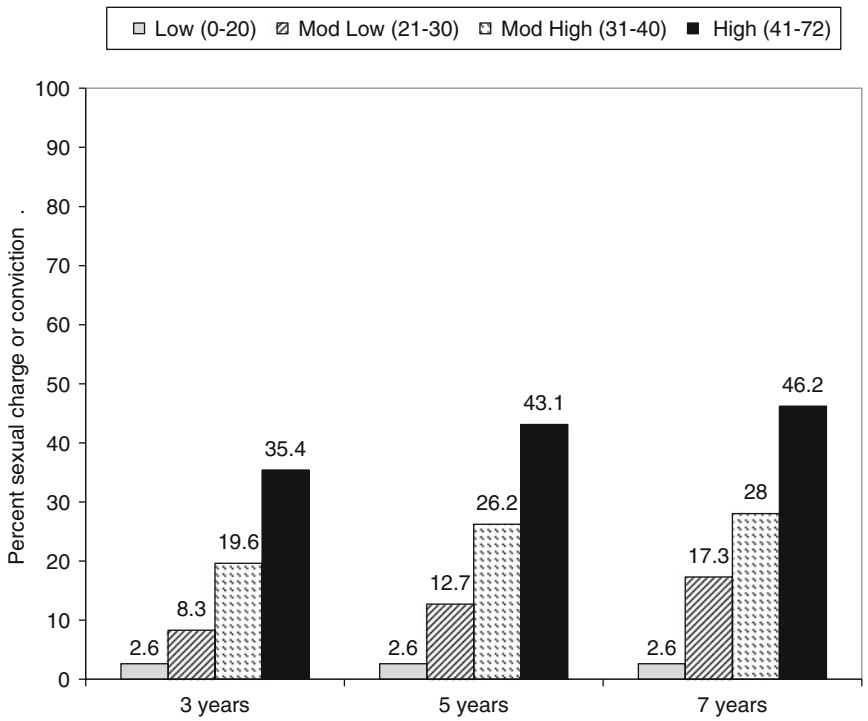

Fig. 2 VRS-SO recidivism norms: base rates of any new sexual charge or conviction at 3-, 5-, and 7-year follow-up (*Note* Group bin sizes (Total *N* = 321): Low = 39, Moderate–Low = 110; Moderate–High = 107; High = 65)

In addition to risk cutoffs and recidivism probabilities, percentile ranks also can be reported. A percentile refers to the percentage of scores that is below the score in question; if a certain score is at the 90th percentile, then 90 % of all the scores in a certain sample are below that score. Percentile ranks provide another appraisal of the individual's risk and an additional piece of information for decision-making by comparing an individual's score with that of a cohort, in this case, the scores of other incarcerated sex offenders in the normative sample. Whereas dividing the sample into the four risk bins essentially ranks the individual by way of one of the four groups, the percentile scores give a more precise ranking of the individual within the entire cohort, although small differences in percentile ranking may not be very meaningful. The percentile ranks for the VRS-SO posttreatment total and the three dynamic factor scores are available in the technical manual.

Assessing Criminogenic Needs and Identifying Treatment Targets

The percentile ranks of the three VRS-SO factor scores give an indication of the relative significance of three broadly defined criminogenic need domains of the individual. The items within each of the factors that are scored 2 or 3 are the more specific criminogenic needs within each factor. For instance, the items Sexually Deviant Lifestyle, Offense Planning, and Deviant Sexual Preference might be identified as criminogenic (scored 2 or 3) within the Sexual Deviance factors and are thus specific treatment targets for service providers to focus on.

The scoresheet has been structured so that factor scores corresponding to the three broad dynamic factors can be computed to derive a risk profile, and individual items and their scores (0, 1, 2, or 3) within each factor can also be identified and displayed. The VRS-SO scoresheet thus provides a graphic and numerical summary of the pattern(s) of criminogenic needs, at both the factor and the item level, that contribute to sexual offending risk for each individual case. The individual's OABs and ORBs identified for each of the criminogenic items would take the specification of the individual's criminogenic behavior to levels that are observable by treatment and service providers in the day-to-day interactions with the individual. As indicated before, changes or lack thereof in the OABs and ORBs would indicate corresponding changes in sexual recidivism risk, thus closing the loop, so to speak.

Stage of Change Assessments

Each dynamic item identified as a treatment target should be given a stage of change rating to indicate the individual's degree of readiness to work on his/her problem areas and to assess treatment progress by monitoring progress in the stages. These ratings are particularly informative for treatment and service providers tasked with assisting the individual to make changes to reduce risk. Treatment and therapeutic approaches obviously have to be adjusted to fit the stage of change of the individual. The stage of change can also indicate the level of motivation indicated by the individual to change: those with many criminogenic needs and with most or all of them rated in the Precontemplation stage are expected to be highly recalcitrant and resistant to attempts at risk-reduction intervention; as such, their risks are not expected to be easily reduced. Evaluators would likely take such assessment information into account in decision-making.

While offender self-report is an important source of information, it is only one source. Given the potential for impression management, exaggerated self-reports of improvement, and patient demand characteristics, offender self-report information should not form the sole or necessarily even the primary basis for evaluating treatment changes. Evaluators are recommended to attend closely to the stage of change criteria and to note the relevant OABs and ORBs for a given dynamic risk factor. Collateral information sources are particularly important, including assessments from other criminal justice personnel (e.g., parole or probation officers), results of PPG testing or polygraph, and observations made from other treatment or institution staff who have the opportunity to observe the individual in contexts outside of treatment.

Similarities and Differences Between the VRS-SO and Other Risk Assessment Tools

Most sex offender risk assessment tools are developed for the prediction of sexual recidivism, and there are a number of them available for use. Hanson and Morton-Bourgon (2009) have demonstrated that there does not appear to be an appreciable amount to be gained in predictive accuracy by using one tool over another. A recent meta-analysis also found highly similar predictive efficacies among tools used to predict nonsexual violence (Yang, Wong, & Coid, 2010). In essence, many of the available sexual risk assessment tools that incorporate static or both static and *dynamic* factors, including the VRS-SO, have similar and acceptable predictive accuracy. However, if one goes beyond risk prediction to risk reduction through treatment and rehabilitation, then one has to use tools with causal risk factors (CRFs; Kraemer et al., 1997). Other than being putatively changeable, that is, being conceptually dynamic, such as attitudes and beliefs, changes in these CRFs must be empirically shown to be linked to corresponding changes in future sexual recidivism, that is, decreases in CRFs have to be shown to result in decreases in sexual recidivism by way of an appropriately designed empirical study. The latter is a key requirement for the appropriate use of CRFs in treatment planning and delivery, since treatment providers then can have a certain level of confidence that improvement in these CRFs in treatment would likely lead to reductions in sexual recidivism. Kraemer et al. (1997) discussed in detail the necessary and sufficient conditions for a risk factor to be deemed a CRF. In the literature, the term *dynamic risk predictors* is often used to indicate, in a general way, conceptually changeable risk factors without making the clear distinction of whether or not evidence is available to show that the requirements of a CRF have been met.

There are several risk assessment tools with dynamic or putatively changeable risk factors, using Kraemer's terminology, aside from the VRS-SO. Some examples of these tools include the Stable-2000 (Hanson & Harris, 2001) and

Stable-2007 (Hanson et al., 2007), Sexual Violence Risk-20 (SVR-20; Boer et al., 1997), Risk for Sexual Violence Protocol (RSVP; Hart, Kropp, & Laws, 2003), and the Sex Offender Assessment of Risk and Need framework (SARN; Thornton, 2002; see also Craig, Thornton, Beech, & Browne, 2007). In our recent review of the literature on risk assessment (Wong, Olver, & Stockdale, 2009), only the VRS-SO, to this point, appeared to have presented empirical evidence that satisfies the requirements of CRF, and the original validation work is one of few studies that have examined the dynamic nature of putatively dynamic variables. A recent paper examining predictive efficacy research of the VRAG with intellectually disabled sexual and violent offenders made a similar observation (Camilleri & Quinsey, 2010). Much more research is required in this area.

The family of sex offender risk assessment instruments that incorporates putative dynamic variables is an important contribution in promoting an evidence-based and clinically sound integration of sex offender risk assessment and treatment in order to reduce and manage risk and prevent future occurrences of sexual violence. The VRS-SO, for instance, fits well within the risk-need-responsivity framework. Risk scores and cutoffs can inform the appropriate intensity of intervention (e.g., high risk would suggest prescribing a high-intensity program), as per the risk principle. A risk-need profile of criminogenic items can be created, as per the need principle, to identify where (and where not) to intervene. As outlined in the instrument description near the beginning of this chapter, treatment resources, often in scarce supply, should be directed toward high-priority areas but not toward low-risk or non-criminogenic areas. Consistent with the responsivity principle, the stages of change rating also speak to an individual's readiness, motivation for change, and the necessity for stage-matched interventions. For instance, interventions such as consciousness raising, environmental reevaluation, dramatic relief, and gentle efforts to engage the offender may facilitate movement from Precontemplation to Contemplation (Tierney & McCabe, 2005).

The VRS-SO's modified application of the TM also enables the documentation and quantification of changes in sex offender risk. In the initial validation of the VRS-SO using a sample of 321 treated sex offenders with a mean 10-year follow-up, it was found that changes in risk were associated with reductions in sexual and violent recidivism after controlling for baseline risk level (Olver et al., 2007; Olver & Wong, 2009); VRS-SO pre- and posttreatment change scores were significantly associated with reductions in sexual recidivism after controlling for multiple indicators of baseline risk, including the use of both the VRS-SO total static factor score and pretreatment total (static plus dynamic) score. Change scores were also significantly negatively correlated with sexual recidivism ($r = -0.15$) among offenders scoring as high risk on the Static-99, another way of accounting for baseline risk level. These results indicate that risk is dynamic in that changes in participants' risk after attending a high-intensity treatment program (the Clearwater Program in CSC) were associated with reductions in sexual recidivism.

In a subsequent study based on this dataset and sample, Olver and Wong (2011) dichotomized offenders scoring moderate-high or high on the Static 99 into high (n = 104) and low (n = 100) change groups. Both groups had nearly identical Static-99 scores (high risk/high change $M = 5.7$, $SD = 1.3$; high risk/low change $M = 5.6$, $SD = 1.4$), but compared to the low-change group, the high-change group had significantly lower rates of sexual recidivism. Even more compelling was that, after treatment, the sexual recidivism rate of the high-risk/high-change group was now statistically indistinguishable from that of the actuarially low-risk groups. The results of the two studies are consistent with the conclusions that sexual offending risk is dynamic and changeable through treatment; that static tools, such as the Static-99, cannot accurately measure and reflect such changes in risk; that the dynamic risk predictors in the VRS-SO are causal risk factors based on criteria set forth by Kraemer et al. (1997); and that the tool can be used to assess risk changes. These tentative conclusions need to be further tested empirically.

In their independent cross-validation of the VRS-SO on a sample of 218 child molesters who received sex offender treatment from the Kia Marama program in New Zealand, Beggs and Grace (2010) obtained strong support for the predictive accuracy of the VRS-SO for sexual recidivism, obtaining AUC values of 0.79 and 0.80 for pre- and posttreatment total scores, respectively. In the original dissertation (Study 2) of this body of work, Beggs (2008) examined the relationship of pre- and posttreatment change scores to outcome. Change scores were also found to be significantly negatively correlated with sexual recidivism across the entire sample ($r = -0.15$) and were associated with reductions in recidivism after controlling for the Static-99 measure of baseline pretreatment risk ($e^B = 0.76$, $p < 0.06$). Changes made on the Sexual Deviance factor specifically were significantly associated with reductions in sexual recidivism, which were also retained after controlling for the Static-99 ($e^B = 0.57$, $p < 0.05$). This body of work provides further supports for the dynamic nature of sex offender risk and the use of dynamic risk tools to assess such changes.

Future work on the VRS-SO is to extend and further validate the use of the VRS-SO in risk management and treatment, such as identifying and refining offense-linked proxy or analogue behaviors (OABs) which may represent manifestations of the offending behaviors in custodial settings. The normative base of the VRS-SO, in turn, may lend itself to possible use in SVP and DO assessment contexts given that these tend to involve incarcerated or hospitalized clients.

Possible Use of the VRS-SO in the Preventive Detention of Sex Offenders

Many developed countries such as the USA, UK, Canada, and Australia have enacted preventive detention legislations for the management of particularly high-risk offenders (Calkins Mercado & Ogloff, 2007). Some of the legislation applies to high-risk offenders in general, such as the dangerous offender designation (Sec. 753, CCC) in Canada; others are specific for sex offenders, such as the sexual violent predator law now in place in a number of states (see Schlank & Cohen, 1999; for a recent review see Prentky, Janus, Barbaree, Schwartz, & Kafka, 2006). Reviewing the range of preventive detention legislations, their merits, practicality, and legitimacy are beyond the scope of this chapter. From time to time, validated risk assessment tools will be used by practitioners in their work, including preventive detention assessments. We wish to comment on the possible use of the VRS-SO in addressing some of the requirements of these legislations. Our comments should *not* be interpreted as an endorsement of using the VRS-SO for preventive detention assessments; every clinician has to make such a determination for her/himself. Instead, such comments should be seen as a discourse of possible contributions, limitations, and, in particular, caveats in using the VRS-SO in such assessments.

Assessing the need for preventive detention usually involves determining the presence of a mental disorder, the presence of a history of violent and/or sexually violent criminal acts, the likelihood of future violence including sexual violence, and, in some cases, the potential for rehabilitation. As well, there is a provision for treatment and rehabilitation services to reduce the risk of future violence, in particular, sexual violence, to those detained under these laws. As such, there is a need to assess treatment changes and the corresponding change in violence or sexual offending risk. Other than the presence of a mental disorder, an assessment using the VRS-SO can provide information to address some of the other requirements of these laws.

Past Violence and Likelihood of Future Violence

The VRS-SO static factors are selected to provide a measure, both conceptually and quantitatively, of the extent of the individual's track record of sexual violence, including the type of sexual offenses, the extensiveness of past criminality, types of victims, age of first sexual offense, and so forth. Inspection of the scoring of the static factors can provide information about the individual's history of sexually inappropriate behaviors. Additional dynamic factors such as the Deviant Sexual Lifestyle and Sexual Offending Cycle can provide further information on the persistence of sexually inappropriate behaviors. The prediction of future sexual and nonsexual violence, as discussed in some detail earlier, is provided by the total score of the VRS-SO and will not be discussed further here.

Potential for Rehabilitation, Treatment Progress, and Risk Changes

The stage of change ratings of the VRS-SO dynamic items that are identified as treatment targets can provide an indication of the individual's readiness for change item by item. Generally, one can observe a predominant stage of change for an individual, that is, a stage of change that applies to the majority of the treatment targets, and this would indicate the individual's overall willingness or readiness to make changes or, at that moment in time, his/her potential for engagement in rehabilitation work. Since motivation and readiness can change over time, such potential can also change and must be reassessed, reviewed, and revised as appropriate: readiness is a state rather than a trait.

Before assessing treatment progress, one needs to assess and determine what to treat, that is, to identify treatment targets. As discussed earlier, the rating of the VRS-SO dynamic factors can assist in the identification of treatment targets, that is, risk factors that are linked to sexual offending or inappropriate sexual behaviors. Identifying the corresponding OABs and ORBs for the treatment target can determine, at an individualized level, the day-to-day behaviors that treatment staff should attend to closely in the delivery of treatment to sex offenders. Treatment progress and the corresponding risk reduction are best assessed within the VRS-SO using the modified stage of change rubric discussed earlier. Progress through the stage of change suggests that problem areas are being addressed and positive skills are used to manage high-risk factors leading to risk reduction. Research evidence suggests that progress in the stage of change is linked to reduction in sexual recidivism in the community (Beggs, 2008; Olver et al., 2007). However, it should be noted that for some sex offenders, such as child molesters, progress to the Maintenance stage on some dynamic factors such as Offense Planning may not be possible within an institutional environment such as a prison or hospital setting. Such environments do not provide sufficient opportunity to practice or generalize treatment gains to a variety of contexts that may tax an individual's coping resources through exposure to high-risk situations (e.g., access to victims).

While the VRS-SO evaluations have been used by expert witnesses and admitted to evidence in Canadian courts, including DO hearings, and we think that the VRS-SO can provide useful information for preventive detention evaluations, we would *not* suggest that it be used as a stand-alone tool for such evaluations. Rather, it may provide one source of risk- and

treatment-related information that can be used in the overall evaluation. As well, risk prediction is not an exact science, inferences of individual performance (e.g., individual risk level) from group and normative research data (e.g., group recidivism data) should be interpreted with due caution similar to the interpretation of any psychological test results. Needless to say, assessments for preventive detention must be carried out with extreme caution since any false-positive or false-negative errors would exact very high human and resource costs.

Clinical Case Example of the VRS-SO with a Treated SVP-Adjudicated Rapist[1, 2]

Mr. Brown is a 33-year-old male, recently adjudicated a sexually violent predator (SVP) assessment as per the state legislation in his jurisdiction after serving an 8.5-year sentence for sexual assault and assault causing bodily harm. Mr. Brown has two previous convictions for sexual assault, as well as a prior conviction for a nonsexual assault and a miscellany of property crimes. Although Mr. Brown completed a sex offender treatment program as he approached the end of his sentence, he was referred for an evaluation pursuant to the sexually violent predator legislation at the request of his parent institution. The VRS-SO was completed on Mr. Brown as one component of appraising his risk which was part of the overall SVP evaluation. The circumstances surrounding his offenses and synopsis of information to rate his static risk variables on the VRS-SO are outlined below.

Offense History and Information to Rate Static Items

Mr. Brown's first criminal charge for a sexual offense involved an attempted rape of a 40-year-old female real estate agent when he was 18 years old. According to official documentation, Mr. Brown approached the victim, a stranger who was taking photographs of a house (his residence), and invited her in for a tour. He engaged her in some topical conversation about the home and, when the agent turned her back, grabbed her, wrestled her to the floor, and attempted to disrobe her. As the front door was open, the agent struggled and screamed for help, and Mr. Brown fled. Mr. Brown's second criminal charge for a sexual offense occurred when he was 22 years of age. He reported that he had just gotten off work and was walking home when he came across the victim, a 19-year-old woman walking through a park. Mr. Brown was cutting through a park when he saw the victim (also a stranger) and ran up behind her to catch up with her. He engaged her in casual conversation; the victim quickened her pace and responded tersely, stating that her boyfriend expected her home. Mr. Brown then grabbed the victim and tried to kiss her. She resisted, and both fell to the ground. Pinning her down, Mr. Brown forced off the victim's lower clothing and forced vaginal intercourse. After a few minutes, he got up and asked her if she was interested in dating him; when he let his guard down, the victim ran to safety and later reported the incident to the police. Mr. Brown received a 4-year sentence for this matter and was paroled after serving 3 years.

Mr. Brown's most recent sex offense occurred against a 63-year-old woman from whom he was renting a basement suite. According to official documentation, the victim went downstairs to retrieve an item and came across Mr. Brown, who was wearing one of her dresses. Mr. Brown grabbed the victim and punched her in the face and stuffed a shirt in her mouth, covering her face so that she could not scream. A 64-year-old male acquaintance of the victim was upstairs watching television during the assault. Mr. Brown forced the victim on the bed, smothering her, and forced off her top layer of underclothing. The victim managed to gasp out a scream, and, alerted by the commotion, the male acquaintance came downstairs to the victim's aid. Mr. Brown attacked the man, punching him several times in the face. During the commotion the victim fled to safety and contacted the police. The police apprehended Mr. Brown shortly thereafter nearby the residence.

Mr. Brown received a score of 14 on the VRS-SO static items given that he has three unrelated victims (all adult females), two prior sexual convictions, and six total prior sentencing occasions (including his prior nonsexual assault and property crimes). He was under 20 years of age when he was charged for his first sex offense and would be 33 years old if released at the expiration of his sentence.

Pretreatment Dynamic Item Ratings and Relevant Case-Related Information

A detailed assessment was completed on Mr. Brown, which included two 3-h clinical interviews and drew on past treatment reports, psychological assessments, and other collateral documentation (e.g., victim impact statements, court transcripts, police reports).

[1]The following are Canadian Court cases in which the VRS-SO has been explicitly mentioned in the judicial disposition as an instrument used by an expert witness to complete a psychological risk assessment that was accepted as part of expert testimony in court. These are Dangerous Offender or Long-Term Offender hearings held in Court of Queen's Bench for Saskatchewan (SKQB):

R. v. Brass, 2009 SKQB 360 (CanLII) Par. 290–292

R. v. E.D., 2006 SKQB 498 (CanLII) Par. 34, 64

R. v. I.N.H., 2004 SKQB 402 (CanLII) Par. 7

R. v. C. (G.), 2001 SKQB 2 (CanLII) Par. 70

[2]Although based on an actual case, essential identifying characteristics have been changed to preserve anonymity.

In terms of relevant historical information, Mr. Brown reported that his parents divorced when he was very young; although he lived with his mother during his early childhood, he was placed in foster care at age 10. Mr. Brown reported that his mother worked late nights in a bar and at times brought home strange men. He also reported having been fondled by an uncle when he was age 8 and having witnessed his mother engaging in sexual activity with her various partners at home. He reported that he began to masturbate in his mid-teens to fantasies of female peers as well as pornography.

Mr. Brown stated that he got mixed up with the "wrong crowd" in school, smoking marijuana and drinking on weekends, and was involved in minor property crimes. He reported that his first consenting sexual encounter occurred at the age of 16 with a 17-year-old girl he knew from school who hung out with his peer group. His school record was patchy at best, and he quit school in grade 10. Most of his jobs were unskilled labor in fast-food restaurants, and he had experienced bouts of unemployment. Mr. Brown continued to associate with negative peers and, estranged from his family, became increasingly involved in the drug culture of his city of residence.

Mr. Brown has never been married and reported having mostly short-term relationships that were sexual in nature. Although he denied being physically violent in these relationships, from his descriptions, they were often dominated by interpersonal dynamics that included emotional abuse, jealousy, and possessiveness. Mr. Brown reported that his longest relationship was a live-in relationship that lasted approximately 1 year; however, it ended when his girlfriend informed him she had become pregnant from an affair she was having and left him to be with the other man. It should be noted that Mr. Brown committed his index sexual assault less than a week after the breakup.

Mr. Brown had a rather lengthy history of sexual maladjustment, and near the end of his sex offender treatment at his parent institution, it came to light that he committed at least five more sexual assaults for which he had not been charged. He had also stalked and fantasized about raping other women. He reported that these women were unaware of being stalked, and he simply lacked the opportunity to rape them. These incidents, which are detailed in collateral documents, were largely opportunistic in nature and contained several common elements outlined below.

Mr. Brown reported that he is very easily sexually aroused by heavyset women with buxom builds, and he frequently targeted this type of victim in his offenses. He reported that he experimented a little bit with cross-dressing and, in the past, had stolen women's underwear, which he would use to masturbate. Mr. Brown reported that his most common type of fantasy was engaging in intercourse from behind with a large Black woman wearing stirrups, whom he would slap on the buttocks and make denigrating remarks to. He reported having engaged in sexual activities with approximately 20 prostitutes and had about 15 other consenting sexual relationships prior to his index incarceration. He reported currently masturbating about four or five times a week. He admitted having indulged in fantasies of past victims as well as consenting fantasies involving some female staff, although he stated that more than half of his fantasies were consenting encounters with past partners or with females he saw on television. In contrast, he reported that about 90 % of his fantasies in the community were deviant.

In addition to having deviant sexual interests and preoccupations, very strong indications of compulsive sexual activity, and a lifestyle congruent with sexual deviance, Mr. Brown has a distinct offending cycle. The sexual assaults were typically clumsy, partially premeditated, and frequently opportunistic offenses that occurred in the midst of sexual arousal and emotional dysregulation (e.g., anger, frustration, or feelings of humiliation, perceived rejection, or inadequacy) and were exacerbated by intoxicants. At times, emotional triggers, such as feelings of rejection or frustration, would co-occur with sexual arousal triggered by an accessible and preferred victim with a certain body type. Mr. Brown would resort to whatever means necessary to meet his sexual needs with little concern for the welfare of the victim. At times, he would engage in denigrating remarks to the victim (e.g., calling her "bitch" or "whore") and then, strangely, engage in conciliatory gestures afterward toward the victim.

Prior to his current incarceration, Mr. Brown lived a marginalized and dysfunctional lifestyle, with nonexistent prosocial associates and support and in the presence of substance abuse, unstable relationships, and unhealthy sexual outlets. He held disparaging views toward women and had pervasive attitudes of sexual entitlement. For Mr. Brown, the philosophy of his sexuality seemed to be one of "I want, I take," irrespective of others' well-being.

As mentioned above, Mr. Brown completed an 8-month treatment program. However, his continued masturbatory fantasy life and what seemed to be occasional preoccupations with female staff suggested the presence of important offense analogue behaviors that suggested he had made little change and was largely still in the Precontemplation stage of change on most of his criminogenic needs. According to collateral reports from his parent institution, Mr. Brown became jealous of the attention that one female therapist would provide to other patients, eventually accosting her and saying accusatorily, "You women are all alike." Staff expressed concerns that Mr. Brown's preoccupation with, and jealousy around, certain female staff was a quasi-stalking behavior akin to that displayed with his victims in the community. Reports indicate that he was exquisitely sensitive to perceived rejection and that Mr. Brown struggled with emotional dysregulation, being easily triggered and having few resources to self-soothe or otherwise mollify the intensity of negative emotion. Mr. Brown's engagement in the past sex offender programming was inconsistent and marginal at best.

Mr. Brown received a pretreatment VRS-SO dynamic score of 45, with Item 11 (Released to High-Risk Situations) omitted, given that he was now serving a period of civil commitment and his release timeline was very uncertain. He was rated as being in the Precontemplation stage of change on all of his criminogenic needs, given his reluctance to fully engage in programming and to make substantive changes on criminogenic domains. Overall, Mr. Brown received a total prorated score of 61.6, placing him in the high-risk range at the 99th percentile compared against a sample of over 300 federally incarcerated sex offenders on which the instrument was developed. In the normative sample, 43 % of offenders scoring in the high-risk range were charged or convicted for a new sex offense within 5 years of their release. In terms of the factor domains, Mr. Brown scored at the 100th percentile on Sexual Deviance, 99.7th percentile on Criminality, and 97.8th percentile on Treatment Responsivity.

Posttreatment VRS-SO Ratings and Case-Relevant Information

Mr. Brown was adjudicated an SVP subsequent to his evaluation. Several months following his adjudication, he completed three phases of a high-intensity sex offender treatment program (SOTP) for SVP-adjudicated offenders over the course of 18 months. In addition to SOTP, Mr. Brown also participated in a DBT skills group and substance abuse treatment and routinely worked with various therapists in individual counseling. Mr. Brown also held some institutional employment working in the hospital kitchen. His attitudes, behavior, emotional functioning, and ultimately risk-related treatment progress are briefly documented, including his VRS-SO risk rating posttreatment.

In terms of targeting his sexual deviance, Mr. Brown participated in group and individual treatment that targeted deviant fantasies and interests. This also included phallometric testing and a polygraph sexual history examination. Mr. Brown disclosed the extent of his sexual offending, both adjudicated and unreported, and completed a detailed sexual autobiography that outlined his deviancy. Mr. Brown kept a masturbation log, monitoring the frequency of deviant and appropriate fantasies as well as the frequency of masturbation. Over the course of treatment, Mr. Brown's reports indicated a decrease in the frequency of deviant fantasies (especially rape fantasies); however, he admitted to occasionally fantasizing about female staff members' "body parts." Mr. Brown has also developed a comprehensive offense cycle detailing the cognitive, behavioral, emotional, and situational dynamics of his sexual offending, namely, his pattern of unstable relationships, deviant sexual preoccupations, response to emotional triggers (e.g., frustration), substance abuse, extreme self-centeredness, and tendency to use sex as coping.

Mr. Brown has done some work in this regard with his distorted thinking. His perceptions of women and sex were highly self-centered and distorted; Mr. Brown has done well to complete group exercises to challenge and confront distorted thinking and to accept responsibility for his sexual assaults. Mr. Brown has begun to develop some understanding of the distorted nature of his thinking around women and his hypersensitivity to perceived rejection, although his encounters with some female staff suggest this is still an area needing continued remediation for Mr. Brown.

Specifically, Mr. Brown has had his ups and downs in treatment. The DBT skills group has enabled him to develop some skills to self-soothe, manage negative affect, and respond appropriately to interpersonal triggers. However, Mr. Brown has struggled with modulating negative affect. According to treatment reports, Mr. Brown has made snide or inappropriate comments to female staff when he feels "sloughed off" or rejected. At other times, he has pushed boundaries with female staff, for instance, asking them personal questions or commenting on their appearance. Mr. Brown reported that he attempts to avoid encounters with female staff to whom he is attracted, but this is difficult to verify nor is it a viable long-term risk management solution.

Some of Mr. Brown's aggressive interpersonal tendencies have decreased, and he was able to manage some important interpersonal triggers. For instance, he became involved in an altercation with another patient in group, and, although this patient also insulted Mr. Brown, he took a time-out and journaled the incident. Other times, however, he was not as positive. For instance, Mr. Brown was caught taking food from the kitchen where he worked; when confronted by a female staff member, he swore and yelled at her. Mr. Brown subsequently lost his job and, rather than taking responsibility for his mistakes, was mired in self-pity. After a successful period as an institutional cleaner, Mr. Brown reacquired his kitchen job in the past 2 months and, recently, received a positive work appraisal.

Mr. Brown had also developed a romantic relationship with a woman he met over the Internet but had never met in person. He had been maintaining telephone contact with her, a prosocial, college-educated young woman who believes that sex offenders can be rehabilitated. The staff voiced some concerns about this arrangement, given Mr. Brown's history of unstable relationships and the unusual manner in which he met this woman. Although the hospital does not allow conjugal visits, they have maintained contact. Mr. Brown stated that it is the best relationship that he has ever had. Specifically, he reported that he has maintained open and respectful communication, was able to disclose and manage his feelings, and has provided his partner with positive emotional support.

Finally, Mr. Brown has been engaging in some release planning and has been working to secure community supports. Specifically, Mr. Brown applied for housing at a community residential treatment facility. The facility is run by a Christian

organization and includes a combination of attending religious services and receiving supportive counseling. The facility is drug- and alcohol-free, and no conjugal visits are allowed. Approved visitors (including romantic partners) can come to attend religious services but then must leave immediately afterward. Mr. Brown has also reportedly rekindled some contact with a sister, who resides in a neighboring county approximately 30 miles from his planned release destination.

Mr. Brown received a posttreatment VRS-SO dynamic score of 39.5. Item 11 (Released to High-Risk Situations) was rated since he had engaged in release planning and would be undergoing an evaluation of his progress for possible conditional release within the next year. Being released to high-risk situations has been a significant criminogenic factor for him in the past, but because he has begun to make changes in this area with the support of his treatment and case management teams, he was given a 2 rating and evaluated to be in the Preparation stage on this item. Mr. Brown's global progress could be construed as one in which he takes two steps forward and one step back. Most of the criminogenic factors are in the Preparation stage of change, which is his predominant stage at this point in his treatment program (see his scoresheet). Although he has made tangible behavioral gains, including the increased use of cognitive and behavioral skills to manage his risk factors, Mr. Brown has also encountered many lapses along the way. He has yet to maintain these positive changes, use his skills over a sustained period of time, and withstand a greater number of challenges and setbacks without lapsing, which are the prerequisites for his further progression along the VRS-SO stage of change metric. His progress, as such, is the hallmark of the Preparation stage of change. As a result, he was rated as being in Preparation on most criminogenic items. Having reduced his overall score to 52.5, Mr. Brown still scores in the high-risk range on the VRS-SO at around the 97th percentile. His scores on the broad factor domains, although lower, are still quite high: Sexual Deviance (94.1 percentile), Criminality (97.8 percentile), and Treatment Responsivity (82.6 percentile). The amount of change that Mr. Brown has made is not trivial, but he still has a long way to go. However, it should be emphasized that Mr. Brown should be able to continue to advance in his treatment, and the trajectory of progress is positive and points toward further risk reduction in the future. Reassessment with the VRS-SO in about 12–18 months is advisable when progress along the stage of change could be further evaluated.

Credentials Required in Using the VRS-SO

We concur with the recommendations by Hare (2003) regarding the appropriate use of assessment tools such as the Psychopathy Checklist-Revised. Questions regarding who is qualified to administer and use an assessment tool "are issues more properly addressed by test publisher, professional organizations and other regulatory bodies, and by informed and competent evaluation in the courts" (Hare, 2003, p. 16). It should be noted that the following are our recommended guidelines for the non-research use of the VRS-SO; special conditions should be assessed by consultation with a knowledgeable professional:

There are two levels of usage for the VRS-SO.

First-Level Usage
Rate the VRS-SO static and dynamic variables using interview and file information, sum the scores, calculate prorated scores, and identify treatment targets, strengths, and treatment readiness using the VRS-SO dynamic variable scores.
First-Level Usage Qualifications:
Possess a post-secondary degree or diploma in an area of social or human services or healthcare studies, such as psychiatric nursing, or other equivalent post-secondary education, plus appropriate training in the use of the VRS-SO. In the absence of such academic background or training, supervision by someone with the appropriate first- or second-level qualifications and experience is required for first-level usage.
Second-Level Usage:
First-level usage plus interpretation of the total VRS-SO pre- and/or posttreatment scores in terms of level of risk in relationship to normative samples, interpretation of any changes in risk, and provision of treatment or other recommendations for decision-making purposes incorporating VRS-SO ratings.
Second-Level Usage Qualifications:
Possess an advanced academic degree in the social, medical, or behavioral sciences such as an M.A., M.Ed., M.S.W., Ph.D., Psy.D., D.Ed., or M.D., and/or have appropriate professional credentials such as registration with the local state or provincial registration body that regulates the assessment and diagnosis of mental disorder, plus appropriate training in the use of the VRS-SO. In the absence of such credentials, supervision by someone with the appropriate second-level qualifications and experience is required for second-level usage.

A qualified person who supervises the assessment should take responsibility for users who do not meet all the above qualifications.

Conclusion

Readers who manage to get to this point (and are still awake!) might already have concluded, without further prompting, that the VRS-SO is a not a simple or cookbook-type risk assessment and management tool that professional or even clerical staff can complete without too much training. This is our view as well, and we do not feel the need to be apologetic

about it. The tool attempts to incorporate under one roof, so to speak, some of the key tasks necessitated by the theory of the psychology of criminal conduct and the principle of effective correctional treatment (vis-à-vis the risk, need, and responsivity principles) with the often elusive and difficult tasks of assessing and quantifying treatment changes and their impact on risk predicated on the stage of change model, all of which are linked to empirical evidence in research. These clinical and risk management tasks are seldom simple and straightforward and require a certain level of clinical skill to navigate. Given that the VRS-SO attempts to capture and quantify the gist of these rather complex and, at times, difficult tasks, a certain level of complexity in the tool is to be expected. It follows that appropriate training in using the tool is also called for.

The tool is theory based as well as empirically driven and validated; it is not a tool that was totally empirically derived and thus devoid of any overarching theoretical framework. The theory of the psychology of criminal conduct, the RNR principles, the TTM-SOC model for assessing treatment change, the cognitive-behavioral and relapse prevention approaches in intervention, and acceptable practices in risk assessment developed over the last few decades are all subsumed within the tool. Validation of the tool through research is progressing. Those who subscribe to the above theoretical premises should find the conceptual framework of the VRS-SO quite familiar, whereas those who subscribe to different theoretical models to guide their approaches to correctional assessments and interventions, or those who prefer an atheoretical approach to risk assessment, may find the tool less relevant to their practice. This is not unexpected. We do not try to be all things to all people but would rather be guided by our reckoning of what the theoretical and empirical literature deems to be effective and efficient practice in this line of work.

Structured Professional Judgment: Applications to Sexual Offender Risk Assessment and Management

Caroline Logan

Introduction

The ultimate purpose of risk assessment is to prevent future harmful conduct such as sexual violence in those with a history of such conduct, i.e., convicted sexual offenders. Whether the risk assessment process involves the quantification of harm potential or the generation of structured professional judgments about the risks posed, the objective is to take action informed by the assessment—risk management strategies, collectively referred to as a risk management plan—which will ensure that the feared outcome does not happen. The ultimate goal of prevention is not disputed. However, the methods used to prepare assessments of sexual violence risk have been the subject of much and sometimes heated debate in the last 10–20 years. Risk assessment and the means by which assessment findings can inform risk management planning in continuous action towards harm prevention are the focus of this chapter. Several different approaches to risk assessment will be mentioned, but the emphasis of this chapter is on the Structured Professional Judgment (SPJ) approach specifically. This approach lends itself to the needs of practitioners working directly with clients who are at risk of sexually harmful conduct (Hart & Boer, 2010). It is to this group of professionals whose engagement with their clients can be long-term and focused on risk management that this chapter is primarily directed.

The chapter will begin with a brief overview of the task of clinical risk assessment and management. As will become clear, the SPJ approach emphasizes the importance of *understanding* the risks posed by individual clients. Therefore, the chapter will go on to describe the SPJ approach to risk formulation, an essential process that links risk assessment with risk management via an understanding of the function or purpose of sexual violence for the individual. The structured professional judgment approach will then be illustrated through a description of the development and application of the *Sexual Violence Risk-20* professional guidelines (SVR-20; Boer, Hart, Kropp, & Webster, 1997) and the more recent structured professional guidelines known as the *Risk for Sexual Violence Protocol* (RSVP; Hart et al., 2003). A case study will be provided to illustrate the main features of the SPJ approach to working with sexual offenders. The chapter will end with a set of practice recommendations and suggestions for future research into sexual violence risk assessment and management using the SPJ approach.

Risk Assessment and Management in a Nutshell

In the last 20 years, since the development of a number of standardized measurement guides, the practice of clinical risk assessment has advanced a great deal. Such guides—also known as risk assessment instruments or tools—are based on research identifying the variables most frequently or strongly associated with the harmful outcome of interest (Otto & Douglas, 2010). For example, a history of deviant sexual arousal is very strongly associated with sexual violence recidivism (e.g., Hanson & Morton-Bourgon, 2009). Consequently, deviant sexual arousal is a risk factor for sexual violence recidivism in several sexual violence risk assessment guides (e.g., the SVR-20 and the RSVP). Essentially, risk assessment guides provide lists of risk factors that the relevant research has suggested are associated with the specific outcome to be prevented. Guides vary in content based on the outcome they are intended to prevent (e.g., violence, stalking, domestic violence, sexual violence, suicide, and so on) and on the research selected to justify the inclusion of individual risk factors and, if applicable, the weight given to each. Practitioners are required to examine their client in relation to all the risk factors listed in the risk

assessment guide they have elected to use and to denote through a rating whether the factor is present or not, and if present, the extent to which it is present (e.g., partially, definitely).

Once all risk factors have been examined, some form of risk estimate or judgment—generally an indication of level of risk, expressed as high, medium/moderate, or low risk—is then derived. This risk estimate may be based on the number of risk factors present in the client's past or recent history; scores given to present risk factors are summed and the total score related to a level of risk derived from data from similar others (e.g., recidivist sexual offenders) measured on the same risk factors. Thus, clients who have many risk factors that the research suggests are also present in recidivist sexual offenders are regarded as more likely to reoffend (their risk estimate may be medium or high) compared to those who have only a small number of risk factors in common with recidivist offenders (their risk estimate may therefore be low).

An alternative way of deriving a risk estimate or judgment is to make a structured professional judgment about the individual's potential to be harmful in the future based on an appraisal of all the present factors. This judgment may be structured very simply by the professional appraisal of the risk factors that are present—the judgment of high, medium, or low risk is deduced from the pattern of risk factors identified and the significance given to them by the practitioner undertaking the assessment (Douglas, Webster, Hart, Eaves, & Ogloff, 2001; see also Pedersen, Rasmussen, & Elsass, 2010). However, the risk judgment can be more substantially structured by involving a formal process of formulation (Hart & Logan, 2011; Logan, 2014), which organizes the information derived about prior harmful conduct into an explanation for why it happened as it did and when, therefore identifying the circumstances in which it could potentially happen again. In such structured formulations, risk estimates or judgments (high, medium, or low risk) are in fact obsolete because what is prepared is a plan of action for continuously monitoring risk and adjusting risk management. This latter process is structured professional judgment at its most refined.

As stated above, the ultimate goal of risk assessment is the prevention of harmful outcomes. The very act of doing a risk assessment heightens the awareness of practitioners about the possible risks posed by an individual client. It also demonstrates to others that risk has been considered; it forms evidence of attention to risk in the event that disaster does happen and the post-incident review or subsequent litigation proceedings search for oversights and omissions on which to blame the un-prevented offense. However, risk assessments that produce risk judgments based on summed scores or an appraisal based on the risk factors that are present have at least a broad link to risk management. Assessments generating conclusions about level of risk—high, medium, or low—imply a volume of risk management, although not necessarily its focus. Therefore, sexual offenders judged to be at a high risk of reoffending are likely to receive more restrictive risk management interventions (e.g., imprisonment) than those rated with a low risk of sexual reoffending.

In many circumstances, this blunt matching of risk assessment findings to risk management interventions is all that is required, such as where a practitioner is asked to offer an opinion to the Court about level of risk in order to inform sentencing. However, there are many circumstances where a closer link between risk assessment findings and risk management interventions is required; for example, where a practitioner in a prison or forensic mental health facility is required to engage with a convicted sexual offender to understand and address specific relevant risk factors as a condition of the offender's release from detention and subsequent monitoring in the community. The latter form, which produces a formulation of past harmful conduct and future potential to harm, requires a detailed evaluation in which assessment findings are linked directly to often long-term prevention strategies, namely risk management. This is structured professional judgment, and it is to this topic that we will now turn.

Structured Professional Judgment

SPJ risk assessment and management is a form of evidence-based practice that has its roots in clinical medicine. Evidence-based practice is defined as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients" (Sackett, Rosenberg, Muir Gray, Haynes, & Richardson, 1996, p. 71). This is now a very popular form of practice, which has been likened to a "revolution … [asserting] the supremacy of data over authority and tradition" (Patterson, 2002, p. 71). Evidence-based practice in health services is generally exemplified by the production of clinical guidelines which synthesize evidence relevant to specific topics for practitioners to refer to in order to ensure their practice is informed by the most recent research findings and techniques (Logan, Nedopil, & Wolf, 2011). Evidence-based practice carries a great deal of moral authority (Tanenbaum, 2005); Why would one wish to practice in a way other than that recommended by the evidence and reproduced by our peers in the form of guidelines? However, while the supremacy of evidence-based practice is not disputed, the form of the clinical guidelines into which it is translated is.

Evidence-based practice in risk assessment and management may be defined as "the process of gathering information about people in a way that is consistent with and guided by the best available scientific and professional knowledge to

(a) understand their potential for engaging in violence against others in the future and (b) determine what should be done to prevent this violence from occurring" (page 85, Hart & Logan, 2011). SPJ tools, such as the RSVP, are a form of guided professional judgment (Hart & Logan, 2011). SPJ risk assessment guides are the translation of relevant evidence into a practice instrument, a tool for understanding the harmful potential of an individual client in order to prevent that potential from being realized. A number of tools have been produced to support this practice, the most well known of which is the HCR-20 (Douglas et al. 2013; Webster, Douglas, Eaves, & Hart, 1997). However, the RSVP and SVR-20 are also SPJ tools as are the *Spousal Assault Risk Assessment Guide* (SARA, Kropp, Hart, Webster, & Eaves, 2001), the *Structured Assessment of Violence Risk in Youth* (Borum, Bartel, & Forth, 2002), and the *Stalking Assessment and Management Guide* (Kropp, Hart, & Lyon, 2008). These guides have been available for some time—the SPJ process underpinning them has only more recently been exemplified (Douglas et al., 2013; Hart et al., 2003).

Operationalizing SPJ in Risk Assessment and Management

The application of SPJ guidelines for risk assessment and management involves six discrete steps. In the first step, information is gathered from a variety of sources, including the client, if he or she chooses to collaborate in the assessment. The information gathered pertains to the past offending behavior and lifestyle of the client; its identification is prompted and its interpretation is framed by the risk factors described in the guidelines. In the second step, practitioners determine the extent to which each of the risk factors identified in the guidance being used are present in the client. In the third step, practitioners determine the extent to which, in their opinion, those risk factors that are present are also *relevant* to the client's potential to be harmful again in the future. For example, one client may only have committed his or her offenses in the context of substance abuse, making substance abuse both present and potentially relevant to any future offending. However, another client may have a history of substance abuse, but his or her offending post-dates that experience and is not relevant to future potential. A risk factor can, therefore, be present in a client's history but not be relevant to offending behavior. This critical judgment of relevance is what is required at this step.

In the fourth step, the risk factors identified as relevant are supplemented by clinical judgments about potential protective factors (e.g., positive attitudes toward treatment and risk management), and all are woven together into a formulation—an understanding—about future potential for harm. This critical step, which directly links risk assessment with risk management, will be described in more detail below. In the fifth step, risk management strategies are identified. Strategies—covering the main areas of treatment, supervision, monitoring, and victim safety planning—are linked directly to the risk formulation derived from the identification of the most relevant risk and protective factors. These strategies—hypotheses for ensuring the prevention of future harmful conduct by the client—are intended to influence the operation of relevant risk and protective factors on overall risk potential, diminishing it in the short-term. Finally, in the last step, summary judgments are made regarding the urgency of action or case prioritization, risks in other areas (e.g., self-harm or suicide, nonsexual violence), any immediate action required, and the date for next case review including reassessment of risk. This is the SPJ process in a nutshell and is illustrated in Fig. 1.

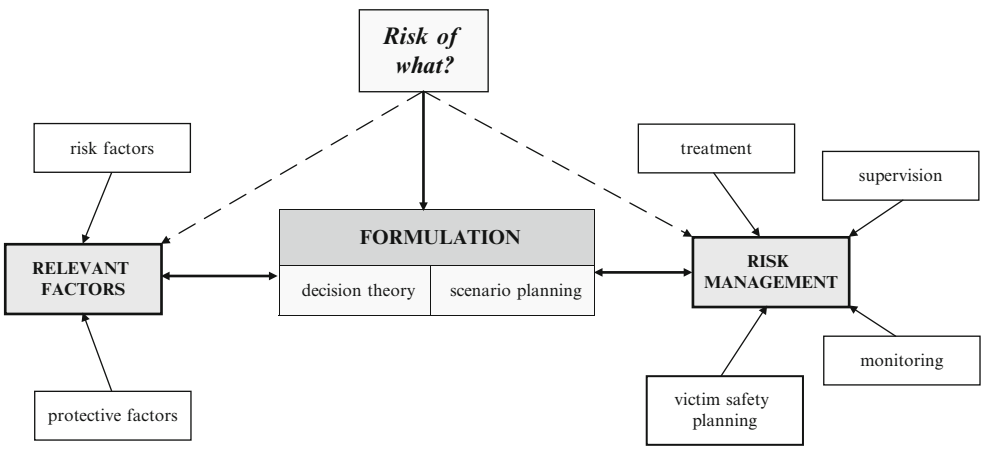

Fig. 1 Structured professional judgement in a nutshell

Risk Formulation

The critical fourth step identified above is that of risk formulation. Clinical formulation is an organizational framework based on theory and evidence used to produce a narrative description that explains the underlying mechanism involved in the development of the presenting problem, which is in turn used to generate hypotheses regarding action to facilitate change (e.g., Bruch & Bond, 1998; Johnstone & Dallos, 2006; Persons, 1989; Tarrier, 2006). Risk formulation is very similar. Risk formulation is an organizational framework for producing a narrative description that explains the underlying mechanism involved in the generation of harmful behavior—in this instance, sexual offending—and for proposing hypotheses regarding action to facilitate change (that is, harm prevention or managed risk). The evidence base for risk formulation is provided by the list of carefully selected risk factors (e.g., deviant sexual arousal) examined in the earlier steps of the SPJ process (Logan & Hird, 2014). The theory underpinning risk formulation is decision theory (Hart & Logan, 2011) supported by scenario planning (Chermack & Lynham, 2002; van der Heijden, 1994), which ensures that the risk formulation is relevant to future harm potential rather than just an explanation for past harm.

What does risk formulation involve exactly? Its starting point is clarity about what is to be prevented—an answer to the question: "Risk of what?" Answering this question is an essential first step because many clients present multiple risks that can have multiple antecedents—offenses against children *and* offenses against adults or sexual violence towards intimate partners *and* sexual violence towards stranger females. Identifying several answers to this question informs the practitioner undertaking the assessment that multiple scenarios will have to be plotted and risk management plans prepared to take all into account. The answer to the question "Risk of what?" is equivalent to identifying the presenting problem(s) or chief complaint that characterizes clinical formulation.

Next, information is collected about risk—and protective—factors, using risk tools as a guide. Those factors thought to be most relevant to a specific client's potential to be sexually harmful again in the future are identified, and the formulation process proceeds in the following way. First, a decision theory framework is used to interrogate the information collected about relevant risk and protective factors in order to determine why the individual made the choice to be sexually violent in the past. The use of decision theory is based on the assumption that individuals make a choice to be harmful, however rapidly that decision is made, that harmful conduct is purposive behavior intended to achieve a goal or goals (Hart & Logan, 2011). The process of making such a choice includes a number of key stages: (1) the idea of being harmful towards another person is experienced consciously and not dismissed; (2) one or more possible positive consequences of being harmful are identified; (3) possible negative consequences are considered and the costs judged to be acceptable or affordable; and (4) options for being harmful are considered and one or more are regarded as feasible and achievable. Finally, a course of considered action is implemented when it is judged that the conditions are right. Therefore, the first part of the risk formulation process is to use the information collected about relevant risk and protective factors to determine *how and why this person made the decision to be sexually harmful before* and to understand the specific roles of factors as motivators or drivers, destabilizers, and (dis) inhibitors in relation to specific harmful acts.

In the second stage, scenario planning is used to project this decision-making process into the future to answer the question: *Under what circumstances could this person decide to be sexually harmful again in the future?* (Hart & Logan, 2011). Scenario planning "is a process of positing several informed, plausible and imagined alternative future environments in which decisions about the future may be played out, for the purpose of changing current thinking, improving decision-making, enhancing human and organization learning and improving performance" (Chermack & Lynham, 2002, p. 366). It is a particularly useful technique to use in situations where there is uncertainty and also a strong need to prepare for all or the most serious eventualities (van der Heijden, 1994), such as in a military operation where the consequences of inadequate preparation and anticipation of problems could be measured in lives lost and serious injuries sustained. Scenarios are descriptions of possible futures; in the case of sexual violence, possible ways in which a particular client might be sexually harmful again in the future given what is known about his (or her) past and current situation and decision-making processes. Therefore, scenarios are not predictions. Instead, they are forecasts based on an understanding of why the client has acted in a similar way in the past. As a consequence of their uniqueness to the client's personal circumstances, preferences, and decision-making, only a limited number of scenarios are likely to be plausible. And it is these scenarios, with their origins laid bare by the evidence-based risk assessment and formulation process, which underpin risk management; treatment, supervision, and monitoring strategies, and victim safety plans are designed to prevent the identified future scenarios from occurring.

Risk Management

Risk management is the action that is taken to prevent potentially harmful outcomes where the nature of those potential outcomes has been speculated about through the

scenario planning process. Risk management strategies for sexual offenders should include direct treatment interventions for offending behavior and conditions linked to offending (e.g., substance misuse), supervision strategies like restricted contact with potential victims and imprisonment, the active monitoring of risk factors through surveillance in the course of supervisory contacts, and victim safety planning in the event that a previous victim could be re-victimized (e.g., the offender's own child) or the offender may come into contact with new potential victims (e.g., a new partner or a female supervising officer). Risk management per se has not been subject to a great deal of research (Heilbrin, 2001); certainly nothing commensurate with the research carried out into risk assessment. This is unfortunate—while it is the case that on the whole, interventions with sexual offenders have had a positive impact on the frequency and severity of offending, it is not yet clear what works best for whom under what circumstances to prevent reoffending. The potential for risk management to exceed the risks presented by the individual is significant, something that is certainly not tolerated in Europe in the age of the European Convention on Human Rights and proportionate legal sanctioning. This situation as regards evidence is only likely to change when the link between risk assessment and risk management processes is better conceptualized. In SPJ, risk management consists of three necessary components—treatment interventions, supervision, and monitoring—and an additional optional component of victim safety planning, which is required when a potential victim of the client can be identified (Hart et al., 2003). Each of these options will now be discussed in turn.

Treatment

Treatment strategies for risk management are those active interventions that are intended to repair or restore deficits in functioning linked to risk. Therefore, treatment strategies are intended to diminish the potency of risk factors linked to harmful conduct and include, but are not limited to, medication for the symptoms of the mental health problems that disinhibit the client, treatment for the substance misuse problem that causes the client overwhelming problems with achieving and appropriately maintaining intimacy, and treatment for the range of interpersonal, cognitive, emotional, and social deficits experienced by many sexual offenders and encapsulated in a sexual offender treatment program. In addition, treatment strategies are intended to enhance the power of protective factors, such as couple therapy to improve the client's capacity to utilize and benefit from social support, and interventions to compensate for cognitive or learning difficulties that limit the effectiveness of other treatments. Broadly, treatment strategies for sexual offenders include psychopharmacological interventions (e.g., anti-psychotic medication, mood stabilizers, anti-libidinals), psychological therapies (e.g., cognitive-behavior therapy for mood problems, cognitive-behavioral interventions for criminogenic needs), and psychosocial interventions (e.g., detention in a therapeutic community or in a setting offering neurocognitive rehabilitation or compensation).

Supervision

In risk management terms, supervision targets the environment or the setting in which the client is currently based or likely to be based in the future in order to limit the potency of risk factors and enhance the effectiveness of protective factors to diminish risk potential. Supervision refers to two types of intervention. First, supervision refers to those restrictions imposed on the client's activities, movements, associations, or communications that are intended to limit his or her access or exposure to the circumstances that could trigger one (or more) of the hypothesized scenarios (Hart et al., 2003). Examples of supervisory risk management strategies include denial of unsupervised access to specific victim groups such as children, a ban on drinking alcohol or drug-taking, residency curfews, restriction orders, non-association lists as part of conditional release requirements, and of course imprisonment, which serves the joint purpose of punishment and restricting access to potential victims. Second, supervisory strategies can also refer to those adjustments—enhancements—to the individual's lifestyle that are intended to improve the effectiveness of protective strategies. Examples of this kind of supervisory strategy include support to secure and maintain suitable paid employment that offers routine, purpose, financial reward, and a social role, as well as regular contact with an understanding person, such as involvement with Circles of Support and Accountability.

Monitoring

Monitoring as a risk management activity is the identification of early warning signs of a relapse to sexual harm, ideally derived from the client through their engagement with treatment and supervision. Monitoring also refers to the preparation and implementation of plans to be vigilant in looking for evidence of the presence of these early warning signs. Such plans would include the actions to be taken to prevent early warning signs from evolving into new offenses like the ones mapped out in the scenario-planning stage. Plans might include recall to prison or an increase in the frequency of meetings with a supervisor. Monitoring strategies are intended to be implemented by the client and by others

(e.g., probation officers, managers of approved premises, etc.), where others will be relied upon more if the client's insight into his or her offending behavior is limited or their motivation to engage is only partial. Monitoring in risk management terms differs from supervision because monitoring focuses on surveillance rather than controlling or managing the client's activities, making monitoring much less intrusive although just as essential.

Victim Safety Planning

Finally, victim safety planning refers to the action that might be recommended to a past or possible future victim of the client in order to keep them safe. The client may have victimized a potential victim in the past but future contact is nonetheless possible or desired by both parties (e.g., an abusing parent and an abused child) or required (e.g., between former intimate partners who have to stay in some kind of contact with one another because they have children together). A potential victim could also be an as yet unknown partner (e.g., a future girlfriend or boyfriend) or provider of treatment or supervision (e.g., a psychologist, social worker or probation officer) who may become victimized when, for example, they make emotional demands on the individual or endeavor to enforce the limitations that were an agreed requirement of conditional release. Victim safety plans could include provision of emergency safety procedures or personal alarms, prohibition of unaccompanied meetings, and so on.

Concluding Comments

SPJ is a guideline for risk assessment and risk management tailored to the needs of individual clients and the practices of the practitioners who work with them, anchored by evidence about the harmful conduct to be prevented. SPJ approaches to risk assessment and management lend themselves to particular kinds of practice settings, such as those in which convicted sexual offenders are subject to treatment and supervision, in institutions or in the community, and to legal settings where risk management is a primary consideration (e.g., Parole Board hearings). Specific risk assessment guides are available that exemplify the SPJ process as described, and it is to those tools that we will now turn.

The SVR-20 and the RSVP

The SVR-20 (Boer et al., 1997) was one of the first of the SPJ clinical risk assessment tools to be published. This instrument was designed to support forensic and clinical practitioners concerned about their sexually harmful clients and intent upon preventing them from being harmful again in the future. In brief, the SVR-20 manual guides practitioners through their evaluation of 20 possible risk factors for sexual violence. The 20 risk factors are listed in Table 1. On the basis of those risk factors that are deemed to be present, especially if they are present currently or recently, the practitioner makes a risk judgment (high, medium, or low risk). This risk judgment, in addition to the risk factors identified as present, is then used to plan and implement action intended to reduce risk or to maintain it at its lowest possible level.

Table 1 Risk factors in the SVR-20 risk assessment guidelines (from Boer et al., 1997)

Number	Risk factor title
Psychosocial adjustment	
1	Sexual deviance
2	Victim of child abuse
3	Psychopathy
4	Major mental illness
5	Substance use problems
6	Suicidal/homicidal ideation
7	Relationship problems
8	Employment problems
9	Past nonsexual violent offenses
10	Past nonviolent offenses
11	Past supervision failure
History of sexual offenses	
12	High density sex offenses
13	Multiple sex offenses
14	Physical harm to victim(s) in sex offenses
15	Uses weapons or threats of death in sex offenses
16	Escalation in frequency or severity of sex offenses
17	Extreme minimization or denial of sex offenses
18	Attitudes that support or condone sex offenses
Future plans	
19	Lacks realistic long-term goals
20	Negative attitude toward intervention

Risk Assessment Using the SVR-20

The SVR-20 defines sexual violence as the "actual, attempted, or threatened sexual contact with a person who is non-consenting or unable to give consent" (Boer et al., 1997, p. 9). This definition allows practitioners to include and prepare to prevent acts of sexual violence that would not necessarily result in a criminal conviction (e.g., a sexual assault by a patient on another patient in a secure hospital facility, which may not result in criminal conviction or even charges). Using the SVR-20, and keeping this definition in mind, practitioners are required to collect information about their client and then to rate him (or her) against descriptions of the individual risk factors identified from the literature by the authors of the tool as of potential relevance to those who engage in repeated acts

of sexually harmful conduct. Individual risk factors are rated on the basis of the extent to which they are *present* in the client, where ratings are either N not present or does not apply, ? is possibly present or present to only a limited extent, or Y the risk factor is definitely present. Practitioners have the option of omitting ratings on individual risk factors if there is a total lack of information to permit a decision concerning presence or absence of a risk factor (Boer et al., 1997). Practitioners are also required to identify whether there has been a *change* in any of the risk factors during the recent past (e.g., 6 or 12 months) where rating options are + (there has been an exacerbation or deterioration in the risk factor), 0 (meaning there has been no change), and − (meaning there has been an amelioration or improvement in the risk factor).

After all the risk factors have been rated, practitioners have the option of adding additional risk factors that they think are important to understanding and managing risk in the individual case. Finally, a summary risk rating is made where the client's risk of being sexually harmful again in the future—high, moderate, or low—is determined on the basis of the number and range of the risk factors deemed to be present. In the SVR-20, high risk is defined as "the individual is at high or very elevated risk for sexual violence" and in urgent need of a risk management plan; moderate risk is defined as indicating that the practitioner thinks the client is at "somewhat elevated risk for sexual violence" and in need of risk management planning; and low risk means the client is "at no risk or very low risk for sexual violence" and not in need of any special intervention or supervision strategies (Boer et al., 1997, pp. 34–35). The summary risk rating is not linked directly to the number of risk factors present or to the sum of numerical values associated with degree of their presence. Indeed, Boer and colleagues acknowledge that the correlation between present risk factors and the summary risk rating may not be linear and depends on specific risk factors or specific combinations among them. Professional experience and judgment are to be utilized to derive the summary risk rating using the range of present (and recently changed) risk factors as a guide.

As regards risk management—what happens next?—communication about the findings of the risk assessment are expected to answer the following questions (from Boer et al., 1997, pp. 20–2):

1. What is the likelihood that the individual will engage in sexual violence if no efforts are made to manage risk?
2. What are the probable nature, frequency, and severity of any future sexual violence?
3. Who are the likely victims of any future violence?
4. What steps should be taken to manage the individual's risk for sexual violence?
5. What circumstances might exacerbate the individual's risk for sexual violence?

Given that risk is dynamic and likely to change as circumstances change, written communications describing the results of SVR-20 assessments are also expected to provide an indication of when reassessments should take place.

The SVR-20 is recommended for use in pretrial and presentence assessments to aid in decisions pertaining to indeterminate detention or risk management, at correctional and forensic mental health intake and discharge, especially if that discharge—or release—is conditional, in family cases where custody or access are an issue, in relation to duty to warn cases, and in critical incident reviews and quality assurance exercises. Practitioners responsible for SVR-20 assessments should have experience conducting individual assessments and expertise in the study of sexual violence. They may use the SVR-20 with males aged 18 years of age or above with a known or suspected history of sexual violence and, with some considerations (Logan, 2008), with adult females.

This is the SVR-20. It is an example of SPJ, but it is a comparatively lightweight representation of SPJ compared with some of the tools that have followed it. For example, there is no consideration given in the SVR-20 to the *relevance* of risk factors—just their presence—or to protective factors, and formulation does not feature at all. Risk management is guided only by the questions listed above, and there is no direct link between risk assessment and any action taken towards risk management. The RSVP was intended to make up that shortfall and to develop the science—and art—of SPJ.

The RSVP

The SVR-20 was developed in the mid-1990s for practitioners involved in the care and management of sexual offenders. Work began on the RSVP only a few years after the publication of the SVR-20 because it was recognized quite quickly that specialists in the assessment and management of those who are sexually harmful may benefit from additional guidance in understanding the risks posed by their clients and in the management of those risks in a transparent, fair, proportionate, and demonstrably effective way. What are the main differences between the two approaches? What is the added value of the RSVP?

First, the RSVP offers additional guidance in the process of assessing and formulating a client with a known or suspected history of sexually harmful conduct and preparing risk management plans linked directly to an understanding of the motivation for his or her previous and possible future sexual violence (Logan & Hird, 2014). This guidance is supported by a 12-page worksheet that steps the practitioner through the entire assessment process (as described above), from information gathering in step 1 to summary judgments

in step 6, the core part of which is illustrated in Fig. 1. Therefore, the RSVP is intended not only to record that a risk assessment has been carried out on a client but to make the practitioner explicit about the process they have engaged in to obtain relevant evidence, derive a formulation based on that evidence including scenarios, and prepare a risk management plan. This makes the RSVP an explicit decision-making aid, which the SVR-20, with its brief one-page worksheet of risk factors, which are just checked and not explained, does less well.

Second, the SVR-20 makes provision for summary risk ratings at the end of the worksheet. These summary risk ratings—of high, moderate, or low risk—are made on the basis of professional experience and judgment and amount to a recommendation of the degree of effort or level of intervention required in the individual case (Hart & Boer, 2010). In the RSVP, summary risk ratings are not made—concerns about the risks posed by a client are not encapsulated by a single word describing a briefly defined level of required intervention. Instead, individual risk is understood through the process of formulation grounded on evidence-based assessment, which in turn structures the risk management plan to follow. This means the RSVP requires more effort to complete—time spent interviewing the client and thinking about the formulation and risk management plan. However, the level of detail in the finished product pays off the effort expended. This makes the RSVP more suitable for clients with whom that degree of effort is both required and available to be exercised. Consequently, the SVR-20 is more suitable for clients with whom more rapid and superficial evaluations are necessary.

Third, the RSVP contains a small number of risk factors that do not feature in the original SVR-20. These risk factors are chronicity and diversity of sexual violence, which add more to understanding about the length, depth, and breadth of sexual violence, psychological coercion or grooming, problems with self-awareness or insight, problems with stress or coping, and problems with non-intimate relationships. Therefore, the RSVP broadens the range of psychological characteristics practitioners are asked to consider, leading to a more comprehensive assessment. A full list of the 22 risk factors described in the RSVP is provided in Table 2.

Fourth, the system for rating risk factors in the SVR-20 and the RSVP is similar in terms of ratings of presence (Y, ?, and N) and recent change (there has been a slight change in these ratings, from +, 0, and − to Y, ?, and N again). However, the RSVP requires additional ratings of *relevance* to be made for each risk factor (Y, ?, and N). The relevance of a risk factor is determined on the basis of its relevance to the cause of future sexually harmful conduct. For example, if a convicted child sexual offender definitely presents with evidence of deviant sexual interest (pedophilia) and there has been recent evidence of his sexual interest in children (e.g., through internet activity or recorded attempts to groom a young child), this risk factor is likely to be highly relevant to this client's risk of future sexually harmful activity towards children. Additionally, the relevance of a risk factor may be judged in terms of its relevance to risk management. For example, if a convicted sexual offender has pronounced psychopathic personality traits, these are likely to be very relevant to the amount of optimism practitioners should have—or not have—about treatment outcomes and the amount of effort they will have to invest instead in supervising the client given that he may be reluctant to tolerate or comply with restrictions on his movements or associations.

Finally, most risk assessments suggest attention be paid to protective factors but have been unclear about how and when this should happen in the assessment process. Throughout formulation and risk management planning, the importance of identifying, understanding, and supporting the role of protective factors (e.g., positive attitudes towards intervention) is emphasized. The RSVP promoted this broadening of attention and later SPJ instruments, such as the *Short-term Assessment of Risk and Treatability* (START, Webster,

Table 2 Risk factors in the RSVP risk assessment guidelines (from Hart et al., 2003)

Number	Risk factor title
Sexual violence history	
1	Chronicity of sexual violence
2	Diversity of sexual violence
3	Escalation of sexual violence
4	Physical coercion in sexual violence
5	Psychological coercion in sexual violence
Psychological adjustment	
6	Extreme minimization or denial of sexual violence
7	Attitudes that support or condone sexual violence
8	Problems with self-awareness
9	Problems with stress or coping
10	Problems resulting from child abuse
Mental disorder	
11	Sexual deviance
12	Psychopathic personality disorder
13	Major mental illness
14	Problems with substance abuse
15	Violent or suicidal ideation
Social adjustment	
16	Problems with intimate relationships
17	Problems with non-intimate relationships
18	Problems with employment
19	Nonsexual criminality
Manageability	
20	Problems with planning
21	Problems with treatment
22	Problems with supervision

Martin, Brink, Nicholls, & Middleton, 2004) and the *Structured Assessment of Protective Factors* (SAPROF, de Vogel, de Ruiter, Bouman, & de Vries Robbé, 2009), have embraced protective factors or strengths with energy and purpose, making them a key component of their assessment procedure.

Do the SVR-20 and the RSVP Work?

There are a number of ways of determining whether the SVR-20 and the RSVP achieve the outcome of managed risk of sexual violence. This section examines the extent to which the two instruments can be used reliably and with validity to assess sexual violence risk and ultimately to manage and prevent it. Note that the facility within the SVR-20 to make summary judgments about risk means there is data available on its predictive validity, and this data will be examined. However, the RSVP is not intended to be used to predict risk in the individual case; therefore, no such data can be summarized. More detail about the nature and findings of studies looking at the reliability and validity of the two instruments can be found in Hart and Boer (2010).

Can the SVR-20 and the RSVP be Used Consistently by Practitioners?

Studies examining the inter-rater reliability of the SVR-20 and the RSVP—a combination of published papers, unpublished research, and conference presentations—report relevant samples (convicted offenders in correctional and forensic psychiatric facilities and in the community, treated, and yet to be treated) of good size—from a sample of 10 reported by Rettenberger and Eher (2007) in Austria and 15 reported by Sjöstedt and Långström (2003) in Sweden to $n=90$ in Watt and Jackson (2008) in a Canadian study and $n=166$ in Hill, Habermann, Klusmann, Berner, and Briken (2008) in Germany.

Single-rater intra-class correlation coefficients (ICC1) for individual items of the SVR-20, rated on the basis of file information only, were reported to be poor (<0.39) to fair (between 0.40 and 0.59) in some studies (e.g., Sjöstedt & Långström, 2003) but good (0.50 to 0.74) to excellent (>0.75) in others (e.g., Pérez Ramírez, Redondo Illescas, Martínez García, Carcía Forero, and Andrés Pueyo (2008). ICC1 values were best for SVR-20 assessments when raters were more experienced or better trained (Sjöstedt & Långström, 2003; De Vogel, de Ruiter, van Beek, & Mead, 2004) or when items were recoded and summed to create section and total SVR-20 scores (Barbaree, Langton, Blanchard, & Boer, 2008; Hill et al., 2008; Rettenberger & Eher, 2007; De Vogel et al., 2004; Watt & Jackson, 2008; Zanatta, 2005).

Data on the inter-rater reliability of the RSVP is more limited and for the present, restricted to as yet unpublished studies. For example, Hart (2003), Watt and Jackson (2008) and Watt, Hart, Wilson, Guy, and Douglas (2006) reported that the inter-rater reliability of RSVP ratings for the presence and relevance of individual items were between "good" (ICC1 reported between 0.50 and 0.74) and "excellent" (ICC1 greater than 0.74), with the majority "excellent." Ratings of domains—clusters of items measuring sexual violence history, psychological adjustment, mental disorder, etc. (see Table 2)—and ratings of case prioritization were also demonstrated to have "good" or "excellent" inter-rater reliability in these studies. However, Sutherland et al. (2012) report less positive findings. In their UK study, inter-rater reliability was "fair" overall with ICC2 values ranging from "poor" to "excellent;" only 30% of items in this study achieved ICC2 values that were "good" or "excellent" (including attitudes that support or condone sexual offending, problems resulting from child abuse, major mental illness, and problems with treatment). In contrast, items with poor reliability were psychological coercion, problems with stress and coping, and problems with planning. The authors were unclear why some items achieved greater levels of inter-rater reliability than did other items, but training (specifically, RSVP training) and professional experience were thought likely causes, as well as the fact that the study utilized comparatively brief case vignettes.

The limited evidence there points to the broadly reliable administration of both instruments with reliability increasing in more experienced raters, and when, for research purposes, items are recoded and summed to create domain and total scores for each instrument. More research is required, however; the more reliable both instruments are—the more that is understood about how to achieve and demonstrate a high level of reliability in the administration of all SPJ guidelines—the more opportunities will become available to demonstrate their validity.

Do the SVR-20 and the RSVP Require Practitioners to Evaluate the most Important Risk Factors for Sexual Violence?

Content validity is the extent to which a measure represents all relevant facets of a given construct. Do the SVR-20 and the RSVP measure all that a sexual violence risk assessment instrument ought to? The two instruments originated in comprehensive reviews of the literature on sexual violence and sexual violence recidivism (Boer et al., 1997; Hart et al., 2003). The reviews were carried out on the scientific, professional, and relevant legal literatures in order to obtain the most comprehensive range of potential risk factors possible that would be of assistance to practitioners undertaking a

range of tasks with the sexual offenders in their care. Items were identified as risk factors if they were associated with various facets of sexual violence and not just risk prediction (e.g., those associated with the nature, severity, frequency or duration, imminence of reoffending, and with risk management, such as more dynamic risk factors). That is, the predictive validity of a characteristic identified as a risk factor was very important but not the only basis upon which a risk factor was identified. This enabled the inclusion of characteristics that are relevant to some but not most sexual offenders (e.g., extreme minimization or denial of sexual violence) and that are relevant to managing risk as well as its assessment (e.g., problems with treatment, problems with management). In addition, existing sexual violence guidelines and risk assessment procedures were reviewed, as were those in other areas of risk assessment (e.g., nonsexual violence risk assessment). It is appreciated that the broad range of items included in the RSVP, and to a lesser extent in the SVR-20, may make the defense of its use problematic in some adversarial settings where risk *assessment* only is the focus. However, the inclusion of such a range of items with relevance to sexual offender risk assessment and management is valuable and indeed essential when they are used in settings where risk *management* is a primary concern.

A preliminary list of risk factors was derived for the SVR-20, a process repeated and extended several years later for the RSVP. Provisional lists were then discussed with professional and academic colleagues and subjected to extensive field-testing. The final contents of the instruments were compared to other professional guidelines for assessing sexual violence risk and other tests, mainly actuarial tests, of sexual violence risk (see Tables 4 and 5 in Hart et al., 2003 for comparisons between the RSVP and other guidelines and tests). The overlap between the SPJ and the actuarial instruments found to be good in terms of item content—many items in actuarial scales feature in the SVR-20 and the RSVP—and the RSVP contained more items besides. Finally, content validity is also evidenced by empirical research that demonstrates the capacity of the SVR-20 and the RSVP to distinguish between groups of sexual offenders, such as recidivists and non-recidivists (e.g., Dempster & Hart, 2002 using the SVR-20; Hart & Jackson, 2008 using the RSVP) and contact versus non-contact reoffenders (McPherson, 2003 using the SVR-20).

Do the SVR-20 and the RSVP Predict Sexual Offending?

There is significant overlap between the SVR-20 and the RSVP and the contents of many other risk assessment guides, and they share a common purpose in trying to prevent future harm. Consequently, correlations among the SPJ guides and between them and the other risk guides available for use with sexual offenders are expected and indeed usually found to be present (see Hart & Boer, 2010). Independently rated SVR-20 and RSVP assessments on the same participants are highly correlated (e.g., Jackson & Healey, 2008), suggesting they are tapping the same constructs. Further, the SVR-20 correlates well with actuarial measures of sexual violence risk and nonsexual violence (Langton, 2003; Rettenberger & Eher, 2007; Zanatta, 2005) and with other SPJ measures of risk (e.g., the HCR-20, reported in Dietiker, Dittmann, & Graf, 2007). Likewise, the RSVP demonstrates good concurrent validity in significant correlations with actuarial sexual offender risk assessment instruments (e.g., Hart, 2003; Jackson & Healey, 2008; Klaver, Watt, Kropp, & Hart, 2002; Kropp, 2001; Watt et al., 2006) (See Hart and Boer (2010) for more details).

While a common purpose is shared between SPJ tools like the SVR-20 and the RSVP and actuarial and other risk assessment instruments, like the Static-99, the *Sexual Offender Risk Assessment Guide*, and the *Violence Risk Scale-Sexual Offender Version* (VRS-SO), they differ in their outcome, making comparisons between the approaches problematic (Douglas & Kropp, 2002; Litwack, 2001). The outcome of the administration of actuarial risk assessment tools is a statement of probability—a guide on the similarity of the individual client to a group of people with a known rate of sexual violence reoffending. Actuarial instruments do not provide predictions of *individual* risk (Hart, Michie, & Cooke, 2007), just comparisons between individuals and groups on the basis of which judgments of individual potential for sexual reoffending might be made. Expert tools like the VRS-SO provide the basis for a more comprehensive evaluation of a client and offer the opportunity to monitor change over time in response to intervention. However, formulation doesn't feature in the use of the VRS-SO, and risk is measured rather than understood. In contrast, the outcome of the administration of an SPJ tool is an improved understanding of the reasons for the individual client's past sexual violence, an acquired understanding about the circumstances in which the same individual may choose to be sexually harmful again in the future, and on the basis of that understanding, the interventions required to encourage the client to make different and less harmful decisions. Therefore, the approaches differ in what they are used for, and direct comparisons of tools in terms of predictive validity are problematic.

Nonetheless, evidence for the predictive validity of the SVR-20 has been reported to be good in some studies (e.g., Hanson & Morton-Bourgon, 2009; Pérez Ramírez et al., 2008; De Vogel et al., 2004) although not all (e.g., Craig, Browne, Beech, & Stringer, 2006; Sjöstedt & Långström, 2003), but generally equivalent to actuarial risk assessments if not better for summary risk ratings (high, moderate, or low risk) and summed total scores (e.g., Dempster, 1998; Hanson

& Morton-Bourgon, 2009)—although substantial variability is evident across the as yet limited number of studies examining this issue. As regards the RSVP, little research has looked at predictive validity because this is not the purpose of this instrument. However, Kropp (2001) and Hart and Jackson (2008) reported final case prioritization to be significantly correlated with sexual violence recidivism, although not with summed RSVP item scores measuring presence-past or presence-recent.

Are the SVR-20 and the RSVP Effective in Preventing Sexual Offending?

In 2002, Douglas and Kropp wrote the following: "Risk assessment can be considered successful when we can demonstrate reduced rates of violence *in connection with risk assessment procedures*" (p.623; emphasis added). Despite empirical and professional support for the SVR-20 and the RSVP as risk assessment guides, it is not yet clear that the use of these tools contributes to reduced rates of sexual violence. However, it is also not clear that the use of any of the established risk assessment tools can demonstrate reduced rates of harm. It is the case that harmful conduct is being prevented every day by the actions of careful practitioners working in correctional, mental health, and community services to moderate risk factors and enhance protective factors with their interventions and support. But what role does the time-consuming and usually compulsory process of risk assessment play in this prevention process? Given that prevention is the ultimate goal and that the vast industry of risk assessment was established to this end, why are we still unable to demonstrate unequivocally that it works, that the effort put into risk assessment makes a difference in and of itself to the frequency and the severity of harmful behavior?

The answer to both these questions would appear to lie in part in the nature and the volume of research carried out into risk assessment linked to risk management—it appears that there is not enough of the right kind of research to demonstrate that risk assessment itself is a valuable process in the enduring task of harm prevention (Douglas & Kropp, 2002). Indeed, Heilbrin (2001) commented that risk management science was around 10 years behind risk assessment science. It appears that little has changed in the years since Heilbrun's observation was published—research into the success of treatment or supervision interventions for offenders, while invaluable, rarely links change to an overarching model of risk assessment and management or comments on the role played by risk assessment per se. (For an exception in the general criminality literature, see Andrews, Bonta, & Wormith, 2006). However, the answer may also lie in the disagreement that persists in the field internationally about which approach to risk assessment is best and the predominance of risk prediction research. Creative research evaluating treatment interventions for offenders alongside models of risk assessment and risk management remains a rarity (see Douglas & Kropp, 2002).

An Illustrative Case

The RSVP advocates the use of clinical skills in assessment and formulation to derive a risk management plan for those at risk of sexual violence. The following fictional case study illustrates the use of the RSVP in order to demonstrate its potential. (See also Logan & Hird, 2014).

The illustrative case describes Mr. Green, who is a 51-year-old gentleman detained in a secure forensic psychiatric hospital. Mr. Green is applying through the mental health courts for permission to be discharged to live in the community. He has been a resident in a forensic hospital for most of the last 23 years. He was transferred to hospital from prison following his fourth conviction for a sexual offense, which happened when he was 28 years of age. All his offenses were committed against adult females, two in their 60s, and two of the victims were known to him previously. His convictions on these occasions were for two counts of rape and two counts of indecent assault. He committed his first sexual offense when he was 15 years of age. In hospital, Mr. Green was diagnosed with a severe personality disorder (his score on the Psychopathy Checklist-Revised is in excess of 25 and he has a clinical diagnosis of antisocial personality disorder), which subsequent treatment was designed to address. He was released from hospital after 14 years of treatment, and he remained in the community for just under 2 years, offense-free. However, in rapid succession, he was accused of two offenses of indecent assault on a girl aged 8 years of age and a boy aged 11 years of age, and, on arrest, he was recalled to hospital. Mr. Green has been in forensic mental health facilities ever since. He denies having committed both of the latter offenses; he says people he owed money to falsely accused him. Mr. Green also continues to grossly minimize the preceding four offenses, which he regards as just misunderstandings between himself and the women involved. He has undertaken minimal structured treatment while in care and no interventions for sexual offending because he denies being a sexual offender. The objective of the present assessment was to assess the risks posed by Mr. Green if he was to be discharged into the community.

Relevant Risk and Protective Factors

The overall framework used for the assessment of Mr. Green's future risk of harm and the preparation of a risk management plan for him was that of structured professional

judgment. More specifically, the *Risk for Sexual Violence Protocol* risk assessment guide (RSVP, Hart et al., 2003) was used to formulate Mr. Green's risk of harm to others. The RSVP requires assessors to gather information from their client and his or her records regarding 22 characteristics that the research indicates are important to consider in individuals with a history of sexual violence. The risk and protective factors identified as most relevant to the client are then woven into a risk formulation, which is an explanation for why and how he or she may choose to be sexually violent in the future.

There follows an account of those factors that appear to *predispose* Mr. Green to violence, those factors that we understand *trigger* individual acts of harm (also known as precipitating factors) and those that *maintain* harm as a potential outcome in this gentleman (also known as perpetuating or maintenance factors). A small number of *protective* factors, characteristics or circumstances that appear to moderate risk, are then described.

Predisposing Factors

A critical risk factor for future sexual offending is Mr. Green's long-standing (*chronic*) and *diverse* history of sexual offending. He has a total of six convictions for sexual offenses stretching from when he was 15 years of age through when he was 43 years of age. He has sexually offended against a pubescent (or pre-pubescent) boy and girl, two adult females, and two older adult females (aged 66 and 72 years), two of whom were known to him while two were strangers, attacking them in their homes (one) and in his home (one), as well as in public places. He has sexually offended very quickly upon release from prison following punishment for his previous sexual offense. All his sexual offenses have involved some degree of *physical coercion*; he has taken what he wanted or needed from his victims when he needed it or thought it was available to him without regard for any effort at psychological coercion or grooming, or for the feelings and safety of his victims. Offending behavior analysis, on the basis of what is known about Mr. Green's offending behavior, suggests at the very least a powerful sexual drive that appears to have been disinhibited by opportunity and possibly also alcohol. Such a long and diverse history of sexual offending raises serious questions about the presence of *deviant sexual arousal*. Deviant sexual arousal can be assessed a number of ways—by an analysis of offending behavior, self-report assessment, and objective assessment. Mr. Green has been subjected to a number of assessments of his sexual interests, none of which have been especially clear in their findings. He denies deviant sexual arousal; examination of witness statements, which might have been helpful, has been restricted because of their unavailability. This is most unfortunate, but the facts of his offending behavior are indisputable, even if the latter two offenses, which Mr. Green denies, were set to one side. Mr. Green's history of sexual offending is significant and relevant to future sexual offending because it creates a precedent that may be hard to alter, despite Mr. Green's many years in institutions, because his insight into his conduct appears minimal, and his tendency to blame others for his misfortune is substantial.

On the matter of Mr. Green's attitude towards his offending behavior, he has a long-standing pattern of *minimizing his sexual offenses if not denying them entirely*. This is a problem because Mr. Green's denial of the latter two offenses against the children means that he is *unsuitable for sex offender treatment*, despite his partial admission of responsibility for two of his previous offenses. Even on the occasions when Mr. Green admitted some responsibility for the sexual offenses of which he was later convicted, he suggested the contact he had with his victims was accidental or exaggerated by them and therefore not his responsibility. Thus, Mr. Green's offending behavior remains unaddressed. Mr. Green's failure to take responsibility is a risk factor, alongside a more general *problem with self-awareness* and *antisocial/psychopathic personality traits* characterized by impulsive and irresponsible behavior as well as a difficulty experiencing guilt because it suggests he is neither motivated to change nor to prevent himself from being harmful towards others in the future. Further, Mr. Green has experienced problems *complying with the conditions of supervision* in the past. This fact supports the presence of a more pervasive problem with rule adherence, which means risk management will require extra safeguards to ensure compliance and therefore managed risk.

Mr. Green denies planning his offenses; he is adamant that they occurred on the spur of the moment or *impulsively*. This emphasizes the point that his awareness of his risk cycle and, therefore, his capacity to intervene to prevent future offenses from occurring is minimal and that he requires assistance to manage his risk of reoffending.

While at liberty, Mr. Green had a *problem with his use of alcohol*. Alcohol has accompanied almost all of his sexual offenses, and he has additional—separate—convictions for alcohol-related crimes. However, Mr. Green denies that alcohol played a role in his sexual offenses or that his drinking was severe—he suggested instead that arrests would follow the detection by a police officer of any scent of alcohol on the breath of a member of the public, in other words, that they were an over-reaction and therefore not serious. This is unlikely to be the case. However, a lack of clarity about the exact role of alcohol in Mr. Green's offending behavior means that it is problematic to be exact about its role as a risk factor.

Finally, Mr. Green has *very limited experience of intimacy*. He has experience of only one relationship in his life,

which was of 3 weeks duration. His ex-partner was a victim of one of his sexual offenses. Problems with achieving, maintaining, and gaining satisfaction from intimacy may be a motivation for sexual offending—difficulties with intimacy may have led to sex being over-valued and to the development of an inadequate range of skills with which to achieve and sustain intimacy. Problems with intimacy—linked to sexual violence—point to more general problems with understanding and meeting his own needs.

Precipitating Factors or Triggers

What appears to trigger a harmful act in Mr. Green? The answer to this question is not at all clear. Mr. Green is unable to state what might have been a trigger to past acts of sexual violence. He denied alcohol was a trigger. He denied any intent to commit sexual assault on any of the occasions on which he was accused. He denied that anything at all might trigger an act of sexual violence in the future—he denied that any such act could possibly occur again. He was unable to tell me why he could be so sure, except that he had decided that it would be so. Mr. Green was unable to tell me what he would do to ensure that he would never offend again. The absence of any clarity about precipitating factors or triggers for past offending behavior, on the basis of which the risk of any future offenses could be managed and such incidents prevented, is a problem because it limits attempts to formulate or understand risk and means risk management will have to be more restrictive in order to try to cover all possible offending eventualities.

Protective Factors

There are several protective factors that appear to be acting to mitigate the risk factors identified above. Mr. Green's involuntary detention in prison and in hospitals has resulted in a comparatively settled lifestyle where he has been able to form stable bonds with peers, engage in pleasurable activities (mainly art), and be given opportunities for treatment. A regular, routine lifestyle has in all likelihood also had something of a stabilizing effect.

Risk Formulation

The following risk formulation is more speculative than is preferable because of the absence of good information about potential triggers to sexual violence; a good enough understanding of Mr. Green's past sexually violent acts does not exist and therefore it is difficult to be confident as an assessor about his future potential to act in a similar way. However, the following tentative formulation may still be proposed.

Sexual violence has been the outcome of Mr. Green spending time in the community since he was in adolescence. Consequently, he has spent very little time at liberty since this formative time of his life. For reasons that are unclear to him—and/or deliberately withheld by him—he becomes reckless with the safety of some of the vulnerable people he encounters either by accident or by design. He is sexually aggressive towards them without regard for their comfort, safety, or their wishes—and he has been persistently so over a 26-year period despite repeated punishment and opportunities for treatment and change. A pro-criminal orientation, a very long-standing reluctance to take responsibility for what he has done or to acknowledge the consequences for himself as well as for others, and more general problems with planning and impulse control (possibly exacerbated by drink) and in achieving and maintaining intimacy with others appear to be the broad drivers of this history. What triggers individual instances of sexual violence—why he chooses to offend against a particular victim at a particular time—appears to be linked in part to alcohol and opportunity. However, other factors are very likely to be relevant—lots of men (and women) have antisocial personality disorder, a history of substance abuse and poor impulse control, but do not sexually offend. Deviant sexual arousal is likely to play an important role then in both creating opportunities and in directing Mr Green's behavior when opportunities arise. The identity of other factors remains unclear, and therefore this formulation is incomplete. Such an incomplete understanding of sexual violence potential has to mean more restrictive risk management in order that responsible authorities can be reassured that risk is being managed.

Future Risk Scenarios

The most likely scenarios for sexual violence in the future could involve Mr. Green being alone in the community (unsupervised) and able to suit himself in terms of lifestyle (including alcohol consumption). Limited insight or concern about risk means he will not be aware of what he needs to do to keep himself safe and others safe from him. An inadequate or incompetent approach to an adult female—possibly because he is seeking comfort or intimacy or sex—could result in conflict because of the victim's fear of his intentions, Mr. Green's fear of being reported, or because of direct harm caused. An accusation of threat or actual sexual assault could arise. An alternative scenario may arise were Mr. Green to make an approach to a child—male or female—possibly because he is seeking sex. This scenario could result in actual harm to the victim or accusations arising from fear

that harm may have been threatened. Such scenarios are likely to be activated when Mr. Green's lifestyle is unstable and he is unsupervised; that is, others are not present to monitor risk on Mr. Green's behalf. While Mr. Green is detained in his current secure facility and in receipt of only escorted leave, he is at very low risk of being harmful towards others—his access to potential victims is limited and his lifestyle subject to close and supportive monitoring.

Treatment Needs

In terms of risk management, treatment needs are defined as treatment (or rehabilitation) strategies designed to moderate risk factors or enhance protective factors; that is, interventions intended to repair or restore deficits in adjustment and functioning that have been linked to sexual violence in the past. Mr. Green has received or been given opportunities to access a great deal of treatment in the last two decades. This treatment may have been effective, but it is disappointing that obvious evidence of successful treatment—increased self-awareness, increased knowledge of risk factors and risk management requirements, the retaining of information about what is effective and what is not—is absent. Mr. Green stated the treatment received has been interesting, but he was unable to recall what lessons he had learned or insights gained and what he had to do differently in the future as a result of these interventions. Thus, treatment needs can be identified, but Mr. Green's capacity to respond to them may be limited. Alternative treatment modalities could be considered—for example, interventions that do not make assumptions about Mr. Green's level of understanding and are better tailored to meet his intellectual level. The following treatment needs have been identified:

- Despite his many years in detention, Mr. Green remains an untreated sexual offender. He is unlikely to engage in this form of intervention now, having been given many opportunities to do so in the past by a number of very skilled and experienced practitioners. In any case, he is consistently regarded as unsuitable for this form of intervention because of his denial of several of his convictions for sexual offenses. In the absence of this specific form of treatment for a very obvious criminogenic need and in the absence of evidence of any motivation to understand the concerns of others and to change his conduct to reduce the possibility of risk factors, especially triggers, Mr. Green has to be regarded as a gentleman who still has the potential to reoffend sexually because a critical risk factor is unchanged despite the many years that have passed since his last conviction. Mr. Green is now 51-years of age. Do his advancing years matter? It depends. Were Mr. Green to have deviant sexual interests—in rape or children—these interests will not diminish much with age despite a decreased level of sexual performance. We are uncertain of the extent to which Mr. Green retains deviant sexual interests and their role in his offending behavior. Consequently, it would be irresponsible to disregard the possibility that they are present and do play a role in offending behavior and conclude that risk is no longer an issue just by virtue of the years that have passed.
- Mr. Green has engaged in alcohol/drug use interventions in the past. However, he was unable to recall any key lessons learned from such interventions. Further work is indicated and he is likely to agree to do this particular kind of work. The target for this work would be his motivation to moderate drinking because of its potential effect on his risk of harm. However, while Mr. Green regards himself as being at no risk to others and to regard the role of alcohol in his past offenses as minimal, this work may be pointless. This intervention would only be warranted if he is to receive unescorted leave at some time in the future.

Supervision Needs

Treatment options for Mr. Green are limited. Therefore, risk management rests substantially on supervision and monitoring activities. In terms of risk management, supervision needs are defined as restrictions on activity, movement, association, or communication that are intended to control risk factors—to limit Mr. Green's opportunity to be sexually violent—as well as enhancements to his lifestyle in the form of structure, boundaries, and role expectations, intended to promote the effectiveness of protective factors. The following supervision needs have been identified.

- Mr. Green's continued detention in a secure facility and his community integration through escorted leave only are the supervision strategies currently being employed to manage his risk of future sexual harm. In the absence of evidence of the effectiveness of treatment, such supervision strategies are critical—they are the only way his clinical team can feel confident that they are managing all the risk factors they think or suspect to be relevant to his potential to be sexually harmful again in the future. Is the deployment of these particular strategies a disproportionate response to the risks posed by Mr. Green? He thinks so. However, in the absence of a clear understanding (formulation) about Mr. Green's motivation to offend in the past and about any possible desire to do so again in the future, and in the face of a significant reluctance on his part to acknowledge the concerns of others, such a comprehensive albeit restrictive response is justified.

Monitoring Needs

In terms of risk management, monitoring needs are defined as those early warning signs that are an indication of a relapse to harmful behavior or any other indicator of a change in risk. Monitoring strategies, therefore, attempt to address triggers to offending, to ensure their early detection and management. In the absence of a good understanding of what has triggered Mr. Green's sexual offending in the past and what might trigger it once again in the future, the monitoring strategies recommended below are somewhat crude and nonspecific.

- Opportunity and alcohol are possible triggers. Therefore, risk is managed if Mr. Green's opportunities to offend are limited, as with his access to alcohol. Monitoring should therefore focus on where Mr. Green spends his time when not subject to supervision if this were to happen. In the event that he continues to remain subject to supervision, as he is now, no particular monitoring strategies are required to manage risk because continued restrictions are effectively managing risk.

Concluding Comments

This section has examined the risk and protective factors that appear to be most relevant to Mr. Green—a fictional illustrative case—and his potential to be harmful again in the future, proposed a formulation—or explanation—for his sexual violence potential, and suggested some hypotheses or strategies for moderating risk, key amongst which is supervision via restrictions on unescorted leave. The recommendation in this case would be for this gentleman to remain in a secure forensic setting. The detail provided in the assessment undertaken is the basis for a justification of this recommendation both to the mental health courts and to the client himself. The process exemplified by the RSVP—structured professional judgment—underpinned this examination.

Practice Recommendations

In this chapter, SPJ has been outlined using the SVR-20 and the RSVP as examples and proposed as a useful model for risk assessment and management in clinical settings where the ultimate goal is harm prevention. SPJ holds promise as a risk assessment and risk management process that provides the level of detail required in some settings, and it is attractive to many practitioners charged with managing the risks of their sexually violent clients in the medium to long term. How can practitioners continue to improve their practice using SPJ?

First, practitioners should be clear about when an SPJ approach would be more beneficial in the risk assessment of a sexually harmful client than an alternative approach, such as the use of an actuarial tool like the Static-99. Where practitioners wish to use an assessment procedure to understand their client, where they have the time and the opportunity to access records—and the client—to ask about their harmful conduct and their decision-making processes leading to harmful conduct in the past, and where they will be required to plan and implement risk management strategies in a transparent, accountable, proportionate way, the use of an SPJ tool to structure their risk assessment is recommended. Where the practitioner requires only a very quick, "ballpark" comparison, between his or her client and a group of people with a known rate of reoffending, and where the practitioner can be confident that his or her client is comparable to that group, an actuarial tool might be helpful if the practitioner ensures that they do not assume risk is being predicted in the individual case and that anchoring bias can be prevented.

Second, ascertain the answer to the question, "Risk of what?" (see Fig. 1) as the first stage in a clinical risk assessment and management evaluation. If the answer to this question is sexual violence, then use the SVR-20 or the RSVP. The manual of the HCR-20 violence risk assessment guide suggests that all sexual assaults should be considered violent behavior (Douglas et al., 2013, p. 69). This is of course true. However, for the purpose of an evaluation specific to the risks posed, if the answer to the question, "Risk of what?" is risk of sexual assault, then a tool that draws the attention of the evaluator to variables with demonstrable relevance to sexual violence is strongly recommended. Reserve the use of the HCR-20 for those clients who pose a risk of nonsexual harm and use the SVR-20/RSVP and the HCR-20 together if the client under scrutiny is at risk of both sexual violence *and* nonsexual violence. In such a case, use the assessment and formulation process to determine what risk—and protective—factors are specific to risk of violence as opposed to risk of sexual violence and what are common to both, and determine what would appear to be the triggers for the different outcomes. Risk management plans can then be tailored to the prevention of a violent and sexually violent outcome.

Third, under what circumstances should the RSVP be used in favor of the SVR-20? The SVR-20 is a comparatively lightweight instrument that takes a somewhat superficial overview of the client and his or her future risk and is therefore valuable for those who are not sexual offender specialists or likely to be involved in sexual offender treatment (Hart & Boer, 2010). The RSVP, in contrast, is a more involved and therefore demanding and time-consuming evaluation process that emphasizes the potential role of

several psychological factors that are not considered in the SVR-20. The RSVP also demands greater attention to risk formulation and to risk management planning, and it does so in a structured way. Select the RSVP if there is time and opportunity to undertake such a detailed assessment, if the practitioner has the skills and experience to accomplish it, and when the purpose of the evaluation is to inform long-term risk management.

Finally, SPJ tools—the SVR-20 and the RSVP—were designed to help practitioners understand their clients and to make useful plans to prevent their future harm. These tools are decision-making aids, the RSVP more so than the SVR-20. The role of formulation is critical to their proper use, and this function should not be overlooked (Logan & Hird, 2014).

Pointers for Future Research

As indicated already, future research must move on from risk prediction studies to studies of risk management processes and the efficacy of treatment and supervision interventions, in particular, based on a cohesive model of risk. SPJ is one such model, but others exist (Hart & Logan, 2011)—the point is that research should test entire models, not just one relationship (e.g., the correlation between a collection of risk factors and a particular event, such as reoffending). In addition, future research has to do better at modeling the work of experienced practitioners—who read files but also interview their clients, often many times and in the course of trying to manage risk—with a view to enhancing their practice within the real clinical world and not recommending excessive or unrealistic assessment goals based on studies of files reviewed by inexperienced graduate students. However, a priority for future research in the risk field is demonstrating a change—ideally a reduction—in rates of violence in connection with risk assessment and risk management procedures. This would show that the huge effort put into risk assessment has an impact on the outcome; such an effort is intended to prevent (Douglas & Kropp, 2002; Hart & Boer, 2010). Without this research, the point of risk assessment is unclear and its future questionable.

Concluding Comments

This chapter began with a brief overview of the task of clinical risk assessment and management, emphasizing the importance of understanding the risks posed by individual clients within an SPJ approach. The SPJ approach to risk formulation was then described, the essential process that links risk assessment with risk management via an understanding of the function or purpose of sexual violence for the individual. The SPJ approach was then illustrated through a description of the development and application of the SVR-20 and the more recent RSVP professional guidelines and with the illustrative case of Mr. Green. The chapter has concluded with a set of recommendations for practice and future research in the area. It will be no mean feat to accomplish the recommendations made. However, progress is essential if the field is to move on from prediction to prevention. The future of risk assessment, its credibility and purpose, depends on it.

Part III

Management and Public Policy Issues Regarding Sexual Offenders

Models of Sexual Offender Treatment

Pamela M. Yates

Sexual offending is a serious problem that has significant impacts on victims, their families, and society at large and continues to garner increased attention among the public, legislators, and media. This impact and increasing attention has resulted in the development and implementation of interventions designed to reduce the likelihood of re-offending. The availability of treatment programs for sexual offenders has increased dramatically with greater attention to this issue, as has empirical research designed to assess the effectiveness of these interventions. Although there is debate among researchers with regard to treatment efficacy, current best practice involves the application of cognitive-behavioral interventions that target risk and that adhere to specific correctional and clinical principles. Recent meta-analyses (Hanson et al., 2002; Lösel & Schmucker, 2005) have found cognitive-behavioral treatment to be most effective in reducing re-offending in comparison to both other types of treatment and to criminal sanctions. Furthermore, research indicates that treatment is most effective when it adheres to the principles of effective correctional intervention (Andrews & Bonta, 2010) with various types of offender groups (Andrews, Zinger, Hoge, Bonta, Gendreau, & Cullen, 1990; Dowden & Andrews, 1999a, 1999b, 2000, 2003), including sexual offenders (Hanson, Bourgon, Helmus, & Hodgson, 2009). Finally, best practice also includes the use of effective therapists and therapeutic techniques (Beech & Fordham, 1997; Marshall, Anderson, & Fernandez, 1999; Marshall et al., 2002; Shingler & Mann, 2006; Yates et al., 2000). In this chapter, I will review these principles of intervention and describe cognitive-behavioral treatment methods and targets with a focus on two treatment models—the good lives model and the self-regulation model—that have been proposed as alternatives and enhancements to traditional approaches to sexual offender treatment.

Principles of Effective Correctional Intervention

In their original work, Andrews and Bonta (2010) proposed four principles as essential to ensuring that interventions with correctional populations are effective in reducing re-offending rates: *risk*, *need*, *responsivity*, and *professional discretion*. Although originally intended to apply to sanctions as well as treatment (Andrews & Bonta, 1998), these principles have predominantly been applied in practice to treatment implementation and are collectively referred to as the risk/need/responsivity (RNR) model.

The *risk principle* states that, in order to be maximally effective, the intensity of correctional interventions must be matched to the level of risk posed by the offender, with the most intensive levels of service, including treatment, reserved for higher-risk offenders. Lower levels of intervention, or no intervention, should be applied to lower-risk offenders. More specifically, this principle states that intervention (i.e., treatment and supervision) should be longer in duration, applied more frequently, and include a greater number of treatment hours as levels of risk increase. While there is little direct research with respect to the appropriate duration of treatment and practice varies considerably, the research on both general and sexual offenders suggests a duration of 100–200 h for moderate-risk sexual offenders and a minimum of 300 h for sexual offenders with high risk and high needs. Low risk offenders may not require specialized treatment at all (Hanson & Yates, 2013).

Research indicates that, in addition to being the best use of limited resources (Prentky & Burgess, 1990), treatment is most effective when intensity level is matched to risk (Andrews & Bonta, 2010; Gendreau & Goggin, 1996, 1997; Gendreau, Little, & Goggin, 1996; Gordon & Nicholaichuk, 1996; Nicholaichuk, 1996). Furthermore, research indicates that mismatching risk and treatment intensity can result in

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_27

increased offending, both among higher-risk offenders who receive lower-than-required treatment intensity and among lower-risk offenders who receive higher-than-required treatment intensity (Andrews & Bonta, 2010; Lowenkamp & Latessa, 2002; Lowenkamp, Latessa, & Holsinger, 2006).

The *need principle* states that interventions should target the criminogenic needs of offenders—that is, the specific risk factors that can be changed through intervention and that are associated, both empirically and in individual cases, with risk and recidivism (Andrews & Bonta, 2007). This principle further argues that treatment should not focus on *non-criminogenic needs*—those factors not known to be associated with risk and recidivism—as such a focus is unlikely to impact re-offending. Among sexual offenders, criminogenic needs include such risk factors as sexual deviance and anti-social lifestyle, which represent the two strongest predictors of recidivism among sexual offenders (Hanson & Morton-Bourgon, 2004, 2005), with dynamic risk factors such as intimacy deficits and lack of social supports representing additional factors that have weaker relationships to recidivism (Hanson et al., 2009). Non-criminogenic factors include such areas as self-esteem and personal distress, which have not been found to be associated with recidivism (Hanson & Bussière, 1998).

The *responsivity* principle is concerned with the interaction between the individual and treatment, and it states that treatment should be delivered in a manner that is responsive to various characteristics of the individual, such as language, culture, personality style, intelligence, anxiety levels, learning styles, and cognitive abilities (Andrews & Bonta, 2010). Such factors can affect individuals' engagement with the treatment process and their ability to understand and apply information presented in treatment to their own personal circumstances. According to the responsivity principle, treatment methods should be varied and adapted to an individual's styles and abilities in order to maximize their potential effectiveness.

The principle of *professional discretion* states that clinical judgment should override the other principles if circumstances warrant and allows for flexibility and innovation in treatment under certain circumstances. Because this principle has received comparatively little attention in both research and practice, it is not discussed further, although it is suggested that recent theorizing and developments in sexual offender treatment allow for greater adherence to this principle than has traditionally been the case.

Empirical support for the application of the RNR model to offender populations is strong, clearly indicating the superiority of treatment complying with these principles over criminal sanctions, inappropriate treatment, or unspecified treatment. Specifically, in a series of meta-analyses, treatment adhering to these principles has been found to be effective for offenders in general (Andrews et al., 1990), juvenile delinquents (Dowden & Andrews, 1999a, 2003), violent offenders (Dowden & Andrews, 2000), and female offenders (Dowden & Andrews, 1999b). With respect to sexual offenders, a recent meta-analysis (Hanson et al., 2009) found that adherence to the RNR model was associated with reduced sexual re-offending, with the most significant treatment effect found among treatment programs that adhered to all three principles. Specifically, treatment effectiveness increased as a function of adherence to none, one, two, or all three principles (odds ratios of 1.17, .64, .63, and .21, respectively). Finally, adherence to the RNR principles provides a context within which increased program integrity, organizational adherence to integrity standards, and better staff practice can improve treatment outcomes (Andrews & Dowden, 2005; Dowden & Andrews, 2004).

Despite this strong empirical support, criticisms of the RNR model have been put forward regarding its underlying theory, implications for practice, and lack of scope (Ward & Brown, 2004; Ward & Gannon, 2006; Ward, Melser, & Yates, 2007; Ward & Stewart, 2003). Specifically, it has been argued that, while necessary, the focus in treatment on addressing dynamic risk factors (criminogenic needs) is not sufficient to ensure treatment effectiveness and that it is necessary to broaden the theoretical formulation of the RNR model, its application in practice, and the scope of interventions stemming from the model. In addition, it has been suggested that the RNR model, through its sole focus on risk management, is unable to provide therapists with sufficient tools to engage and work with offenders in therapy or to provide offenders with sufficient motivation to engage in the treatment process (Mann, Webster, Schofield, & Marshall, 2004; Yates, 2009). This is especially important given that sexual offenders tend not to be particularly motivated to participate in treatment (Thornton, 1997). In addition, it has been suggested that the RNR model pays insufficient attention to the importance of the therapeutic alliance in treatment, which has been shown in both general clinical practice and with sexual offenders as essential to treatment and as accounting for a significant portion of the variance in treatment outcome (Marshall et al., 2003; Yates, 2003). This research highlights the importance of attending to non-criminogenic needs such as motivation and low self-esteem, which are important to the treatment process yet not directly concerned with targeting risk. Finally, it has been suggested that the RNR model is often translated in practice in a "one size fits all" manner that fails to take individual needs into account and thus fails to fully adhere to the principles of risk, need, and responsivity (Ward & Stewart, 2003).

Cognitive-Behavioral Treatment

Cognitive-behavioral treatment is currently the most widely accepted model of intervention for individuals who have offended sexually (Barbaree & Seto, 1997; Becker & Murphy,

1998; Freeman-Longo & Knopp, 1992; Grubin & Thornton, 1994; Hall, 1995; Laws, 1989; Looman, Abracen, & Nicholaichuk, 1999; Marshall et al., 1999; Yates, 2002) and has demonstrated the greatest effectiveness in reducing recidivism (Hanson et al., 2002; Lösel & Schmucker, 2005). Treatment within this model is based on behavioral learning models such as classical (Pavlov, 1927) and operant (Skinner, 1938) conditioning, cognitive theory (Beck, 1964, 1967, 1976), and social learning theory (e.g., Bandura, 1986). Sexual offending is viewed as a behavioral and cognitive pattern that has developed and been maintained during development over time via processes such as modeling, observational learning, and reinforcement, resulting in entrenched maladaptive responses, coping mechanisms, and cognitive schema. The focus of cognitive-behavioral treatment is to alter patterns of behavior and cognition that support sexual offending, such as maladaptive or deviant responses, and replace them with pro-social beliefs, attitudes/schema, behavior, and responses. This is accomplished by targeting specific risk factors known to be linked to risk for re-offending.

Briefly, cognitive-behavioral treatment typically involves changing attitudes; altering cognitive distortions and schema; developing effective problem-solving abilities; improving sexual, intimate, and social relationships; managing affective states; reducing deviant sexual arousal; and developing adaptive thinking processes, affect, and behavior (Barbaree & Marshall, 1998; Marshall et al., 1999; Yates, 2002, 2003; Yates et al., 2000). This is typically done via group therapy in which offenders address specific deficits and develop and rehearse new skills and ways of thinking that ultimately result in reduced risk of re-offending. Common treatment targets, matched to established dynamic risk factors (e.g., Hanson, Harris, Scott, & Helmus, 2007), include attitudes supportive of sexual offending, cognitive distortions that facilitate offending, deviant sexual preference and arousal, intimacy and attachment deficits, deficits in sexual and general self-regulation, emotion regulation, and posttreatment follow-up to maintain treatment gains, monitor risk, and allow for the provision of support (Marshall, Marshall, Serran, & Fernandez, 2006; McGrath, Hoke, & Vojtisek, 1998; Wilson, 2007; Yates et al., 2000). Treatment also typically addresses factors such as empathy deficits, accountability or responsibility for offending, and denial. Despite an absence of research suggesting that such factors are associated with risk for re-offending, these areas are included, as they are often considered moderating factors in offending and may interact with other criminogenic needs related to offending. In targeting known risk factors, cognitive-behavioral treatment should incorporate extensive rehearsal because new cognitive and behavioral skills require considerable practice and repetition in order to become well entrenched in the individual's repertoire (Hanson, 1999; Hanson & Yates, 2004). Finally, cognitive-behavioral interventions may be implemented in conjunction with adjunctive therapy, such as pharmacological interventions designed to reduce levels of arousal or to address mental health concerns, or treatment targeting substance abuse problems for those offenders warranting these interventions (Wilson & Yates, 2009; Yates, 2002).

The most common cognitive-behavioral approach used in sexual offender treatment programs has been the relapse prevention (RP) model (e.g., Laws, 1989; Pithers, 1990; Pithers, Kashima, Cumming, & Beal, 1988; Pithers, Marques, Gibat, & Marlatt, 1983). Adapted to sexual offender treatment from the treatment of alcoholics, the original RP model (Marlatt, 1982, 1985) was intended as a posttreatment follow-up program for motivated patients who successfully ceased alcohol use but who experienced difficulty maintaining abstinence. RP was applied to the treatment of sexual offenders and underwent some revisions to adapt the model to this population (Laws, 1989; Marlatt & Gordon, 1985; Marques, Day, & Nelson, 1992; Pithers, 1990; Pithers et al., 1988). Because of its intuitive appeal and likely as a result of a lack of available information regarding the risk of sexual aggression, dynamics of offending, and treatment at that time, the model was unquestioningly embraced as the approach to the treatment of sexual offenders (Laws, 2003; Laws & Ward, 2006; Yates, 2005; Yates & Ward, 2007).

The goal of treatment using RP with sexual offenders is to assist them in identifying and anticipating problems and high-risk situations that could lead to a *lapse*, defined in the original model as a temporary return to the problematic behavior (Marlatt, 1982), and to a *relapse* (i.e., a return to sexual offending behavior) and to teach them a variety of skills to cope with these problems when they arise and to mitigate skill deficits (Laws & Ward, 2006; Marques et al., 1992; Pithers, 1990, 1991). Despite a lack of empirical research supporting its use and problems with the theoretical model (Hanson, 1996, 2000; Laws, 2003; Laws, Hudson, & Ward, 2000; Laws & Ward, 2006; Yates, 2003, 2005; Yates & Kingston, 2005; Yates & Ward, 2007), the RP model gained wide acceptance as a treatment approach for sexual offenders.

The RP model has been criticized for theoretical inadequacies, incoherence, inconsistencies, lack of scope, problematic definitions of its constructs, and practical limitations (Laws, 2003; Laws & Ward, 2006; Yates, 2003, 2005; Yates & Kingston, 2005; Yates & Ward, 2007). Problems with the model include: a narrow view of behavior that does not adequately address the heterogeneity of sexual offenders and the pathways they follow to offending; its reliance on a single pathway to offending; the lack of applicability of core constructs of the model to sexual offenders; an inaccurate conception of sexual offending behavior as identical to addictive behavior; its focus on negative affective states as necessary, sufficient, and essential to the offense process; an

inadequate conceptualization of offense planning; and a nearly sole focus on avoidance strategies to manage risk to re-offend. Two alternative models, the good lives model (GLM; Ward & Gannon, 2006; Ward & Stewart, 2003) and the self-regulation model (SRM; Ward & Hudson, 1998), have been proposed as alternative approaches that address problems inherent in both the traditional RP approach and the RNR model and are described later in this chapter.

Within treatment, in addition to targeting known risk factors associated with risk to re-offend, attention has been paid to the importance of the therapeutic processes and methods by which treatment is implemented (Beech & Fordham, 1997; Hanson et al., 2009; Marshall et al., 1999, 2002; Shingler & Mann, 2006; Yates, 2002; Yates et al., 2000). Research indicates that specific therapist characteristics and techniques, and establishing a positive therapeutic relationship between the client and therapist, account for a significant proportion of the variance in treatment outcome, both among sexual offenders and in general non-offender therapy for such problems as depression, mental health, and addictions (Marshall et al., 1999, 2003).

Creating a positive and therapeutic treatment atmosphere requires that clinicians avoid taking punitive, aggressive, or confrontational styles of relating to the offender, as this leads to increased resistance, argumentativeness, denial, lack of cooperation and compliance with treatment, a negative effect on treatment progress, and premature termination or dropping out of treatment (Beech & Fordham, 1997; Kear-Colwell & Pollack, 1997; Marshall et al., 1999; Miller, 1995). Since research clearly indicates that offenders who do not complete treatment re-offend at significantly higher rates than offenders who complete treatment (Hanson & Bussière, 1998; Hanson et al., 2002), the importance of treatment processes that function to retain offenders in treatment is immediately evident. A variety of therapist characteristics and behaviors have been shown to maximize treatment gains (Fernandez, 2006; Marshall et al., 1999, 2002). These include empathy, respect, warmth, friendliness, sincerity, genuineness, directness, confidence, and interest in the client. An effective therapist is also one who is a pro-social model; who communicates clearly; who is appropriately self-disclosing, reinforcing, encouraging, and non-collusive; who deals appropriately with frustration and other difficulties which offenders present in treatment; who asks open-ended questions; and who is appropriately challenging without being aggressively confrontational. Effective therapists actively listen to their clients, support their clients without being collusive, are open and interested in their clients, hold and express the belief that the client is capable of change, create opportunities for success, motivate the offender to change, and create a treatment atmosphere which is secure for the offender.

Good Lives Model of Sexual Offender Rehabilitation

As indicated above, the RNR model of sexual offender intervention has been criticized as being insufficient and narrow in scope, and it has been suggested that interventions within this model be broadened (Ward, Melser, & Yates, 2007). This broadening of scope would include taking into account the promotion of basic human goods alongside risk management as emphasized in the good lives model (Ward & Gannon, 2006; Ward & Stewart, 2003). A principal criticism of the RNR model has been that the focus on criminogenic needs is a *necessary* but not *sufficient* condition for effective treatment (Ward & Gannon, 2006, emphasis added). Specifically, the model is unable to provide clinicians with sufficient tools to engage and work with offenders in therapy as a result of (a) difficulty motivating offenders by focusing primarily on avoidance goals and risk reduction (e.g., Mann et al., 2004); (b) ignoring the importance and role of personal or narrative identity and agency (i.e., self-directed, intentional actions designed to achieve valued goals) in the change process (e.g., Maruna, 2001); (c) paying insufficient attention to the therapeutic alliance; and (d) failing to acknowledge that human beings naturally seek and require certain goods in order to live fulfilling and personally satisfying lives (e.g., Ward & Stewart, 2003).

While a comprehensive review of the GLM is beyond the purview of this chapter, briefly, the model proposes that, like other human beings, sexual offenders are goal directed and seek to acquire fundamental primary human goods—actions, experiences, and activities that are intrinsically beneficial to individual well-being and that are sought for their own sake. Examples of primary human goods include relatedness/intimacy, agency/autonomy, happiness/pleasure, and emotional equilibrium. The GLM proposes that sexual offending results not from the desire to obtain these goods but from the methods and strategies offenders use to attain these. These maladaptive strategies derive from offenders' backgrounds, developmental histories, and internal and external capabilities to attain these goods in non-offending ways. For example, an offender may desire intimacy but, as a result of discomfort and fear of adults, turns to children to meet this need. The problem, therefore, is not the desire to attain intimacy, but the manner in which the individual attempts to achieve this desire (i.e., with children rather than age-appropriate partners). Viewed this way, dynamic risk factors and criminogenic needs are seen as symptoms or markers of ineffective or inappropriate strategies employed to achieve primary goods or goals. Although this is a very cursory overview of the GLM, this model has significant implications for the treatment of sexual offenders (see below).

It is important to note that the GLM is not a treatment program itself, but represents an overarching rehabilitation framework for the treatment of sexual offenders. While the particular focus in treatment is on the promotion of goods (see below), it is essential that this is done in conjunction with risk management. It is suggested, however, that the addition of a GLM focus to the treatment of sexual offenders will contribute to further reductions in risk and that its inclusion will increase offender motivation and engagement with treatment via increased attention to responsivity needs and the creation of a stronger therapeutic alliance (Ward & Stewart, 2003; Yates, 2009). In fact, although at preliminary stages, research to date indicates that the application of the GLM to a risk-based program improves motivation to participate in treatment, treatment progress, and completion rates (Simons, McCullar, & Tyler, 2008; Yates, Simons, Kingston, & Tyler, 2009) and that good lives constructs are differentially associated with offense characteristics (Yates, Kingston, & Ward, 2009), as well as static risk to re-offend, dynamic risk factors, and sexual offense pathway (Kingston, Yates, Simons, & Tyler, 2009). Thus, initial data support the potential utility of the GLM with sexual offenders.

Finally, the GLM approach is consistent with both the responsivity principle and with effective clinical practice, as discussed above. In order to ensure the inclusion of risk factors and risk management, the GLM has recently been integrated with the self-regulation model (SRM) of the offense process as a comprehensive approach to treatment (Ward, Yates, & Long, 2006; Yates, Kingston & Ward, 2009; Yates & Ward, 2008) that is consistent with the principles of effective correctional and clinical practice with sexual offenders. The SRM is described below.

Self-Regulation Model of the Sexual Offense Process

Alongside the development of the GLM has been the application of the self-regulation model (Baumeister & Heatherton, 1996; Karoly, 1993; Thompson, 1994) to sexual offending (Ward & Hudson, 1998). The SRM began as a nine-stage model of the sexual offense process, developed specifically for sexual offenders, that explicitly takes into account variability in offense-related goals and the manner in which individuals regulate their behavior in order to achieve these goals. Within the SRM, offense-related goals include both the attainment of desired states and outcomes (appetitive or approach goals) and the avoidance of undesired states and outcomes (inhibitory or avoidance goals). The model acknowledges that some sexual offenders may attempt to refrain from offending, whereas others will actively seek out opportunities to offend. In addition, in attempting to achieve these goals, the SRM proposes that individuals demonstrate differences in self-regulation capacity, with some offenders failing to control behavior (*under-regulation/disinhibition*), others attempting to actively control behavior using strategies that are ultimately counterproductive and ineffective (*mis-regulation*), and others having intact self-regulation abilities but holding inappropriate goals, such as the explicit desire to harm others, which motivate offending in the absence of self-regulation deficits.

The original SRM delineates a nine-phase offense progression model that results in four distinct pathways that lead to sexual offending. The nine phases of the offense process are illustrated in Fig. 1 and are briefly described below. For a comprehensive description of the nine phases and four pathways, see Ward and Hudson (1998) and Ward, Bickley, Webster, Fisher, Beech, and Eldridge (2004).

In the SRM, the offense progression is triggered by a life event and resultant appraisal of this event based on individuals' cognitive schema, goals, needs, and implicit theories (Phase 1). The life event may be a major event, such as the loss of a relationship or a job, or it may be a relatively minor event, such as an argument or the presence of a child in the individual's environment. Consistent with cognitive theory, this appraisal is hypothesized to occur relatively automatically, to influence the information to which the individual attends, and to activate entrenched cognitive and behavioral scripts and emotional states (positive or negative) developed during the individuals' lives via their learning experiences and associated with previous offending history. The life event and its appraisal trigger the desire for offending or for behaviors associated with sexual offending (Phase 2). This desire may be explicitly related to sexual offending, as when deviant sexual urges or fantasies are triggered, or may represent a desire to achieve other states that are indirectly related to offending, such as the desire for intimacy, dominance, or the expression or release of anger. In our recent reconstruction of this model (Yates & Ward, 2008), these desires have also been expanded to include goals related to the attainment of primary goods.

In response to the desire to offend, the individual establishes an offense-related goal (Phase 3). As indicated above, individuals may establish an avoidance goal, in which they desire to prevent offending, or an approach goal, in which they work toward offending. At this phase, individuals also evaluate the acceptability of this goal and their ability to tolerate the affective states associated with the desire to offend. The offense-related goal determines the manner in which the individual next proceeds in the offense progression (Phase 4), in which the individual selects strategies that will achieve the goal of either avoiding offending or approaching offending. In selecting strategies, individuals with avoidance goals will implement either no strategies or strategies that they

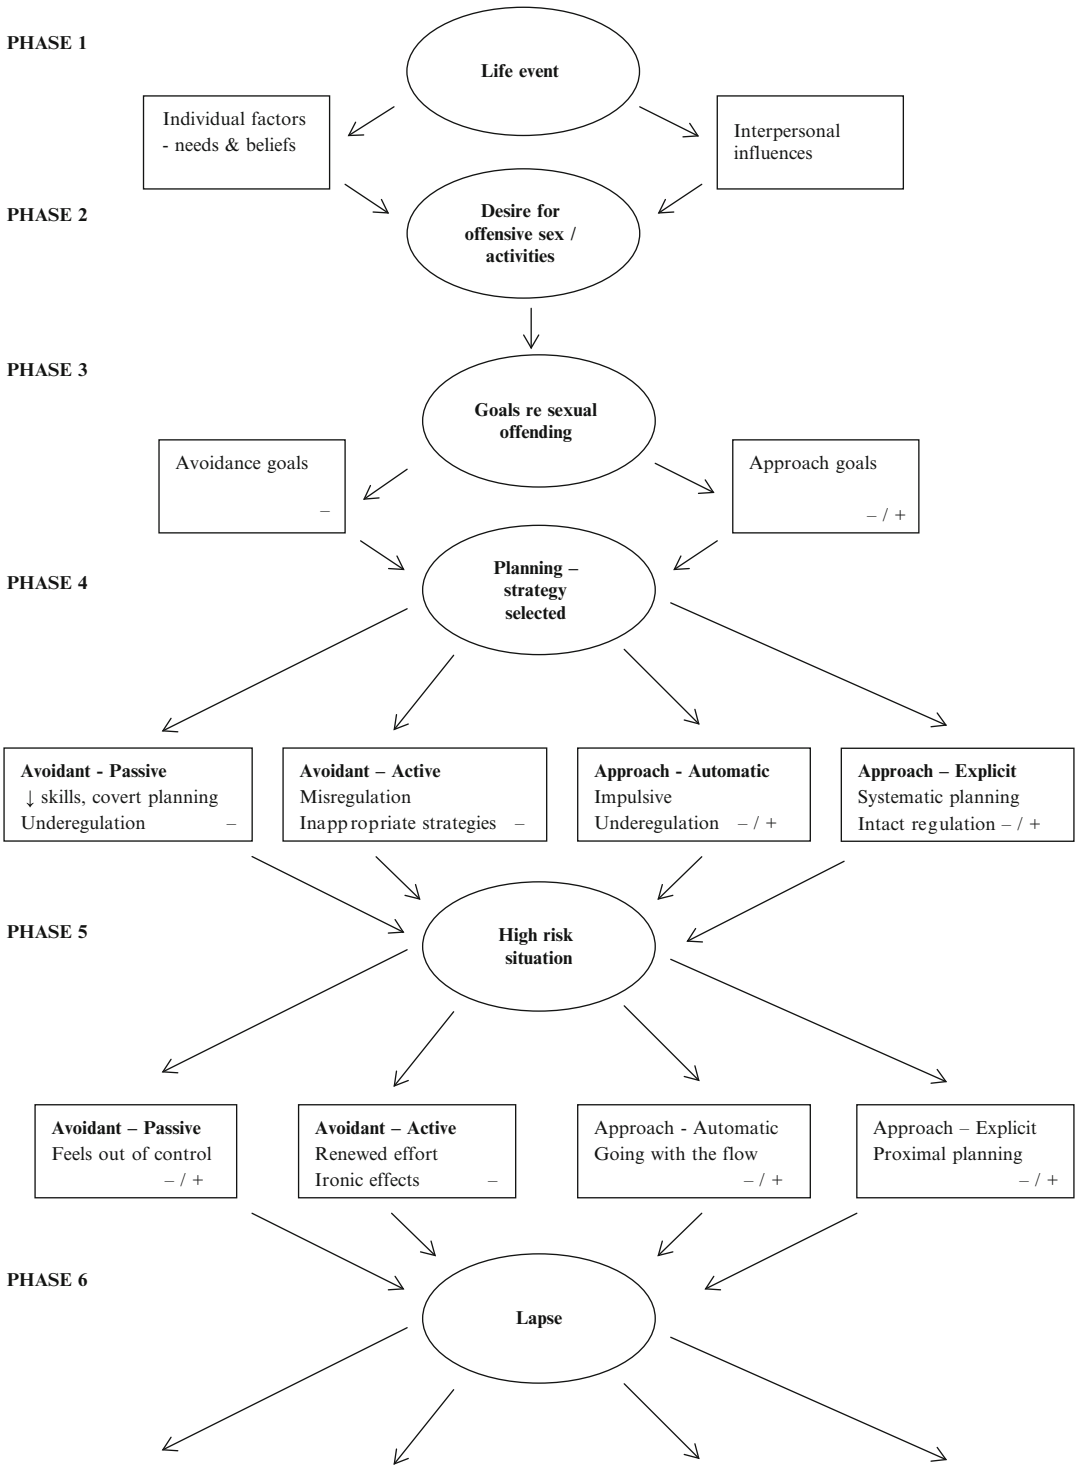

Fig. 1 A self-regulation model of the relapse process [*Note* From Ward et al. (2006), *The Self-Regulation Model of the Offense and Relapse Process. Vol. 2: Treatment* © 2006, Pacific Psychological Assessment Corp. Reprinted with permission]

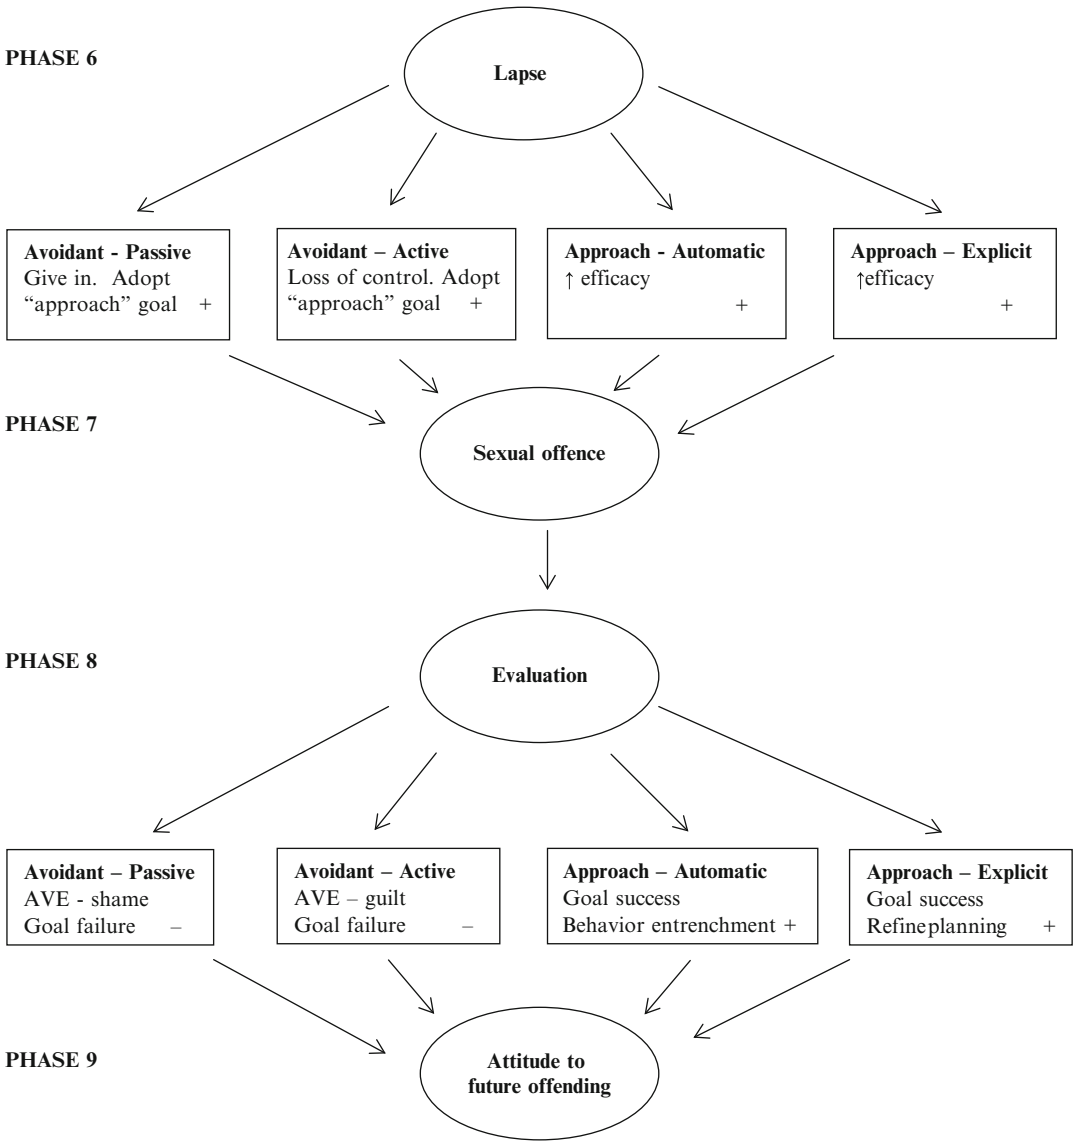

Fig. 1 (continued)

expect will reestablish self-control and that will prevent offending, whereas individuals with approach goals implement strategies that will serve to achieve the goal of offending. The combination of offense goals (Phase 3) and strategy selection (Phase 4) determines the pathway the individual follows to offending (see below).

In the next phase of the offense progression (Phase 5), individuals encounter a high-risk situation, such as access to a potential victim. Depending upon individuals' goals and strategies, such access may be accidental, incidental, or opportunistic or may result from either implicit or explicit planning. The individuals evaluate this situation in light of their offense-related goals and expectations regarding the likely effectiveness of strategies selected to achieve the goals. For individuals holding avoidant goals, this situation signals a failure to control behavior, whereas for offenders holding approach goals, this situation signals progress toward achieving the goal and is an indicator of success.

Once individuals have encountered the high-risk situation, the next phase in the offense progression (Phase 6) is the occurrence of a lapse, defined in the SRM as pre-offense behaviors that are likely to lead to sexual offending. For offenders with avoidant goals, the SRM proposes that, via processes such as cognitive deconstruction and failure to achieve this goal, individuals abandon the higher-order goal (avoidance) in favor of more proximal goals in the immediate situation (e.g., sexual gratification, achievement of intimacy). It is hypothesized that these individuals temporarily switch to an approach pathway, leading to the commission of a sexual offense (Phase 7). For individuals holding

avoidance goals, engaging in lapse or pre-offense behaviors is consistent with their offense-related goals, leading to the commission of the offense.

Unlike other offense process models, the SRM also considers individuals' experiences following the commission of a sexual offense via two post-offense phases during which individuals evaluate themselves and their behavior immediately after the offense (Phase 8) and develop intentions and expectations with respect to future offending (Phase 9). Following the offense, at Phase 8, individuals holding avoidant goals are expected to experience guilt, shame, a sense of failure, and cognitive dissonance associated with the disparity between their behavior (offending) and their goal (to avoid offending). They are likely to attribute the cause of offending to stable, internal, uncontrollable factors, to have cognitive distortions that justify offending based on these causes, and to regard the commission of the offense as a failure experience. Conversely, individuals holding approach goals are hypothesized to attribute their offending behavior to external causes and to have cognitive distortions that place responsibility for offending outside themselves, such as blaming the victim. Individuals with approach goals regard the commission of the offense as a success experience with respect to achieving the offense-related goal.

Finally, the SRM posits that, based on the offense experience and its evaluation, individuals form intentions with respect to future offending (Phase 9). Individuals holding avoidant goals may resolve not to offend again in the future, or alternatively, they may conclude that they lack the requisite skills to prevent offending and, consequently, adopt an approach goal with respect to future offending. Conversely, offenders holding approach goals are reinforced as a result of their "success" in achieving offense-related goals and may use the offense experience to refine offense strategies in the future.

Within this nine-phase offense process, the combination of offense-related goals and the strategies used to achieve these goals (i.e., self-regulation capacity) reflects four distinct pathways to sexual offending, each associated with varying degrees of awareness and planning associated with decision-making with respect to offending. These four pathways include:

1. *Avoidant-passive pathway.* Offenders following this pathway desire to refrain from sexual offending (avoidance goal) but lack the awareness and the required skills to effectively control their behavior in order to achieve this goal. Offending is associated with negative emotional states and disinhibition of behavior, loss of control, impulsivity, and anxiety when the individual is confronted with offense-related desires and opportunities to offend. These individuals may attempt to manage the desire to offend but do so typically by simply denying its existence or attempting to distract themselves from offense-related urges and desires (under-regulation). Negative affective states are the predominant emotional states throughout the offense progression, cognitive dissonance is evident, and offending is poorly or only covertly planned and is associated with goal failure.
2. *Avoidant-active pathway.* Similar to the avoidant-passive pathway, offenders following this pathway hold an avoidance goal with respect to offending (i.e., they desire to refrain from offending), but, unlike the avoidant-passive pathway, these individuals actively implement strategies to cope with the desire and opportunities to offend. That is, rather than simply denying or ignoring desires and urges, they attempt to regulate behavior via the use of specific strategies. However, the strategies they select are ineffective (mis-regulation) and, in some instances, result in the ironic effect of increasing the likelihood of offending. For example, individuals may engage in behavior such as masturbating to deviant images to avoid committing a hands-on offense or may use substances to regulate mood. Such behavior, however, functions to disinhibit the individual or to further entrench deviant arousal, thus increasing risk to offend. Predominantly negative affective states are evident throughout the offense progression, as is cognitive dissonance, and offending results from the implementation of ineffective strategies to prevent offending and is associated with goal failure
3. *Approach-automatic pathway.* This pathway is associated with approach-motivated goals with respect to offending and is characterized by *under-regulation* in achieving these goals. These individuals do not desire to prevent offending nor do they attempt to refrain from pursuing offense-related goals. Their self-regulation style is relatively automatic and impulsive, as they respond to situational cues in the immediate environment based on well-entrenched cognitive and behavioral scripts that guide behavior. Offense planning is rudimentary and unsophisticated, and offending is typically associated with positive emotional states, such as anticipation of sexual gratification, or may be associated with the attainment of specific negative goals, such as achieving revenge or dominance. Following offending, these individuals view their behavior positively, as they have achieved their goals, and are unlikely to experience cognitive dissonance, as their goals and behavior are consistent with each other.
4. *Approach-explicit pathway.* This pathway is associated with intact self-regulation. That is, individuals following this pathway do not have deficits in their ability to regulate their behavior, nor do they experience the disinhibition or loss of control evident in other offense pathways. Sexual offenses are explicitly and overtly planned in order to achieve a desired objective, such as sexual gratification,

and offending is associated with attitudes and core beliefs that support sexual aggression as an appropriate means by which to achieve these goals. Offending tends to be associated with positive affective states, and cognitive dissonance and goal conflict are absent.

As can be seen from the above brief overview, the SRM is more comprehensive than previous offense process models in that it acknowledges the heterogeneity in offense pathways and motivations for offending. The model is also consistent with the RNR principles, as treatment can be explicitly varied and adapted to individual offenders' needs, and is amenable to treatment using cognitive-behavioral methods. For example, within the SRM, dynamic risk factors can be more fully integrated with offense motivations, dynamics, and planning and can be linked to self-regulation capacity, offense-related goals, and offense strategies. This is discussed further in the following section.

Research to date on the SRM supports the validity of the model and its use in treatment. Specifically, there is support for the validity of the self-regulation model, including the existence of multiple pathways to sexual offending; offense characteristics such as offense planning and victim type; variability in pathways across different types of offenders (Bickley & Beech, 2002, 2003; Kingston, Yates, & Firestone, 2012; Proulx, Perreault, & Ouimet, 1999; Simons et al., 2008; Ward, Louden, Hudson, & Marshall, 1995; Yates & Kingston, 2006), as well as variations in actuarially measured static and dynamic risk (Stotler-Turner, Guyton, Gotch, & Carter, 2008; Kingston et al., 2012; Kingston et al., 2009; Leguizamo, Harris, & Lambine, 2010; Simons et al., 2008; Yates & Kingston, 2006); association with offense specialization (Leguizamo et al., 2010) and psychopathy (Gotch, Carter, & Stotler-Turner, 2007); and differential association with recidivism (Kingston, Yates, & Olver, 2013 under review; Webster, 2005). In addition, different pathways have been found to be differentially associated with treatment participation, compliance, motivation, progress, and outcome (Simons, Yates, Kingston, & Tyler, 2009). Taken together, research support is considerable for the use of the SRM in the treatment of sexual offenders.

An Integrated Approach to Cognitive-Behavioral Treatment with Sexual Offenders

As indicated above, research indicates that cognitive-behavioral treatment is the most effective approach to the treatment of sexual offenders, and adherence to the principles of risk, need, and responsivity shows the greatest treatment effect with respect to reduced recidivism. Recently, the GLM and SRM have been integrated into a comprehensive treatment approach (Ward et al., 2006; Yates, Prescott, & Ward, 2010; Yates & Ward, 2008) that can be delivered in a manner that effectively addresses risk, adheres to the RNR model, and utilizes cognitive-behavioral methods but that is also motivating to participants and that increases engagement with treatment. Integration of models also acknowledges the heterogeneity of offenders, the pathways they follow to offending, and the primary goods they seek to obtain via offending. Within this integrated model and in keeping with the RNR model, risk is assessed prior to treatment and appropriate treatment intensity levels are determined and applied. Based on the evaluation of both static and dynamic risk, higher-risk offenders are assigned to more intensive intervention, offenders posing a moderate risk to re-offend are assigned to moderate intensity interventions, and lower-risk offenders are assigned to minimal or no intervention. Also, in keeping with the RNR model, dynamic risk factors are explicitly assessed and treatment targets established accordingly and on an individualized basis. In addition to the evaluation of risk, individuals' good lives goals and self-regulation pathways are explicitly assessed using a structured protocol (Yates, Kingston & Ward, 2009), which also forms part of the treatment plan (Ward et al., 2006; Yates & Prescott, 2011; Yates et al., 2010; Yates & Ward, 2008).

In assessing good lives goals, part of the assessment process involves evaluating both that which the individual values and hopes to achieve in life generally and the goods the individual was attempting to acquire via offending, either directly or indirectly via a formal assessment protocol (Yates, Kingston & Ward, 2009). Attempts to attain these goods are reflected in dynamic risk factors. Thus, for example, individuals seeking to attain intimacy (a primary human good) may do so via sexual and intimate activity with children, manifesting as the dynamic risk factor of intimacy deficits and possibly deviant sexual interest. Individuals seeking to attain personal autonomy may have attempted to achieve this via sexual and/or physical aggression against an adult female, such as violent rape. The key activity in determining goods sought through offending is to establish the overarching good the individual sought to attain via offending.

Similarly, assessment of offense pathway, using the nine-phase SRM offense process model described above, assists in evaluating the route individuals have followed to offending and in delineating both good lives and offense-related goals implicated in offending, such that these may be targeted in treatment (Yates, Kingston & Ward, 2009, 2010; Yates et al., 2010). Furthermore, different offense pathways prescribe different approaches to treatment and different treatment objectives. For example, as is clear from the above discussion of offense pathways, some individuals require awareness raising and skill development in order to refrain from offending and to manage risk, whereas others require interventions designed to alter attitudes and core belief systems and cognitive schema that support offending.

In this integrated approach, the aim is not to change individuals' overarching goals (i.e., primary goods sought) but rather the methods used to attain these goods and the associated offense-related goals and strategies. Thus, treatment does not aim to eliminate offenders' needs for intimacy but to alter the manner in which they attempt to achieve intimacy such that it is sought with age-appropriate partners rather than with children and to develop the requisite skills and capabilities to achieve this. Similarly, treatment does not aim to eliminate offenders' need for autonomy, but helps them to achieve autonomy without dominating, controlling, or aggressing against others and to alter the belief that such behaviors are appropriate means to meet this need.

As is evident from this brief description, dynamic risk factors such as intimacy, interpersonal aggression, and problems with general or sexual self-regulation are addressed in treatment, thus adhering to the requirement of effective intervention to target known dynamic risk factors for offending. Furthermore, this integrated model represents a more positive approach to treatment than previous models such as RP and traditional RNR approaches that tend to focus on deficits and on the avoidance of problematic situations rather than inculcating positive approach goals. Within the integrated GLM/SRM model, there is at least equal importance placed on positive approach goals as on offense-avoidance goals—assisting the offender to achieve that which they value in life and enhancing well-being by actively working toward achieving important goals via pro-social, non-offending means in addition to managing risk. This is an important feature of treatment, particularly since such approach goals are more motivating and are more easily attained than are avoidance goals (Mann, 1988; Mann et al., 2004).

In treatment using this integrated model, treatment targets and methods also vary in accordance with offense pathways. Each of the four pathways described above is associated with different offense-related goals, strategies to achieve these goals, and self-regulation capacity. As such, treatment needs to be tailored to the specific goals and strategies of individual offenders. As indicated above, avoidant pathways are associated with the desire to refrain from offending, an objective that should be reinforced in treatment with offenders following this pathway. However, the two avoidant pathways, and their treatment requirements, differ in that individuals following an avoidant-passive pathway tend to be unaware of the offense progression as it unfolds, whereas individuals following an avoidant-active pathway demonstrate the capacity to monitor their behavior and responses to particular situations. Thus, treatment with offenders following the former pathway must focus on raising awareness of the offense progression in addition to assisting the individual to develop skills to monitor the environment and cope with circumstances and risk factors. By comparison, treatment of offenders following the avoidant-active pathway will focus less on raising awareness of the offense progression and more on awareness that strategies to achieve the avoidance goal are ineffective, as well as assisting the individual in developing skills and strategies that will be effective in managing risk. By contrast, as noted above, individuals holding approach goals with respect to offending actively work toward offending. A major target of treatment, therefore, is altering offense-supportive goals, beliefs, and attitudes and changing cognitive schema. In addition, because offenders following an approach-automatic pathway tend to respond relatively rapidly to situational and environmental cues and because this pathway is associated with general criminality (Kingston et al., 2012; Yates & Kingston, 2006; Kingston et al., in press), impulsivity typically needs to be targeted in treatment with these individuals, in addition to offense-supportive attitudes and cognitive schema. By contrast, individuals following an approach-explicit pathway tend to plan offenses carefully and explicitly and typically do not require intervention for impulsivity or other skills deficits. With these offenders, the primary treatment focus is on attitude and goal change.

As can be seen from the above discussion, using an integrated GLM/SRM model in treatment is consistent with the RNR model and principles of effective intervention and is amenable to the use of cognitive-behavioral methods and procedures. Adopting a GLM focus in particular also adheres to the principles of effective clinical intervention described above. Specifically, the GLM, with its positive approach, is more likely to motivate offenders to engage with treatment and with the change process via the establishment of mutual treatment goals that serve not only to reduce risk but also to improve well-being and life satisfaction. Adopting an SRM focus is also consistent with the principles of risk/need/responsivity, and it allows treatment to be better tailored to individual risk and criminogenic needs and to be responsive to individual offense pathways and motivation for offending.

Regardless of the approach that is followed in treatment, the principles of risk, need, and responsivity are important in determining treatment intensity and targets, as well as additional interventions that may be required, such as mental health interventions. For example, treatment may need to be longer in duration when significant risk factors such as sexual deviance or psychopathy are present. In such cases, additional risk management may be required, such as external supervision and monitoring.

Implementing a GLM/SRM treatment intervention may initially appear difficult, given how well-entrenched deviant sexual and criminal behavior may be among some clients. It is suggested, however, that these models will still apply in such challenging cases. In terms of the integrated GLM/

SRM model, sexually sadistic or psychopathic offenders may highly value such primary goods as happiness (under which is subsumed sexual pleasure) as well as autonomy and a sense of power, which is attained by manipulating, abusing, or controlling others. Similarly, such offenders may be more likely to follow approach pathways, such as the approach-explicit pathway, a pathway that is associated with higher levels of risk and that challenges current treatment methods generally (Ward et al., 2004). In such cases, it is suggested that the SRM can be of additional benefit, given that it better takes into account such factors as offense planning, positive affect, and positive reinforcement for offending, than does the traditional RP model. It is also suggested that the GLM can be of added value in such cases in addition to cognitive-behavioral treatment, as the origins of the behavior can be linked to what is important to the individual in his life, and alternative methods to attain such states as personal power and sexual gratification can be an integral part of treatment. Furthermore, by focusing on what the individual will gain from treatment (an essential element of the GLM approach), treatment is expected to be more motivating for individuals who may not view their behavior as problematic and who may be more amenable to an approach that focuses explicitly on what they personally have to gain by not offending and by engaging in treatment. As indicated above, regardless of the inclusion of the GLM and SRM in a specific treatment program, engaging offenders in treatment regardless of risk factors is essential to ultimate success, as is addressing risk and need. As with any treatment program, the right series of interventions is necessary to reducing risk to re-offend. It is suggested that the addition of the GLM and SRM to existing approaches will enhance treatment and lead to better achievement of this objective.

Conclusions

This chapter provided an overview of effective intervention with sexual offenders, with a focus on cognitive-behavioral intervention designed to alter patterns of behavior and cognition associated with sexual offending. The GLM and SRM models that have recently been developed and integrated into the treatment of sexual offenders hold promise to increase treatment effectiveness while adhering to research and established best practices. It is suggested that an integrated approach incorporating comprehensive assessment, the principles of risk/need/responsivity, cognitive-behavioral methods, effective clinical/therapeutic methods, and a positive approach that incorporates offender heterogeneity and variability in offense pathway will assist in increasing the effectiveness of sexual offender treatment and reducing the risk of future sexual violence.

Forensic Psychotherapy for Sexual Offenders: Has Its Effectiveness Yet Been Demonstrated?

Harry M. Hoberman

Introduction

To what degree has psychotherapy been empirically demonstrated to result in the prevention of future acts of sexual offending? That is, what scientific evidence exists that demonstrates that psychosocial interventions with sexual offenders consistently and effectively lead to enduring reduced rates of future sexual offending? Psychotherapy is generally conceived of as a process through which clients attempt to "change" problematic or maladaptive aspects of themselves through interactions with clinicians–persons with particular qualifications (e.g., training and experience). Such psychosocial interventions broadly involve clinicians providing various means of providing support, understanding, and "influence" so that help-seeking persons achieve some desired outcome by promoting self-understanding and/or exposing them to experiences and methods for changing their behaviors, thoughts, attitudes, and emotions. Consequently, it seems conceivable that psychotherapy has the potential to play some role in the management of sexual offenders, at least theoretically, by facilitating personal change in factors presumably related to the initiation and/or maintenance of sexual offending. As with other persons with significant behavioral problems, it is plausible that mental health professionals might be effective to some demonstrated degree in providing varied but identified means for sexual offenders to "change" in ways that their propensity for sexual behavioral problems is eliminated or substantially reduced. From a criminological perspective, it has been argued that potential evidence indicating general criminal recidivism can be reduced short term by some psychotherapeutic interventions suggests that sexual offenders too might respond to such interventions. However, while both conceivable and plausible, ultimately it is an *empirical* question as to whether psychosocial interventions have been or can be proven on the basis of scientific study to affect change in sexual offenders or decrease the risk of sexual offense recidivism. The results of that empirical question also have critical and important policy implications. It has significant implications if psychotherapy has not or cannot be demonstrated to be an effective mechanism of personal change for sexual offenders. First, both therapists and society may demonstrate a false sense of security that once a sexual offender has been involved in a treatment program that their risk of sexual reoffending has been reduced. As a recent treatment review stated:

> As a matter of social justice for the offend, and to provide reassurance to the community, it is essential that the treatments provided work and therefore inspire confidence that offenders who have completed treatment programs really are at reduced risk of sexual reoffending. (Dennis et al., 2012, p. 7)

Without the type of "proof" that is expected for other psychosocial interventions, then mental health professionals cannot make claims that their efforts at such treatment of sexual offenders matter. Further, in the absence of scientific demonstrations of psychotherapy effectiveness with sexual offenders, it becomes reasonable and necessary for alternative management approaches to be employed with sexual offenders as a means of preventing or reducing the risk of future sexual offenses.

For mental health professionals (MHP), generally, there is an assumption or belief that psychotherapy should and does make a difference to their clients; there is a strong expectancy effect that psychosocial interventions should be effective. In particular, for MHP providing psychosocial interventions for sexual offenders, it appears that clinicians have very strong beliefs that sexual offender treatment can and does have a powerful and enduring effect on their "clients" (e.g., Fortney, Baker, & Levenson, 2009). However, such beliefs should obviously not be assumed or taken on faith. For example, as scientific evidence appeared, the sexual offender field shifted from a reliance on unstructured clinical judgment (clinical intuition) to a reliance on

empirically validated risk assessment approaches. Similarly, as with any intervention for a serious behavioral problem, the effectiveness of psychotherapy for sexual offenders should be clearly and consistently demonstrated by scientific study. Olver, Stockdale, and Wormith (2011) emphasized that the central purpose of offender treatment programs is reducing the recurrence of future criminal acts; thus, the primary purpose of sexual offender treatment is to affect a reduction in sexual offense recidivism. As Hanson et al. (2002) wrote: "If treatment is to be widely used in the management of sex offenders, then it is important that it works." As the Association for the Treatment of Sexual Abusers (ATSA, 2008, p. 1) has noted, treatment for sexual offenders is significantly different than that for other clients because of "a focus on the harm causes to the victims, the protection of future victims and the prevention of re-victimization" (emphasis added). For many psychological conditions or disorders, the evidence for the *efficacy* of psychotherapy is much more limited than often assumed or believed. While psychosocial treatments have been demonstrated to affect positive outcomes for some "emotionally distressed" persons, there is far less evidence that they have substantive short- or long-term effects for those with multiple or more severe "behavioral problems" that have led to significant impairments or distress. There is also evidence that beyond being ineffective, some psychosocial interventions may actually create "harm" for clients and society (e.g., Lillenfeld, 2007; Arkowitz & Lilienfeld, 2006). Thus, for a number of important reasons, MHP who provide psychotherapy for sexual offenders should have an accurate view regarding the empirical evidence that exists regarding the degree of effectiveness of the services they provide to sexual offenders. Other stakeholders concerned about sexual offending should also possess accurate knowledge about whether scientific evidence exists that sexual offender treatment might be effective.

Some may assume that the sexual offender who ends up as a participant in sexual offender treatment is the only client in that process. However, unlike other presenting problems, for sexual offending, most commonly there are several other "clients" invested in the importance of effective management of that problem. In addition to the sexual offender, the community is also a primary client of sexual offender treatment because ineffective treatment can directly create significant risks and consequences for public safety; unsuccessful sexual offender treatment may lead to additional future sexual offense victims. As Berliner wrote in 2002: "The big difference for sex offender treatment is that the price of failure is the victimization of an innocent person rather than continued suffering by the client" (p. 196). Similarly, Hall (1995) wrote: "…the expectation of psychological treatments for sexual offenders is no recidivism because of the serious effect of even a single act of sexually aggressive behavior. Every act of sexual aggression adversely affects a person other than the perpetrator…" (p. 802). Moreover, the degree and relative persistence of harm that results from various forms of sexual offending can be profound; as Marshall et al. (2003) stated, such effects can be "devastating." This is a relatively unique state of affairs relative to almost all other types of mental health presenting problems where the consequence of ineffective treatment is primarily borne by the individual with the problem, leading to personal distress or impairment. Forensic psychotherapy is typically defined as that which pertains to "justice-involved clients," where the clinical outcomes of interest are most often focused on rule-breaking conduct and the determination of treatment benefit is most focused on a relatively specific outcome, namely, future criminality or reoffending (Mitchell, Simourd, & Tafrate, 2014).

Thus, almost all psychotherapy with sexual offenders would necessarily be regarded as "forensic psychotherapy," commonly understood as the psychological treatment of persons who have committed violent or aggressive offenses against others or themselves, who are often ordered into a therapeutic setting by the legal system, and who have particular sets of psychological and/or psychiatric characteristics that, to a large degree, define their criminogenic and treatment needs.

Further, to the extent that psychotherapy for a sexual offender is either required or funded by someone other than the offender, those sources are also a client. Certainly, public (government) and private (e.g., health insurance) funding sources of mental health programs are increasingly focused on empirically demonstrated effective interventions or evidence-based practice as a bottom line criterion for committing resources to publicly or third-party-funded interventions. Particularly, in times of limited economic resources, it seems unlikely that funding will be provided for treatment programs unless there is clear evidence of substantive effectiveness. Similarly, in addition to the primary victims of subsequent acts of sexual offending, other persons ("secondary victims") and entities bear the personal and financial responsibility of providing support and short- and long-term care and services for the effects experienced by the primary victims. In addition, almost all sexual offender treatment in North America is either explicitly or implicitly mandated by the criminal justice system; thus, again, it would be most appropriate to refer to sexual offender treatment as a form of forensic psychotherapy. Clearly, it is essential that all stakeholders relative to the management of identified sexual offenders—those persons involved in managing sexual offenders (particularly those who provide psychotherapy), those who are existing or potential direct victims or affected parties of sexual offending, and those entities that provide the funding for sexual offender treatment—have an accurate understanding of the nature and effectiveness of the existing

scientific literature on psychosocial treatment of sexual offenders.

Given the broad set of stakeholders involved with and affected by the effective management of sexual offenders, the issue of the relative value of sexual offender treatment as a component of that management system is of great significance. Unfortunately, the utility of psychotherapy for sexual offenders may, at best, be viewed as at a crossroads. For more than 30 years, there has been genuine and well-founded controversy about whether such interventions produce substantive and lasting changes for sexual offenders related to the prevention of future acts of sexual offending or reduced sexual offender recidivism. Relative to the conventional standards utilized to gauge treatment outcome studies, the existing scientific evidence does not yet provide support for the proposition that psychotherapy is an effective primary agent for "treating" or "changing" sexual offending or to reduce their potential for sexual reoffending. A series of reviews, including meta-analyses, have suggested—at best—"limited" or "cautious" evidence for the effectiveness of available psychosocial programs of sexual offender treatment for the typical sexual offender, at least as measured by the reduction of future sexual offense recidivism. That is, as even proponents of the efficacy of sexual offender treatment admit, the general results of studies of varying rigor have demonstrated only "small," qualified positive outcomes for such interventions for select sexual offenders. Further, such proponents acknowledge that the evidence for such "small," "promising" effects relies exclusively on scientifically "weak" studies and that the more rigorous scientific studies of sexual offender treatment have failed to show an effect of intervention. Even the Association for the Treatment of Sexual Abusers (ATSA) concluded in 2010: "After 50 years, the field of sex offender treatment cannot, using generally accepted scientific standards, demonstrate conclusively that effective treatments are available for adult sex offenders" (p. 1).

It is also important to consider broader contexts relative to the failure to demonstrate effectiveness of psychotherapies for sexual offenders. As Lilienfeld (2011) has pointed out, "Data indicate that large percentages of the general public regard psychology's scientific status with considerable skepticism…" (p. 1); he notes that the widespread and long-standing public skepticism of psychology reflects the mental health profession's failure to police itself and its problematic public face reflects the failure of the professional mental health field "to get its own clinical house in order and winnowing out the elements of our profession that are scientifically dubious, some of which have tarnished our hard-fought credibility…" (p. 125). As a function of some of these issues, the field of psychotherapy is facing an increasingly uncertain future, specifically the diminishing perceived value and utilization of psychotherapy. At a time when the demand for mental health care is actually growing (almost doubling in the past 20 years), substantially less of it is being provided by nonmedical providers such as psychologists, social workers, etc. Very recently, several articles have pointed out that the field of nonmedical mental health providers has not made a convincing case for the use of psychosocial interventions and, in fact, by largely disavowing the need for evidence-based (largely scientifically evaluated) psychotherapies and effectively abandoning the mental health field to pharmacotherapy. Gaudiano and Miller (2013) noted that psychotherapy use is on the *decline* despite overall *increased mental health utilization*. They noted that from 1998 to 2007, there was approximately a 5 % decline in the use of psychotherapy alone and 8 % decrease in the use of psychotherapy with adjunctive medication. Several years ago, Baker, McFall, and Shoham (2009) pointed out that the lack of adequate training in and acceptance of the science of psychotherapy was leading to a greatly diminished role for psychotherapy in the mental health treatment field. In particular, they point to psychologist's preference for valuing personal experience over research evidence—a "prescientific" perspective—as flying in the face of the evolution in health-care decision-making which places a premium on converging evidence that "a treatment is efficacious, effective-disseminable, cost-effective, and scientifically plausible" (p. 67). Similarly, Gaudiano and Miller place the responsibility for this decline in the utilization of psychosocial interventions primarily on psychotherapists' tendency to rely on "personal experience" and "intuition" in performing their clinical work. Gaudiano and Miller argue that psychologists and other psychotherapists' rejection of the principles of evidence-based practice largely stand in contrast to psychiatry's training and practice model with its presumptive reliance on evidence-based medication research, primarily controlled studies involving random assignment of clients and similar scientific practices. Moreover, they point out that "the train has already left the station," stating:

> …as psychologists hem and haw about potential constraints placed on psychological practice by increasing scientific standards, and thus resist the notion of more prescriptive treatment approaches, the health care system has already adopted such an approach, is implementing it, and is holding psychologists accountable to it through reimbursement restrictions. (p. 816)

Thus, in the private sector, personal experience and judgment about "what works" with clients is being accorded increasingly little role in the endorsement of interventions. Moreover, psychotherapists and psychotherapies for various types of clients are progressively and increasingly rapidly being disenfranchised and excluded from possible treatment possibilities as a result of clinicians' rejection or ignorance of currently available accepted empirical evidence and other supportive information related to such evidence-supported therapeutic practices.

Unfortunately, as a result of this longstanding failure to demonstrate clear effectiveness for psychosocial treatment, both policy makers and the more general community either are or are likely to be appropriately skeptical about practitioners' claims for sexual offender treatment effectiveness. In turn, the lack of demonstrated efficacy for psychotherapy for sexual offenders may increase reluctance to allow select sexual offenders to avoid incarceration or be released earlier from incarceration simply because they "participated in" or "completed" treatments, without scientific evidence that has demonstrated that such treatment results in decreased risk for sexual offense recidivism or relevant offender change. Further, in the absence of scientifically demonstrated results, the public and government stakeholders have been and are increasingly disinclined to endorse funding for the research of and/or implementation of existing or more novel programs of sexual offender treatment. In short, the relative role of psychotherapy as a component of a broad management approach for general sexual offenders necessarily remains in question.

This chapter is intended to provide a relatively straightforward, reasoned, and accessible review of the existing findings and issues regarding psychotherapy for sexual offenders. First, a brief synopsis of the research literature regarding psychotherapy in general shall be presented. Both the accepted methodological practices utilized in studying the effectiveness of psychosocial treatment as well as the results of the extant psychotherapy outcome literature will be summarized. Such a review provides a context for viewing the parameters for the more specific research literature on sexual offender treatment outcome. Second, the primary systematic reviews and meta-analyses of sexual offender treatment will be examined. The consensus of these reviews would appear to best be summarized as suggesting that to date the general efficacy of sexual offender treatment has not been scientifically demonstrated; few or no claims can be made for the "success" of such interventions. Third, a critical analysis of the methodological issues and inadequacies related to results of existing treatment research will be presented that provides perspective on the failure to yet demonstrate the effectiveness of sexual offender treatment.

The Nature, Methods, and Findings in General Psychotherapy Outcome Research

Methodological Principles in the Scientific Investigation of Possible Outcomes of Psychosocial Interventions

The available research on psychotherapy has been periodically summarized in the five sequential editions of the Handbook of Psychotherapy and Behavior Change, originally edited by Bergin and Garfield (1971, 1978, 1986, 1994) and more recently by Lambert (2004, 2012). Kazdin (1986, 1994); Kendall, Holmbeck, and Verduin (2004); and others have described the nature of how models or theories of psychosocial intervention should be examined via a program of research that could delineate if and how psychosocial treatments might be effective with particular types of patients. Historically, the essential question for the scientific study of the effectiveness or efficacy of psychotherapy involves a scientific or empirical investigation to determine for persons with a particular presenting problem who want treatment: (1) whether the "average" person who participated in a particular treatment program had a better outcome than the "average" person who did not participate in that treatment *and* (2) if a benefit is observed, is it due to the intervention itself (or other factors). The goal of psychotherapy outcome research is initially to determine whether evidence can be obtained or demonstrated that particular treatments have *specific* effects, that is, an effect above and beyond those placebo/expectancy effects of those of nonspecific or common factors. Chambless and Hollon (1998) characterized psychotherapies as being efficacious if they work better than no treatment and as being specific if they are demonstrated to work better than nonspecific controls or credible alternative interventions. Hollon and Beck (2013) suggested that the term superior be applied when a given treatment outperforms all other viable alternative interventions.

According to both Kazdin (1986, 1994) and Kendall et al. (2004), as for other treatment outcome research methodologists, the essential approach to study of if and how psychotherapy might be efficacious is through randomized controlled trials (RCTs) of an intervention hypothesized to benefit a clinical population. Following the methodology of basic experimental science, a proposed psychosocial treatment approach is first studied or tested under specified controlled conditions; this provides an opportunity to determine the *effectiveness* of a proposed treatment approach—does it work with a relatively homogeneous group of persons with a similar presenting problem who are actively seeking (voluntary) treatment to address the presenting problem? Initially, such comparisons are typically conducted with more homogeneous individuals with the targeted presenting problem and may be comparable to other persons with more complex presentations or circumstances. Thus, Kendall et al. identified that to be most useful, treatment outcome studies required a controlled comparison of a specified intervention technique or program, with randomly selected clients exposed to the experimental treatment and control group(s) composed of relatively identical persons not exposed to that particular intervention. The first objective of outcome research is to determine if any consistent change occurs for persons receiving a positive treatment outcome relative to those not receiving that treatment [and not some unintended negative consequences as can happen (e.g., Rice & Harris, 2003;

Seto et al., 2008)]. Thus, some interventions may not result in desired change for clients as manifested on the relevant outcome measures of the presenting problem.

If treatment appears to show a benefit for those who participated under controlled conditions, an additional key objective is to determine if that change is, in fact, related to the specific treatment itself as opposed to other factors (e.g., spontaneous remission or the passage of time, dissimulation by clients, receiving a therapist's attention, the experience of repeated assessments). Such possible extraneous factors need to be "controlled" in a research study in order for one to have confidence that the treatment itself was responsible for any observed change. A control group provides the key means of potentially controlling for some factors (like characteristics of the subjects) that might be related to the outcome regardless of the experience. Consequently, a key issue in general psychotherapy treatment outcome research (similar to medication treatment studies) is to utilize a *control condition or group(s)*, particularly one that accounts for obvious potentially confounding factors such as client expectations or nonspecific factors related to interacting with a therapeutic agent. A "no treatment" control condition still may not protect findings from potentially confounding factors of an active treatment such as the anticipation of treatment, expectancy for change, and/or the act of meeting with a therapist. Even the so-called attention-placebo or nonspecific treatments, which may provide a reasonable measure of positive expectancy, may not be comparable to a condition where therapists provide a specific intervention to which they may be committed to ("believe in") as an effective treatment. Typically, only an alternative treatment condition (e.g., treatment as usual, another specific model of treatment) allows for controlling for nonspecific effects of treatment such as the length of treatment or client and therapist expectancies. Ideally, a treatment outcome study would involve at least three groups: a group that receives the treatment believed to produce a desired outcome, a group that receives an alternative credible intervention, and a group that does not receive any substantive intervention.

Almost all empirical, controlled studies begin with clients who are relatively compliant and motivated individuals; in addition, the treatment recruitment and delivery process typically induces expectancy bias for participants as well as their therapists. Given the possibility that client characteristics may strongly influence the outcome of an intervention, beyond controlled comparisons, the *random assignment* of clients in controlled psychotherapy trials is viewed as the second critical factor in treatment outcome research to ensure initial comparability between treatment and control groups. Random assignment of persons who are interested and motivated to address a particular presenting problem should eliminate unwanted potential effects of extraneous factors [demographic variables (such as age, socioeconomic status, intelligence, education, and so on) as well as more substantive factors (such as the nature and degree of likely risk factors)]. Obviously, it would be problematic to allow the subjects themselves to select whether they are exposed to a particular experience or not exposed to a particular experience; the motivation and/or expectancy to either be exposed or not be exposed to the particular experience (or related characteristics) might determine the treatment outcome of participating subjects. Consequently, as Kendall et al. (2004) wrote:

> …comparisons of persons randomly assigned to different conditions are required to ensure control of the effects of factors other than the treatment. Comparable persons are randomly placed into either the control condition or the treatment condition, and by comparing the changes evidenced by the members of both conditions, the efficacy of therapy over and above the outcome produced by the extraneous factors can be determined. (p. 19)

Then, "When treated clients evidence significantly superior improvement over non-treated clients, the treatment is credited with producing changes. This control procedure has desirable features and eliminates several rival hypotheses…" (p. 19). At the same time, randomization does not guarantee comparability, and the actual comparability of the participants in the treatment and control conditions should be examined. However, while the random assignment via RCT does not absolutely assure absolute comparability of the control and therapy conditions on all measures, it does maximize the likelihood of comparability. That is, randomized and controlled trials offer the best research design strategy for distributing pretreatment differences randomly; effectively, only randomization can eliminate the subtle selection biases that affect even the best alternative study designs. Almost all independent medical research groups (such as the Cochrane Collaboration) as well as various policy-making entities, including the US Center for Disease Control and Prevention and the US Food and Drug Administration, define and determine effective interventions based on the results of RCT. Further, as Howard et al. (1996) wrote, given the high degree of experimental controls imposed by RCT design: "…it is quite rare that a randomized experiment fails to conclude that the experimental treatment works" (p. 1060).

In addition, another preferred method for treatment outcome research involves the "intent-to-treat" design. That is, in more contemporary psychotherapy treatment outcome studies, the experimental or treatment group consists of *all* persons originally assigned to that group, whether or not they complete the intervention (e.g., those who complete and those who drop out of an assigned treatment or control group). The degree to which persons are retained in and complete the assigned treatment is considered an important aspect of the outcome or results of the treatment comparison; a treatment that loses a significant number of participants

and succeeds only for some persons would not necessarily be considered a successful or effective intervention (although it might provide useful information about which persons are most and least responsive to a particular treatment). Consequently, the outcome for individuals who drop out of or are terminated from treatment is typically counted as part of the intervention group's results. Thus, methodologically superior treatment outcome studies utilize "intent-to-treat analyses where the treatment group consists of all persons who began the treatment, including those who technically completed the program as well as those who dropped out after being assigned to the treatment group" (e.g., Chambless & Holon, 1998).

Standards exist and have achieved wide acceptance concerning the determination and rating of the methodological quality of treatment outcome research. For example, Sherman et al. (1998) developed a scale of methodological rigor, known as the Maryland scale, to provide a clear perspective on the quality of the scientific quality of crime prevention programs. The scale provides an assessment of the quality of the research design and whether study results can reasonably be used to draw conclusions about the effectiveness of sexual offender treatment. Thus, per the Maryland scale, a score of "1" indicates that a correlation exists between a treatment program and an outcome measure, a score of "3" indicates that the study included an intervention group and a comparison group, and a top score of "5" indicates that the study used both random assignment and an analysis of comparable intervention and comparison groups.

Once the *effectiveness* of a particular psychotherapy approach is initially established under controlled conditions to limit potential methodological confounds, the outcome comparison is typically the subject of attempts to replicate or cross-validate the results, ideally by other investigators than those who initially developed and tested the approach. Assuming multiple successful replications from RCTs performed by scientists of varying allegiance to that approach, the experimental intervention is tested with RCTs in more naturalistic situations with clinically representative clients with the primary presenting problem (e.g., those outside of university research settings, typically with more complex presentations and/or severity). Thus, once robust evidence exists that a psychosocial intervention is effective in RCTs (under more controlled conditions), the intervention can be systematically tested with an expanded group of clients with the presenting problems (e.g., those with more severe or comorbid conditions). At that point in time, modifications of treatment procedures may also be tested under controlled conditions to optimize the potential outcome with more heterogeneous clients. If positive outcomes consistently result in more naturalistic or clinically representative settings, then the psychosocial intervention is said to have demonstrated *efficacy*.

In the 1990s, the general psychotherapy field moved to endorse a model of Empirically Supported Therapies (ESTs). As Arkowitz and Lilienfeld (2006) noted, this move was fueled by several considerations. First, ESTs are argued to protect clients against "a seemingly endless parade of fad therapies of various stripes…" (p. 45), a number of which have been found to be ineffective or even harmful. Second, ESTs are viewed as performing a quality control function for health-care agencies and policy makers to make scientifically informed decisions about which treatments should be reimbursed; "By placing the burden of proof on a treatment's proponents to show that it is efficacious, the EST list helps to ensure that therapies promoted to the general public have met basic standards" (p. 45). In 2005, the American Psychological Association (APA) issued a policy statement regarding evidence-based practice (EBP) in psychology, stating: "Evidence-based practice in psychology (EBPP) is the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (p. 13). They noted that this was similar to the definition of evidence-based practice adopted by the Institute of Medicine in 2001, where evidence-based practice (EBP) was defined as the integration of best research evidence with clinical expertise and consideration of patient characteristics; it was recommended that therapists determine the applicability of available research conclusions to the needs of particular help-seeking clients; thus, treatment should involve the application of available research evidence with probabilistic inferences for help-seeking clients based on current scientific knowledge.

To What Degree Are Psychosocial Treatments Generally Effective?

To provide a context for considering the effectiveness of sexual offender treatment, it obviously makes sense to consider to what degree and in what ways psychotherapies are effective in the broader field of mental health problems. There has been a long controversy as to whether psychotherapy as a type of interventions has been demonstrated to be effective. Thus, in 1952, Eysenck published a review of 24 studies and concluded there was no research evidence to support the effectiveness of persons participating in psychotherapy compared to groups not participating in psychotherapy. In contrast, since Eysenck's publication, most studies evaluating the outcome of psychotherapy have been more positive despite the increasing methodological rigor that characterized those studies.

Subsequent to Eysenck's review, meta-analyses (MA) or analyses not of subjects but of existing studies began to appear. In MA, statistical methods are used to obtain a quantitative estimate of the overall or cumulative effect of a set of existing interventions on an outcome. By combining results of multiple smaller studies (e.g., in terms of sample size) and weighting them by size, it is hypothesized that the combined

results (now based on a larger number of subjects) provide greater power and might allow for identifying "effects" across studies that might be missed in individual studies, particularly those with small numbers of subjects. In addition, a potential strength of meta-analysis comes from the use of a standardized unit to compare outcomes from studies that may use different measures and by averaging effect sizes across different studies and comparisons. This increases the effective sample size for investigation and potentially minimizes the influence of extraneous factors in individual studies. Such a practice allows for a more precise evaluation of the efficacy of treatment programs. However, as Lambert (2013) pointed out: "Meta-analysis is not a panacea and cannot be used to create worthwhile information if it's based on poorly designed studies or is biased" (p. 206).

As meta-analytic statistical techniques emerged, reviews of the expanding literature on psychotherapy have been subjected to a more sophisticated quantitative analysis. However, clear evidence that psychotherapy was associated with positive outcomes for general mental health problems did not emerge for 30 years after the Eysenck study. Smith et al. (1977, 1980) conducted a particularly significant MA of the extant psychotherapy literature. They analyzed more than 475 studies and demonstrated that the effects of psychotherapy were superior to no treatment and to placebo control conditions, typically for clients with some form of emotional distress or "neurotic" condition. Lipsey and Wilson (1993) reviewed 302 meta-analyses of a range of psychological, educational, and behavioral treatment and found a strong positive effect. They utilized more stringent criteria to examine a limited sample of studies (156 meta-analyses) and found that the average treatment effect size was 0.47.[1] They concluded that the evidence from this MA indicated that psychosocial treatments "generally have positive effects" (p. 141) on those who participated in them relative to a control condition.

However, based on an earlier analysis of the literature, Shadish et al. (1997) suggested that previous meta-analyses had overestimated the effects of treatment because they calculated *unweighted* effect sizes, which gave more importance to studies with larger N's. Thus, they recalculated the effect sizes for the Smith et al. (1980) data set and found an effect size of 0.60 (a medium effect) as opposed to the 0.85 effect size (a large effect) originally reported by Smith et al. (1980), and Wampold et al. (1997) also reanalyzed previous meta-analyses and noted that the effect size of psychotherapy compared to no treatment was 0.82 (considered a large effect); however, the effect size of psychotherapy compared to a placebo condition was 0.48, and the effect size of placebo vs. no treatment was 0.42. Thus, the relative effectiveness of psychotherapy was reduced to a medium effect when compared to placebo condition; further, a placebo condition, in and of itself, produced a medium-sized effect. These results suggested that a significant mechanism for the positive effects of psychotherapy was nonspecific and that, for predominantly emotional problems (such as anxiety or depression), positive benefits of psychotherapy may be largely due to factors such as clinical attention and/or expectation of change. Westen et al. (2005) pointed out that when investigators have compared two bona fide intent-to-succeed treatments, the outcome effects are generally small (e.g., an average ES or d of 0.20). That is, when two meaningful interventions are compared to one another (as opposed to a no treatment condition), the effect size was substantially reduced for clients.

Lambert and Ogles (2004) concluded that studies that were representative of clinical settings and conditions (e.g., more varied clients with comorbid conditions) appeared to produce generally similar effects to those that were not representative of clinical conditions. However, they also noted that higher-quality RCTs of treatment for actual clinical conditions were generally lacking; most extant positive studies for psychosocial interventions were conducted in research settings with more pure and circumscribed client samples. Most recently, Lambert (2013) wrote: "From 40 to 60 % of clients show a substantial benefit in carefully controlled research protocols, *although far fewer attain this degree of benefit in routine practice*" (p. 204, emphasis added).

Another critical question regarding psychotherapy concerns whether clients maintain whatever measured "gains" or initial response that they are reported to have made in treatment. Nicholson and Berman (1983) conducted the earliest and most influential meta-analysis regarding follow-up outcome of persons treated with psychotherapy. In their study of 67 studies, while noting some divergence in the studies, they reported that treatment gains were maintained (largely for the treatment of problems of emotional distress). Later, however, Lambert and Ogles (2004) identified several methodological concerns that prevent reaching broad conclusions about the maintenance of treatment gains. First, they noted that client attrition from the end of treatment to follow-up data collection was a critical issue (as well as attrition during treatment itself); that is, a significant number of persons who participate in treatment studies either leave the study during or after the controlled intervention phase. Consequently, only smaller groups are available for study at points distal to the end of psychotherapy. Second, in the majority of cases, most studies do not continue to follow subjects in control groups after treatment ends making follow-ups "naturalistic" (and *not* controlled or "comparative"). Westen and Morrison (2001) found that only 36–38 % of persons treated for depressions remained improved at a 2-year follow-up and that there were low levels of "sustained efficacy"; if those individuals who began but did not complete psychotherapy were included for study, the improvement rate dropped to approximately 25 %. They noted that

[1]Cohen (1992) identified the benchmarks for effect size for comparing independent means as 0.20 (small), 0.50 (medium), and 0.80 (large).

the available follow-up results were worse for clients with anxiety disorders. Westen and Morrison (2001) argued that psychotherapy provided to relatively pure samples of depressed and anxious clients, with rigorous inclusion and exclusion criteria, results in improvement/initial response of pathological states (as distinguished from disorders) which was approximately 50 % for those persons who complete psychotherapy but that the majority of clients do not show sustained improvement over 1–2 years, particularly for "generalized affective states." That is, the average client will maintain a mild but clinically significant level of symptoms after intervention, but "a substantial number of patients will continue to be highly symptomatic" (p. 885).

At best then, the available evidence suggests that various types of psychosocial interventions are somewhat effective in treating persons with relatively unidimensional presenting problems of emotional distress (primarily for anxiety and depressive conditions) most commonly found in typical clinical practice (i.e., for which people seek treatment). However, the evidence for the effectiveness of psychotherapy for more severe problems is much less clear. Compared to treatment for more circumscribed problems such as emotional distress, Lambert and Ogles (2004) showed that the average effect size for efficacy is much lower (e.g., approximately 50 % lower) for more severe problems such as schizophrenia, alcoholism, and delinquency and for persons characterized by "social detachment." Lynch, Laws, and McKenna (2010) in a meta-analysis of well-controlled RCTs found that CBT was not effective in reducing symptoms or preventing relapse for schizophrenia or in reducing relapse in major depression or bipolar disorder. Even in the treatment of major depression, they found that the effect size for reducing symptoms was small. Hollon and Beck (2004) concluded: "It remains unclear just how effective CBT (including relapse prevention) is in the treatment to substance abuse. It typically outperforms minimal treatment control, but is has a more inconsistent record relative to attention placebos and rarely exceeds alternative interventions" (p. 474). As noted, Kopta et al. (1994) showed that patients with significant characterological issues (e.g., maladaptive personality traits or personality disorders) required much "stronger" doses of treatment over a longer period of time prior to showing symptomatic improvement (e.g., treatment sessions that were more frequent and of longer duration); similarly Tyrer and Johnson (1996) also showed that clients with comorbid personality disorders have the highest initial levels of symptoms and improved the least over follow-up. Clarkin and Levy (2003) reported that clients with a greater number of personality disorder traits also had difficulty staying in active treatment and would drop out at a higher rate. Multiple reviews of the treatment of personality disorders, particularly Borderline and Antisocial Personality Disorders have found no or little scientific evidence that such conditions can be treated efficaciously (e.g., Binks et al., 2006; NICE, 2009a, b; Duggan et al., 2007; Gibbon et al., 2010; Stoffers et al. 2012). Further, in general, available studies show that individuals with maladaptive traits or personality disorders have much higher relapse rates when compared to patients with no such comorbid problems. In addition, methodological problems of lower power and attrition are more common among across studies of persons with more severe and/or chronic problems. While it can be said there is some evidence for psychotherapies involving persons with severe or chronic problems having a relatively positive effect on some elements of their problems and on "satisfaction" with the therapy experience, in a significant number of cases, "treated" clients continued to manifest ongoing symptoms of varying degrees of severity and/or to convert to other significant psychiatric conditions.

Currently, there is little evidence that any specific type of psychotherapy [e.g., cognitive-behavioral therapy (CBT)] is more effective than another therapy, particularly when the allegiance (expectancies of treatment success) of the investigator and study therapists is controlled. Wampold et al. (1997) and Wampold (2001) in reviewing their own MAs and those of others concluded that there was little evidence that specific ingredients are necessary to produce change as a result of exposure to psychotherapy. [Note that many of these studies involved the treatment of emotional distress, again typically anxiety or depression.] In a later MA, Wampold et al. (2002) also found that CBT was not more effective than other bona fide (credible) psychotherapies for unipolar depression and that all bona fide psychological treatments were equally effective in mood improvement. In their review in 2004, Lambert and Ogles concluded: "There is a strong trend toward no differences between techniques are modes in amount of change produced which is counterbalanced by indications that, under some circumstances, certain methods (generally cognitive behavioral) or modes (family therapy) are superior" (p. 164). They concluded that extant research "shows surprisingly small differences between the outcomes for patients who undergo a treatment that is fully intended to be therapeutic" (p. 164). With some exceptions, research generally supports that somewhat greater effectiveness of CBT over alternative psychotherapies has been demonstrated for clients with anxiety or depressive disorders and particularly for individual but not group psychotherapy. However, the mechanism of action for such outcomes is unclear regarding CBT. Per Longmore and Worrell (2007), review of CBT identified three empirical anomalies in the CBT empirical literature:

> Firstly, treatment component analyzes have failed to show that cognitive interventions provide significant added value to the therapy. Secondly, CBT treatments have been associated with a rapid symptomatic improvement prior to the introduction of specific cognitive interventions. Thirdly, there is a paucity of data that changes in cognitive mediators instigate symptomatic change…. A comprehensive review of component studies finds little evidence that specific cognitive interventions significantly increase the effectiveness of the therapy…. Although evidence for the early rapid response phenomenon is lacking, there is little empirical support for the role of cognitive change as causal in the symptomatic improvements achieved in CBT. (p. 173)

> More generally, collectively, research findings indicate that substantive behavioral change both precedes and lays the foundation for later cognitive change. Finally, it must be noted that very recent evidence suggests that modern CBT clinical trials appear to provide smaller decreases in depressive symptoms as compared with earlier research trials.

Measurement of clinical change has also been problematic in the general psychotherapy outcome literature. The percentage of persons considered "improved" has been shown to have more to do with particular rating scales and sources of information (e.g., global, self-report ratings) rather than actual behavioral change (e.g. Hill & Lambert, 2004). When more specific problems and behaviors were rated for change, there is less evidence of significant change or improvement. Weiss et al. (1996) reviewed 41 studies and found a basic lack of agreement regarding the nature of improvement; when agreement between client and therapist was found, it was not high. Both Pekarik and Guidry (1999) and Rosenblatt and Rosenblatt (2002) reported very similar results. In contrast, agreement was higher between clients and external raters or judges, clearly suggesting that clinicians were poor judges of treatment-related behavioral change (e.g. Johnson & Friberg, 2015). In other research, Gregerson et al. (2001) looked at ratings of treatment made pre- and posttreatment. They found that the difference in the size of treatments of pre- and posttreatment suggests that retrospective (post) evaluations of treatment change "overestimated treatment effects" by a *factor of two* compared to actual pre-/post-measurements. "Life records" and real outcome measures would be considered to be the least reactive of available assessment methods. Hill and Lambert (2004) noted that differences in outcome results have been found to be a function of a source (e.g., client, therapist, expert judges, and significant others) and not content (the actual functioning of a client). They concluded that therapist ratings of treatment outcome and global ratings of change are associated with an illusory "perception of greater effectiveness" of treatment compared to more specific and more distal measures. In their review, Hill and Lambert also pointed out that data from therapists who are aware of the treatment status of clients produce larger positive ratings than those from virtually all other sources. Similarly, they found that global ratings of change produce larger estimates of change than ratings on specific dimensions, symptoms, or problem areas and that proximal ratings lead to more positive ratings of change than distal ones. Physiological measures, in contrast to those by therapists or "unblinded" evaluators (those who know the treatment status of the client), typically show small effects of treatment, even when they are the targets of treatment. They noted in their review that global ratings of treatment goals are characterized by multiple methodological problems. Among them were high correlations among goal ratings (a "halo" effect); the use of relative perceived goal change as opposed to absolute, well-defined, standardized criteria for change; and a confounding between therapist expectancy and their ratings. They recommended that to the extent, global ratings are utilized to measure outcome that follow-up evaluators be as independent as possible from therapists/goal setters so that there is maximal independence of and objectivity in ratings.

Other issues have been identified relative to determination of aspects of the effectiveness of psychotherapy. There has been a consistent finding in the general treatment outcome literature that the investment of a researcher/therapist to a particular model of intervention accounts for a significant amount of the measured outcome in treatment studies that find particular interventions effective. Recently, Munder et al. (2013) conducted a MA of 30 studies of Researcher Allegiance (RA). They found that the mean RA-outcome association was statistically significant ($r = 0.26$) corresponding to a moderate effect size and that this relationship was robust across several moderating variables including characteristics of treatment, population, and the type of RA assessment. Munder et al. concluded that the RA-outcome association is substantial and robust. In addition, Lambert and Ogles (2004) reviewed several large treatment outcome studies that attempted to "dismantle" or study components of interventions. Results indicated that treatment outcome was not related to which specific components clients received or the acquisition of skills (symptoms improved before skills training and potential behavioral change). More recently, a meta-analysis was conducted on both additive and dismantling studies, which examined their effect both at the end of formal treatment and at follow-up. Bell et al. (2013) found that for dismantling studies, there were no significant differences between the full treatments and the dismantled treatments. For additive studies, the treatment with the added component showed a small but significant effect at completion and a large effect at follow-up. However, this was only true for specific problems that were targeted for intervention. Thus, some specific intervention components, directly related to the primary treatment target, made only a modest contribution at outcome. In short, other than investigators "finding" what they expect or want to, there are significant questions about what elements of psychotherapy "matter" or "work" relative to "symptom relief" or "behavior change."

In research settings, treatment dropout or attrition has averaged to 47 % and is even higher in actual clinical settings (e.g., Lambert & Ogles, 2004); per a meta-analysis, approximately 47 % of patients dropped out of psychotherapy (Wierzbicki & Pekarik, 1993). Clarkin and Levy (2003) identified that clients with maladaptive personality traits (such as those with personality disorders) were at high risk for premature dropout, with dropout rates varying from 40 to 67 %. Three client variables found to be particularly related to negative outcomes were overall problem severity at intake, interpersonal difficulties, and comorbid personality disorders

(e.g., Lambert & Ogles, 2004). Lillenfeld (2007) reported on a number of psychotherapies for specific problems that actually demonstrated harmful outcomes for clients. More generally, as many as 10 % of clients' problems worsen as a result of their participation in psychotherapy (e.g., Lambert & Ogles, 2004).

Research has also examined therapist and client variables related to treatment outcome. Lambert (1992) concluded in an earlier review that as much as 40 % of client improvement may be attributed to client variables and extra-therapeutic influences. Thus, number and severity of maladaptive personality traits and social detachment were also found to be associated with poor psychotherapy response (e.g., Clarkin and Levy, 2003). Some clinicians appear to be "outliers" in terms of their increased effectiveness as psychotherapists (Lambert & Ogles, 2004; Lambert, 2013); that is, in particular, it appears that specific therapists account for a disproportionate percent of "successful cases" in treatment outcome studies, leading to suggestions that there should be increased study of the "empirically validated therapist." Per Lambert and Ogles (2004), the importance of the so-called therapeutic alliance is a necessary but not sufficient condition for change in psychotherapy. They view the therapeutic alliance as a manifestation of the critical role of common factors in effective psychotherapy. However, they determined: "…we simply do not know enough yet about the therapist factor to specify when and how it makes a difference, nor when it matters more than technique" (p. 168). Similarly, Crits-Christoph, Johnson, Connolly Gibbons, and Gallop (2013) concluded:

> Despite extant research, there are mixed reviews on the importance of the therapeutic alliance in treatment outcome;" they pointed to a recent MA that found a "small to moderate relationship between the [therapeutic] alliance and therapeutic outcome (r=0. 27)." (p. 302)

Crits-Christoph et al. also pointed to research which suggests that early positive change in symptoms is the actual *cause* of a positive or improved "therapeutic alliance," as opposed to the opposite process.

Summary of Psychotherapy Outcome Literature

Relative to control conditions, psychotherapy has been found somewhat to be moderately beneficial for persons motivated for change in their lives, particularly for persons who seek treatment primarily because they themselves are disturbed by moderate to high degrees of emotional distress (e.g., they "feel badly"). For many persons who seek psychotherapy for anxiety or depression, the effects of treatment appear to be somewhat enduring (albeit these have typically been relatively "pure" clients by virtue of exclusion criteria that screen out significant—and typical—comorbidity, for example). In contrast, for persons seeking treatment to address more complex or severe behavioral problems, there is little to some evidence for the relative effectiveness of psychotherapy typically for particular features of those conditions (and not necessarily changes in key signs or symptoms). In general, greater problem severity and chronicity, comorbid psychiatric conditions (in particular, maladaptive personality traits), and functional impairment in everyday life were each associated with decreased response to psychosocial treatments. Researcher allegiance appears to account for a significant amount of variance in outcome; those invested in a particular intervention are more likely to find it effective. There is *decreasing* evidence that *specific types* of psychotherapy produce differential degrees of improvement, including even the treatment of emotional distress. Thus, most interventions are equally effective for persons with emotional distress. Little superiority of CBT has been demonstrated for more severe and/or behavioral conditions. To be effective, psychotherapy needs to be provided in a sufficient dose relative to the severity of the individual's presenting problem; a greater number of and/or more severe problems require more intense and/or higher doses of psychotherapy. Clearly, client characteristics have a particularly significant role in or influence on the outcome or benefit realized in psychotherapy. Therapist characteristics also impact the outcome of psychosocial treatment for common presenting problems; some individuals appear to be much more effective with clients than other clinicians. In 1986, Lambert concluded that common (therapeutic) factors accounted for 30 % of the therapeutic effect, technique 15 %, expectancy (placebo-effect) 15 %, and spontaneous remission 40 %. More recently, Lambert (2013) suggested that improvement from psychotherapy is a function of the following four factors to the indicated degree: client/life situation (40 %), common factors (30 %), client expectancy (15 %), and (specific) techniques (15 %).

Key Reviews of Sexual Offender Treatment Outcome Reviews

General Systematic Reviews of Sexual Offender Treatment

Systematic reviews (SR) of treatment research involve a particular approach to the examination of scientific literature, one that attempts to identify and appraise available studies regarding interventions for a particular problem or condition. SRs include a clearly formulated question; use systematic and explicit methods to identify, select, and critically appraise relevant research; and collect and analyze data from the studies that are included in the review. Specific statistical methods (e.g., such as meta-analysis) may or may not be used to

analyze and summarize the results of the included studies. In most fields of medicine or mental health more specifically, SRs are limited to a focus on high-quality studies such as RCTs. In certain cases, SRs involve simply a sequential discussion of selected studies with a critical discussion of the apparent results across studies. A second type of review is, in effect, a subsection of systematic reviews and often relies on meta-analysis (as noted previously, a particular statistical technique which appraises the combined results of varied studies utilizing common metrics). It is worth noting that a recent review of 300 studies by Moher et al. (2007) found that all systematic reviews were not equally reliable. Moher et al. concluded that the quality of reporting in such reviews was often inconsistent. For therapeutic reviews, the comparison of Cochrane[2] and non-Cochrane reviews provided discouraging results and suggested little improvement in the quality of reporting of non-Cochrane reviews over time. It was found that many non-Cochrane reviews did not report key aspects of systematic review methodology. Further, strong evidence of bias in outcome reporting was noted for non-Cochrane reviews.

In the first modern SR of sexual offender treatment, Furby et al. (1989) found few well-designed studies of sexual offense recidivism, including those where offenders received specialized sexual offender treatment or generalized treatment. In particular, they noted that the most common design for studies they reviewed were single-group, posttest-only designs; these were investigations where a group of sexual offenders were provided treatment and a recidivism rate was determined for that group. Thus, these studies did not include a "no intervention" control group to compare sex offense recidivism rates for comparable sexual offenders who did not receive treatment. Furby et al. concluded that there is "as yet no evidence that clinical treatment reduces rates of sex reoffenses" (p. 27).

White et al. (1998) developed the first Cochrane review (CR) of "Managements for people with disorders of sexual preference and for convicted sexual offenders." White et al. attempted to identify all relevant randomized controlled trials and could identify only three methodologically sound studies of the type typically considered for medical efficacy treatments and only two of these were psychological interventions: Romero and Williams (1983) compared psychodynamic group treatment to probation, while the Sex Offender Treatment Evaluation Project (SOTEP) Marques et al. (1994) was the preliminary report of what would eventually be the largest RCT of CBT-RP specific to sexual offender treatment. White et al. concluded:

> It is disappointing to find that this area lacks a strong evidence base, particularly in light of the controversial nature of the treatment and the high levels of interest in the area…large, well-conducted randomized trials of long duration are essential if the effectiveness or otherwise of these treatments are to be established. (Abstract)

Alexander (1999) reviewed 79 studies of rates of sexual offense recidivism of sexual offenders ($n = 10, 988$) as a means of opining whether sexual offender treatment might make a difference in such recidivism. She explicitly rejected applying a meta-analytic approach due to methodological issues regarding the lack of standardized research designs, making it problematic to determine whether observed differences were the result of exposure to treatment or to other study or group differences (e.g., follow-up periods, offender samples, recidivism criteria, or other design features). Further, as she noted: "The current subject pool does not include subjects who dropped out or were terminated during the course of the treatment. Dropouts/non-completers were excluded due to the lack of consistency with which data on these subjects were reported in their various studies" (p. 103). Alexander reported a very *slight* difference in sexual offense recidivism in favor of treatment ($d = 0.12$). Again, the majority of studies included no control group let alone subjects randomized to treatment; thus, the treated and untreated sexual offenders (the "quasi" control group), in most cases, were from different samples. As a result, it was unclear what kind of comparative conclusion could be reached. Hanson et al. (2002) indicated that a valid criticism of Alexander's results was that there was too much method variance across studies to allow for clear conclusions.

In a SR, Gallagher et al. (1999) examined 25 published and unpublished studies on the effects of sexual offender treatment on sexual reoffending. Of these, 22 are related to adult sexual offenders. They found that 11 or 44 % of the studies included no comparison group and 9 or 36 % included "nonspecialized" treatment. Further, only 2 studies used random assignment (RCT), only 5 used subject level matching, and only 12 % included treatment dropouts. The authors conducted a meta-analysis but provided little detail of their particular methodology. Overall, they concluded that most treatment groups fared better than comparison groups relative to sexual offense recidivism. They found a "medium" effect size, but they also found that effect sizes varied greatly, "suggesting genuine differences in treatment effect estimates across studies" (p. 22). [Of note, they considered the earliest publication of the SOTEP study, which showed more promising results than the final version.] Gallagher et al.

[2]The Cochrane Collaboration consists of systematically reviewing randomized trials of the effects of varied health interventions. Cochrane reviews (CR) are viewed a scientific investigation in itself, with a preplanned method section and an assembly of original studies (predominantly randomized controlled trials and clinical controlled trials). The results of these multiple primary investigations are synthesized by using strategies that limit bias and random error. The Cochrane Collaboration provides a handbook for systematic reviewers of interventions across various mental and physical health domains. Over 150,00 RCTs exist in the Cochrane library, and they are recognized as a key resource in evidence-based medicine.

showed that neither the strictly behavioral nor the augmented behavioral treatment produced significant reductions in recidivism. They reported that cognitive-behavioral treatment programs appeared to be effective in reducing sexual offense recidivism. Gallagher et al. found no difference between studies using cognitive-behavioral therapy alone or with relapse prevention methods. They concluded that despite heterogeneity of effects and various methodological issues, there was "sufficient evidence" to suggest the effectiveness of CBT for sexual offenders. However, as Hanson et al. (2002) indicated, the Gallagher et al. review included six studies in which biases in favor of a treatment effectiveness might be expected; in addition, the Gallagher review was also based on the preliminary results of studies in which the final or later results were more negative for the same studies (e.g., SOTEP).

Grossman et al. (1999) attempted to review what they regarded as available key papers presenting data on outcomes for sexual offenders in treatment programs. They noted that generally results suggested that biological and psychosocial interventions appeared to reduce sexual offense recidivism. However, they concluded: "Although some forms of treatment for sex offenders appear promising, little is known definitively about which treatments are most effective for which offenders, over what time span, or in what combinations" (p. 358). "In particular, they noted that available findings appeared to suggest that the more high risk a sexual offender was, the less confident we can be that treatment will have lasting benefits" (p. 359). Grossman et al. urged caution in "unfolding the implications of the positive treatment findings in the literature," stating that while treatments exist and results indicate some potential, "They are, however, complex, difficult to interpret and cause for cautious optimism as best. If mental health professional and society at large are to accept the challenge of promoting treatment for sex offenders, vigorous ongoing research efforts are mandatory" (p. 359).

Also in another SR from 1999, Polizzi, MacKenzie, and Hickman (1999) observed that the "The recent reviews and meta-analyses concerning the efficacy of sex offender treatment provide conflicting viewpoints" (p. 370). They compared prison-based to community-based sexual offender treatment programs. A key feature of this review is that they utilized the so-called Maryland criteria to assess scientific rigor. Initially, they began with consideration of 21 studies. However, the investigators rejected 8 studies as "too low in scientific rigor," leaving just 13 studies to examine. Polizzi et al. identified that approximately 50 % of the remaining studies showed statistically significant findings supportive of sexual offender treatment in reducing sexual recidivism. Most of these studies employed a CBT approach to treatment. They concluded that community-based programs were "effective." However, they only identified two studies that they characterized as possessing "scientific merit" [one of child molesters (from 1988) and exhibitionists (from 1991)]. More importantly, in the studies examined in their SR, Polizzi et al. did not control for the effect of dropouts/refusers on the recidivism rates of untreated comparisons. They concluded that "non-prison-based sex offender treatment programs using cognitive-behavioral treatment methods are effective in reducing the sexual offense recidivism of sex offenders." Thus, they claimed community-based CBT for sexual offenders "works." In contrast, they concluded that prison-based programs using CBT were "promising," "but the evidence is not strong enough to support a conclusion that such programs are effective" (p. 20). Of note, the authors included the SOTEP study as a community-based program, whereas the participants were actually prison inmates whose treatment site was a state hospital. The authors noted that there were too few studies focusing on particular types of sexual offenders to draw conclusions about whether treatment was effective for rapists, child molesters, or "high-risk" sexual offenders. Polizzi et al. concluded: "Any conclusions drawn from this review must remain tentative. With a heterogeneous population, it is difficult to provide general conclusions about the effectiveness of sex offender treatment programs" (p. 372).

Bilby, Brooks-Gordon, and Wells (2006) conducted a SR of quasi-experimental and nonrandomized controlled trials with matched and non-matched controls, including 21 quasi-experimental studies from the UK, USA, Canada, and Europe. They noted that due to the wide variety of outcome measures, they felt that they could not conduct a meta-analysis. They pointed out that although the majority of these studies were matched studies: "The problem with type of study is that, to match successfully, investigators need to know about all the relevant factors which may influence outcome, and this is unlikely to be the case, leading to potential differences between experimental and control groups" (p. 470). They also noted that 13/21 studies did not specifically match participants and that control groups were drawn from very different samples. In a later article, Brooks-Gordon and Bilby (2006) wrote:

> Most participants in matched trials where a significant treatment effect was found were allocated to treatment groups according to sentencing decision and post-sentencing risk assessment. Most of these studies were matched retrospective trials carried out on offenders in the criminal justice system; matching was done retrospectively. Matching offenders with a control group is problematic and can threaten the quality of the research. The results here were equivocal: more studies found no statistically significant treatment effect than found a significant effect. (p. 5)

Bilby et al. (2006) found that 7 studies showed a statistically significant treatment effect and 10 did not, while in 4 studies the data were not clear enough for analysis.

Brooks-Gordon et al. (2006) conducted a SR of RCTs regarding the effectiveness of psychological treatments for

sexual offenders. They found nine RCTs (all reported before 1998 and totaling 567 offenders), 231 of which had been followed up for 10 years. They concluded: "Analysis of the nine trials showed the cognitive behavioural therapy (CBT) in groups reduced re-offence at 1 year compared with standard care ($n = 1{,}555$) but increased re-arrest at 10 years" (p. 442). They noted that if the Romero and Williams (1983) study had had only a few more rearrests in the intervention group, it could be suggested that treatment was less effective than doing nothing. Brooks-Gordon et al. wrote that their findings were "likely to be controversial as there is a huge investment in sexual offender treatment programmes, and many policymakers erroneously and unreservedly assert that sexual offender treatment therapy is effective—whereas our findings show that uncertainty about effectiveness of treatment remains" (p. 460). Further, they stated:

> The ethics of providing this still-experimental [sexual offender] treatment to a vulnerable and potentially dangerous group of people outside of a well-designed evaluative study are debatable…Psychological interventions could help or they could harm sex offenders…In an environment of limited resources it would seem imprudent to allocate funds to unproven and potentially harmful interventions. (p. 461)

Kenworthy et al. (2003, 2004) initiated an updated CR of White et al.'s (1998) earlier study, noting that there was significant political and institutional pressure to prove that treatment works. However, they concluded: "To date, no positive treatment effects have been found in quasi-experimental institutional programmes" (abstract). They examined nine random assignment studies involving treatment of over 500 sexual offenders that were available as of 2002; thus, they evaluated the same studies as Brooks-Gordon et al. (2006). However, Kenworthy et al. found that a lack of relevant data made it impossible to draw conclusions for clinicians, concluding:

> Limited data make recommendations difficult. One study suggests that a cognitive approach results in a decline in re-offending after one year. Another large study shows no benefit for group therapy and suggests the potential for harm at ten years. The ethics of providing this still-experimental treatment to a vulnerable and potentially dangerous group of people outside of a well-designed evaluative study are debatable. This review proves such studies are possible. (abstract)

The Institute for Health Economics (IHE) in Alberta, Canada, provides evidence in health technology assessment to assist in health policymaking and best medical practices. The IHE, like the Cochrane Collaboration, is an independent, not-for-profit organization that performs research in health economics and synthesizes evidence to assist health policymaking and best medical practices. The IHE published a Health Technology Assessment (HTA) Report entitled "Treatment for Convicted Adult Male Sex Offenders" (Corabian, Opsina, & Harstall, 2010a). [Subsequently, Corabian et al. (2010b) provided an e-journal summary of the IHE study.] The IHE identified eight SRs conducted on the effectiveness of sexual offender treatment interventions that met their inclusion criteria; all eight focused on the use of psychotherapy and one also included studies of surgical castration and hormonal medication (e.g., Losel & Schmucker, 2005). These studies were selected as meeting the IHE inclusion criteria, which by virtue of design and quality of reporting were most likely to provide "high levels of evidence." They concluded that a subset of the studies showed "small but statistically significant reductions in sexual and general recidivism rates among convicted adult male sex offenders treated with various cognitive behavioural therapy (CBT) approaches…" (p. iv). Yet they noted when analyses were restricted to the few available RCTs, a mean effect was shown, but it was *not* statistically significant. Further, the IHE also stated:

> Confidence in these findings, however, must be tempered as the available evidence is based mostly on poor quality primary research studies…Given the methodological problems of the available primary research it is difficult to draw strong conclusions about the effectiveness of sexual offender treatment programs using various CBT approaches for such a heterogeneous population. (p. iv)

In addition, the IHE stated: "SOT programs neither cure sexual offending nor guarantee a complete cessation of offending…" (p. 37). At best, they noted that such interventions represent but one element in a comprehensive risk management strategy for sexual offenders. The IHE further noted: "Overall, the results reported by the selected SREs provide little direction regarding how to improve current treatment practices…There are still uncertainties reading the most useful elements and components of a SOT program for convicted adult male sex offenders." They concluded that the available research indicated "…more and better research was needed to clearly answer the set of remaining questions" (p. iv).

Later in the IHE report, they noted:

> …since the evaluated programs were not sufficiently documented…it was not possible to identify if any characteristics or elements contributed more or less to the success or failure of a program and who of the involved offenders were most likely to benefit from or be harmed by treatment. SOT programs typically work within a broad CBT framework but may vary in terms of resources, philosophy of a program and its treatment objectives, timing, duration, format, intensity, and content of treatment, level of worker expertise and treatment fidelity/integrity as well as the referred sex offenders' characteristics and selection criteria for participation in the program (which can be based on various risk assessment modalities or no risk assessment at all). (p. 33)

Ultimately, the IHE concluded: "Any conclusions drawn from this overview of SRs remain tentative. Given the methodological problems of the available primary research, it is

difficult to draw strong conclusions about the effectiveness of SOT programs using various CBT approaches for such a heterogeneous population" (p. iv).

In 2011, the Swedish Council on Health Technology Assessment HTA (identified by its Swedish acronym of SBU) was assigned by the Swedish government to conduct a SR of "Medical and Psychological Methods for Preventing Sexual Offenses Against Children." This review provided an extensive and detailed report of the existing SRs and meta-analyses of sexual offender treatment. The SBU found that in examining seven previous SRs:

> …the debate in the scientific literature on what sexual offender treatment interventions works for adult male sexual offenders remains divided…Although some of the selected SRs suggest a positive effect for CBT on both sexual and general recidivism, methodological problems, inconsistency results, and a lack of high-quality primary research studies included in the SRs raise uncertainty about which of the available approaches work for adults male sex offenders. (p. 32)

The SBU SR stated that the available evidence provided evidence for some effectiveness of treatment in reducing sexual offense recidivism, noting that existing SRs showed small reductions in such recidivism for sexual offenders after undergoing CBT. However, the SBU concluded:

> Major deficiencies were found in the evidence concerning effective medical and psychological interventions for individuals that have committed sexual offences against children. This is serious since the purpose of this treatment is to prevent new offences… For adults that have committed sexual offenses against children the scientific evidence is insufficient for determining which treatments that could reduce sexual reoffending. The lack of evidence concerns both benefit and risk for pharmacotherapy and psychological treatment programmes. (pp. 4–5)

In addition, the SBU concluded: "Sexual offender treatment programs neither cure sexual offending nor guarantee a complete cessation of offending, and they represent one element in a comprehensive risk management strategy designed for convicted adult male sex offenders…Not all sexual offender treatment interventions and programs are effective in reducing sexual/non-sexual recidivism in this population" (p. 37).

Most recently, Langstrom et al. (2013) conducted a systematic review of medical and psychological interventions of sexual offenders who committed sexual offenses against children. They reviewed 1,447 abstracts, retrieved 167 full text studies, and finally included eight (8) studies with low to moderate risk of bias. They concluded that there was "weak evidence for interventions aimed at reducing offending in identified sexual abusers of children…For adults, evidence from five trials was insufficient regarding both benefits and risk with psychological treatment and pharmacotherapy." Langstrom et al. noted: "Despite severe consequences for victims and society, this systematic review identified remarkably little research of acceptable quality on individual-level prevention of child sexual abuse" (p. 3). Of more recent studies, they identified only one RCT involving offenders who had sexually abused children. Overall, effectively, they concluded that no evidence exists of the effectiveness of cognitive-behavioral treatment or pharmacological interventions, noting "the remarkable lack of quality research studies in sexual abuser of children…" (p. 4). They expressed the hope that such treatments might be found to have some positive effects if and when large, methodologically rigorous, studies are implemented. However, they are also warned of the potential consequences of denying treatment to offenders for whom it might have benefit and, conversely, of providing unproven treatment that might increase the risk for future sexual offending.

Meta-Analyses of Sexual Offender Treatment

Kendall et al. (2004) identified that meta-analytic statistical techniques could be useful because they synthesize results across multiple studies by converting the results of each investigation into a common metric (usually, the "effect size"). Such a method increases the potential power of experimental studies by combining the results of a number of investigations (typically with relatively small numbers of subjects) to increased statistical power to determine if there is a trend or clear effect over the aggregated studies. As noted previously, such an effect size (ES) provides a measure of the magnitude or "strength" of the experimental effect; in and of itself, the effect size is not an indication of causality.[3] The outcomes of different treatment comparisons can then be compared with respect to the magnitude of difference reflected in such statistics. As noted, a key issue that arises in meta-analytic studies has to do with whether studies of inferior methodological quality should be included or omitted. Kendall et al., among others, agree that it is important to eliminate those studies whose quality does not allow them to contribute meaningful findings as a result of basic inadequacies in research design. A recommendation that a particular approach is effective or more effective than an alternative approach cannot be determined if that recommendation is based on inadequate research:

> If the research evidence is methodologically unsound, it is insufficient evidence for a recommendation; it remains inadequate as a basis for either supporting or refuting treatment recommendations, and therefore it should not be included in cumulative analyses…Caution is paramount in meta-analyses in which various studies are said to provide evidence that treatment is superior to

[3]The effect size (ES) is typically derived by computing the difference between the mean of the treatment group and the control group at post-treatment and then dividing the difference by the pooled standard deviation of the 2 group.

> controls. The exact nature of the control condition in each specific study must be examined…Meta-analyzers cannot tabulate the number of studies in which treatment is found to be efficacious in relation to controls without examining the nature of the control condition. (Kendall et al., 2004, p. 37)

Thus, a critical issue for interpreting the results of any MA is reliant on the quality of the specific investigations that compose the MA; the inclusion of methodologically weak or inadequate studies limits any conclusions drawn from that MA.

Hall (1995) conducted the first MA of sexual offender treatment studies that appeared after the review by Furby et al. He studied only studies that include some comparison group and utilize recidivism rates between each treatment and comparison groups (alternative or no treatment) as the outcome measure. Of 92 studies available, 80 were eliminated from consideration because they had fewer than 10 subjects, lacked a comparison or control groups, or did not report sexual offense recidivism rates. For the twelve studies Hall deemed adequate for evaluation, his MA revealed a "small" but statistically significant overall treatment effect ($r = 0.12$); however, the treatment ES across studies were significantly heterogeneous. Effect sizes were significantly greater in studies of outpatients than for studies of institutionalized offenders, potentially an effect of the severity of participant psychopathology. Hall concluded that comprehensive cognitive-behavioral treatments (CBT) showed better outcomes than purely behavioral treatments. Hall noted conservatively that 36 % of those eligible for participation in sexual offender treatment were typically excluded from participating in treatment: "In general, the most pathological participants were excluded from samples (e.g. extensive offense history, psychotic, organic brain syndrome, denied offenses, management problem in prison, withdrew from treatment program)" (p. 803). Consequently, he wrote, "Thus, the currently reviewed treatments may be less effective with the most pathological sexual offenders" (p. 808). In addition, it was found that 1/3–2/3 of participants refused hormonal treatments, while refusal and dropout rates for CBT were found to be about 1/3 of eligible participants. Hall concluded that his meta-analysis results suggested "the effect of treatment with sexual offenders is robust, albeit small…" (p. 808).

In 2002, Hanson et al. published the first report from a Collaborative Outcome Data Project (CODP) established by the Association for the Treatment of Sexual Abusers (ATSA). They noted that a primary objective of the CODP was "to promote professional debate concerning the relative quality of treatment outcomes studies for sex offenders" (p. 173). Hanson et al. conducted a MA that combined data on 43 psychosocial treatment programs involving 9,454 sexual offenders who were either assigned to either sexual offender treatment, were untreated or were provided other interventions. Of the treatments reviewed, 23 were offered in institutions, 17 in the community, and three in both settings; the major sponsor of the programs studied were departments of corrections ($n = 26$). The treatment studies considered were delivered between 1965 and 1999; only 23 studies had been published in either a book or a journal and approximately ½ were from the USA (Canadian samples made up another 16 studies). Approximately 80 % of the sexual offenders received "current" treatment (defined as CBT offered after 1980 or behavioral, other psychotherapeutic, and/or mixed treatments delivered between 1998 and 2000). The median length of the follow-up was 46 months for both treatment and comparison groups or just less than 4 years. Sexual offense recidivism was defined by reconviction in 8 studies, rearrest in 11 studies, while 20 studies used broad definitions (e.g., including parole violations, readmissions to institutions, unofficial community reports, or all of these). Thirteen programs reported outcome only on sexual recidivism, five reported only on general recidivism outcomes, and 25 reported on both.

Hanson et al. (2002) grouped the studies that they considered into several categories. The first category was based on the strongest method for comparing different comparison groups, random assignment; in these studies, persons were randomly divided into groups who received treatment and those who did not. The second category that Hansen et al. considered relative to treatment outcome was referred to as "incidental assignment" to treatment. In these studies, sexual offenders who were provided with sexual offender treatment were compared to varied comparison groups that were "created" from some pool of sexual offenders available to investigators. Per the 2002 review, such control groups were matched in various ways to those who received treatment. Thus, the control samples were selected according to varied criteria in specific studies, including offenders who (1) had been released before the implementation of the treatment program (5 studies); (2) had received no treatment or received treatment judged to be lower in quality, due to such administrative reasons such as too little time remaining on their sentences (5 studies); (3) matched from archives of criminal history records (3 studies); or (4) had received an earlier version of the treatment (2 studies). Hansen et al. labeled these 17 studies as involving "incidental assignment" because it was theorized or believed that there was no "obvious" or "a priori" expectation that the treated and untreated offenders should differ in risk and thus have no "obvious" bias in group composition. In addition, an additional category of subjects considered by Hanson et al. was those deemed "assignment based on need," where treatment [was] given to those assessed as requiring treatment. Finally, they compared any treatment attendance (including dropouts), treatment completers to treatment dropouts, and treatment dropouts to treatment refusers.

Results of the MA of 5,078 treated and 4,376 untreated sexual offenders found that the *unweighted* averages across all studies indicated the sexual offense recidivism rates were lower for the treated groups (12 %) than for the comparison groups (17 %). The chief conclusion drawn by Hanson et al. (2002) from these results was that "there was a *small* advantage for the treated versus the untreated offenders," and this finding was statistically significant (p. 181, emphasis added). However, this overall analysis included the results of sexual offender treatment for juvenile sexual offenders, which, were more likely to show a positive outcome for offenders (albeit largely for multiple trials of one particular method of treatment). Further, Hanson et al. noted considerably variability across studies, with treatment effects much larger in studies that had not been published. Of significance, when only the four methodologically superior RCT studies were examined, *no* treatment effect was found. In contrast, evidence for treatment effectiveness was found only in the results from the incidental assignment studies which, on average, showed statistically meaningful reductions in sexual offense recidivism, albeit with more variability than expected by chance. Perhaps oddly, Hanson et al. then combined the nonsignificant findings from the methodologically superior random assignment studies with the significant effects of the 17 methodologically inferior incidental assignment studies of "current" treatments and, on this basis, concluded that "current" treatments were associated with significant reductions in both sexual (from 17.3 to 9.9 %). Thus, the results that Hanson et al. found for treated sexual offenders over a mean 4-year follow-up (12 %) were comparable to the rates of sexual offender recidivism that had been found for largely untreated sexual offenders in the two MA of risk factors for sexual offender recidivism; respectively, Hanson and Bussiere (1998) and Hanson and Morton-Bourgon (2004, 2005) indicated that the mean 5-year rates of sexual reoffending for the two large samples of almost exclusively untreated sexual offenders were 13 and 14 %. Thus, the results for sexual reoffending that Hanson et al. (2002) reported for the treated sexual offenders in their treatment MA were equivalent to the rate of much larger samples of untreated sexual offenders in varied comparison groups.

According to Hanson et al. (2002), other findings from their meta-analysis included:

> studies comparing treatment completers to dropouts consistently found higher sexual and general recidivism rates for the dropouts, regardless of the type of treatment provided. Even in studies where there was no difference between the treatment group and the untreated comparison groups, the treatment dropouts did worse. (p. 182)

Although it was determined that dropouts were approximately twice as likely to sexually reoffend, in their analysis of the untreated "comparison" groups, Hanson et al. did not account for or control for such dropout effects; there was no analysis of intent to treat. Hanson et al. also reported "offenders who refused treatment were not at higher risk for sexual recidivism than offenders who started treatment" (p. 182), a finding that conflicts with that of the other reviews. Interventions that were viewed as "current" treatments were found to be associated with greater reductions in recidivism. In contrast to what Polizzi et al. (1999) reported, Hanson et al. (2002) found that both institutional and community treatments showed equal results regarding the degree of recidivism associated with the different types of programs.

However, a key finding by Hanson et al. was that "Offenders referred to treatment based on perceived need had significantly higher sexual recidivism rates than the offenders considered not to need treatment" (p. 182). The odds ratio was 3.4 (with an outlier study removed), and there was no significant variability, indicating that this was a robust phenomenon. Hanson et al. concluded: "Studies that compared sex offenders who 'needed' treatment to less needy offenders consistently found *worse outcomes for the treatment group*. It appears that evaluators are better able to identify high risk offenders than to change them" (p. 187, emphasis added).

Hanson et al. offered a considerably measured conclusion to their MA, writing, "We believe the balance of available evidence suggest that current treatments reduce recidivism, *but that firm conclusions awaits more and better research*" (p. 186, emphasis added). They indicated that when random assignment and incident assignment studies were combined, there was a *reduction* in sex offense recidivism and "These reductions were not large, but they were statistically reliable and large enough to be of practical significance" (p. 187, emphasis added). They concluded that the absolute reduction in recidivism rates was *modest* even among the better-designed studies of current treatments and that no treatment effect was found among the best-designed studies. The results reported by Hanson et al. suggested that treatments that appeared effective for adult sexual offenders were more "current" programs providing some form of CBT. They also reported no "setting" effect for sexual offender treatment; both institution-based and community-based programs for adults were found to be associated with reductions in sexual recidivism of adult sexual offenders. Hanson et al. did not identify specific interventions that provided guidance on the effectiveness of any sexual offender treatment interventions for different types of sexual offenders (e.g., "rapists" vs. child molesters or mixed offenders). Finally, the authors concluded that the results of their meta-analysis provided little direction in terms of how to improve current practice.

Several years later, Losel and Schmucker (2005, 2008) conducted another meta-analysis of both published and unpublished sexual offender "controlled" outcome studies available as of 2003, involving either psychosocial **or** biological

treatments. Losel and Schmucker (2005, 2008) reviewed 69 studies with more than 22,000 subjects; unpublished investigations comprised 36 % of the study pool. Of those studies, approximately 18 % were analyses of biological treatment (e.g., hormonal treatment and surgical castration). Of the remaining studies identified, 46 % were of CBT and 18 % were "classical" behavioral psychosocial treatments. Per their 2008 paper, however, "60 % of the identified studies used clearly non-equivalent control groups" (emphasis added, p. 16, emphasis added). About one-third of these studies had been reported since 2000, but the actual program implementation started earlier (e.g., in the 1990s). Approximately 70 % of these studies were conducted in North America. The definition of recidivism varied across studies: arrest (24 %), conviction (30 %), and charges (19 %). Recidivism was recorded after an average follow-up period of more than 5 years. Sexual recidivism outcomes were reported in 74 of the 80 comparisons. Although most treatments were specifically designed for sexual offenders, the authors found it difficult to rate whether treatment was implemented reliably, as three-quarters of the studies did not provide information on program integrity. Residential (institutional) treatment was somewhat more frequent than outpatient treatment; approximately one-half of the studies were implemented in an institutional setting. Although a group format was most frequently used, almost 50 % of the programs included at least some individualized treatment. Sexual offenders who received treatment participated voluntarily in most studies; however, 30 % of the comparisons referred to offenders who were at least partially obliged to attend treatment. In more than 50 % of the primary research studies, the authors were affiliated with the treatment program that was implemented (raising the question of allegiance issues).

Methodologically, approximately one-third of the comparisons contained fewer than 50 sexual offenders as subjects, while 46 % included 100 subjects or less. Only seven comparisons were based on random assignment and just six studies received a Level 5 designation of the Maryland scale. Conversely, 60 % of the treatment comparisons were at Maryland Scale Level 2 such that treatment and control group could not be considered equivalent; in an additional 24 % of studies, the equivalence of the two groups was simply assumed by the original investigators. In approximately 24 % of the comparisons, the control group consisted of treatment refusers.

Of note, when recidivism rates were calculated for treated and comparison subjects initially using unweighted averages, a treatment effect was found. However, when weighted averages were utilized (e.g., taking into account relative numbers of persons in treatment and comparison groups), "the difference in recidivism rates vanished completely (11 % each for treated and comparison participants)," (p. 127) although the authors dismissed this issue.

Subsequently, Losel and Schmucker (2005) utilized the mean effect size, which showed that the majority of effects were positive; they then calculated odds ratios.[4] Including treatments for **both** biological and psychological treatments, the mean odds ratio for sexual offense recidivism was 1.7, which was highly significant so that the absolute difference in sexual recidivism between the "any" treatment group (e.g., biological **and/or** psychosocial intervention) and the heterogeneous control groups was 6 %. The rate of sexual recidivism for the overall treated groups (e.g., psychosocial **and/or** biological treatments) was 11 % (the control groups showed an average sexual offense recidivism rate of 17.5 %). However, as with the Hanson et al. (2002) meta-analysis, there were considerable, statistically significant differences in effect sizes across the comparisons studied indicating considerable heterogeneity beyond what would be expected by chance. Large effects of treatment were found more frequently in studies with small sample sizes. Of note, medical treatments (e.g., hormonal treatments or surgical castration) were found to have considerably higher effect sizes than those for CBT (e.g., 2–10 times larger, respectively). Of psychosocial interventions, only cognitive-behavioral and "classic behavior therapy" generally showed a significant impact on sexual offense recidivism. An important issue relative to how the Losel and Schmucker (2005) results are typically discussed is that the widely reported reduction in sexual offense recidivism as a result of "treatment" includes the combined results of both biological and psychosocial interventions; the reported 6 % (or "37 %" relative reduction) for sexual offense recidivism resulted from a comparison of *both biological and psychosocial interventions* and would not apply to just psychosocial interventions. Losel and Schmucker (2005) reported that after removing those studies involving surgical castration (which had the highest effect size of all treatments), the effect size for treatment generally decreased and the relative sexual offense recidivism "drop" for nonsurgical treatments decreased by approximately one-third.

In contrast to the Hanson et al. (2002) findings, more modern sexual offender treatment programs were no more effective than earlier programs. Losel and Schmucker and Losel (2008) noted that "Some recent evaluations have revealed rather small or no positive effects…As follow-up one of the soundest evaluations has also found no positive effect…" (p. 136). That is, as with the Hanson et al. (2002) meta-analysis, Losel and Schmucker's (2005) review did not include the final results of the Marques, Wiederanders, Day, Nelson, and Ommeren (2005) study that showed no effect of sexual

[4]Odds ratio is the *odds* of being in one group relative to the *odds* of being in a different group and is used with categorical variables (e.g., treatment, no treatment; reoffend, not reoffend). The odds ratio is not the chance or likelihood but the ratio of the odds, not the percentages. The odds of an event occurring is the probability of an event divided by the probability of an event not occurring.

offender treatment utilizing a RCT. No difference was found between group and individual treatment programs by Losel and Schmucker (2005). Per their 2008 report, "Only outpatient treatment showed a significant effect" (p. 13). The odds ratio for institutional sexual offender treatment was considerably lower than that for outpatient treatment and *not* significant. Thus, similar to Polizzi et al.'s findings, prison-based programs or hospital-based sexual offender treatment programs showed outcome results that indicated little difference between sexual offender treatment participants and nonparticipants. No significant difference was found for treatments for adult and those for adolescent sexual offenders. In their two reports, Losel and Schmucker (2005, 2008) found that only sexual offender treatment programs involving *voluntary participation showed a significant effect*; programs that *involved* "a more or less coerced treatment" *did not show a significant effect* (2008, p. 13). Further, "Whether treatment was terminated regularly or prematurely had an impact on sexual recidivism. Whereas "regular" completers showed better effects than the control groups, dropouts did significantly worse. Dropping out of treatment doubled the odds of relapse…" (2005, p. 132). However, effect sizes that referred to treatment completers revealed considerable heterogeneity. Various methodological differences related to sample size and design quality were identified in comparisons between those who completed and those who did not complete sexual offender treatment. However, those differences were neither uniform or provided clarity as to their implications. However, those differences were neither uniform or provided clarity as to their significance.

Losel and Schmucker (2005) noted that their analyses repeatedly indicated problems of confounded moderators. Consequently, they tested to see to what degree the treatment effects were confounded with methodological and other study characteristics. Methodological characteristics accounted for a considerable amount of variance in outcome for treatment (e.g., 45 %). Of these methodological characteristics, general characteristics of treatment were most important, including specificity of treatment for sexual offenders, involvement of authors in the program, and a group format contributed to a 9 % increase in explained effect size variance. Thus, for example, treatment studies in which the study author(s) was in some way involved in the program delivery more likely showed significant treatment effects, but programs that were evaluated by independent researchers did not; this strongly suggests the so-called allegiance effects. They concluded that "… methodological factors play an important role and seem to be confounded with treatment and offender characteristics. This problem of confounded moderators is rather general and difficult to solve…" (p. 138).

In their conclusions, Losel and Schmucker (2005) stated: "Bearing the methodological problems in mind, one should draw very cautious conclusions from out meta-analysis. The most important message is an overall positive and significant effect of sex offender treatment" (p. 135); however, it appears that this conclusion was *inclusive* of surgical castration and hormonal treatments that were more effective than psychosocial treatments. As the authors pointed out in 2005, differences in treatment and comparison groups "most probably" related to their inclusion of both medical and psychological modes of treatment because, "The average effect of physical a treatment is larger than that of psychosocial programs" (p. 135). Further, the authors also cautioned, "One must bear in mind that outcomes of treatment often decline when model projects are transformed into routine practice" (p. 137). In 2008, Losel and Schmucker wrote:

> The size of the [treatment] effect is small to moderate… However, the evidence is based on studies that mostly apply a weak methodological standard. *Restricting the analysis to a few randomized trials shows a comparable mean effect but it does not render it statistically significant*…Obviously we need more high quality evaluations on the whole range of sexual offender treatment to come to unequivocal conclusions. (p. 17, emphasis added)

In their 2008 paper, Schmucker and Losel noted methodological study characteristics explained the largest proportion of variability in effect size variance; they concluded that "Overall, findings are promising but more differentiated evaluations of high quality are needed" (p. 1).

Hanson et al. (2008, 2009) completed an updated but somewhat different MA of sexual offender treatment relative to the 2002 paper. At the outset, they stated:

> All reviews have concluded that more and better studies are needed. Few studies have used strong research designs (i.e. random assignment), and there are even fewer studies with strong research design examining interventions consistent with contemporary standards. Consequently reviewers are forced to consider whether the less than ideal studies are "good enough." (p. 866)

Hanson et al. (2009) considered sexual offender treatment in the specific context of treatment of general criminal offenders (e.g., a criminological perspective) and not that of psychotherapy outcome research per se. More particularly, they examined the utility of the risk, need, and responsivity (RNR) model (e.g., Andrews & Bonta, 2006) which states that "… treatments are most likely to be effective when they treat offenders who are likely to reoffend (moderate or higher risk), target characteristics that are related to reoffending (e.g. criminogenic needs), and match treatment to offenders' learning styles and abilities (responsivity; cognitive-behavioral interventions work best)" (p. 866). Thus, Hanson et al. (2009) addressed the question of whether the principles of effective general criminological interventions also applied to the psychological treatment of sexual offenders. They also examined whether different results were found in better-quality studies than in studies that met only minimum standards of acceptability (e.g., weak designs) and relied on the Collaborative Outcome Data Committee (CODC, 2007a, b). Thus, they

noted that a "strong" study would be one that involved "a well-implemented random assignment study (e.g. uncorrupted random assignment, 5 or more years of follow-up, sample size >100, < 20 % attrition, no preexisting differences between the groups found post hoc)" (p. 869).

Hanson et al. (2009) found that no studies reported findings for different intensities of treatment services within the same setting. Studies were therefore coded as adhering to the risk principle if their treatment group was higher risk than average for sexual offenders. Programs were considered to meet the need principle if the majority (51 %) of the treatment targets were criminogenic needs. It was assumed that CBT programs adhered to the responsivity principle. Of the 23 studies accepted for analysis, 14 were published and 9 were not. Most of the studies were Canadian (12) or American (5). Only 19 studies focused on adult sexual offenders. Of the 23 programs, 10 were offered in institutions and 11 in the community; 16 programs were sponsored by corrections. In total, 22 studies examined 3,121 treated sexual offenders and 3,625 untreated sexual offenders.

Regarding results, the sexual offense recidivism rate for treatment groups had an unweighted mean of 11 % and for comparison groups 19 %. The odds ratio for sexual offense recidivism with a fixed weighted mean was 0.77, but there was more variability than would be expected by chance. For 22 studies examining the sexual recidivism rate, results from both fixed-effect and random-effect analyses indicated significantly lower sexual recidivism rates in the treatment groups than in the comparison groups. However, of note, the combined rate of sexual and other violent offenses was not significantly lower for treatment groups relative to comparison groups, while general recidivism rates were lower for the treatment groups. Again, Hanson et al. (2008) found no differences as to whether treatment was delivered in the community or in institutions; recent treatments were found to be more effective. The treatment effects on both sexual and violent recidivism were smaller in the good-quality studies than the weak studies.

Only two studies were each rated as following two of the three RNR principles. Analyses found that programs were more effective when they targeted criminogenic needs or delivered in a manner that was likely to engage sexual offenders (e.g., responsivity via CBT). Support was demonstrated for both the need and responsivity principles. However, Hanson et al. (2009) did not find that the risk principle was supported; that is, available program results were *not* significantly more likely to be effective when they treated offenders who were rated as at higher risk to reoffend. Overall, regarding sexual offense recidivism, results indicated that the relative effectiveness of sexual offender treatment increased according to the degree that treatment adhered to the RNR model, except for the risk principle. However, for the 10 studies that examined both sexual and violent recidivism as the outcome variable, there was no significant difference based on adherence to the RNR model.

Hanson et al. (2009) reported that the sexual and general recidivism rates for the treated sexual offender were lower than for comparison groups (based on unweighted averages). However, for a median follow-up of 4.7 years, the results for sexual offense recidivism that Hanson et al. (2008) found for treated sexual offenders (11 %) were again comparable to the rates of sexual offender recidivism that had been found for largely untreated sexual offenders in two MA of risk factors for sexual offender recidivism [respectively, Hanson and Bussiere (1998) and Hanson and Morton-Bourgon (2004, 2005) indicated that the mean 5-year rates of sexual reoffending for the two large samples of almost exclusively untreated sexual offenders were 13 % and 14 %]. Thus, the results that Hanson et al. (2009) found for the treated sexual offenders in their treatment MA were largely equivalent to the rate of much larger samples of untreated sexual offenders. Unfortunately, Hanson et al. (2009) noted that not one "strong" study of sexual offender treatment could be identified per CODC criteria. Hanson et al. concluded:

> Confidence in the findings, however, must be tempered by the weak research designs. Even after excluding the worst 80 % due to inadequate study quality, still only 5 of the remaining 23 studies were rated as good according to the CODC guidelines (18 were weak). The effects tended to be stronger in the weak research designs compared to the good research designs. *Reviewers restricting themselves to the better-quality, published studies…could reasonably conclude that there is no evidence that treatment reduces sex offense recidivism.* (p. 881, emphasis added)

In 2012, Dennis et al. (2012) authored another CR of psychosocial interventions for adults who had been sexually offended. In keeping with similar reviews, their selection criteria involved randomized trials comparing psychological interventions with standard care or another psychological therapy provided to adults in either institutional or community settings for sexual behavior. The authors stated: "While this review adopts the Cochrane principles of examining only evidence from RCTs, we do so without any apology, in the belief that other types of trial evidence are likely to inflate the positive findings for the intervention" (p. 27). They found ten studies that met their criteria involving a total of 944 male adults, of which four compared CBT with no treatment or wait list control and one which compared CBT with standard care. Four other studies involved behavioral programs and one study compared psychodynamic intervention with probation. For CBT, Dennis et al. reported: "The result of comparing reconviction for sexual offences between conditions was not statistically significant" (p. 23). Similarly, for the psychodynamic intervention, there was no difference in rate of sexual rearrest at 10-year follow-up. Thus, the investigators reported: "The main finding of this systematic review is that there was no evidence from any of the trials in favour of the active intervention in a reduction of sexual recidivism –the primary outcome" (p. 25). For both CBT and psychodynamic interventions with meaningful follow-up

data, Dennis et al. noted that "…neither showed any benefit for the intervention. Thus, neither…appeared to reduce sexual recidivism" (p. 35). They stated:

> The inescapable conclusion of this review is the need for further randomized controlled trials. While we recognize that randomisation is considered by some to be unethical or politically unacceptable (both of which are based on the faulty premise that the experimental treatment is superior to the control—this being the point of the trial to begin with), without such evidence, that area will fail to progress. Not only could this result in the continued used of ineffective (and potentially harmful) interventions, but it also means that society is lured into a false sense of security in the belief that once the individual has been treatment their risk of reoffending is reduced. Current available evidence does not support this belief. Future trials should concentrate on minimizing risk of bias, maximizing quality of reporting and including follow-up for a minimum of five years 'at risk' in the community. (p. 3)

Summary of Reviews of the Effectiveness of Sexual Offender Treatment

In his meta-analysis, Hall (1995) found a "small" statistically significant effect for sexual offender treatment for highly screened subjects and concluded that such treatments might be less effective with more "severe" sexual offenders. He found that outpatient sexual offender treatment appeared more effective than institutional treatment. Like Hall, Hanson et al. (2002) concluded from their meta-analysis that "there was a *small* advantage for the treated versus the untreated offenders" (emphasis added) and this finding was statistically significant. However, they found that if only those studies that utilized random assignment of sexual offenders to treatment were examined, no treatment effect was apparent. In addition, Hanson et al. identified a "robust" finding that sexual offenders referred to sexual offender treatment based on "perceived need" (e.g., likely higher-risk sexual offenders) had substantially higher sexual offense recidivism rates than those with less need and concluded such offenders were less responsive to sexual offender treatment. Hanson et al. concluded that "We believe the balance of available evidence suggest that current treatments reduce recidivism, but that firm conclusions await more and better research" (p. 186). Losel and Schmucker (2005, 2008) also concluded from their meta-analysis that a majority of treatment studies (a combined set of biological and psychosocial treatments) suggested a positive effect for sexual offender treatment. Losel and Schmucker found that "obligatory participation" in treatment resulted in no treatment effect. Thus, according to the conclusions of Hanson et al. and Losel and Schmucker, both higher levels of need and mandated participation were associated with no treatment effectiveness. In contrast to Hanson et al., Losel and Schmucker found no differences between "current" and older sexual offender treatment programs. Another difference between the Hanson et al. (2002) and Losel and Schmucker (2005, 2008) meta-analyses was that the latter identified a trend for lower effectiveness in institution-based programs, whereas the former did not. This was similar to what Polizzi et al. (1999) concluded, namely, that "…the evidence is not strong enough to support a conclusion that [prison-based programs] are effective." Relative to the effectiveness of sexual offender treatment, Losel and Schmucker (2005) concluded "one should draw very cautious conclusions from our meta-analysis" (p. 135), while Hanson et al. (2002) opined "firm conclusions await- more and better research" (p. 186). Hanson et al. (2008) found that unweighted rates of sexual offense recidivism were lower for the treated sexual offender than for comparison groups (based on unweighted averages). They did not find support for the risk principle—treatment was not more effective with more high-risk sexual offenders—comparable to their earlier finding about perceived need. They found no studies of adult sexual offenders that targeted risk, needs, and responsivity. Hanson et al. (2009) concluded that much could be done to increase confidence in outcome studies on sexual offender treatment. The IHE report interpreted the available data to suggest that sexual offense treatment had been shown to provide "small" reductions in sexual offense recidivism. However, the SBU found that the scientific evidence was insufficient for determining whether that such treatment could reduce sexual offending. Finally, one of the most recent, most rigorous reviews of treatment, for both CBT and psychodynamic interventions with meaningful follow-up data, Dennis et al. (2012) noted that "…neither showed any benefit for the intervention. Thus, neither…appeared to reduce sexual recidivism" (p. 35). This finding was also confirmed by Langstrom et al. (2013).

A key issue identified by most SRs and MAs was the dearth of high-quality research methodology in the available studies. Losel and Schmucker (2005, 2008) noted that only 6 of 69 studies available were considered to meet the Maryland Level 5 standard; as did most recent and prior reviewers, they emphasized that most of the studies included in their meta-analysis were of poor methodological quality. In addition, as noted, Losel and Schmucker did not include the final report from the Marques et al. study, the only contemporary RCT for psychosocial treatment for sexual offenders. Further, Hanson et al. (2002, 2009) pointed out that the treatment effects on sexual recidivism were, in fact, smaller in the good-quality studies than in the weak studies, suggesting that it was low-quality studies that inflated the already small positive outcome. Similarly, Losel and Schmucker (2005, 2008) showed that larger effects of treatment were found more frequently in studies with small sample sizes. In addition, they reported that the largest treatment effect was found for Maryland Level 3 studies in which the equivalence of comparison groups was assumed; thus, their results were

similar to those of the Hanson et al. meta-analysis where only incidental assignment ("assumed equivalence") showed an effect for sexual offender treatment. Hanson et al. (2009) also found that approximately 80 % of included studies were characterized by weak research designs and that more positive results were associated with more methodologically flawed studies. They concluded that if only higher-quality studies were considered, it would be reasonable to conclude that there was no evidence that psychosocial treatment decreased sexual offense recidivism. Langstrom et al. (2013) noted "the remarkable lack of quality research studies in sexual abuser of children…" (p. 4). Thus, all of the systematic reviews and meta-analyses, to date, have concluded that the field of sexual offender treatment was characterized almost exclusively by poor-quality methodology (primarily lack of RCTs and/or small numbers of subjects), that little information was provided about program integrity, and/or that no or minimal information was found as to elements of sexual offender treatment that were related to the outcome of the interventions. There was unanimity in the SRs and MAs that there was a strong need for more research of sexual offender treatment characterized by significantly higher scientific rigor.

Thus, at best, if one considers quasi-experimental research studies (consistently viewed across reviews as methodologically weak) only, a relatively small effect regarding decreased recidivism is sometimes demonstrated for treating low- to moderate-risk sexual offenders.[5] However, if only higher-quality, methodologically rigorous research studies (such as RCTs) are considered, from a scientific perspective, no definitive evidence has yet been presented by any researchers that psychotherapy is associated with any substantive reduction in sexual offense recidivism.

A Critical Perspective on the Results of Existing Systematic Reviews and Meta-Analyses of Sexual Offender Treatment

From an empirical perspective, no clear evidence of a scientific nature has yet been found via rigorous scientific study that psychotherapy is associated with a consistent, meaningful effect in the reduction of sexual offense recidivism; no substantive or strong proof yet exists that psychosocial interventions "work" in reducing future sexual offending at this time. In their own MAs, Hall (1995), Hanson et al. (2002), and Losel and Schmucker (2005, 2008) acknowledged that the effect sizes obtained in their meta-analyses for psychosocial treatments of sexual offender were "small"—despite the inclusion of and primary reliance on studies with acknowledged poor quality (e.g., problematic control groups) as well as relying on offender samples that likely enhanced the probability of obtaining positive outcome found for treatment conditions (e.g., predominantly low-risk offenders with few additional psychiatric or psychosocial issues). Langstrom et al. (2013) came to the conclusion that no evidence exists of the effectiveness of cognitive-behavioral treatment relative to sexual offender treatment for child molesters. Dennis et al. (2012) concluded that neither CBT nor other psychosocial interventions with meaningful follow-up data showed any benefit for the intervention; they did not appear to reduce sexual recidivism. Thus, to date, no investigator or scientific authority has produced or found what he or she consider to be a rigorous scientific evidence for and/or concluded that sexual offender treatment has been demonstrated to be "very" or "greatly" effective for sexual offenders. Rather, at best, if quasi-experimental research studies (e.g., incidental assignment) are included, the current findings indicate that such treatment might be "somewhat" "slightly" effective with voluntary, low-need/low-risk sexual offenders who are volunteers and are not "mandated" for participation in sexual offender treatment. Each available SR or meta-analysis has commented on the poor quality of the existing treatment outcome literature, and each has strongly recommended the need for additional studies, better designed with strong methodological qualities, particularly random assignment of subjects to treatment and control groups. In 1997, Hanson wrote: "Meta-analyses rely on the quality of the original studies, and skeptics can claim that there is an insufficient number of well-controlled studies to justify meta-analytic review" (p. 139). Even at present, it appears that an insufficient number of such studies exist.

Further, as Berliner wrote of the Hanson et al. meta-analysis at the time of its publication in 2002:

> The conclusions of this study, however, should not be exaggerated nor considered the final word on sex offender treatment. The studies measure reductions in recidivism and its elimination. *The effect sizes for recidivism reduction are not large, thus there will still be failures, the cost of which will be born by victims. It is not at all clear that these results can be generalized to the highest risk offenders. Even if they could be applied to these offenders, a moderate effect size reduction would still mean that high-risk offenders continue to be dangerous*. (p. 196, emphasis added)

Such comments are equally applicable to the subsequent meta-analysis by Losel and Schmucker (2005, 2008). [In addition, as will be reviewed in more detail, if one was to factor in (1) the sexual offenders who denied consideration

[5]While not intended as a study of sex offender treatment outcome, Helmus (2009) in her meta-analysis of factors in base rate variability in sexual offender samples found that the effects of sex offender treatment (among other variables) on sex offense recidivism. She compared offenders who completed treatment, dropped out of treatment and those who did not attend treatment. There was no difference in the rate of sexual reoffending relative to treatment participation; similarly, there was no difference between offenders who started treatment and those who completed treatment.

for treatment initially and/or (2) those who refused participation, and/or (3) those who dropped out of or were demitted from treatment, the minimal effects of sexual offender treatment outcome studies would almost certainly be even smaller or potentially nonexistent.] Beggs (2010) pointed out something obvious that is largely not addressed in the available sexual offender treatment literature—"the fact that residual post-treatment reoffending occurs at all indicates that not everyone who completes the same treatment will derive the same benefit" (p. 369). Of note, recent systematic reviews by the IHE, the SBU, Dennis et al. (2012), and Langstrom et al. (year) concluded that there was, at best, slight and, at worse, *no* scientific evidence of the effectiveness of sexual offender treatment. At this date, at best, no reviewer has concluded there is strong or even moderate empirical support for the effectiveness of psychosocial treatment for sexual offenders relative to reducing future sexual offense recidivism; at worse, the more consistent conclusion has been that there is no strong empirical evidence for the effectiveness of sexual offender treatment. This finding stands in marked contrast to the available scientific literature on psychotherapy more generally; as Westen et al. (2005) wrote: "The data are now clear that virtually anything researchers do for 10–20 sessions with patients that they firmly believe will be efficacious in fact leads to better outcomes than experimental conditions not intended to work…" (p. 428). Yet, despite what one presumes to be the best intentions of those providing sexual offender treatment, from the perspective of a "hard" outcome that matters most to stakeholders—reducing future sexual offending—there is little indication that psychosocial interventions are efficacious for participating sexual offenders.

In their article "Psychotherapy on Trial," Arkowitz and Lilienfeld (2006) enumerated a variety of reasons as to how clinicians can be misled into concluding that an ineffective psychotherapy is in fact efficacious. They identified that several phenomena that can make psychosocial interventions "appear" effective as justification as to why scientific psychotherapy outcome research is necessary: spontaneous remission, placebo effects, regression to the mean, treatment/programming interferences, selective attrition, effort justification, and demand characteristics. Each of these factors can be viewed as applicable to sexual offender treatment as well as general psychotherapy research. Since Furby et al.'s (1989) initial review of sexual offender treatment outcome, a number of general and specific methodological concerns have been raised regarding interpretations of the existing reviews of sexual offender treatment, including the select meta-analyses typically relied upon as the basis for the claims that sexual offender treatment "works." Beyond the failure of available sexual offender treatment outcome studies to empirically establish clear effectiveness of such interventions, a number of serious methodological issues undermine results obtained to date, which further qualify claims made in support of the effectiveness of sexual offender treatment. Such methodological issues in sexual offender treatment literature include limitations of meta-analysis, inadequate length and methods of follow-up of subjects, failure to utilize survival analysis in outcome measurements, allegiance effects, the general failure to use RCT designs (e.g., to use random assignment of motivated or genuinely help-seeking subjects to treatment and control groups), and distinct problems in the existing choices of control groups. Each of these factors seriously qualifies the already uncertain findings of the available sexual offender treatment outcome literature, particularly the last two.

Issues with Meta-Analyses

An initial issue for extant reviews that relied on meta-analysis is the well-known limitations of that method of evaluation. In the general psychotherapy outcome literature, a number of criticisms have been offered regarding meta-analytic studies of treatment outcome and the limitations of existing meta-analyses. Sharpe (1997) identified the primary criticisms of meta-analysis: (1) mixing dissimilar studies, (2) publication bias (including published studies which typically favor those with positive outcome), and (3) inclusion of poor-quality studies. Chambless and Hollon (1998) emphasized that in the absence of sufficient high-quality studies available for study, the results of meta-analyses were not dependable. Lambert and Ogles (2004) also opined that while there had been recent improvements in meta-analytic methodology, significant and problematic variability in meta-analytic methodology remains. The results of any meta-analysis of treatment outcome studies will be dependent upon the essential quality of available studies for analysis such that "summarizing" poor-quality or methodologically limited studies is not likely to be particularly informative. As Kendall et al. (2004) wrote, "Meta-analyzers cannot tabulate the number of studies in which treatment is found to be efficacious in relation to controls *without examining the nature of the control condition*" (p. 37, emphasis added). Specifically, virtually all of the SRs, including the meta-analyses, have noted the poor quality of existing sexual offender treatment outcome studies with virtually not of the available studies rating high on the Maryland scale or any other metric of study quality. As Eysenck (1994) stated, "…a good meta-analysis of bad studies will still result in bad data" (p. 789). He went on to state: "Meta-analyses are often used to recover something from poorly designed studies, studies of insufficient statistical power, studies that give erratic results, and those resulting in apparent contradictions…Effect sizes summed over such exceedingly heterogeneous data can hardly be accorded any validity, yet these data are often cited as proving the efficacy of psychotherapy" (pp. 791–792). As noted, Hanson (1997) offered a similar

opinion. Craig et al. (2003) noted the "considerable variability" in sample selection among studies of sexual offense recidivism and that sexual offenders are a particularly heterogeneous group of offenders. Many experts note the high degree of selectivity—investigator allegiance—that operates in the selection of which studies are included or disqualified and note that the problem of remaining "blind" in meta-analytic research has not been adequately addressed in such investigations (e.g., Eysenck, 1994; Westen & Morrison, 2001). Further, Matt (1989) demonstrated that judgmental factors are involved in selecting effect sizes from a meta-analysis. Average of varied effect sizes from the same studies showed variability; this can have a very significant influence on the reported results, to the point of reducing reported effect sizes by half. In addition, Hemphill (2003) noted: "It is important to recognize that different effect sizes to not produce results that are necessarily interchangeable. The magnitude of effect size cannot even be generalized across time within a single study because long follow-up periods increase observed base rates, which in turn influence magnitudes of effect sizes." Given that, like other criminal and violent outcomes, the base rate of sexual offense recidivism increases with longer follow-up periods (e.g., tripling over a 15–20 years interval), this suggests that current effect sizes would not provide a meaningful measure of treatment effectiveness, even if the current effect sizes were empirically meaningful. At present, even with a greater number of studies available, virtually no modern methodologically adequate—e.g., meaningfully controlled—studies have been conducted. Consequently, the low methodological quality of existing meta-analysis constitutes a "rate limiting factor" study (particularly considered within the context of issues in meta-analysis generally) that will continue to qualify any interpretation of the results of meta-analyses of sexual offender treatment outcome studies.

Issues with "Official" Recidivism as an Outcome Measure and Sample Censorship

Sexual offense recidivism is the primary outcome variable of interest relative to the efficacy of sexual offender treatment, that is, the primary concern as to whether psychotherapy "works" for sexual offenders as opposed to more common psychotherapy goals such as symptom relief or reduced personal distress. Such offense recidivism is the key metric for determining the efficacy of such interventions for several reasons. First, most generally, such recidivism best captures what Westen and Morrison (2001) referred to as sustained efficacy, the ability of treatment to produce lasting changes rather than an apparent positive initial response. Second, as forensic psychotherapy, the intention of such interventions, as well as the basis for providing public funding of sexual offender treatment, is public safety, specifically the prevention of future harm to possible victims.

The conventional means of measuring sexual offense recidivism in existing studies of sexual offender treatment is typically one rearrest or reconviction as measured by existing official criminal records. Thus, there is no "count" as to whether those "treated" sexual offenders who "failed" by sexual reoffending after treatment had one or multiple victims, the number of times they victimized one or more victims or the degree of harm that resulted from the sexual offense for primary or secondary victims. Rather, it appears that almost all existing treatment studies have relied on available criminal justice outcome measures and typically for follow-up periods of no more than 5 years. However, as Douglas et al. (2006) pointed out, "Sole reliance on official records will invariably underestimate actual criminal behavior" (p. 545) and lower base rates of actual recidivism. Regarding violent behavior generally, Douglas and Ogloff (2003) found that when criminal records were supplemented by other archival sources, the base rate *quadrupled* from approximately 10 to 40 %. Similarly, Monahan et al. (2001) found that the inclusion of information from official records, other collateral sources, and self-report increased recidivism rates by a factor of six! For sexual offense recidivism specifically, the results of Prentky, Lee, Knight, and Cerce (1997) reported they found a marked underestimation of sexual offense recidivism specifically depending on whether the criterion was based on charges, conviction, or imprisonment. Further, some offenders commit multiple sex offenses or victimize the same individual repeatedly over a follow-up period. Further, it is near universally agreed that such official rates of sexual offense recidivism "miss" most sexual offenses, because such offenses are not reported by victims or not processed through the criminal justice system (e.g., Craig et al., 2003). As Hanson (1997) noted that while "detected" recidivism is a credible measure, it is "an insensitive measure," pointing out that since most sexual assaults, particularly those against children are never reported to police; "It is impossible to study…that which remains hidden…Rarely will sexual offenders be falsely reconvicted, but many sexual offenses will go undetected" (p. 131). Craig et al. (2003) concluded: "…sexual recidivism could be underestimated by as much as 40 % in some studies" (p. 72). In addition, numerous studies via self-report in varied contexts have shown that under conditions created to maximize veracity, sexual offenders of all types reported substantially greater frequency (and diversity) of sexual offending (e.g., Abel, Blanchard, & Becker, 1978; English et al. 2000; Heil, Simons, & Ahlmeyer, 2003; Ahlmeyer et al., 2000; Hindman and Peters, 2001, 2010). Yet sexual offender treatment studies rely on the relative minority of actual sexual offenses that are detected, reported to, and processed by the criminal justice system. Consequently, using sexual offense recidivism

as measured by official records of arrests and/or convictions provides a grossly insensitive index of outcome, leading to a likely significant underestimate of both the frequency and severity of sexual reoffending.

In addition, it is the consensus that sex offense recidivism rates increase substantially with increased periods of follow-up (e.g., Rice & Harris, 2003); per Harris and Hanson (2004), rates of sexual reoffending almost double when follow-up periods are extended from 5 to 15 years (e.g., 14–24 %), and offenders have greater "opportunity time" in the community to commit new sexual offenses. Given such measured base rates for detected sexual offense recidivism, it makes little sense to investigate the effect of psychotherapy on sexual offense recidivism for periods of less than 5 years; as the results of Prentky et al. (1997) showed that for a 5-year study, only ½ of the total number of cases of sexual offense recidivism would have been identified. Similarly, Craig et al. (2003) noted that with a 5-year follow-up to treatment studies, "only one-half of the total number of cases of sexual reoffending – would likely have been identified. Thus, extended periods of follow-up are necessary to determine if true, meaningful reductions in sexual offense recidivism occur." Several studies have shown that sex offender recidivism increased to approximately a rate of 40 % by a 20-year follow-up, approximately triple the rate of 5 years sex offender recidivism rates (40 %, e.g., Hanson, Morton, & Harris, 2003; Harris & Hanson, 2004; Harris & Rice, 2007). Doren (2002) noted that there are no research studies of sex offender recidivism through the death of the entire sample (e.g., a lifetime rate of such recidivism). Sexual offenders demonstrate "first-time" sexual reoffending even 20–30 years after release from institutionalization (e.g., Hanson, Steffy, & Gauthier, 1993; Prentky et al., 1997); Hanson et al. (1993) reported that 23 % of sexual offender recidivists were reconvicted for more than 10 years after release.

Sample censorship is another issue relative to the accuracy of sexual offender recidivism rates. The common method of simply counting the percentage of individuals who sexually reoffend over a limited period of time for several reasons has several limitations that make it very likely to produce an underestimate of the true rate of such recidivism. First, persons with more severe histories of sexual offending may serve longer sentences of being indeterminately confined or detained and thus "unavailable" to sexually reoffend. Second, of those individuals released to the community, a significant number may only reside in the community for brief periods of time (e.g., due to re-incarceration of secondary to high general criminal recidivism rates or parole revocations) and will also be "unavailable" to sexually reoffend. Relative to this second point, Langan, Schmitt, and Durose (2003) found that 43 % of sexual offenders were rearrested for some crime (75 % of which were felonies) within 3 years of their release from prison. Even more recently, Durose, Cooper, and Snyder (2014) showed that 71 % of violent offenders (including sexual offenders) were rearrested for some criminal offense within 5 years of release from prison. Given these results from the Department of Justice, a significant proportion of released sexual offenders are jailed or re-imprisoned during what would have been their "follow-up" time and, obviously, less "available" to commit another sexual offense. Epperson (2009) found that over 52 % of moderate-risk sexual offenders, 56 % of higher-risk sexual offenders, and 65 % of the highest-risk sexual offenders released from prison on conditional release experienced revocation that in a number of cases would have led to additional periods of jail or prison time. Thus, higher-risk sexual offenders were more likely to be out of the community during some portion of a potential "follow-up" period. Furthermore, since the late 1990s (e.g., Prentky et al., 1997; Rice, 1997), the scientifically endorsed method for follow-up studies of sexual offenders is survival analysis. This method takes into account not only whether members of the groups of sexual offenders commit subsequent sex offenses but also when the end of sexual offender treatment or release from incarceration occurs and the length of time "available" to each offender for sexual offending activity in the community (e.g., not or deceased and/or incarcerated or jailed for lengthy periods of time). That is, survival analysis only counts the time that an offender is, in fact, "available" to sexually reoffend; as a data analytic procedure, survival analysis provides a better estimate of sexual offense recidivism (relative to a point recidivism rate) as it takes into account the "opportunity time" for each offender who has been "in the community" and actually had the chance to sexually reoffend. Of note, when Olver, Beggs Christofferson, Grace, and Wong (2013) controlled for risk and individual differences in follow-up time using survival analyses over an 8-year fixed follow-up period, the overall group of treated sex offenders did not demonstrate significantly lower rates of sexual recidivism than a much smaller control group. Relative to this point, Langan, Schmitt, and Durose (2003) found that 43 % of sexual offenders were rearrested for some crime (75 % of which were felonies) within 3 years of their release from prison. Even more recently, Durose, Cooper, and Snyder (2014) showed that 71 % of violent offenders (including sexual offenders) were rearrested for some criminal offense within 5 years of release from prison. Since most sexual offender treatment studies to date have failed to employ survival analysis, it seems highly likely that existing treatment studies overstate any benefits of such studies, since they are likely "missing" a substantial number of sexual offenders in general—and higher-risk sexual offenders more specifically—during the follow-up period.

Posttreatment Experiences of Treatment Participants

Another methodological issue concerns posttreatment experiences or services that treatment participants may have received. Following their experience of sexual offender treatment, some portion of "treated" sexual offenders remain in institutions and/or are followed in the community over time after their experimental treatment experience. During this period after sexual offender treatment, there are often further opportunities for exposure to many possible events that might have short- or long-term impact on their sex offense recidivism rates. That is, after the initial intervention hypothesized to be effective at reducing sex offense recidivism, it seems quite possible—and even likely—that treatment subjects and control subjects may have obtained additional treatment experiences, social services, and/or some degree of parole supervision, all of which might be significant factors related to lowering recidivism rates. It is commonly noted that sexual offenders in the Canadian correctional system may receive additional, often substantial, rehabilitation or pro-social programming (e.g., substance abuse treatment, criminal thinking interventions, reintegration services) while institutionalized and/or during probation, including additional specialized sexual offender treatment as they are placed sequentially at different institutions. Obviously, the nature (intensity of conditions) of post-release supervision or probation as well as varied types of post-release or posttreatment aftercare may have a significant and differential effect on those who did and did not participate in sexual offender treatment.

Treatment Allegiance

Allegiance to a treatment approach refers to the degree to which a therapist providing the treatment believes that the psychotherapy is effective; in effect, this constitutes an expectancy effect and potential bias. Those who develop or are advocates for particular or general treatment programs may be relatively zealous about the likely benefits for their own proposed or endorsed interventions. Unlike medications studies (which can be administered in a blind or double-blind manner), allegiance effects in psychotherapy cannot easily be controlled. Wampold (2001) reported that early meta-analyses showed that treatment effects for which the clinician had an allegiance or expectancy produced an effect that was approximately 1/3 larger than the opposite condition. He noted that in one meta-analysis, the correlation between allegiance ratings and the effects of the study approached 0.60, while another similar study suggested that allegiance effects might be somewhat less. However, Wampold (2001) concluded:

> …it is clear that allegiance of the therapies is a very strong determinant of outcome in clinical trials. That the effects due to the allegiance accounts for dramatically more of the variance in outcome than does the particular type of treatment implies that therapist attitudes and expectancies about the results of psychotherapy are a critical component of effective therapy…. (p. 168)

As noted in a MA, Munder et al. (2013) found that research allegiance to the intervention itself showed a moderate effect size with treatment outcome; psychotherapy researchers are likely to "find" what they want or intend to "prove." Not surprisingly, allegiance effects apply to sexual offender treatment as well. In their articles, Losel and Schmucker (2005, 2008) found that in more than 50 % of the primary research studies, the studies' authors were affiliated with the treatment program that was implemented (suggesting allegiance issues). Not surprisingly then, they showed that for such treatment, studies (in which the study author(s) was in some way involved in the program delivery) showed clearly significant treatment effects. Yet in contrast, programs that were evaluated by *independent* researchers did *not* show positive treatment effects; this strongly suggests the so-called allegiance effects.

The Lack of Randomized Controlled Studies: A Multitude of Problems

The primary methodological criticism of the existing literature on psychotherapy for sexual offenders concerns the almost uniform failure to utilize accepted standardized research designs for interventions (e.g., RCTs involving both random assignment of similar subjects to a psychotherapy condition and at least one control condition). Hanson et al. stated that a "strong" treatment outcome study would be one that involved "a well-implemented random assignment study (e.g., uncorrupted random assignment, 5 or more years of follow-up, sample size >100, < 20 % attrition, no preexisting differences between the groups found post hoc)" (p. 869). In contrast, the available sexual offender treatment research literature relies almost exclusively on experimental and control groups that are *each* biased in the direction of providing the appearance that sexual offender treatment has been demonstrated to be effective. While RCTs offer one perspective as part of an evidentiary hierarchy and of evidence-based practice and do not necessarily avoid some methodological issues themselves, they are the critical standard in providing key experimental findings that are more conclusive in establishing casual relations of treatment effects than results obtained utilizing other methods or approaches. As Kendall et al. (2004) articulated from a research perspective and the Cochrane Collaboration emphasized from a health policy/health economics perspective, RCTs provide the fundamental basis for evidence-based intervention research and resultant health-care treatment policies. Sacket et al. (1996) wrote "…we should avoid non-experimental approaches…since these routinely lead to false positive conclusions about efficacy…[so that]

the systematic review of several randomized trials… has become the 'gold standard' for judging whether a treatment does more good than harm" (p. 171). RCTs are studies that enable stakeholders a relatively unique opportunity to assess whether an intervention itself, as opposed to other factors, is responsible for observed outcomes in clients. RCTs are designed most likely to nullify unknown or hidden threats to internal validity or confounding factors. The failure to utilize random assignment of comparable and motivated sexual offenders to intervention or control conditions dramatically works to prevent reaching any meaningful conclusion that sex offense treatment might be effective at reducing sex offense recidivism. As noted previously, in the general psychotherapy literature, RCTs are considered the sine qua non of methodologically correct scientific study of treatment outcome.

McConaghy (1993) was one of the first authorities to emphasize the importance of RCTs and the limitations of uncontrolled sexual offender treatment studies. The unique significance of RCTs in sexual offender treatment specifically has been repeatedly emphasized by numerous individual authorities (e.g., Quincy et al., 1993; Rice & Harris, 1997; Quinsey, Khanna, & Malcolm, 1998, 2006; Rice & Harris, 2003; Seto et al., 2008). Seto et al. (2008) noted that primary health-care research and policy agencies, including the Cochrane Collaboration, the US Center for Disease Control and Prevention, and the US Food and Drug Administration, each identify effective interventions exclusively based on RCT results. As Seto et al. stated, from an experimental design perspective, RCTs "are the best at distributing [pretreatment] differences randomly, and only randomization can eliminate the subtle selection biases that affect even the best incident study designs" (p. 249). Similarly, the SBU stated:

> The ideal study design is the randomized controlled trial (RCT), where offenders or people at higher risk of becoming offenders are randomly assigned to either a treatment (i.e. the studied intervention) or a control group (e.g. another intervention or no treatment)…[as a result of this procedure] we can be relatively confident that a difference in reoffending is a result of the treatment. (p. 16)

Since 2010, the Association for the Treatment of Sexual Abusers (ATSA) has been on record that:

> [I]t recognizes randomized clinical trials (RCT's) as the preferred method of controlling for bias in treatment outcome evaluations. ATSA promotes the use of RCT to distinguish between interventions that decrease the recidivism risk of sexual offenders and those program that have no effect or are actually harmful…full RCTs are always preferable, and are unparalleled for determining causal relationships between treatment and outcome. (ATSA, 2010a)

RCTs provide for two factors that allow conclusions to be reached about the possible effectiveness of intervention. First, they require that an intervention condition be contrasted with one or more control conditions; thus the RCT design provides a preliminary determination as to whether subjects who received the intervention may have received some specific positive benefits relative to the control conditions. In an early paper, Quinsey et al. (1993) (as cited in Rice & Harris, 2003) first advocated criteria that could provide useful scientific data on the effectiveness of treatment, stating "…unless a study measures officially recorded recidivism from at least two distinct groups of sex offenders (at least one of which receive treatment), and unless the groups are, except for treatment, comparable, that study has no scientific value in evaluating treatment" (p. 431). McConaghy (1993) noted that random allocation of subjects in sexual offender treatment is the only procedure that offers the possibility of controlling all relevant variables, known and unknown. Generally, some 30 years ago, Cook and Campbell (1979) pointed out that the main problem of quasi-experimental design is the differential selection of subjects that receive the program compared to the subjects that do not receive the program. If at the beginning of the program the groups are not equivalent for the relevant variables, then the posttest comparison of the two groups can produce a biased estimate of the effect size. More recently, regarding sexual offender treatment specifically, as Miner (1997) put it:

> The major problem with uncontrolled designs is that they provide no means for assuring the internal validity of the study. The lack of control or comparison groups makes it plausible that any changes in subject status could be attributed to factors other than the intervention itself. This leaves the researcher unable to conclude much about the effectiveness of treatment. (p. 99)

As Schlank (2010) noted, several common psychological phenomena can affect intervention results. For example, she identified the Hawthorne effect, where a temporary change in measured behavior occurs as a result of subjects' awareness that they are being observed. In addition, she also noted the Pygmalion effect when a perceived "leader" or teacher's expectations affect the behavior of students (or clients), at least temporarily (a problem often related to allegiance effects).

A related methodological issue is the comparability of intervention and control groups; both groups must be relatively equivalent in key characteristics. As Miner (1997) stated: "The major problem with nonequivalent groups designs is an issues of the linkage between cause and effect," (p. 100) noting that differences in groups on variables as simple as motivation for treatment make it difficult to conclude that group differences may be related to an intervention condition. Thus, similar to standard psychotherapy outcome research, in order to best assure comparable treatment and control groups, it is necessary to start with subjects comparably interested in and motivated for treatment and then randomly assign them to treatment or control groups. Similar to Miner, Rice and Harris (2003) emphasized that investigators

generally agree that it is desirable to limit or control possible sources of measurement bias in the study groups and that the best and necessary means of accomplishing this is through random assignment via an RCT. With random assignment of subjects to intervention or control group(s), the allocation of similarly motivated subjects to either intervention or control groups is determined solely by chance (and not by personal preference or social mandate). [Such groups may differ by chance, as Rice and Harris noted that while "the gold standard is a random assignment study, but even with random assignment the treatment does not guarantee the groups are comparable: random assignment merely guarantees that differences are randomly distributed" (p. 429).] Thus, RCTs are a necessary but not necessarily sufficient condition to demonstrate that any differences found between experimental/treatment and control groups are most likely the result of the intervention and not simply the result of preexisting differences in the experimental and control groups.

Rice and Harris (2003, 2012) and Seto et al. (2008) have identified that, historically, several significant studies of medical and psychosocial interventions were initially conducted without random assignment of subjects to intervention and control groups and initially appeared to show that a particular treatment was effective (including studies of delinquency intervention, arthroscopic knee surgery, drug abuse prevention, and critical stress debriefing). However, when RCTs were utilized for these and other problems, either no or even negative effects were demonstrated for what had previously been regarded as theoretically sound interventions. Consequently, without the use of RCTs, inadequate and/or harmful interventions would have gone undetected. Similarly, regarding sexual offender treatment, Seto et al. (2008) commented on the possibility that "unproven treatment might have harmful effects, unintentionally increasing recidivism and thereby harming victims, offenders, and their respective families" (p. 250). They provided several examples of how current practices in sexual offender treatment might hypothetically lead to increased risk for sex offense recidivism. Other authorities have echoed these concerns (e.g., Corabian et al., 2010; Dennis et al., 2012).

Schmucker and Lösel (2008) acknowledged that 60 % of the studies they reviewed "used clearly non-equivalent control groups" (p. 16). In considering the sexual offender treatment outcome studies reviewed by Hanson et al. (2002) assigned to the category of random assignment of subjects (to either psychological treatment or no psychological treatment), Rice and Harris (2003) noted that Hanson et al. found only three studies in total that could be assigned to this category. Two of these studies indicated deleterious effects of treatment and one indicated reduced general but not sex offense recidivism. Only one RCT study reported positive treatment results for sex offense recidivism; Borduin et al. (1990)[6] provided "multisystemic therapy" (MST—a model not easily applied to adults) for a small group ($n = 24$) of adolescent offenders with positive effects. Subsequently, Rice and Harris agreed with the conclusion by Hanson et al. "that no empirical support for treatment effectiveness can be drawn from the random assignment studies, especially not for sex offender specific treatment for adults" (p. 434). Of note, Losel and Schmucker (2005) similarly found: "The size of the [treatment] effect is small to moderate…Restricting the analysis to a few randomized trials shows a comparable mean effect but it does not render it statistically significant." Eggers et al. (2001) demonstrated how conclusions from a meta-analytic review based on a number of small-scale trials were subsequently contradicted by results from a single study containing a much large sample; as McGuire has stated "The two most frequently repeated criticisms of meta-analysis, are loosely termed, those of 'garbage in—garbage out' and 'apples and pears'." With the absence of positive results from the very few RCTs for sexual offender treatment outcome, Rice and Harris wrote: "…weak inference evaluation leads to too many errors (and incorrectly accepting the existence of beneficial effects)…" (p. 429).

Further, another significant methodological issue makes even random assignment of potential sexual offender participants in treatment problematic. Typically, in RCTs for mood/anxiety and/or behavioral problems, the initial subject pool for treatment or control group assignment is persons who have volunteered to participate in such treatment. Consequently, most psychotherapy investigations start with persons who truly want—are motivated—to participate in such intervention to relieve personal distress or impairment. In fact, they are likely to be persons who may have tried other treatments without success and have elevated positive expectations and enthusiasm for treatment participation. Subsequently, that group of motivated help-seeking persons is typically randomly assigned to either treatment or control conditions. However, almost all extant sexual offender treatment outcome studies have not included motivated or help-seeking sexual offenders in comparison or control groups. Rather, these studies involve the biased preselection or composition of either or both the experimental/treatment group and the control group. More specifically, as will be seen, persons who end up participating in sexual offender treatment are generally likely to have lower sexual offense recidivism a priori, while those who decline such treatment are likely to have higher sexual offense recidivism rates a priori.

[6]Of note, per Westen et al. (2005), when MST was "transported" from research ("effectiveness" to community settings "efficacy," with effect sizes diminished by as much as 1/3 when provided by community therapists (as opposed to carefully supervise graduate students); in addition, there were relatively small effects on individual psychopathology relative to family relations.

Thus, a significant issue is which sexual offenders are included in sexual offender treatment outcome studies. First, many or most sexual offenders appear to not even be offered treatment. As Marshall (Marshall & Marshall, 2007; Marshall, Marshall, Serran, & O'Brien, 2011) has pointed out, most RCT treatment studies involved exclusion criteria that are often quite extensive (e.g., not disruptive, no below average intellectual functioning, no comorbid psychiatric conditions, and so on), and as a result, those offenders who participate in treatment are much more likely to have lower recidivism rates even prior to treatment. In addition, other investigators have differentially excluded particular groups of sexual offenders from possible participation in treatment studies. Reviewers have identified that a number of treatment programs only included offenders deemed less "severe" (e.g., of only low or moderate risk) and *excluded* more high-risk or "severe" sexual offenders for participation in sexual offender treatment. For example, in Hall's meta-analysis, as many as 33 % of sex offenders eligible for treatment were "screened out" and *not offered* treatment; specifically, Hall noted that the more "severe" sexual offenders (e.g., those with more extensive sexual offense histories, with mental health problems, who denied their sexual offense history, perceived as management problems, etc.) were not offered treatment in the studies that he reviewed. Similarly, Jones, Pellissier, and Klein-Saffran (2006) reported that 16 % of persons who had volunteered for sexual offender treatment were refused because of psychological reasons including lower intellectual capacity, severe mental illness, low motivation, history of treatment failure, and nonacceptance of responsibility for sexual offending. An additional 22 % of sexual offenders were refused treatment after being accepted and assigned to treatment. In addition, Marques et al. (2005) excluded any sexual offender with more than two prior felonies; thus, the treatment candidates were a low- or moderate-risk group to begin with. They also excluded offenders who denied their crime. Further, Marques et al.'s study could be viewed as "incentive laden" in that it involved a transfer from a prison to a one specific hospital setting, further limiting potential candidates. After selection criteria in SOTEP, 68 % of participants were low or medium risk. As Marshall and Marshall (2007) have pointed out:

> These exclusionary criteria would have biased the SOTEP *in favor* of finding a treatment effect… "they pointed out"…it seems reasonable to conclude that the nonvolunteers were among the most treatment resistant offenders and likely the ones in most in need of treatment. (p. 183, emphasis added)

[Despite this bias, of course, the SOTEP did not identify a positive treatment effect for CBT-RP and aftercare.] Thus, outside of mandated/coerced sexual offender treatment, as Harris, Rice, and Quinsey (1998) suggested, relying on persons who volunteer for and persist with treatment effectively screens out most high-risk sexual offenders and consequently participation in "…treatment over the long terms serves as a filter for detecting those offenders who are relatively less likely to reoffend…" (p. 103).

Beyond higher risk, other factors also influence the inclusion of offenders into sexual offender treatment; these include acknowledgement of some history of sexual offending and self-reported motivation for intervention. Beyond eliminating offenders with more serious sexual offending history (e.g., per risk studies, higher-risk sexual offenders), studies have typically selected only those offenders who (1) (must) admit to their offenses and/or (2), to varying degrees, are willing to participate in sexual offender treatment, either because they believe it is beneficial or because they may view such participation as providing them some gain or advantage (e.g., early release). Tierney and McCabe (2002) noted that some treatment programs target only the most "motivated" sexual offenders because they are considered most likely to change their behavior. In the SOTEP (Marques et al., 2005), only 1/3 of sexual offenders invited to participate in sexual offender treatment were willing to enter the research intervention; that is, **2/3** of sexual offenders offered sexual offender treatment refused to even consider entering the sexual offender treatment study. Thus, in this unique modern RCT, there was a highly significant degree of self-selection relative to a willingness to pursue sexual offender treatment. Rice and Harris (2003) pointed out that, in general, offender self-selection for sexual offender treatment has been the norm. Losel and Schmucker (2005) found that only 16 % of sexual offender treatment participants could be characterized as "volunteers." Further, Larorchelle et al. (2011), in their review of 18 studies, found that between 15 and 86 % of sexual offenders who began sexual offender treatment dropped out (the most consistent predictor being antisocial personality disorder and other antisocial characteristics). Thus, outside of mandated/coerced sexual offender treatment, Rice and Harris (1998) suggested that the utilization of persons who volunteer for and persist with treatment effectively screens out the higher-risk sexual offenders. As a result, in most contexts, sexual offenders who do "volunteer" for and remain in sexual offender treatment appear to an extremely different group of sexual offenders (e.g., lower risk for sexual reoffending) from those who choose not to participate or those who are excluded from participating.

Yet another issue to be considered relative to those sexual offenders who "agree" to participate in sexual offender treatment is the degree to which entering into sexual offender treatment is truly voluntary. Marshall and Barbaree (1990) noted, "quite a number of patients are under judicial or administrative pressure to enter and remain in treatment" (p. 375). As Losel and Schmucker (2005) reported, only sexual offender treatment programs involving *voluntary* participation by offenders showed a significant effect; programs that involved "a more or less coerced treatment" did not

show a significant treatment effect. Other studies have also found that the degree of mandate or coercion is related to treatment outcome in offender populations.

In short, to date, those person who have been studied after receiving sexual offender treatment are a minority of sexual offenders, apparently lower-risk offenders, those without comorbid psychiatric disorders or intellectual disabilities, and those with mixed or uncertain motivation (e.g., some intrinsically motivated and others mandated and with external motivation). Consequently, the experimental or treatment groups in sexual offender treatment outcome research should be viewed skeptically as representatives of sexual offenders in general, relative to their apparently unique identification or interest in seeking treatment as well as their degree of risk and associated disorders.

In addition, the nature of the comparison or control group in sexual offender treatment outcome studies is another highly significant methodological issue that potentially contaminates the results of such studies. As Marshall and Marshall (2007) noted:

> One problem with the incidental design, however, is that there may be a plethora of undetected but significantly influential differences between the treated and untreated subjects aside from the usual matching variables (i.e. some limited demographic and offense history features). Frustration with not begin given access to treatment, differential responses by the authorities to treated and untreated subjects (e.g. refusal to grant parole to untreated offenders, placement in a less attractive prison setting) may provoke responses in the untreated subjects that might confound the matching process. (p. 186)

The majority of sexual offender treatment outcome studies that utilize a nonrandom assignment control group are characterized as "incidental assignment" studies and constitute what is referred to as "quasi-experimental" designs. Since they are not RCTs, they have not randomly assigned comparable, motivated offenders to either treatment or a control condition. Thus, in the existing incidental assignment studies, researchers have resorted to utilizing various groups of offenders to serve as a "control" condition including identified treatment refusers; treatment dropouts; persons selected from a general group of sexual offenders (sometimes contemporaneous offenders and sometimes from a different time period); and/or general sexual offenders matched to a treatment group on one or more variables. However, it has been demonstrated that such comparison groups are each problematic for determining if the treatment condition for sexual offenders is actually effective. It can be demonstrated that for at least the first three potential control groups, their use of such types of sexual offender as a control group is compromised since each group—a priori or pretreatment—would almost certainly have a higher rate of sexual offense recidivism than those persons typically screened or volunteering for participation in sexual offender treatment.

The general group of sexual offenders, particularly after removing those selected as potential treatment candidates or who volunteer for sexual offender treatment, consists relatively of sexual offenders who would either refuse sexual offender treatment or would likely drop out of such treatment; both groups are known to be at higher risk of sexual offense recidivism than the "average" sexual offender. Using persons for control groups who have or would refuse sexual offender treatment will lead to a control group that is already characterized by an elevated risk for sexual offense recidivism. Thus, several years before Hall's initial meta-analysis, Quinsey et al. (1993) had argued that treatment refusers should not be ignored in considering treatment efficacy because of their particularly high rate of recidivism. More generally, this recommendation was in line with the increased importance of intent-to-treat (ITT) analyses in the general psychotherapy outcome literature. "Intent to treat" is a strategy for the analysis of randomized controlled trials that compares all clients based on the groups to which they were originally randomly assigned. Thus, to meaningful measure how well a particular intervention works, all individuals randomly assigned to that treatment condition are followed and evaluated, regardless of whether they actually entered, dropped out, or completed that treatment. ITT analysis reflects the practical clinical scenario because it recognizes the meaning of treatment noncompliance, later treatment rejection and treatment protocol deviations. Clinical effectiveness may be overestimated if an intention to treat analysis is not done (e.g., Hollis & Campbell, 1999); for example, how effective is surgical castration if few or no persons are willing to consent to it? Of note, the FDA of the USA recommends ITT analyses, noting the results of a clinical trial should be assessed not only for the subset of patients who completed the treatment but also for the entire sample of individuals who were randomized to treatment or control conditions.

As Harris et al. (1998) initially pointed out for Hall's (1995) meta-analysis in several studies, "all or most of the control group were men who refused or quit treatment…" (p. 102). Losel and Schmucker (2005) showed that in approximately 24 % of the psychosocial sexual offender treatment comparisons, the control group consisted of treatment refusers. Treatment refusers are clearly not characterized by significant motivation for sexual offender treatment. Marshall and Barbaree (1990) commented on earlier research by Abel, noting that almost 35 % of sexual offender entering his program withdrew or were terminated; "the highest rates of withdrawals from their program occurred in those patients who felt the greatest pressure to participate in therapy" (p. 375). Olver et al. (2013) noted that if dropout rates were not carefully managed and reduced, dropping out might act like a self-selection process, unwittingly resulting in the treatment of predominantly or exclusively lower-risk offenders. As

noted previously, in the SOTEP study by Marques et al. (2005), initially, 2/3 of sex offenders offered sexual offender treatment refused to consider such intervention. Later, an additional 21 % of that 1/3 that had previously volunteered for sexual offender treatment withdrew prior to the beginning of treatment. Given that 66 % of sexual offenders declined to participate in sexual offender treatment initially and then additional 21 % of those assigned to treatment refused, a basic issue raised regarding sexual offender treatment is the level of interest or motivation for participating in a particular intervention program. Such sexual offender treatment refusers have been identified as characterized by higher sex offense recidivism rates than persons who volunteer for sexual offender treatment (Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988, as cited in Quinsey et al., 1993). Utilizing a control group of sexual offenders who appeared to be untreated sexual offenders, Olver et al. (2013) found that "The importance of controlling for risk was underscored by the fact that untreated offenders scored significantly higher on [a static risk measure] and thus were higher risk for sexual and violent recidivism overall" (p. 415). That is, as with many studies that utilize a quasi-experimental design, those sexual offenders selected for control purposes were at elevated risk for sexual violence to begin with. As Rice and Harris (2003) wrote, "It is highly probable that, irrespective of the effects of treatment, those who refuse represent greater risk than those who volunteer for and completed…" (p. 432). More recently, Seager et al. (2004) found that treatment refusers had particularly high rates of sex offense recidivism relative to treatment completers (e.g., 42 %).

It is also problematic to utilize persons for control groups who have dropped out of or been terminated from treatment as that will also lead to a control group that is characterized by an elevated risk for sexual offense recidivism. As noted previously, for psychotherapy in general, treatment dropout or attrition from research studies has averaged 47 % and in actual clinical settings has been found to be even higher (e.g., Wierzbicki & Pekarrik, 1993). Quinsey et al. (1993) also pointed out that sexual offender treatment dropouts should not be ignored in considering treatment outcome because of their particularly high rate of recidivism. Beyko and Wong (2005) noted, "Unfortunately, attrition from many sexual offender treatment programs is high, up to 30–50 % in both residential and community programs" (p. 376). In SOTEP, Marques et al. (2007) found that 18 % of the small group of sexual offenders that had previously volunteered for and were assigned to sexual offender treatment did not complete the program (27 voluntarily withdrew and 10 were demitted because they presented as "severe management problems in the hospital"). Thus, dropout rates for persons placed in sexual offender treatment are very high.

More importantly, most available data suggests that treatment dropouts (or persons terminated from such interventions) are each characterized by higher recidivism rates than persons who volunteer for sexual offender treatment (Abel et al., 1988, as cited in Quinsey et al., 1993); failure to complete sexual offender treatment was a significant predictor of sex offense recidivism. As Olver et al. (2011) stated: "The clients who stands to benefit the most from treatment (i.e. high-risk, high-needs) are least likely to complete it" (p. 6). Marshall (1993) concluded "dropouts included a significant proportion of those sex offenders at greatest risk to offend" (p. 526). Specifically, Miner and Dwyer (1995) showed that treatment dropouts sexually reoffended at a rate three times that of treatment completers. Miner (1997) noted in his research that he "found higher reoffense rates in those [offenders] who terminated prematurely" (p. 101). As Seager et al. (2004) pointed out, Hanson and Bussiere (1998) found that there was a 17 % difference in sex offense recidivism rates between treatment dropouts and completers. Alexander (1999) found that dropouts were twice as likely to sexually reoffend. While Hanson et al. (2002) did not report the frequency with which control groups contained treatment dropouts, they did find that persons who eventually dropped out of treatment had consistently higher rates of sex offense recidivism. More recently, Seager et al. (2004) also found that treatment dropouts (as well as persons who were rated as failing to complete treatment) had particularly high rates of sex offense recidivism relative to treatment completers (e.g., six times greater). In this last investigation (albeit a small sample), the following rates of recidivism were found: 18 % for treatment dropouts and 100 % for those terminated from treatment. As noted, Losel and Schmucker (2005) reported, "Whether treatment was terminated regularly or prematurely had an impact on sexual recidivism. Where as regular completers showed better effects than the control groups, dropouts did significantly worse. Dropping out of treatment doubled the odds of relapse…" (p. 132). Langton, Barbaree, Hansen, Harkins, and Peacock (2007) also found that treatment dropouts showed the fastest failure rates.

Hanson (per a personal communication cited by Rice & Harris, 2003) agreed that, in fact, there were a priori reasons why treatment dropouts should be considered at higher risk to reoffend. Generally, as with sexual offender treatment refusers, dropouts are identified as likely to be more impulsive, show less self-control and other antisocial characteristics, and possess fewer social skills, all factors known to be associated with increased recidivism risk (e.g., Marques et al. 1994; McConaghy, 1999; Rice & Harris, 2003, 2012; Seager et al., 2004). Langton et al. (2006) also found treatment dropouts had significantly higher PCL-R scores (more psychopathic traits) than offenders who completed the same treatment program. Similarly, Beyko and Wong (2005) found that sexual offender treatment dropouts were characterized by two clusters of behaviors, one which they related to

criminogenic needs (e.g., aggression, rule-breaking behavior, longer offense histories, and more criminalized) and a second which they viewed as a responsivity issue (e.g., lack of motivation and denial). Olver and Wong (2009) found that 56 % of sexual offender treatment dropouts met study criteria for psychopathy. Nunes and Cortoni (2008) found that treatment dropouts were significantly associated with elevated general criminality characteristics. Olver et al. (2013) found that their untreated (but not randomized) control group scored as higher risk for sexual and violent offense recidivism than their treated group. In short, since sexual offenders who drop out of sexual offender treatment appear to be different and, most importantly, higher risk for reoffending than offenders who complete such treatment, "intent-to-treat" or treatment as assigned analyses appear imperative to rule out the significance of pretreatment differences.

A number of outcome studies for sexual offender treatment have utilized persons selected from some general group(s) of sexual offenders. Based on the research findings cited above, the majority or a large percentage of a general group of sexual offenders would refuse to participate in such interventions. In addition, such general groups of sexual offenders would include persons typically or historically excluded from treatment studies because they would be deemed high risk, mentally ill, intellectually limited, unmotivated, and so on, by virtue of what is known about treatment exclusion criteria. More importantly, as should be apparent from the just reviewed studies, since the great majority of sexual offenders either refuse or withdraw/drop out of sexual offender treatment, any group of general sexual offenders would almost certainly contain a substantial group of likely treatment refusers/dropouts if placed in or offered treatment. Thus, whether a control group included persons typically excluded from sexual offender treatment studies or treatment refusers/dropouts, such control groups would necessarily be composed of persons who, *prior* to any treatment being provided in a study, would very likely be sexual offenders at much higher risk to reoffend: high risk, unmotivated, more severely and comorbidity disordered, and likely to drop out if placed in treatment.

Another mechanism employed to create a control group relative to a treatment group is to attempt to "match" characteristics of the treatment group in the selection or creation of a control group, with the notion that such matching might result in equivalent groups for comparison. However, McConaghy (1993) noted that it is not possible to match offenders on all relevant variables as many offenders are not possible to assess accurately and many relevant variables were (are) not yet known. Similarly, relative to matching, as Seager et al. (2004) pointed out, studies rarely use more than three risk factors to match subjects, and they are often unable to match all treated subjects with untreated controls on the specified risk factors. In addition, while the comparison group may be "matched" on certain variables, the members are still selected from the larger set of sexual offenders, which is to say that they include persons typically excluded from sexual offender treatment studies and/or treatment refusers/dropouts. Further, it is important to note that the most sophisticated sexual offender treatment outcome study, the SOTEP (prior to randomization), matched potential treatment candidates on age, criminal history, and type of offender (Marques et al., 2005) but still found no treatment effect. As the SBU indicated, when control groups are created for comparative purposes not by random assignment, there can be no certainty that any difference obtained between treatment and control group is the result of treatment; even with statistical attempts to control for variability between the groups, "since the differences between the groups cannot be attributed to chance, we can never be completely certain that the results are not due to some unmeasured, and perhaps unknown, risk factor that is more common in one of the groups" (pp. 17–18). Thus, Quinsey et al. (1998), when considering only the available studies from Hall's MA that used a matching or randomization design, found that the effect size fell to 0; that is, the already "small" treatment effect in that MA was eliminated and no longer statistically significant.

As reviewed, the only basis for Hanson et al. (2002) concluding that there was *any* evidence of a treatment effect for psychosocial interventions applied to sexual offenders was their consideration of "incidental assignment" studies. Consequently, it is worth examining those results more closely. Rice and Harris (2003) reviewed the results of Hanson et al.'s (2002) "incidental assignment" treatment control group findings. As noted, in these studies, comparison groups were offenders selected as "matching" according to various methods including similar criminal records but who had been released before the implementation of the treatment program or who came from different geographical areas, who received an earlier version of the treatment, or who received no treatment or an alternative treatment due to such administrative reasons is too little time meeting their sentences. Hanson et al. (2002) labeled these seventeen studies as "incidental assignment" because they believed that there was no obvious a priori reason that the treated and untreated offenders would differ in risk and, thus, no "obvious" bias in group assignment. Of the 17 "incidental assignment" studies, only 11 were considered to be studies involving current treatments (those still being offered at the time of the meta-analysis).

Rice and Harris (2003) pointed out, "…with few exceptions, the studies included in this meta-analysis did not meet our criteria for minimally useful evaluation" (p. 433). They concluded that "the balance of available evidence suggests that various well-known threats to validity and the reliance on non-comparable groups are responsible for apparent beneficial treatment effects…" (p. 438). Rice and Harris (2003) specifically noted that 8 of the 11 "incidental assignment" studies clearly included sex offenders in the comparison group who

were not offered treatment, and thus, such studies appear to *include* likely treatment refusers or treatment dropouts in the control group who were not offered treatment. As noted previously, sex offenders selected for having completed treatment are not comparable to sex offenders who were not offered treatment because both refusal and dropping out are a priori risk factors for increased sex offense recidivism. As Seager et al. (2004) stated:

> Within 'untreated' comparison samples a subset will be refusers and dropouts thus giving rise to concerns because refusers and dropouts reoffend at higher rates than completers. By failing to mathematically remove anticipated refusers and dropouts from untreated comparison groups, there is an inflationary effect for the treatment condition; that is, untreated comparison groups will have an exaggerated recidivism rate relative to the subgroup of untreated offenders who would have accepted treatment and remained till completion if offered the opportunity. (p. 601)

"Given that [a general group of sexual offenders] can be assumed to include a significant proportion who would have refused or quit treatment had it been offered to them and, therefore, are not appropriate comparison or control groups for the evaluation offender treatment" (Quinsey et al., 2006, p. 149) and would have dropped out of treatment had it been offered to them. Of the three remaining studies involving incidental design of current treatments reviewed by Hanson et al. (2002), Rice and Harris (2003) stated that each of them included significant methodological confounds that would neither meet their criteria for minimally useful evaluation nor even the Hanson et al. definition of "incidental assignment." Further, Rice and Harris (2003) and Seto et al. (2008) pointed out that in a number of studies included in "incidental assignment groups" in the Hanson et al. (2002) meta-analysis, a *double error* was found: offenders who refused or would have dropped out of treatment were not counted as part of the treatment condition but were counted as part of the control group. This procedure potentially reduced the measured sex offense recidivism of the treatment group *and* increased the sex offense recidivism of the control group, irrespective of the value of the intervention itself. As Rice and Harris (2003) concluded:

> It is highly probable that, irrespective of the effects of treatment, those who refuse represent greater risk than those who volunteer for and completed…any study that does not track both refusers and dropouts cannot provide scientifically useful data in support of treatment effectiveness because there are clear a priori reasons to expect differences between the groups in recidivism… Samples of untreated sexual offenders will contain a substantial minority who would refuse treatment if offered, and another subset who, after beginning treatment, would quit or be ejected. (p. 432)

Similarly, Seto et al. (2008), responding to Marshall and Marshall (2007), pointed out that the design of the studies that provided the support for the conclusions of Hanson et al. (2002) emphasized that "…this decision creates a selection bias, independent of any treatment effect, that increases the chances of finding newer offense among the treated sexual offenders…" (p. 252). They pointed out that "All of the incidental designs touted by Marshal and Marshall are even more vulnerable to the problem of inadvertent nonequivalence of groups, and all depend on some kind of statistical control from known risk factors" (p. 248). However, unknown risk confounding factors would not be subject to such a priori control. They also pointed out that Marshall and Marshall's rejection of RCTs would not take into account treatment motivation for sexual offender treatment (an issue on which Marshall himself has identified as a more systemic issue in providing interventions for sexual offenders). Barnett et al. echoed this concern stating "One problem with the incidental design, however, is that there may be a plethora of undetected but significantly influential differences between the treated and untreated subjects aside from the usual matching variables (i.e., some limited demographic and offense history features). Frustration with begin given access to treatment, differential responses by the authorities to treated and untreated subjects (e.g. refusal to grant parole to untreated offenders, placement in a less attractive prison setting) may provoke responses in the untreated subjects that might confound the matching process" (p. 186). Most recently, even Hanson (2014) has rejected the results of "incidental design," writing: "Comparisons between treated and untreated offenders from the same setting are usually biased because those who get treatment area systematically different from those that do not…" (p. 6).

Concerning both participants and refusers of sexual offender treatment, it seems clear that both typical treatment study participants and those excluded from inclusion, as treatment participants, are distinct and different groups of sexual offenders from one another. Both the exclusion of potential sexual offender participants by investigators and the self-selection by offenders relative to participation in treatment create meaningful differences in the pool of subjects who have composed treatment conditions. As Harris, Rice and Quinsey (1998) suggested years ago, volunteering for and persisting with treatment appears to effectively screen out most high-risk sexual offenders, writing "the data so far are consistent with the conclusion that agreeing to and persisting with treatment over the long term serves as a filter for detecting those offenders who are relatively less likely to reoffend…" (p. 103). That is, participation in sexual offender treatment does not appear to actually reduce recidivism rates for those who complied with treatment program but merely enables lower-risk, motivated sex offenders to demonstrate their commitment to not reoffend. Later, in 2012, Rice and Harris wrote, "…the predictors of treatment non-completion indicates that those who volunteer for and complete psychosocial treatment would, on average, exhibit a moderate to large difference in recidivism compared to those not offered

treatment, even if treatment had no effect" (p. 11). Effectively, in available sexual offender treatment outcome studies and the MAs and SRs of them, relatively lower-risk sexual offenders are being offered and accepting treatment participation, while higher-risk sexual offenders are both being excluded from or refusing participation in the sexual offender treatment that is the subject of study and often utilized as a comparison group. Further, both actual treatment refusers and dropouts appear similarly higher risk; relative to "intent-to-treat" principles, sexual offender treatment studies must identify and track both treatment refusers and dropouts because there are a priori reasons to expect differences between those groups and treatment volunteer/completers. Consequently, it is not at all surprising that group differences that *appear* to be treatment effects are identified when sexual offenders selecting and/or selected for treatment are compared to those sexual offenders who are not considered for or not volunteering for such treatment (because a significant proportion of who would likely refuse or drop out of such treatment) since a comparison group of non-volunteer sexual offender treatment individuals containing a relatively high proportion of both likely treatment refusers and actual treatment refusers will consist of a significant proportion of persons *already* at higher risk for sexual offense recidivism. Rice and Harris (2003) wrote: "In our opinion, few useful scientific data on effectiveness can come from studies contrasting complete treatment completers with sex offenders not offered treatment because such contrasts almost inevitably entail non-comparable groups" (p. 432). The most reasonable conclusion is that truly volunteering and being motivated for sexual offender treatment are among the most critical factors relative to outcome and that whatever intervention is offered makes little difference to the outcome; psychotherapy is irrelevant once client variables are accounted for.

In short, even prior to implementing treatment, in studies that find "small" differences between treated and untreated offenders, such differences would be expected based simply on the *likely preexisting differences in sexual offense recidivism rates* between persons selected and choosing treatment and other sexual offenders who are utilized as "control" groups. When differences in sexual offender treatment are found in non-RCT studies, the most reasonable conclusion is that sexual offender treatment *does not* lower the rate of sex offense recidivism below that of the average sexual offender; rather the most compelling conclusion is that rates of sex offense recidivism for *persons used as comparison groups are significantly higher than the average sexual offender*. Thus, the differences between treatment and control groups are not the result of treatment but a straightforward consequence of *preexisting risk status*. To this end, it is notable that per Table 1, the 5-year sex offense recidivism rates of sexual offenders who participated in treatment per the 2002 and 2005 treatment meta-analyses (10–12 %) are very similar to the 5-year sex offense recidivism rates of the very large groups of predominantly untreated sexual offenders identified in the risk-factor meta-analyses (13–14 %). Such a point is driven home even more so by the fact that when sexual offender treatment outcome studies utilize an RCT methodology (randomly assigned, comparably motivated, more equivalent treatment and comparison groups), no difference is found between those who participate in sexual offender treatment and those who do not as per Marques et al. (2005) (Table 1).

Thus, to date, scientific evidence has failed to demonstrate that sexual offender treatment completion per se reduces sex offense recidivism generally or for specific types of sexual offenders. Rice and Harris (2003) concluded, "The current empirical support suggesting beneficial effects of treatment rests on the use of non-comparable groups in which control subjects were of higher a priori risk" (437). Rice and Harris indicated, "Weak inference methods (as exemplified by almost all of the studies review by Hanson et al. (2002) ensure that the field of sexual offender treatment will continue to exhibit change without progress" (p. 438). Specifically, they concluded that the studies considered by Hanson et al. (2002), especially those in the so-called incidental category:

> …cannot support even the tentative positive conclusions drawn…Indeed, the Hansen et al. (2002) analysis of incidental designs illustrates an important limitation of meta-analysis. The analysis of a set of uniformly weak designs cannot attribute variation of effect size to study quality. An overall effect size derived from studies of uniformly poor quality cannot obviate universal methodological weaknesses. Conclusions based on such a meta-analysis are no more justified inclusions based on the individual studies. (p. 437)

In fact, Rice and Harris (2003) found "the mean effect of treatment on sexual recidivism indicated a trend toward treatment having been detrimental…" (p. 437). It should also be pointed out that very little knowledge has accumulated about various matters critical to sexual offender treatment, including which aspects of treatment might produce reductions in recidivism or for what types of offenders might be most responsive to treatment. Rice and Harris reported that, "The literature provides almost no information about which treatment be most beneficial…" (p. 437). In fact, they pointed out "the mean effect of treatment on sexual recidivism indicated a trend toward treatment having been detrimental…" (p. 437). Hanson et al. (2009) concluded "Reviewers restricting themselves to the better quality, published studies… could reasonably conclude that there is no evidence that treatment reduces sex offense recidivism" (p. 881). The IHE (2010) stated, "Given the methodological problems of the available primary research it is difficult to draw strong conclusions about the effectiveness of sexual offender treatment programs using various CBT approaches for such a

Table 1 Sexual offense recidivism rates in meta-analyses (MA) and SOTEP

heterogeneous population…Overall, the results reported by the selected SREs provide little direction regarding how to improve current treatment practices…There are still uncertainties reading the most useful elements and components of a sexual offender treatment program for convicted adult male sex offenders" (pp. iii–iv). As per the SBU in 2011, "For adults that have committed sexual offenses against children the scientific evidence is insufficient for determining which treatments that could reduce sexual reoffending." Dennis et al. (2012) concluded: "The main finding of this systematic review is that there was no evidence from any of the trials in favour of the active intervention in a reduction of sexual recidivism—the primary outcome" (p. 25). Rice and Harris (2003) summarized:

> In the end, we are obliged to conclude that the available data afford no convincing scientific evidence that psychosocial treatments have been effective for adult sex offenders… We conclude neither that treatment has been shown to be a waste of time nor that is been demonstrated to be effective. (p. 427)

In 2010, the ATSA Executive Board endorsed the unique value of RCTs as the preferred method of demonstrating if sexual offender treatment is effective, writing: "ATSA believes that RCT can and should be implemented in ways that respect the highest ethical standards. Community safety is better promoted by identifying treatments with strong evidence of effectiveness than by a proliferation of programs for which the efficacy is debatable." There should be little disagreement with this point; no data from RCTs has yet to determine or establish that sexual offenders volunteering for (and not mandated for intervention) and who are randomly assigned to sexual offender treatment (as opposed to control conditions) exhibit lower rates of sexual offense recidivism during time spent in the community.

Other Issues Regarding Outcome for Sexual Offender Treatment

Alternate Outcome Methods and Results from Sexual Offender Treatment

Marshall (1993) has long disputed the notion that RCTs are demanded to make claims about the effectiveness of sexual offender treatment. Marshall and Marshall (2007) claimed

that while elegant, RCT studies "are fraught with all kinds of scientifically unacceptable problems when applied in a practical setting with sexual offenders" (p. 178). Similar to writers in the general psychotherapy field (Howard et al., 1996; Westen et al., 2004), Marshall and Marshall noted the limitations of external validity of RCTs, namely, that because they involve controlled variables but fail to control for all possible variables, and standardized implementation (reliance on manuals or other formal treatments which limit clinical flexibility), which could raise questions about their generalizability. Marshall and Pithers (1994) challenged the utility of carefully controlled investigations of treatment effectiveness, writing, "Highly structured outcomes studies requiring clients to take part in time-limed, inflexibly sequenced interventions are likely to underestimate the potential effectiveness of treatment" (p. 22). In particular, in these various writings, Marshall has argued that research that involves structured intervention programs (e.g., involving manuals, uniformity of treatment elements, prescribed (and limited) number of sessions, and duration of treatment) is problematic as such phenomena undermine the potential influence of the therapist. Marshall has argued that RCT designs are "not suitable for determining the effectiveness of sexual offender treatment" (e.g., Marshall & Marshall, 2007; Marshall et al., 2011); rather, he has suggested that treatment be optimized by largely individualizing treatment for offenders and allowing therapists freedom to be responsive to the particular presentations of specific clients. Similarly, Levenson and Prescott (2013), while calling for "accountability" in treatment outcome research, reject a reliance on methodological rigor as compromising "clinical validity," suggesting that methodological approaches such as RCTs "rarely apply to practice in the field" because results are questionable in translating to therapeutic practice in the "real world." On its surface, such claims are potentially appealing. However, evidence-based practice for any medical or psychological intervention requires some clear and consistent demonstrations of efficacy of particular treatment approaches, with select offenders under relatively controlled conditions and random assignment. Only once some substantial evidence of general treatment effects is demonstrated would it be appropriate to pursue subsequent investigation of whether, in fact, results of more individualized treatment elements (such as therapist variables; longer, more flexible, and intensive treatment programs; greater focus on personality issues and diatheses) be more systematically investigated.

Alexander (1999) while noting that research in sexual offender treatment outcome "remains in the formative stages" claimed, "Should offender treatment be abandoned until its efficacy is incontrovertibly established? While this course may be tempting from a scientific perspective, the public safety ramifications of withholding even relatively ineffective treatment from dangerous offenders cannot be risked" (p. 112). More recently, Marshall (in various publications, e.g., Marshall & McGuire, 2003; Marshall et al., 2011) has argued that a consideration of effect sizes generally would indicate that even if an intervention has a small effect on outcome, it should be considered potentially useful in that it may lead to "harm reduction" (e.g., reduce sexual offense recidivism for some offenders and/or limit the number of victims among high-frequency offenders). He refers to the reported effect sizes of several SRs of sexual offender treatment and of the Hanson et al. (2002) meta-analysis of such studies as suggesting that the effects of studies utilizing incidental assignment allow the conclusion that sexual offender treatment is effective for some sexual offenders. He describes these results both as "encouraging" and as "convincingly demonstrate[ing]" that such interventions are effective. Certainly, the medical outcome literature has shown that when interventions truly show small effect sizes, they can have substantial practical value; however, in such cases (e.g., a daily aspirin is a common example), that might occur if a treatment is relatively inexpensive, is easy to execute, is politically feasible, and can be employed on a large scale so that it affects a large number of individuals. Assuming it was politically feasible, it is unlikely that sexual offender treatment can be delivered in a manner that is easy to execute, particularly in an inexpensive fashion to many or most sexual offenders. More importantly, Marshall's argument on behalf of potential small effect sizes is predicated on what currently is an inaccurate or unproved presumption, namely, that the sexual offender treatment literature actually or "truly" shows a positive effect size, even a "small" one. However, as Hanson et al. (2002) and Losel and Schmucker (2005) demonstrated existing RCTs of sexual offender treatment have *not* shown positive effect sizes, let alone even "small" ones: if the mean recidivism score of the treatment group is significantly reduced by excluding higher-risk offenders and the mean recidivism score of the control group is significantly inflated by including excessive high-risk sexual offenders, then the resultant effect size becomes effectively zero. Consequently, if the effect size is minimal or nonexistent—reflective of the lack of significant differences in RCT comparisons—the harm reduction argument is significantly diminished or eliminated; it becomes moot. Seto et al. (2005) and Duggan and Dennis (2014) have effectively responded to all the concerns raised by Marshall regarding RCTs.

Alternately, arguments have been made that in correctional settings, RCTs for psychosocial interventions are not easily implemented and have been shown to make minimal differences in outcome results (e.g., Landenberger & Lipsey, 2005). However, they are clearly possible (e.g., Davidson et al. 2009; Cullen et al., 2011). In a Cochrane Review regarding CBT's utility in reducing recidivism among general criminal offenders, Lipsey, et al. (2007) made the claim that there

was no difference in results of RCT versus quasi-experimental designs in interventions for criminal recidivism. Yet, regarding their meta-analysis of interventions for general criminality, they noted that only 6/19 RCTs were conducted on "real-world" CBT practice and that a different set of 6/19 RCT studies involved sufficiently high attrition that the validity of their results was compromised. In addition, Lipsey et al. noted that the mean length of the follow-up in most studies of criminal recidivism is rarely longer than 12 months and little information exists about the longer-term effectiveness of such interventions. As other writers (e.g., Sanchez-Meca, 1997) have noted, in the "corrections intervention literature," most if not all of the studies comparing RCTs to "quasi-experimental" groups have relied on relatively short-term follow-ups and that effect sizes typically diminish with longer follow-up periods. In addition and more generally, Sanchez-Meca (1997) also noted other methodological issues in interpreting meta-analytic results of corrections interventions. First, he pointed out that different outcome measures lead to different effect sizes; recidivism as an outcome tends to have the lowest effect sizes, while "expert" [e.g., clinical] ratings produce the highest effect size. Second, studies with larger sample sizes typically evidence the lowest effect sizes. Third, pretest/posttest designs overestimate effect size in comparison with "between-group" designs; this is particularly problematic given the evidence that posttreatment measurements may be "faked" for purposes of impression management or distorted by ego-syntonic personality characteristics. Thus, studies of general psychosocial interventions in correctional settings have relied upon quasi-experimental control methods and are often characterized by factors that inflate their effect size relative to better-designed studies.

Ultimately, as emphasized previously, many or most investigators and research authorities agree that RCTs are the preferred method for evaluating any treatment's effectiveness, including studies of correctional samples generally and sexual offenders specifically (e.g., Seto et al., 2008; Hanson et al., 2009) and specifically relied upon by the gatekeepers of approved interventions and funding stakeholders. However, while sex offense (and other criminal) recidivism has been the primary focus of existing treatment outcome studies, several other research methods have been suggested as an alternative means to evaluate treatment effectiveness. Several writers have noted that simply completing sexual offender treatment provides no guarantee that meaningful personal changes have occurred for treatment participants. Alternately, other writers have argued that reduced recidivism is a too absolute and stringent requirement to judge the potential success of sexual offender treatment; Levenson and Prescott (2013) have argued:

> When measuring sex offender treatment, effectiveness studies have focused almost exclusively on measuring recidivism rates, while other measures of client improvement have been largely ignored. Certainly, given the harm caused by sexual victimization, decreased recidivism is the salient goal of treatment. But dichotomous recidivism measures as the only outcome of importance limit our ability to define success. Traditionally, measurement of success in other types of psychotherapeutic interventions has included a reduction in the frequency, duration and intensity of distressing symptoms, or the increase of desirable behaviours. Such appraisals are relative measures. In contrast, sexual offender treatment outcomes evaluate only recidivism, which is an absolute measure. Recidivism as the only construct of improvement within sexual offender treatment almost surely sets everyone up for failure—sexual offenders, clinicians and the field as a whole. (p. 3)… By measuring only arrests and convictions as therapy outcomes, do we ignore information about other ways that an offender's risk may diminish with treatment? Researchers should consider incorporating relative measures of behavioural change in addition to the absolute measure of recidivism.

One can certainly agree that dimensions of personal change have relevance to sexual offender treatment, particularly if and when a sexual offender is a sole or primary stakeholder in psychotherapy. However, to the extent that the public is a stakeholder, the likely victim of failed or inadequate sexual offender treatment, and the source of funding for such treatment, reducing sexual offense recidivism should be the principal aim of such psychosocial interventions. As Prentky et al. wrote (2011), "…the most compelling reason for treating sex offenders is reducing the likelihood that those offenders will reoffend and create additional victims. The primary goal of sex offender treatment is not to cure sexual offenders or to make them feel better but (a) to reduce the risk that they will reoffend, and (b) to assist with the optimal management of those sexual offenders who are in the community" (p. 117).

In fact, numerous investigations have attempted to examine relative change as a result of sexual offender treatment as means of obtaining perspective as to the efficacy of sexual offender treatment for select sexual offenders. One such approach to outcome research is the measurement of change of putative risk factors believed to be the mediators of sexual offending. Harkins and Beech (2007) reviewed different methodologies utilized to measure the effectiveness of sexual offender treatment suggest that multiple methods have both weaknesses and advantages. They questioned whether distal outcomes such as recidivism should be the only means of determining positive sexual offender treatment outcome. Harkins and Beech suggested that the examination of more proximate outcomes, such as apparent changes within treatment (e.g., intraindividual changes), might allow the comparison of those offenders apparently "successfully" and "unsuccessfully" treated; Hanson (1997) had previously noted that a potential indicator of treatment effectiveness might be to assess within-treatment changes on the typical elements that sexual offender treatment therapists presumably target in their work. Participation in a focused sexual offender treatment (such as one incorporating CBT principles

and techniques) is theorized to produce changes in a sex offender's cognitions, behavior, and affective experiences. If that were the case, it would be presumed that treatment would produce valid proximal changes in treatment targets (which in turn would be associated with more distal changes in a more global outcome measure, namely, sex offense recidivism). Change on treatment targets is typically measured by comparing difference between the treatment and the control group (via a "difference" score created between mean pretreatment scores of variables of interest and mean posttreatment scores). In particular, the so-called risk principle would be expected to be particularly operative; as Olver et al. explained, "as would be predicted by the risk principle, higher-risk individuals, that is, those who have more 'room' to lower their risk, are expected to show more risk reductions in treatment when compared to lower risk individuals, whose potential for risk reduction would be limited by the 'floor effect'" (p. 114). An additional step would be to examine the possible association of differences in intraindividual pre- and posttreatment measures and sex offense recidivism. Historically, CBT was initially studied by determining if specific techniques did, in fact, modify particular targets of intervention in treatment outcome participants. In addition, to serving as another important outcome measure, such assessments might also shed light on what targets of treatment might be mediators of intervention and associated with larger positive treatment outcomes.

However, there are several issues with this proposed method. Hanson (1997) pointed out the primary behavior of interest (sexual offending) would not be expected to occur in most treatment settings; consequently, potential within-treatment changes on primary behavior of interest would be difficult to measure in institutional settings (e.g., with no or limited contact with children or adolescent and adult females). In addition, Harkins and Beech (2007) also noted that the meaning of any identified change would be dependent upon the sensitivity and validity of the measures of such change. As noted earlier for psychotherapy in general, Gregerson et al. (2001) looked at ratings of treatment made pre- and posttreatment. They found that the difference in the size of treatments of pre- and posttreatment suggests that retrospective (post) evaluations of treatment change "overestimated treatment effects" by a *factor of two* compared to actual pre-/post-measurements. Further, there are several issues with regard to the validity of measurement of potential change for sexual offenders. First, in general, Kelly (2000) showed treatment participants generally tend to present themselves to therapists in a socially desirable manner; from a forensic therapy perspective (e.g., with potential sanctions for perceived noncompliance), this would seem likely to be substantially more characteristic of treatment client/offenders. In addition, many of the test or measures for potential outcome or change utilized by extant studies are extremely face valid, such that it is likely clear to an offender what the socially desirable or even expected response might be from the perspective of a therapist or treatment program; Marshall and Eccles (1991) pointed out that the majority of instruments used in measuring select aspects of sexual offenders are relatively transparent and it is relatively obvious in identifying the socially acceptable responses. Gannon and Polaschek (2005) hypothesized that relative to self-report measures, "It may be naïve to assume that offenders will not fake good following treatment. A compelling argument can be made that after (post) treatment, offenders have even more incentive to fake good than they did previously. After all, if they don't demonstrate change after treatment then maybe they are not ready for release, or perhaps the therapist, with whom they may have developed strong bonds will be displeased with lack of change" (p. 196). Gannon and Polaschek (2005) found that evidence for this phenomenon was supported. In a later study, these authors found that when sexual offenders believed they were subject to a polygraph, they admitted to increase offense-supportive cognitive distortions relative to their previous reports and those of a control group, thus suggesting that their report of change was little more than impression management of their clinicians (Gannon et al., 2007).

A particularly critical question has to do with whether relative change as measured by pre-post results of testing is, in fact, associated with sexual offense recidivism and might indicate potential mediators of personal change. As Olver et al. (2013) noted: "Aside from a small collection of studies (e.g., Beggs & Grace, 2011; Olver, Wong, Nicholaichuk, & Gordon, 2007, 2013; Wakeling et al., 2013), remarkably little research has explicitly examined linkages between treatment-related changes in important sexual offender risk–need domains and possible reductions in recidivism." Further, what research that is available has found that pretreatment scores are more predictive than posttreatment or change measures (posttreatment scores–pretreatment scores). That is, almost universally, pretreatment information is more strongly associated with the degree of sexual reoffending after treatment. Marshall and Barbaree (1990) found that clients demonstrated reduced deviant sexual arousals (DSA) at the end of treatment but found that neither pre-, posttreatment, nor change scores of DSA were associated with sexual offense recidivism for either rapists or child molesters. Beggs and Grace (2011) reported that for a group of low-risk child molesters treated with CBT, several measures of treatment gain were associated with small reductions in recidivism for up to a 12-year follow-up (even controlling for pretreatment scores). However, they pointed out that correlations between change scores and recidivism were near zero and stated "Given the transparent nature of the tests and incentives for the men to show improvement, it is likely that much, if not most of the self reported gains were due to impression

management" (p. 9). As Beggs (2010) noted, the significance of secondary gain for sexual offender treatment participants (e.g., early release from institutions or favorable parole boards) and the potential lack of intrinsic motivation for change or treatment may obscure any potential true treatment effects on individuals. Beggs and Grace also noted that their results could mean that offenders who performed better in the program might have actually been at lower risk to begin with. Further and more broadly, as Miner (1997) noted, "There is a tendency for test scores to regress from the extremes to the mean. Thus, changes in measures from beginning of treatment to end may be simply an indication of regression to the mean rather than actual change in the construct being measure" (p. 98). Perhaps, an even more important issue in utilizing pre-post changes in proposed outcome measures is that persons who drop out or are removed from sexual offender treatment are not available to provide posttest outcome measures; this differential availability of offenders is likely to inflate positive results from interventions.

Marques et al. (2005) found that self-reported cognitive distortions and self-reported sexual arousal to children and rape were significantly lower after treatment than before treatment. Williams et al. (2007) found that sexual offenders showed significant improvement on almost all self-reported measures of treatment change including denial, minimization, cognitive distortions, empathy, relapse preventions strategies, and self-esteem. Of note, the largest effect size was for relapse prevention strategies, followed by empathy for victims. Williams et al. also examined the association between risk and change and found that no risk group showed significantly more or less improvement than other risk groups. However, there was no control group, and there was no determination as to what level of these measures individual offenders endorsed prior to exposure to treatment. In combination, then, sexual offenders' responses on self-report measure "appear" to improve, regardless of determined risk level; however, without accounting for individual pretreatment scores, having a control group to determine in what ways offenders' responses change at a second assessment point, or demonstrating an association with decreased sexual offense recidivism, such studies provide little information about the "meaning" of reported "improvement" in self-report of sexual offenders. Thus, it remains unclear if reported change in self-report measures, particularly victim empathy and relapse prevention, is simply about impression management of a clinical team or other public agents.

McGrath et al. (2012) reported that ratings on the Sex Offender Treatment Intervention and Progress Scale (SOTIPS) made at 1, 7, and 13 months after community-based treatment began predicted sexual recidivism at the follow-up (after starting sexual offender treatment) for a group of predominantly (87 %) first-time sexual offenders (e.g., mean Static-99R score = 0.2, SD 2.4). In a repeated measure design, group SOTIPS ratings by therapists and supervision officers, on their own, were predictive of sexual offense recidivism during the short follow-up period; however, offenders were generally rated as showing improvement over time on the measure, and no change scores were apparently utilized. The results were found for sexual offenders against children but not for those with adult victims.

Further, as Nunes et al. (2011) pointed out, such group-level analyses of treatment change are not sensitive to the presence of non-dysfunctional posttreatment status, specifically clinical significance (e.g., did the client reach some target level of function as a result of treatment and whether the amount of improvement found was large than what would be expected by chance alone). Nunes et al. studied treatment change both in the group and individual level. They found, generally, that the results from group-level analyses were more supportive of "change" than those from individual-level analyses. Thus, measurements of the changes for specific individuals indicated more modest gains, with approximately one-third of participants showing reliable change and reaching functional levels posttreatment on specific measures. Nunes et al. also showed that group-level findings of presumed treatment differences were not always consistent with individual-level findings. They also noted a number of methodological issues that might qualify their results.

Change on treatment targets may also be measured in terms of *clinical significance* (the degree to which self-reported measures fall in the "normal" range for a particular variable or measure) to determine if a client is characterized by meaningful improvement during treatment. Mandeville-Norden et al. (2008) examined pre- and posttreatment measures of cognitive distortion, emotional identification with children, victim empathy, self-esteem, loneliness, unassertiveness, ability to cope with negative feelings, and locus of control. They compared used norms on those measures based on correctional officers to compare treated sexual offenders. They found that between 51 and 71 % of sexual offenders (depending on the particular measure) had scores in the "functional" range after treatment. Mandeville-Norden et al. (2008) also tested to determine if this was a reliable change (e.g., not due to chance); they found clinically significant improvement had been achieved by 7–26 % of offenders (depending on the particular measure). However, these investigators failed to separate offenders who self-reported already functional scores at pretreatment from those who were dysfunctional at pretreatment. Thus, the proportion of participants who were in the functional range posttreatment would overestimate the effectiveness of treatment since a significant number were reporting "functional self-reports prior to treatment. More recently, Barnett et al. (2012) also found in a large sample of sexual offenders who received

a mean of 14 months of community-based sexual offender treatment that posttreatment psychometric test scores were less discriminative and less predictive of reconviction than were pretreatment scores; further, when tests were grouped into dynamic risk domains, only the pretreatment scores of the domain-labeled socioaffective function predicted recidivism. They concluded "the poor performance of these measures posttreatment suggests that treatment providers should rely less on these scores as way of assessing risk after treatment" (p. 23). Similarly, based on a similar study of potential measures of treatment change, Olver et al. (2014) concluded "The results from the present sample generally do not support using most of these self-report psychometric measures to assess sexual offender risk or predict recidivism" (p. 13).

Olver et al. (2007) included measures of possible treatment change rated by therapists from records and indicated that the dynamic change measure added incrementally to a static measure of risk of sexual offense recidivism. Similarly, Beggs and Grace (2010) also found that the same "dynamic" scale made independent contributions to risk assessment beyond that of static factors. However, Beggs and Grace noted that the greater association of the dynamic scale might simply reflect its increased breadth and comprehensiveness (e.g., more than twice as many individual items). Beggs (2010) provided a review of within-treatment outcome among sexual offenders. She noted that there was relatively little research yet conducted on possible proximal treatment outcome among sexual offenders. She pointed out that such outcome if based on self-report might be problematic given the transparency of self-report measures and their openness to social desirability bias responding. Beggs concluded that "Overall, it can be seen that as yet there is a lack of reliable and consistent findings linking within–treatment dynamic change (measured psychometrically) with decreases in recidivism…" (p. 375). She further concluded that evidence for the validity of guided clinical judgment was poor regarding within-treatment outcome. In a later study that showed that suggested that measures of change in treatment were associated with sexual offense recidivism, Beggs and Grace (2011) noted that the association between treatment change and sexual offense recidivism was "relatively modest" and that an explanation for those results might be that offenders who were lower risk to begin with performed better in the program. Finally, Beggs (2010) noted that the results of within-treatment outcome change as measured by idiosyncratic systems of clinical rating were varied, including results within the same studies using multiple operationalization of such outcome. She also pointed out that none of the available studies linked specific treatment changes or individual treatment targets with recidivism so their results did not provide insight into potential mechanisms of change related to sexual offender treatment. Most recently, Olver et al. (2013) again reported that record-based "change" scores from pre- to posttreatment added incremental value to static variables and showed good predictive accuracy; after sexual offender treatment, they found significant pre-post changes on rated dynamic factors, ranging from small to moderate in magnitude ($d = 0.22–0.62$) across various intensity programs. These change scores, in turn, were associated with decreases in sexual offense recidivism; the majority of relationships examined attained significance even after partialing out of pretreatment scores. Thus, there is now recent evidence from one research group utilizing a particular measure that rated treatment change is associated with sexual offense recidivism. Yet as the authors noted, there was no control group, and more importantly, risk scores indicate that it was a predominantly moderate- to low-risk cohort of sexual offenders with a lower base rate of sexual offense recidivism relative to other Canadian samples for similar follow-up periods.

Currently, little evidence currently exists that provides reliable empirical support linking proximal changes in treatment targets with distal changes in sex offense recidivism. To date, treatment progress as measured by difference scores between pre- and posttreatment measures has been found to be a poor predictor of sex offense recidivism (e.g., Hanson & Morton-Bourgon, 2004; Marques et al., 2005). Few studies have found a link between treatment changes and sex offense recidivism (e.g., Beech & Ford, 2006). Langton et al. (2006) found that a rating sexual offense response to treatment failed to predict either serous or sexual recidivism. Similarly, Looman et al. (2005) studied whether an offender's risk to reoffend was reduced during treatment based on an overall rating of treatment performance (including performance not only in groups and homework assignments but also on the client's behavior outside of the formal treatment program). However, the performance ratings showed *no* association with posttreatment sexual offense recidivism. Hanson et al. (2008) stated "… much less is known about the processes by which sexual offenders change. Studies frequently find that improvements on factors presumed to be criminogenic have no effect on sexual recidivism rates" (p. 887). In effect, only Olver et al. (2013) reported that after controlling for risk, change scores (total and sexual deviance) were associated with decreases in sexual offense recidivism. However, they noted: "There was no untreated control group with pre- and posttreatment VRS-SO ratings in order to compare change over the passage of time with that made with treatment services. As such, there is some possibility that other change agents, aside from treatment, contributed to the changes… we cannot rule out the influence of other change agents (e.g., participation in other programs, aging) that may have contributed to changes in risk" (p. 12). In a recent review,

Wakeling and Barnett (2014) reviewed the relationship between psychometric test scores and reconviction in sexual offenders participating in sexual offender treatment in the UK. They concluded:

> We believe that these results suggest that it may be unwise to rely on large batteries of psychometric tests to determine change in treatment and that further research is required before we can be sure of the relationship of psychometric tests to recidivism outcome…it is very unfortunate that we are not yet in a position to make reliable estimates of the extent to which such programs have benefited individual participants. The use of psychometric tests may not be so promising as we once thought. Additionally, *the evidence so far suggests that to use change on psychometric test scores for program evaluation (*i.e. *as a proxy measure of reconviction outcome) is not warranted*. (p. 143; emphasis added)

Thus, despite the desire to determine "relative change" in sexual offenders as a means of showing treatment effectiveness, little evidence exists that sexual offender treatment outcome can be meaningfully assessed or demonstrated by the use of within-program, pre-post self-report tests and/or questionnaires.

Further, a number of studies have found that posttreatment measures are either not or are *less* predictive of sex offense recidivism than pretreatment measures. In a key early study, Quinsey (1983) first reported that neither changes in deviant sexual interest indices nor posttreatment deviance measure was associated with subsequent recidivism in treatment sexual offenders. Subsequently, Rice et al. (1991) found that pretreatment measures of deviant sexual arousal were better predictors of sex offense recidivism than posttreatment measures, raising questions about what those posttreatment measures actually assessed. Marshall and Barbaree (1990) also reported that neither pretreatment, posttreatment, nor apparent changes in reducing deviant sexual interests were related to treatment outcome. Thus, it remains unclear if sexual offenders actually change as a result of sexual offender treatment. Langton et al. (2006) noted:

> For some sex offenders, ratings of treatment progress in later, follow-up programs may prove unreliable indicators of any gains made…they may obscure the validity of ratings made for participation in earlier/initial treatment programs as offenders become familiar with program content and expectation s and strive to appear compliant and 'treated' in order to be found eligible for parole or relaxation of supervision intensity…The challenge is, in part, one of measurement. Because sex offenders learn, indeed are expected to learn, the terms and concepts of CBT and relapse prevention, determining the veracity of their presentations will be difficult. (p. 116)

Consequently, while sexual offenders who participate in sexual offender treatment may learn the information related to and terms of sexual offender treatment such that they can answer self-report and even interview questions to reflect such information acquisition, their "internalization" or intent to use that information may remain unchanged.

In a recent paper, Rice et al. (2013) concluded:

> While research on this issue is preliminary, evidence suggests that, given a comprehensive set of valid static, historical factors, pre-release difference scores afford minimal incremental validity (Olver & Wong, 2011; Olver et al., 2007). Again, we conclude this is due to pre-release risk-relevant change on these constructs indexing the same aspects of temperament and personality that are reflected by established static, historical risk factors…. (p. 10)

For example, Rice et al. (2013) noted that the results of Olver et al. (2007) showed that static risk scores were more predictive than either dynamic pre- or posttreatment scores. Olver et al. (2013) were the first and only group to report that "change" scores from pre- to posttreatment added incremental value to static variables and showed good predictive accuracy. After sexual offender treatment, Olver et al. (2013) found significant pre-post changes on select observer-rated dynamic factors, ranging from small to moderate in magnitude ($d = 0.22$ to 0.62) across various intensity programs. These change scores, in turn, were associated with decreases in sexual offense recidivism; the majority of relationships examined attained significance even after partialing out of pretreatment scores. Thus, there is now recent evidence from one research group utilizing a particular measure. However, more broadly, Serin et al. (2013) reported in a review of intraindividual changes in criminal offenders following interventions: "It is apparent within this review that therapeutic change does not consistently lead to reduced likelihood of future crime" (p. 50). They stated:

> It is especially difficult to defend programs when apparent successful adoption of treatment skills does not translate into a definitive lower risk to reoffend. However, it is also difficult to defend successful programs when it is unclear which treatment elements are responsible for presumed or "perceived" change and which offenders might have changed. (p. 50)

As Wakeling and Barnett (2014) also concluded: "Pretreatment psychometric scores appear to have a better relationship [with sexual offense recidivism] than those gained post-treatment, suggesting the former should be preferred to the latter when assessing risk of recidivism outcome…it may be that the [posttreatment] results are negatively impacted by desirable responding…" (p. 143). They recommended that future efforts be directed at developing reliable and valid measures of "risk domains" as opposed to specific risk factors. In short, the fact that pretreatment measures are more predictive of sexual offense recidivism than posttreatment self-report and clinician ratings provides further evidence that even apparent change reported by sexual offenders or perceived by their treatment providers may well not be genuine and that as the SOTEP identified (e.g., Marques, Nelson, Alarcon, & Day, 2000; Marques et al., 2005), sexual offenders can learn the language and "display" motivation while in a sexual offender

treatment program, but fail to demonstrate that motivation or enact purportedly learned skills once returned to the community even with aftercare and supervision.

Of particular interest is the ability of sexual offender treatment therapists to offer a meaningful or valid perspective on the relative progress of their sexual offender clients. Unfortunately, most available studies indicate that sexual offender treatment clinicians' opinions about their clients are not informative. In more general psychotherapy literature, clinicians have typically been found to be poor judges of treatment progress. Thus, research has shown that therapists' ratings of clients' progress are significantly greater than what their clients report or what is reported by client's significant others (e.g., Hill & Lambert, 2004); this is likely to be even more pronounced in forensic therapy settings, where there is significant potential secondary gain for sexual offenders who present as reflecting positive treatment behavior and apparent treatment gains. Further, as noted previously, in their review, Hill and Lambert concluded that therapist ratings of treatment outcome and global ratings of change are associated with the "perception of greater effectiveness" of treatment compared to more specific measures and more distal measures. In their review, Hill and Lambert also pointed out that data from therapists or expert judges who are aware of the treatment status of clients produce larger positive ratings than those from virtually all other sources. Walfish et al. (2012) showed that clinicians providing psychotherapy tended to overestimate the rates of their client improvement relative to their own perceived clinical skills. The same seems to be particularly true for therapists in sexual offender treatment programs; this is a finding that has been replicated over time. Quinsey et al. (1998) first found that therapists' judgments about treatment progress were unrelated or negatively related to recidivism. Similar results were found by Seto and Barbaree (1999) in the initial analyses of a research sample but not found in a somewhat expanded sample from the same source (e.g., Barbaree, 2006). Marshall and Eccles (1991) also opined that generally clinicians' judgments of treatment effectiveness (as well as those of offender clients) were considered unreliable. Citing a variety of earlier studies, Hanson and Harris (2000) noted: "Experienced clinicians are frequently unable to differentiate between sexual offenders who benefited from treatment and those who did not…" (p. 7). In a short-term prospective study, Seager et al. (2004) showed that clinical judgments of treatment (even guided by specific clinical criteria) were unrelated to recidivism failure. Specifically, they found that positive evaluations of treatment changes in posttreatment assessments (e.g., such as quality of disclosure and perceived enhanced victim empathy) showed no correlation with sex offense recidivism. They found that "…clinical judgments of treatment change, although guided by specific clinical criteria, were unrelated to recidivism failure…Narrative commentary on treatment participation appears superfluous in the context of predicting recidivism of rates. Quality of participation appears unrelated to recidivism" (p. 610). Thus, they found that positive evaluations of treatment change such as the quality of disclosure and perceived increased victim empathy found in posttreatment assessments did not correlate with recidivism. Seager et al. (2004) concluded, "…sex offender programs are not changing psychological characteristics that affect recidivism" (p. 610). Hanson and Bussiere (1998) found that most clinical measures of treatment progress were unrelated to sex offense recidivism as did the updated meta-analysis for risk factors for sex offense recidivism by Hanson and Morton-Bourgon (2005). They found that poor progress in sexual offender treatment, measured at the end of such intervention, was unrelated to sexual reoffending. In addition, the aforementioned general and specific findings regarding that allegiance to a treatment model was associated with more positive finding (e.g., Losel and Schmucker, 2005) suggests that clinicians' belief in that model may well account for more variance in outcome than any specific interventions or changes by treatment participants. This corresponds to the consistent finding in the general treatment outcome literature that researcher/therapist allegiance accounts for a significant amount of the outcome in treatment studies that find particular interventions effective. Consequently, there are both empirical and theoretical reasons to view therapist ratings of personal change and individualized risk reduction as non-empirically supported and not particularly useful in gauging the outcome or psychotherapies for sexual offenders.

It should be noted that some writers (e.g., Levenson & Prescott, 2013) call attention to a specific observation reported by Marques et al. (2005), relative to sexual offenders who "got it" or were seen as benefiting from treatment provided as having lower sexual offense recidivism. Several points are worth noting. First, "When the Got It scores of sexual recidivists were compared to those of non-recidivists, no significant differences were found…." When they the investigators employed a median split, the trend was still not significant. No differences in reoffending were found between low and medium treated sexual offenders. However, they reported that "high-risk offenders," "largely accounted for by child molesters" who "got it," showed lower sexual reoffending after treatment. However, per their results, there was only *one* "high" risk sexual offender (a total of 7 treated sexual offenders who got it), who was responsible for their claim of decreased sexual offense recidivism.

In summary, alternative ways of assessing outcome for the efficacy of sexual offender treatment (in contrast to reduced recidivism) also do not provide support for psychotherapy, particularly as a means to measure individual change. While some change is evident on self-report measures in certain instances, most of those measures are quite

transparent, and to date, no consistent, replicated association between pretreatment or "change" scores and recidivism has been demonstrated. Further, clinician-rated improvement in sexual offenders as a function of treatment appears to provide an overly positive view of change. Rather, pretreatment and essentially static constructs show the strongest association with sexual offense recidivism.

The Efficacy of Sexual Offender Treatment for Higher-Risk Sex Offenders

There is a profound lack of information about the RCT-based effectiveness of sexual offender treatment with higher-risk/high-need sexual offender, both from an actuarial perspective and those with a greater degree of criminogenic needs. Not unexpectedly, no RCT of any psychosocial treatment exists at this date for such a subset of sexual offenders. Hall (1995) noted that the most severe sexual offenders were typically excluded from treatment in the studies he reviewed. In the most comprehensive RCT to date, Marques et al. (2005) *excluded* any sexual offender with more than two prior felonies; thus, the treatment candidates were generally a low- or moderate-risk group to begin with (77 % feel into that category and only 22 % were deemed "high risk." They excluded sexual offenders with more than two prior felonies, major mental disorders, and lower IQ and/or those who had displayed severe management problems while in prison (they also excluded any offenders who denied their sexual offense from the "volunteer" group). The SBU review from 201 stated "Unfortunately, no studies have assessed the effects of treating high-risk individuals who have not sexually offended against children" (p. 22). It is notable that numerous studies of sexual offender treatment have systematically excluded high-risk/high-need sexual offenders. That is, the sexual offender treatment outcome literature is marked by "sample censorship" or exclusion for higher-risk sex offenders. Thus, Hall (1995) noted that many more severe sexual offenders were not even offered sexual offender treatment, while the SOTEP study did not include a significantly large group of "high-risk" sex offenders. In SOTEP, most treatment subjects were first-time sex offenders, of low- or moderate-risk groups that per RNR criminological models of intervention should have responded best to intervention and shown decreased sex offender recidivism rates. In short, most of the existing treatment outcome literature relates to low- or moderate-risk sexual offenders; thus, that evidence indicates that sexual offender treatment has not been demonstrated via RCT to be effective with such offenders.

However, what literature does exist indicates that sexual offender treatment is not effective or, at best, is substantially less effective with higher-risk sexual offenders. Both the Hanson et al. (2002) and Losel and Schmucker's (2005) meta-analyses found offenders referred to treatment based on *perceived need* had significantly higher sexual recidivism rates compared to offenders considered not to need treatment. It will be recalled that Hanson et al. (2002) found that "Offenders referred to treatment based on perceived need had significantly higher sexual recidivism rates than the offenders considered not to need treatment" (p. 182). The odds ratio was 3.4 (with an outlier study removed), and there was no significant variability, indicating that this was a robust phenomenon; thus, sex offenders viewed as high need provided sexual offender treatment reoffended over three times the rate of untreated sex offenders. Olver et al. (2011) identified that high-risk/high-need offenders are those persons least likely to complete treatment, presenting with a number of specific responsivity issues such as low motivation, poor engagement, and disruptive behavior. Over just a 2-year follow-up, Friendship et al. (2003) found that high-risk offenders were six times more likely to be reconvicted of a new sexual and/or violent offense than low-risk offenders. Stirpe, Wilson, and Long (2001) found that higher-risk sex offenders who received sexual offender treatment did not maintain motivation over time in the community. In their review, Rice and Harris (2003) also considered Hanson et al.'s (2002) group of studies involving "assignment based on need" and emphasized that the overall odds ratio was 3.0 for sexual recidivism; studies of these offenders "indicated that those [of greater perceived need] who were treated reoffended over three times the rate of the untreated" (p. 434). Olver et al. (2001) applied MA and found that general criminal offender treatment noncompleters (e.g., those who started but dropped out) were higher-risk offenders and rates increased when pretreatment attrition was also included. Olver et al. (2013) also did not find a risk by treatment interaction. Rice and Harris also noted that some "assignment based on need" studies, in effect, controlled for static factors before examining whether the treatment added anything to the assessment of outcome (a methodological plus) but still showed no recidivism lowering effect of sexual offender treatment for higher need sexual offenders. Stirpe et al. (2011) reported that RP-related treatment components showed a steady increase from pretreatment throughout follow-up in the community for low- or moderate-risk offenders, but *not* for high-risk offenders. Both groups improved substantially in level of motivation from pretreatment to posttreatment; however, only those in the low- or moderate-risk group maintained their motivation levels once released to the community; that is, higher-risk sexual offenders did not maintain motivation once released to the community.

Similar to all other presenting problems, it must be the case that some sexual offenders are characterized by sufficient severity, chronicity, and/or a large number of risk factors (as predisposing or maintaining factors). As the larger psychotherapy literature clearly indicates, more severe,

chronic problems are quite resistant to the effects of psychotherapy generally; more typically, more minor changes, at best, result from such interventions and may not be retained. Fifteen years ago, Harris et al. (1998) wrote, "The idea that a high-risk sex offender can be converted into a low-risk offender through the application of treatment or through progress in treatment simply has no empirical support from the literature taken as a whole" (p. 106). Further, as suggested by various writers (e.g., Rice et al., 1999), there may be some offenders whose risk level is sufficiently high that no psychotherapy could reasonably be expected to reduce it to a leave at which release to the community could be recommend and that "The idea that a high-risk offender…can be changed into a low risk offender through treatment or through progress in treatment simply has no empirical support from the literature taken as a whole" (p. 305). To date, little data has accrued that undermines that contention. Thus, as some writers have stated, "…it is important to note that there are some sex offenders whose risk level is so high that no treatment could reasonably be expected to lower it to a level where release to the community could be recommended" (e.g., Harris et al., 1998, p. 106). At the risk of repetition, regarding the Hanson et al. meta-analysis of 2002, Berliner (2002) pointed out: "It is not at all clear that these results can be generalized to the highest risk offenders. Even if they could be applied to these offenders, a moderate effect size reduction would still mean that high-risk offenders continue to be dangerous" (p. 196). In fact, as Hanson et al. (2008, 2009) reported, the risk principle of the RNR model was not confirmed by their meta-analysis; the most high-risk sexual offenders did not respond significantly better to sexual offender treatment relative to lower-risk sexual offenders. [This is actually similar to a work with criminal recidivism where the risk principle showed the smallest effect of the RNR dimensions in relapse prevention programs for criminal offenders (Dowden, Antonowicz, & Andrews, 2003)]. Ten years ago, Rice, Harris, and Quinsey (2001) concluded:

> The idea that a high-risk offender (especially focus serious offenders as serial sexual murderers) can be changed into a low-risk offender through treatment or through progress in treatment simply has no empirical support from the literature taken as a whole…it is also important to point out that there may be some offenders who's e risk level is so high that no treatment could reasonably be expected to lower it to a level at which release to the community could be recommended. (pp. 305–306)

At the present time, nothing in the empirical or scientific literature has emerged that would support the belief that such conclusions would be different for the general high-risk/high-need sexual offender. Rather, each individual's experiences in psychosocial and other adjunctive treatments would need to be carefully considered to offer a well-documented, person-specific opinion that a particular high-risk/high-need sexual offender has changed substantively as a result of such psychotherapeutic efforts.

The treatment of sexual offenders with higher levels of psychopathy, as a specific subset of likely higher-risk sexual offenders, has received research attention. Generally, there has been a pessimistic view that persons with a higher degree of psychopathy can be successfully treated to reduce their potential for future violence, including sexual offending. Ogloff et al. (2013) reported that psychopathic traits are associated with negative behaviors in treatment. More recently, both Langton et al. (2006) and Looman et al. (2005) found that, despite sexual offender treatment, more psychopathic sexual offenders (e.g., with PCL-R scores ≥ 25) reoffended in sexually and/or violently at significantly higher rates than those with lower scores; however, they suggested that there may be a subset of psychopathic sexual offenders who may respond to some interventions. An early study of violent offenders by Rice et al. (1992) found that persons with elevated levels of psychopathic traits who participated in a therapeutic community while incarcerated subsequently had higher rates of violent recidivism than similarly psychopathic persons who did not participate in such an intervention. A similar finding was made by Seto and Barbaree (1999); later studies by Langton et al. (2006) and Looman et al. (2005) did not find an interaction between psychopathy and treatment for increased recidivism. Thornton and Blud reported that both of the aforementioned studies showed that "…offenders in whom higher levels of psychopathy were combined with 'good' treatment performance had worse rates of serious recidivism" (p. 517). Olver and Wong (2009) maintained that with appropriate treatment interventions, sex offenders with significant psychopathic traits can be retained in correctional treatment program and those showing therapeutic improvement can reduce their risk of both sexual and violent recidivism. Doren and Yates (2008) reviewed the effectiveness of sexual offender treatment for psychopathic sexual offenders. They concluded that (1) sexual offender treatment does not appear effective in lowering serious recidivism and (2) sexual offense recidivisms rates were variable for treated psychopaths, but there were indications that some psychopaths did show decreased recidivism after treatment. However, the available research did not indicate which psychopathic sexual offenders benefited from sexual offender treatment and which did not. Doren and Yates (2008) also noted: "The present qualitative analysis also clearly found a consistent absence of untreated comparisons groups in all studies. Hence, no conclusion can be drawn from existing research about the degree to which psychopath offends benefit from sexual offender treatment" (p. 354); thus, again methodological factors precluded drawing absolute conclusions. Several writers have suggested that the most successful interventions for psychopathic offenders are likely to be characterized by high structure, high intensity, and extended duration, a high degree of

involvement by mental health professionals and increased attention to responsivity and, particularly, to maintain such offenders in the treatment process (e.g., Salekin, 2002; Olver and Wong, 2009; Thornton & Blud, 2007). Currently, the most appropriate perspective appears to be that perhaps some sexual offenders with psychopathic traits may respond somewhat differentially to CBT, with some more psychopathic offenders showing a more positive response to such intervention. Thornton and Blud (2007) both review a significant set of factors that would likely lead to the poor outcomes typically found in treating psychopathic offenders; they also offer suggestions about possible aspects of intervention that might lead to more positive outcomes with more psychopathic sexual offenders. In a more pessimistic vein, Harris and Rice (2006) stated:

> We believe there is no evidence that any treatments yet applied to psychopaths have been shown to be effective in reducing violence or crime…We believe that the reason for these findings is that psychopaths are fundamentally different from other offenders and that there is nothing 'wrong' in the manner of a deficit or impairment that therapy can 'fix.' (p. 568)

Ultimately, whether more psychopathic sexual offenders are amenable to psychosocial treatment is an empirical question; since no RCTs of relatively psychopathic sexual offenders have yet been conducted since the review by Doren and Yates (2008), their conclusion remains the same: the available evidence is not generally positive, but no absolute conclusions can be drawn in the absence of scientifically valid research.

If sexual offender treatment cannot be demonstrated to be effective in RCTs with more motivated sexual offenders with fewer comorbid conditions and lower severity of "problems" (e.g., fewer victims, lower density of risk factors and/or criminogenic needs), then even more serious questions are raised about its potential utility for "higher"-risk sexual offenders characterized by entrenched maladaptive behavior patterns maintained by a greater number and severity of risk factors and predisposing conditions. To date, of the various government programs in various jurisdictions that have detained violent sexual offenders (e.g., civil commitment of the so-called Sexually Violent Predators in the USA, Dangerous Offender Programs in Canada, and the Dangerous and Severe Personality Disorder Program in the UK), no data are available—no studies have been published—as to whether more intensive and long-term treatment of high-risk/high-need sexual offenders show reductions in sex offense recidivism as a specific result of treatment received while detained. Consequently, little useful information exists to establish the efficacy of psychosocial interventions in the management of moderate and high-risk/high-need sexual offenders; there are no RCTs of high-risk/high-need sexual offenders; empirically, it is simply unknown as to what the components, other treatment factors, and the length and density of psychosocial treatment are necessary to reduce such offenders' likelihood for sexual offense recidivism. Further, even with studies of the treatment of high-risk/high-need sexual offenders while detained, given that many of these individuals will only be released back to the community under terms of intensive and long-term supervision, it may not be possible to isolate the effects of sexual offender treatment generally or its components for such individuals.

Longer-Term Outcomes for Sexual Offender Treatment

Most sexual offender treatment outcome studies have not followed subjects for lengthy periods of time. Consequently, little is known about the longer-term effectiveness of sexual offender treatment. However, all authorities have stated that sex offense recidivism increases with the length of follow-up (e.g., Hanson et al., 2003; Harris & Hanson, 2004; Harris & Rice, 2007). Other studies demonstrate that even some treated sexual offender reoffends after lengthy periods without a detected sexual offense (e.g., Prentky et al. 1998). Given at best small effects for psychosocial treatments for sexual offender, it is important to know to what degree any positive outcomes may persist for such persons. This is particularly important given the general psychotherapy results regarding the diminishing persistence of treatment-related changes. As noted, Barrett, Wilson, and Long (2003) found that treated sexual offenders showed a significant decrease in rated motivation after release to the community. They wrote:

> The results of this study clearly show that clinicians in community settings should expect to have difficulty re-engaging offenders in the treatment process and should not assume that a positive institutional report will be reflected in a client' attitude and behavior in the community. (p. 279)

Similarly, Stirpe et al. (2001) found that higher-risk sex offenders who received treatment did not maintain motivation for sexual offender treatment practices when released to the community, and within 3 months after release, apparent treatment gains had diminished for higher-risk sexual offenders when returned to the community (even with the benefit of 3 months of additional treatment in the community). Marques et al. (2005) revealed: "We learned from interviews with the offenders that a number of our treatment failures did not use the self-management skills they acquired in the program, and some did not even accept the basic goals of self-control and relapse avoidance…" (p. 100). In summary, then the available literature would suggest that even if some degree of recidivism-related change initially results from sexual offender treatment, that effect may diminish or is eliminated once treated offenders return to the community just as it does for most mental health problems.

Conclusions and Future Directions

Reducing or eliminating sexual offender recidivism is an important and desirable goal and one shared by all stakeholders relative to sexual offending. While short-term recidivism for adult sexual offenders consistently appears to be approximately 12–15 %, perspectives on long-term sexual offense recidivism indicate that sexual reoffending increases over longer follow-up periods to perhaps 40 % detected offenses (e.g., Hanson et al., 2003; Harris & Hanson, 2004; Harris & Rice, 2007). For persons already sanctioned at least once previously for sexual offending, this is a very high rate of violent criminal offending. There can be no question that given the severe consequences of sexual victimization, effective and enduring management of sexual offenders is of critical importance. Psychosocial treatments have long been considered a central component of accepted and implemented management strategies—for many practitioners in the field of sexual offender treatment, they have been perceived as *the* critical element of management. All stakeholders agree on the importance of effective management of sexual offenders for community safety; however, the degree to which psychosocial interventions matter by "working" (as well as other management mechanisms) necessarily must be demonstrated. Consequently, the determination of whether psychosocial treatments for sexual offenders have been empirically established as a mechanism to reduce future sexual offending is of critical importance.

Early in 2010, R. Karl Hanson sent an email stating: "I, for one, have done enough meta-analyses of barely acceptable studies. It is time to counter the political resistance to random assignment studies by getting ATSA to endorse a position statement supporting their use" (cited in, Rice et al., 2013). Subsequently, at Dr. Hanson's recommendation, the Executive Board of the Association for the Treatment of Sexual Abusers (ATSA) proclaimed "After 50 years, the field of sex offender treatment cannot, using generally accepted scientific standards, demonstrate conclusively that effective treatment are available for adult sex offenders" (ATSA, 2010b). More recently, in an editorial, Ho and Ross (2012) criticized public representations regarding the Sex Offender Treatment Programme in the UK and claims that the program "worked;" they wrote:

> Twenty years since the SOTP [in the U.K.] was launched, its efficacy has yet to be convincingly demonstrated…Interventions such as he SOTP are too important in terms of financial cost and cost to society for them not to perform as they are clamed to perform They are too important for the participant men themselves than for anything other than the highest standards of evidence underpin them. In the absence of an enormous effects size, encouraging pilot work and open studies should lead to independently conducted RCTs. (p. 5)

Clearly, at present, there can be little argument with that conclusion. The current review of the scientific evidence of sexual offender treatment is that, at best, minimal evidence currently exists to demonstrate that psychotherapy is effective at reducing sex offense recidivism or at changing sexual offenders in meaningful or substantive ways. The most optimistic perspective that could be gleaned from the existing studies is that the sexual recidivism of select, lower-risk sexual offenders may be lowered when they are treated in community settings; at the same time, as others have written, results could also be interpreted to mean that regardless of treatment, lower-risk sexual offenders (not surprisingly) generally have lower sexual offense rates. In contrast, for higher-risk sexual offenders who are treated in correctional settings, there is no data from controlled trials to suggest a desired reduction in sex offense recidivism can be attributed to psychosocial interventions. In addition, it remains unclear if sexual offender treatment is effective for different types of sexual offender and what, if any, elements of psychotherapy are particularly useful in impacting sexual offenders and sex offense recidivism rates. In actuality, this appears to be the increasing consensus among the experts in the field of sexual offender research.

Perhaps not unexpectedly, the conclusions of this chapter echo those that of several other reviewers of the sexual offender treatment literature. As Furby et al. (1989) stated in their early review of sexual reoffending in both treated and untreated sex offenders, "Many of recidivism studies reviewed here were, unfortunately, not very informative…" (p. 28). In 1999, Gallagher et al. wrote, "The literature on the efficacy of sexual offender treatment programs is inconclusive. The more exhaustive narrative reviews tend to conclude that little current is known due to the considerable methodological weaknesses of the individual evaluations" (p. 19). Hanson et al. (2002) concluded, "we believe that the balance of available evidence suggests that current treatments reduce recidivism, but that firm conclusions wait more and better research" (p. 187). Rice and Harris (2003) have written, "We suspect all would agree that very little knowledge has accumulated about several crucial matters…The dearth of knowledge about sexual offender treatment contrast sharply with the rapid expansion of knowledge in other areas" (p. 437). Noting that methodological factors had a significant effect on their results, Losel and Schmucker (2005) stated: "Bearing the methodological factors in mind, one should draw very cautious conclusions from our meta-analysis… We need more high-quality outcome studies that address specific subgroups of sex offenders as well as more detailed process evaluations on various treatment characteristic and components" (p. 138). Abracen and Looman (2004) opined:

> With reference to sex offender recidivism research, more generally it is quite clear that the quality of many research studies has, to date, been relatively poor…Regardless of the difficulty

> associated with finding statistical significance, there is little rational for poorly conducted studies. (p. 16)

Harkins and Beech (2007) wrote, "The effectiveness of sex offender treatment has been studied and reviewed extensively…in spite of great effort and numerous studies, this has yet to be conclusively demonstrated" (p. 37). Seto et al. (2008), in their consideration of RCT methodology for sexual offender treatment outcome studies, wrote: "It is possible that some adult sex offender treatments currently being offered are effective; it is also likely that some treatments are ineffective, or worse" (p. 253). Schmucker and Losel (2008) wrote that the field should remain critical of existing research results and that "In order to reach a more definitive answer on the questions' Does sexual offender treatment work?' we need more high quality studies" (p. 16). Hanson et al. (2008) wrote "Readers sympathetic to sexual offender rehabilitation may be content with the encouraging findings from weak research designs; however, skeptics will only be compelled to change their opinions by the strongest possible evidence" (p. 887). Over 20 years after Furby et al.'s (1989) SR, the IHE SR in 2010 concluded:

> …research on the efficacy/effectiveness of SOT interventions and programs has been slow to mature, and the results have been contradictory…the perceived efficacy/effectiveness and value of SOT program and the views on how best to manage adult male sex offenders have been inconsistent. (p. 32)

They reported that the current evidence showed a small statistically significant treatment effect but that "a lack of high-quality primary research studies…raise uncertainty about which of the available approaches work for adult male sex offenders" (p. 32). Rice and Harris (2013) summarized the current status of the sexual offender treatment outcome literature, stating "The most parsimonious interoperation of findings from weaker designs is that pretreatment differences and other forms of selection bias are responsible for apparent treatment effects" (p. 23). As a form of criminal recidivism, sexual reoffending appears to be a substantially more difficult problem to successfully address than general criminal behavior. Depending on how the data is viewed, to a certain extent, limited scientific data suggests that the reduction of future nonsexual criminal behavior via psychosocial interventions is somewhat more successful than the ability to show reductions in sexual criminal behavior by similar means. [However, most of those empirical results are based on largely CBT models following the RNR approach but are largely dependent on quasi-experimental findings and follow-up periods of 2 years or less (e.g., Bonta & Andrews, 2006; Landenberger & Lipsey, 2005; Latessa & Lowenkamp, 2006).] More generally, an increasing number of writers have raised concern about the indirect harm that can result from inaccurate conclusions drawn about treatment efficacy, noting that an ineffective treatment that is falsely assumed to be beneficial exacts various costs in terms of both expense and other resources and expectations of clients and other involved or affected parties.

In addition, a number of other key questions have yet to be answered and in some cases have yet to even be addressed. As previous reviews have pointed out, it is unclear what characteristics identify sexual offenders who might respond to psychotherapy initially and maintain any apparent gains at the end of such interventions. As Nunes et al. demonstrated, there are differences between group results and those for individuals. It is likely that particular individual sexual offenders are responsive to psychosocial interventions and do change as a result of them; the question is can those who do change be reliably identified and by what means. Certainly, on an individual level, any sexual offender who has participated in sexual offender treatment should be carefully and comprehensively evaluated to determine if there are substantive grounds in determining a measurable basis for judging treatment progress and potential treatment success. Are there differences in how paraphilic, psychopathic, and/or otherwise personality disordered sexual offenders respond to sexual offender treatment? In addition, it is unclear what elements of sexual offender treatment programs may make significant contributions to potentially positive outcomes for sexual offenders or subgroups of such offenders. To what degree do the intensity, length, and site of treatment, general client characteristics, general therapist characteristics, experience of therapists, the interaction of therapists and clients (and approaches), severity and psychosocial impairment of clients, as well as similar variables relate to the outcome of sexual offender treatment? Beyond what is currently known, are there other identifiers of sexual offenders that distinguish those who refuse, dropout of, or are terminated from sexual offender treatment?

With some distance and a dispassionate perspective, the lack of demonstrated efficacy for sexual offender treatment should not be surprising. Sexual offending lacks a detailed and scientifically defined etiology for either the initiation or maintenance of this particular type of criminal behavior. Both the integrated, multidimensional models of sexual offending lack specificity, and the available empirical studies of risk factors indicate relatively small contributions of multiple, cumulative risk factors. Further, as Hoberman (2013c) notes, the specific treatment elements and delivery of sexual offender treatment lack both an established theoretical and empirical basis; largely, the elements of sexual offender treatment were borrowed from treatments for other presenting problems, and few if any of the elements or delivery issues have been demonstrated to be effective in affecting robust behavioral change. In the context of the general literature on the effectiveness and efficacy of psychotherapy, a number of factors would strongly suggest that psychosocial interventions might have little effect on sexual offense recidivism.

The evidence suggests that psychotherapy is most effective at relieving personal distress, which may be lacking among many sexual offenders. If client variables contribute the most variance to psychotherapy outcome, the multiplicity of personological risk factors acting convergently and cumulatively would make it difficult to affect sexual reoffending. Further, given the likelihood of problem severity and interpersonal difficulties, including the strong association of maladaptive personality traits and disorders with such offending, would suggest that numerous therapy-interfering effects and the general difficulties limiting the change of core signs and symptoms would impose significant limits to potential positive outcomes from psychotherapy. The effects of mandated treatment and a generalized lack of motivation for behavioral change would also impact negatively on the potential "success" of psychosocial interventions. As several authors have noted, perceived high levels of criminogenic needs or risk factors are associated with poor treatment outcomes for sexual offenders. Conversely, the general lack of evidence for outcome effects from specific techniques or strategies would also direct that the varied programs of such techniques and strategies would not be key factors in leading to individual change for many sexual offenders.

The lack of available evidence for the efficacy of sexual offender treatment has a variety of implications for offenders, forensic/clinical practitioners, public safety, and the scientific field of sexual offender management. As Marques et al. (2005) indicated, "Questions about whether and when sex offenders can be treated are extremely important, not just to our field but to victims, policy makers and the public" (p. 104). In turn, this leads to a variety of potential overlapping decision points and courses of action that might be taken relative to the role of psychotherapy in the management of sexual offenders.

Unless evidence of psychosocial treatment effectiveness (defined by accepted scientific practices) is produced, the sexual offender treatment outcome field increasingly runs the risk of being further marginalized and discredited. Lilienfeld (2011) reviewed data that suggests that a large percentage of the public regard the general field of psychology's scientific status with considerable skepticism. Nasrallah (2013), the editor of *Current Psychiatry*, similarly suggests that "…psychotherapy has never been able to shrug off an unwarranted aura of fuzziness as a legitimate medical intervention…Psychotherapy is sometimes perceived as a scam –that is, a placebo packaged and propagated as treatment" (p. 18). In the face of a lack of a strong scientific basis, ongoing affirmation of the tenuous position that sexual offender treatment is effective for most sexual offenders runs the risk that the sexual offender field will become a poster child for "pseudoscience." It is notable that, in the 1980s, it was largely the American Psychiatric Association's decision or belief that sexual offender treatment was not effective that lead to the dismantling of earlier attempts to intervene with such offenders therapeutically and a shift to a relatively exclusive emphasis on correctional management for sexual offenders. As several writers have argued and has been demonstrated by the decreasing research and policy support for sexual offender treatment, there is great danger in promising results that may not be obtainable; the credibility of both practitioners and their professional organizations may suffer long-lasting damage in terms of public mistrust. Marques et al. (2005) stated, "Questions about whether and when sex offenders can be treated are extremely important, not just to our field but to victims, policy makers and the public" (p. 104). In 1999, Alexander wrote: "…public funding for sexual offender research and treatment has declined in the last decades. A poverty of research funds has hampered improved understanding of the effectiveness of various offender treatment interventions, perhaps due to the belief that no treatment is effective" (p. 102).

In a plenary address to the membership of the ATSA in 2005, James Breiling (a branch director of NIMH) strongly encouraged persons in the sexual offender field to confront the lack of empirical evidence regarding sexual offender treatment outcome research or risk losing further credibility with funding agencies and the general public. Dennis et al. (2012) were adamant that without consistent, methodologically sound research to demonstrate that sexual offender treatment is effective, there is a risk "that society [may be] lured into a false sense of security in the belief that once the individual has been treated, then their risk of reoffending is reduced. Currently, the evidence does not support this belief" (p. 28). ATSA too, in 2010, stated: "Community safety is better promoted by identifying treatments with strong evidence of effectiveness than by a proliferation of programs for which the efficacy is debatable" (ATSA, 2010a). Thus, currently, the question, "Does sexual offender treatment work?" cannot technically be answered, because the research base for psychosocial interventions for sexual offenders consists almost exclusively of methodologically limited studies. Moreover, the few available RCTs for such offenders have failed to show that sexual offender treatment decreases sexual offense recidivism rates or affects personal change related to such reoffending.

The present limitations of the available scientific study regarding the potential effectiveness of sexual offender treatment raise a number of practical questions. On the one hand, it might be considered a reasonable option to simply accept the lack of knowledge and the limitations of multiple aspects of individual change as a result of psychotherapy, at least for a select but large groups of such offenders and simply acknowledge that, to date, the efficacy of psychotherapy for sexual offenders has yet to be demonstrated; no robust scientific evidence yet exists that sexual offender treatment

"works." This reasoned conclusion suggests that, at this time, the most appropriate response to the lack of empirical evidence of sexual offender treatment effectiveness should be a greater emphasis on other aspects of social management, perhaps a containment strategy (e.g., see English et al., this volume) that does not accord psychotherapy a primary or central role in the management of sexual offenders. From this perspective, a decision that the extant failure to demonstrate a robust treatment effect for sexual offenders means that other management approaches should be accorded a larger role and appropriately funded as the primary mechanisms to manage sexual offenders. As Harris et al. (1998) opined, "to the extent that treatment fails to reduce recidivism, supervision (including denial of community access) has to take its place" (p. 104). This perspective would emphasize a need for further scientific study of and continued development of mechanisms for differentiating among sexual offenders to provide for the most accurate appraisals of risk and need for sexual offense recidivism. In turn, as risk and other assessments became more refined, they might provide that the basis for more comprehensive alternative management strategies could be directed at those sexual offenders with the highest risk and the greatest needs, without the assumption that systematic means existed to motivate, promote insight and understanding, and accompany psychological change for sexual offenders via formal psychosocial interventions.

Another option would also seem quite reasonable, namely, that new methodologically adequate studies of sexual offender treatments should be developed, funded, and studied toward the end of potentially establishing more definitive and positive results that psychosocial interventions can be effective—either by substantially reducing the future risk of sexual offense recidivism or by a more delimited goal (e.g., clear evidence of individual changes and some relatively rigorous form of harm reduction that would still be socially acceptable). This second alternative would advocate that the most likely means toward scientific and public credibility regarding the potential utility of sexual offender treatment are through applied science, as is the case with other severe presenting problems that threaten the well-being of self and others. Harris et al. (1998) wrote, "to say that treatments have not thus far been conclusively evaluated is not to say that they do not work" (p. 104)—or cannot work for that matter. Langstrom et al. (2013) offered the same observation as well as suggested that professional opinion (e.g., clinicians' judgments based on hope or wishes) was no substitute for evidence. However, Harris et al. also stated:

> It behooves those who provide treatment and supervision, especially when directly or indirectly publicly funded, to reduce the existing uncertainty about the effects of these interventions by conducting scientifically useful evaluations of the services provided. We believe that such evaluations should be mandatory for publicly funded offender treatment. (p. 107)

Thus, one appropriate practical conclusion of this, as well as most other reviews, is that the challenge remains for the field of sex offender research to empirically demonstrate that sexual offender treatment works (particularly for higher-risk sexual offenders) through multiple and repeated RCTs as for other significant social and medical problems. As Hanson (1997) pointed out over 15 years ago, "Independent replication is a foundation of scientific knowledge. It is only through the accumulation of consistent results from diverse studies that skeptics either become convinced or lose their own credibility within the scientific community" (p. 133). Similarly, Miner (1997) wrote, "Science is a process of replication, since any study has flaws. Knowledge is thus advanced through a body of research that builds on what preceded it, correcting the flaws of previous studies, while raising additional questions… (p. 103). It is ultimate, this quantitative accumulation of research findings that will provide scientific evidence of sexual offender treatment effectiveness" (p. 108). More recently, Schlank (2010) also stressed the importance of replication: "Any professional field that is based on scientific research must stress the importance of replication of studies, which can provide either verification or disconfirmation" (pp. 22–23) and noted that in many fields, researchers (and practitioners) will not even consider a study complete until it has been replicated several times.

As pessimistic as the available data are regarding the status of current sexual offender treatment outcome, the path to a more empirically based understanding of such interventions seems fairly obvious. Within the field, there is an increasing consensus as to what should characterize future research efforts. In fact, over the past 30 years, most researchers have consistently spoken of the ways to enhance the understanding and potential credibility of sexual offender treatment. Furby et al. (1989) stated in their early review of sexual reoffending in both treated and untreated sex offenders: "…Progress in our knowledge about sex offense recidivism will continually elude us until adequate resources of time, money, and research expertise are devoted to this issue…It is time that we give this issue the resources and attention it deserves" (p. 28). In 2005, Marques et al. indicated:

> Questions about whether and when sex offenders can be treated are extremely important, not just to our field but to victims, policy makers and the public. The only way to provide answers with confidence is to build a knowledge base on thoughtful and well-controlled studies of treatment effectiveness. (p. 104)

Craig et al. (2003) concluded: "Treatment studies should adopt well matched and randomized controls using appropriate and universal measures of recidivism" (p. 86). Seto et al. (2008):

> Only methodologically rigorous research will allow us to determine which is which…[we] want to identify and disseminate treatments that can effectively reduce the likelihood that sex

> offenders will do further harm, but we believe that only good science can inform good clinical practice and lead to the advancement of sex offender treatment. (p. 253)

Hanson (2014) has stated: "…we know very little about the effectiveness of methods used to rehabilitate sexual offenders…it is hard to make any strong conclusions about whether treatment works at all…This is a depressingly similar conclusion to that of …more than 20 years earlier. Knowing which treatment works for which type of sexual offender remains a distant dream" (p. 5). He states, "Although we, as service providers must believe in what we do in order to do it, we also need the humility to admit that we could be fundamentally mistaken. Consequently sexual offender treatment needs rigorous scientific scrutiny…" (p. 6). Referencing the large number of studies of risk assessment of sexual offenders and the hundreds of treatment outcome for general criminal offenders, Hanson (2014) stated: "What we need now are hundreds of new studies of sexual offender treatment outcome…" (p. 7). He advocated for the significance of evidence-based practice, noting that the growing interest in evidence-based practice in the large mental health field should be viewed as a sign of progress and for those who want science to influence sexual offender practice and should be viewed as a genuine force for the good. In short, further scientific study of sexual offender treatment is a necessary step for the field to advocate that such interventions should be an essential component of sexual offender management. The onus rests solely on the field of sexual offender research and management to establish that sexual offender treatment is clearly effective, particularly for the most high-risk sexual offenders.

Almost all credible researchers agree that the initial step to determining if sexual offender treatment can be effective in reducing sex offense recidivism is to systematically develop a body of methodologically sound RCTs of such interventions, preferably involving a relatively large number of subjects. Langstrom et al. (2013) concluded, "Based on the meagre results from our extensive systematic review, we concluded that there is an urgent need for well designed and well executed trials of treatment for adults who commit sexual offences against children" (p. 4). In their 2912 Cochrane Review, per Dennis et al. (2012), "We concluded that further randomised controlled trials are urgently needed in this area…" (p. 28). Rice and Harris (2003) stated, "…it is abundantly clear that any conclusions about the effectiveness of psychological therapy await many more random assignment studies" (p. 427). Similarly, Seto et al. (2008) declared, "In our view, RCTs are both ethical and necessary in order to prevent more victims of sexual violence and abuse" (p. 254). In addition, Hanson et al. (2009) wrote that:

> …strong studies are needed…we believe that an important requirement of strong research design is the experimenter's ability to determine participant assignment based on a procedure that controls for both measured and unmeasured features of the offenders (i.e. Random assignment)…Random assignment studies remain the best available alternative for minimizing participant election bias. Random selection is also one of the most ethically defensible methods of assigning individuals to treatment when demand exceeds supply or the relative superiority of alternate treatment is unknown. (p. 887)

Shortly after the publication of his 2009 review, Hanson indicated: "I, for one, have done enough meta-analyses of barely acceptable studies. It is time to counter the political resistance to random assignment studies by getting ATSA to endorse a position statement supporting their use" (Hanson, cited in Rice & Harris, 2013). In yet another recent review of sexual offender treatment, Kaplan and Krueger (2012) wrote: "…large, well-conducted randomized trials of long duration are essential if the effectiveness or otherwise of these treatments is to be established. Most of the studies upon which the knowledge base of the treatment of sexual offenders is based are seriously flawed. Overall, however, the evidence base for cognitive-behavioral treatment is extremely limited and empirical research focusing on effective treatment for this population is critically needed" (p. 295). Thus, investigations of the efficacy of sexual offender treatment must begin with RCTs, with largely similar offenders randomly assigned to one or more interventions and control groups of similarly motivated persons. Such studies must involve repeated, multi-method measures of likely psychologically meaningful risk factors. Offender subjects must be followed via survival analysis (with attention to attrition, reincarceration, and other types of reoffending) with any additional relevant experiences (e.g., additional treatment, correctional supervision) that must be accounted for as well. As part of its commitment to promoting evidence-based practices and high-quality research, ATSA (2010) has stated: "ATSA recognizes randomized clinical trials (RCT's) as the preferred method of controlling for bias in treatment outcome evaluations. ATSA promotes the use of RCT to distinguish between interventions that decrease recidivism risk of sexual offenders and those programs that have no effect or are actually harmful." There should be little doubt that RCTs are feasible for sexual offenders. Rice and Harris (2012) noted that there were 267 existing RCTs in the field of criminal justice in 1993 and 87 RCTs in correctional research alone as of 2005. They also noted that there have been several RCTs for adolescent sexual offenders (and of note, studies which have demonstrated the efficacy of one particular model of intervention). Consequently, Rice and Harris (2003) concluded: "It is abundantly clear that RCTs are feasible both ethically and practically in crime and justice fields in general, and in corrections, specifically" (p. 18). A number of such studies have been conducted such as those by Cullen et al. (2011) and Davidson et al. (2009). Further, Hanson et al. (2008) point out that other improvements to research study quality

could be implemented at relatively low cost, including reporting intent-to-treat analyses, using equal and fixed follow-up periods, scoring actuarial risk measures on the treatment and comparison groups, using statistical controls, and matching on risk-relevant variables. They also pointed out that "much less is known about the processes by which sexual offenders change. Studies frequently find that improvements on factors presumed to be criminogenic have no effect on sexual recidivism rates…" (p. 887). Such a perspective echoes that of Borkovec and Castonguay (1998) who wrote: "Creating increasingly effective therapies through between-group designs is best done by controlled trials specifically aimed at basic questions about the nature of psychological problems and the nature of therapeutic change mechanisms. Naturalistic research is important for external validity but is valuable only if it uses scientifically valid methods to address basic knowledge questions" (p. 1). Thus, sexual offender treatment approaches should be rooted in evidence-supported theories of sexual offending and initially determine if sexual offender treatment can be demonstrated through RCTs and several theory-supported models should be evaluated. Such methodologically rigorous studies are only the beginning by establishing internal validity. Subsequently, the heterogeneity of sexual offenders in relation to sexual offender treatment outcome as well as sets of components and parameters of sexual offender treatment can be rigorously evaluated. As with other disorders, methodologically sound investigations should target those criminogenic needs (or in the language of the larger treatment field, risk factors) in the context of evidence-based elements of effective psychosocial interventions. In addition to outcome studies, Hanson et al. suggested that researchers also focus on short- and medium-term changes on intermediate treatment targets and criminogenic needs; they noted that outcome research should help advance knowledge of the change process by examining the relationship between changes on more proximal treatment targets and more distal sex offense recidivism. Following this point, it becomes critical for further investigation into the effectiveness of different targets of sexual offender treatment and comparisons of different methods and approaches for affecting those targets. As with other recurrent, multidimensional problems targeted for change, multiple high-quality progression of methodologically refined studies of sexual offender treatment outcome will be necessary over time to best understand first whether treatment "works," and if so, what aspects of the therapist, client, and treatment program components contribute to effectiveness.

Despite the discouraging findings from scientific evaluations of sexual offender treatment programs at present, updated and innovative perspectives on treatment and on potentially effective approaches to the treatment of sexual offenders have continued to develop, many of which are reviewed by Yates (2015, this book). Such developments include the Self-Regulation (SR) Model (Ward & Hudson, 1998), Good Lives Model (GLM; e.g., Ward & Stewart, 2003), the integrated Good Lives/Self-Regulation Model (Yates & Ward, 2008), a "Strength-Based" Model of psychotherapy (e.g., Marshall et al., 2011), and the Recidivism Risk Reduction Treatment approach (3RT; Wheeler & Covell, 2013). Such approaches uniformly suggest that sexual offender treatment will be most successful when it is comprehensive and incorporates the management of predisposing, risk-related characteristics as well as encouraging the development of positive personal goals and healthy lifestyles. Particularly, given their "positive" approaches to the nature of offenders as individuals and to the goals and methods of therapeutic work, these developments appear to be heartening and inspiring to forensic/clinical practitioners. However, these newer perspectives on sexual offender treatment have and should be met with some significant degree of skepticism by others; 15 years ago, Quinsey et al. (1998) remarked "Overall, it seems clear that the field of sex offender treatment is changing without progressing" (p. 150). The promise of novel or presumed innovative approaches to sexual offender treatment must be put to the test of empirical investigations prior to unquestioned excitement and wide adoption. Both Quinsey et al. (1998) and Hanson (2003) have noted that these and previous novel sexual offender treatment models have been sequentially proposed (and others recommended for rejection) on exclusively or predominantly *nonempirical* or *theoretical bases*, in contrast to models of interventions for this group advancing progressively on the basis of scientifically sound appraisals. Most recently, Hanson (2014), in commenting on the lack of a scientific foundation for sexual offender, stated "The development of the [sexual offender treatment] field cannot be attributed to strong empirical evidence that such treatment is effective *…the changes in our treatment practices during my professional career have had only the lowest inspiration from research findings…It is hard to argue that we switched from aversive conditioning to relapse prevention (RP) and from RP to Good Lives because of any deep commitment to evidence-based practice*" (p. 3, emphasis added). Thus, to date, there are no RCTs of the Self-Regulation Model (SRM; Ward & Hudson, 1998), the Good Lives Model (GLM; Ward & Gannon, 2006; Ward & Stewart, 2003), the combined SR/GLM (Ward & Gannon, 2006; Yates, Prescott, & Ward, 2010; Yates & Ward, 2008), and Marshall et al.'s Strength-Based Approach model (SBA; Marshall et al., 2011) or Recidivism Reduction Therapy (3RT) (Wheeler & Covell, 2013); similarly, there is incomplete evidence that the each of the principles of RNR treatment for general criminal offenders applies to specifically sexual criminal offenders, particularly the risk principle. However, as noted earlier, an increasing number of sexual offender treatment programs in North America and the UK employ aspects of GLM, a

change in practice that is not based on scientific evidence. In part, this reflects a larger issue, a professional reliance on "unstructured clinical judgment," where clinicians overwhelmingly rely on their own beliefs and experiences in their clinical practice as opposed to research findings (e.g., Ogilvie, Abreu, & Safran, 2005; Stewart & Chambless, 2007). This is despite the caution of Langstrom et al. that "Professional *opinion* is no substitute for evidence" (p. 4, emphasis added). Consequently, there continues to be an increasing divergence between what has been (or has not been) scientifically demonstrated regarding sexual offender treatment and what forensic/clinical practitioners actually do with clients who have sexual offended. While intuitively appealing, newer treatment models and interventions (such as the GLM, SR/GLM, SBA, 3-RT, and other positive approaches, motivational interviewing, and treatment preparation) need to be subject to empirical testing to determine their relationship to sexual offender treatment outcome and individual change. Psychosocial interventions should not be abandoned at this point. Rather, as with other complex psychologically based presenting problems, the lack of scientifically demonstrated treatment outcome results should be the urgent impetus for increased study of psychosocial interventions for sexual offenders, informed by existing data and the principles of effective psychotherapy.

In the future, outcome studies of sexual offender treatment must be derived from more evidence-based principles and practices, including the value of careful identification and comprehensive, systematic evaluation of clinical expertise and patient characteristics, preferences, and circumstances (e.g., Spring, 2007). Primarily, treatment outcome studies of sexual offender psychotherapies must rely on RCTs, with similar offenders randomly assigned to one or more interventions and control groups of similarly characterized and motivated sexual offenders. Experimental interventions must be bona fide interventions, and given the current status of the field, it makes sense to study multiple psychosocial approaches in treating sexual offenders. RCT studies of treatments for sexual offenders should involve repeated, multi-method measures of likely psychologically meaningful risk factors. Subjects must be followed via survival analysis, with minimal attrition, overtime, and any additional relevant experiences (e.g., additional treatment, correctional supervision) that must be accounted for as well. Potential moderators and mediators of clinical change need to be further identified, monitored, and refined. Sexual offenders of differing levels of risk, particularly high-risk offenders, need to be the focus of outcome research. As well, it seems timely for the sexual offender field to reconsider what the essential focus/content of treatment approaches should consist of. The criminological literature has suggested that a focus on the so-called criminological needs as the most meaningful treatment targets; this parallels the broader psychotherapy field's increasing focus on personality issues or predisposing condition diatheses which seem to underlie the presenting problems of more psychotherapy-refractory clients; while these are similar, the former relies exclusively on the results of science, while the latter reflects both empirical research and clinical theory. Hanson et al. (2009) pointed out: "Studies frequently find that improvements on factors presumed to be criminogenic have no effect on sexual recidivism rates…" (p. 886). As a result, they advocated for changes in substance of sexual offender treatment programs, stating:

> …it would be beneficial for treatment providers to carefully review their programs to ensure that the treatment targets emphasized are those empirically linked to sexual offense recidivism. Examples of promising criminogenic needs include sexual deviancy, sexual preoccupation, low self-control, grievance thinking and lack of meaningful intimate relationships with adults…Outstanding questions remain, however, concerning potential gains from matching interventions to the needs of individual offenders and whether recidivism can be most effectively reduced by addressing certain combinations of needs. (p. 886)

As noted, both models of other presenting problems/mental disorders as well as sexual offending (e.g., the ITSO; Ward & Beech, 2006) increasingly highlight the potential significance of implicit psychological experiences and intra-individual content and process issues. Potential changes in such needs, implicit theories and issues, and other theory-based treatment-related factors must be tested for reliable, clinically significant, and valid change.

In addition to the focus of sexual offender treatment, treatment delivery issues also need to be investigated in a controlled systematic manner. Per the RNR model of correctional intervention, the importance of the relative intensity and duration of sexual offender treatment as well as responsivity dimensions for offenders with different levels of needs and risk must be carefully examined. Truly effective methods of changing offenders' interconnected thoughts, feelings/motivations, and behaviors need to be identified; the relative value of psychoeducational and experiential treatment tactics needs to be identified and refined; dismantling and recreating truly effective methods and strategies of sexual offender treatment should occur. While intuitively appealing, the so-called positive treatment models and interventions (such as the Good Lives approach, Strengths Approach, 3RT, motivational interviewing, and treatment preparation) must be subject to rigorous empirical testing to determine their relationship to the central outcomes in the treatment of sexual offenders: personal change and decreased sexual offense recidivism rates. Therapist, client, and process variables need to be carefully studied; particularly, for high-risk/high-need sexual offenders, it seems likely that they would benefit from particularly well-trained and experienced therapists and that this would likely be a cost-effective practice. In this vein, Marshall's (e.g., 2005) work regarding

the significance of clinician qualities in impacting sexual offenders seems increasingly important. However, first, the delineation and cultivation of effective psychotherapist qualities and knowledge specific to working with sexual offenders seem essential. Second, multiple investigators must systematically and empirically examine the empirical value of therapist qualities and knowledge. To the extent that the evidence that the therapeutic relationship or alliance is believed to be critical to treatment success, then controlled outcome studies involving enhanced therapist characteristics or therapist–client matching should certainly be conducted. At the same time, issues of treatment fidelity and the value of parameters of clinical supervision remain to be examined in relationship to the effectiveness of sexual offender treatment approaches. The relative contribution of individual and group psychotherapy separately and in combination (and the types of groups such as closed or "rolling") needs to be evaluated particularly in relationship to specific collections of presenting problems and other client dimension; as Hanson et al. suggested, it may be time to more explicitly match treatment approaches to the particular needs of specific offender clients. Ultimately, for the problem of sexual offending, as it would be any type of presenting problem, this is what Paul (1967) wrote over 40 years ago: "…the question towards which all outcome research should ultimately be directed is the following: *What* treatment, by *whom*, is most effective for *this* individual with *that* specific problem and under *which* set of circumstances?" (p. 111). However, the answers to those questions in regard to sexual offender treatment outcome will only be determined by the development of research programs of sexual offender treatment with diverse samples of sexual offenders that are controlled, comprehensive, and able to be replicated across settings.

A key issue for mental health professionals involved in the psychosocial treatment and management of sexual offenders is to come to terms with the role of scientific investigation and results regarding such treatment and the larger field of psychotherapy and mental health interventions. As noted earlier, there is tremendous public skepticism of the mental health field, particularly psychology; as Stanovich (2009) observed, "Most judgments about the field and its accomplishments are resoundingly negative" (p. 175). Lilienfeld (2011) points out that we ignore such skepticism at our peril, in terms of potential client's expectancies about possible improvement, third-party reimbursement, and government funding of significant research questions. Gaudiano and Miller (2013) point out that "Many psychotherapists are opposed to the idea of the specification of evidence-based treatments in principle, viewing psychotherapy at least as much art as science and preferring to rely on clinical intuition and experience instead of scientific evidence…" (p. 815). They note that most clinicians do not base their treatment decisions on "state-of-the-art" clinical research and that approximately 50 % reject the use of more formal, evidence-based treatment approaches and rely primarily on their own subjective clinical experiences. Lilienfeld et al. (2013) provides a wide-ranging analysis of the reasons why mental health professionals have been resistant to evidence-based practice and remedies to those issues. In effect, all of these apply to MHPs practicing in the sexual offender treatment field. As Dennis et al. argued, "…this weaker evidence (and the conclusions drawn from it) often leads to a more optimistic conclusion about efficacy than is warranted, and unfortunately becomes embedded in clinicians' consciousness. This may result in a belief that current approaches area more effective than the evidence suggests" (p. 28). They even noted that previous conclusions of earlier reviews of the limitations relative to the demonstrated effectiveness of sexual offender treatment and the repeated call for further research have typically been cushioned by misleading phrases such as the results are nonetheless "promising. More recently, Duggan and Dennis (2014) noted that there are over 2,900 RCTs of psychosocial interventions for Schizophrenia. Regarding the place of evidence in the treatment of sex offenders, they concluded":

> Although RCTs in any area of healthcare are difficult to conduct, other specialties have overcome the challenges that they present…It is clear that high quality evidence can be produced in most areas of healthcare, if there is the will to do so. For this to happen with respect to treatment for sex offenders, spurious impediments…must be set aside. Those who enter sex offending programmes, together with their past and potential future victims, should expect to be provided with treatments with a strong evidence base. Acquisition of this evidence must be a process, which includes, although is not confined to, RCTs. (p. 160)

Relative to this issue, it is striking that in the sexual offender field, mental health professionals readily accepted and utilized various structured risk instruments based on the finding that experimentally derived statistical information outperforms [pure] clinical judgment. Yet, in marked contrast, given a more striking lack of empirical data and justification for any psychosocial sexual offender treatment, mental health professionals in the sexual offender field have consistently defended their belief or faith in psychotherapy as a viable component of management to reduce sexual offending.

As an antidote to these issues, Lilienfeld (2011) argues that the mental health fields must "police themselves"; he specifically states that while thoughtful debates about the best means of operationalizing evidence-based practice should continue, "practioners with the applied fields of psychology (e.g. clinical, counseling, school) would be well advised to become less tolerant of pseudoscience and more willing to ground their practices in replicated research evidence" (p. 14). Actually, Andrews and Bonta (2006) offered a similar perspective regarding the study of criminal

behavior: "Unsparing criticism is a major source of advancement…all criticism, including criticism of theoretical and research-based assertions, is best combined with respect for evidence…" (p. 3). Placed in the larger national and international context of health economics and management, Baker et al. (2009) stated: "The current context of health care in American (and beyond) demands a higher level of accountability than in the past…the future of clinical psychology will be dictated largely by what data show regarding the relative cost-effectiveness of psychosocial and behavioral interventions compared with other competing intervention options in mental health care…Clinical psychologists must offer compelling evidence relating [to the criteria of such comparisons] if they expect their psychosocial and behavioral intervention s to have a fair chance of gaining widespread support, to be adopted in the health delivery system, and to be funded via health coverage mechanisms…" (p. 69). Baker et al. reviewed the history of the progress of medical care in the USA and offered a convincing argument that the increased, nearly universal acceptance of medical treatment is based on three sociopolitical changes: (1) the scientific grounding of medical practice in experimental study, primarily RCTs; (2) a greatly expanded body of science accompanied by increasingly rigorous training of physicians in evidence-based procedures and standards of practice; and (3) higher standards in training and licensure. Baker et al. note that physicians have almost exclusively positive views regarding experimental evidence such that it constitutes a touchstone regarding practice, and as a result, practice studies show that a very high percentage of medical patients receive interventions that are evidence based. In contrast, they demonstrate that psychologists and other non-medical mental health providers view science and research as having very little relevance to their practice activities and decisions. Moreover, they note that "Clinical psychologists often practice in a manner that *conflicts* with considerable research evidence or at least is not clearly supported by research evidence…practitioners often say they do not care, because they consider the available scientific evidence to be relatively uninformative or irrelevant to their practice decisions…" (p. 80). They argued that unless significant changes occur in the mental health profession's acceptance of a scientific approach to the treatment of mental health problems, MHPs risk being even more devalued and even further reduce in their roles in both the practice and policymaking about the utility of psychosocial interventions.

Thus, to continue to argue—and more importantly to *act*—as if psychotherapy has been empirically demonstrated to be effective at reducing future sexual offending is ultimately to risk the exclusion of such intervention modalities or treatment practitioners as one element in a broad approach to managing sexual offenders. Until strong empirical evidence exists that sexual offender treatment does significantly and differentially reduce sexual offense recidivism, several issues remain for the various participants and stakeholders. This is quite similar to the related field of psychosocial interventions for persons with ASPDa. Duggan (2008), an author of several Cochrane and related reviews of this Personality Disorder, concluded: "The implication is clear: that there is an imperative for scientists and clinicians to provide decision makers with the appropriate evidence to allow the latter to arrive at the best decision…we are in a weak position to influence the political process in the allocation of funds so that unless and until these areas are addressed, interventions for [criminal offenders] with ASPD are likely to continue to remain in a scientific limbo" (p. 2610). Several writers have suggested that the sexual offender field effectively becomes more accurate and honest in representing what sexual offender treatment might offer some sexual offenders. Another perspective to take regarding the lack of evidence of sexual offender treatment is to simply consider if one would recommend to others or choose for oneself a medical intervention that lacked one, let alone replicated, empirically demonstrated trials of its relative effectiveness. Over 15 years ago, advocating for a harm reduction approach to psychosocial interventions for sexual offenders, given the "not particularly optimistic" evidence for treatment success for sexual offenders, Laws (1996) stated:

> The domain of treatment provision is an imperfect one and we should openly acknowledge that…I believe we should stop using the words sexual offender *treatment* to characterize our work and substitute sex offender *management* instead, since it is actually more accurate…*Treatment* suggests sexual deviance may remit or be cured and so, like a treatment for a disease, establish expectations for success which are quite unrealistic… At bottom, our job in managing sexual offenders and reducing harm is, in reality, a sort of social policing…. (p. 246)

However, as Harris et al. (1998) wrote: "It behooves those who provide treatment and supervision, especially when directly or indirectly publicly funded, to reduce the existing uncertainty about the effect of these interventions by conducting scientifically and useful evaluations of the services provided. We believe that such evaluations should be mandatory for publicly funded offender treatment" (p. 107).

Recently, in the ATSA Forum, Pake (2010) opined that the state of science relating to the management of human behavior is not yet at a point when one can proclaim treatment success with any certainty, saying "It is currently impossible to support such a statement scientifically." Further, he notes that whether a sexual offender who has participated in treatment chooses to utilize understanding and learned skills necessarily remains at the discretion of the offender and no therapist can account for a particular offender's choice in any given circumstance. Pake concluded by stating: "By portraying treatment as successful, we offer a false sense of security. Portraying treatment as successful encourages non-clinical

partners in community risk management to perceive our efforts as having eradicated the potential for reoffending on the part of the treated sexual abuser. This is misleading. It leads one to question the profession's intellectual honesty."

Clinician's practicing non-forensic psychotherapy with clients who are independently choosing to engage in and pay for such treatment—for whom the only stakeholders are the client and the therapist—should be relatively free to engage in whatever procedures they mutually believe are in the client's best interest. However, the process of forensic clinicians providing forensic psychotherapy to anticipated or actual forensic clients involves other considerations, particularly the interests and support of other stakeholders—in most cases, the treatment is being funded by third parties (e.g., an agency acting on behalf of society) and the purpose of that psychotherapy is primarily public safety (which is the basis for the agency and/or public funding the treatment). For forensic/clinical psychotherapists in the community and institutions, what does one do in sexual offender treatment? Certainly, there are some sexual offenders who do and will benefit from psychotherapy such as those that are low-risk and presumably one-incident offenders. Psychosocial treatments of some type are likely effective for some specific offenders, but, at present, group data does not support this conclusion. Consequently, the degree to which a particular sexual offender will or does benefit from sexual offender-specific treatment, with or without additional psychosocial interventions, must be carefully considered. [Similarly, whether a particular sexual offender has benefited from psychotherapy cannot meaningfully rely on group outcome data, therapist ratings, or self-reported change but rather must be determined on some individual basis, with its own extensive set of "measurement" issues.] Given the apparent failure to demonstrate effectiveness for general CBT-RP-type sexual offender treatments—and by implication the component "modules" (e.g., Hoberman, 2015)—it appears critical for those who intend to or must provide psychosocial interventions to sexual offenders that they critically examine the components and implementation of their treatment. Clearly, for presenting problems like eating disorders and drug abuse, empirical evidence for the qualified efficacy of existing treatments exists, and both help-seeking and resistant clients are offered psychosocial interventions. Such interventions are necessarily based on demonstrated or hypothesized harm reduction for the individual client and not necessarily as a "cure" (albeit the risk or harm associated with eating disorders and most other presenting problems is largely to the client and not others). However, the "harm" dimension of those disorders relates to the client and not to others/society; harm reduction may be a useful concept for disorders that pose issues of self-harm. However, harm reduction may not be a sufficient outcome for sexual offender treatments as with other violent offenders. It is reasonable to ask that psychological treatments of persons with a demonstrated history and propensity for violent sexual offending against others be demonstrated to be substantively effective if they are to be accorded a primary place in the management of such offenders and/or funded by the public.

To the extent a sexual offender is motivated or can be genuinely influenced to engage in treatment (whether it be intrinsically or extrinsically), several practices seem reasonable. To begin with, there is an ethical and practical issue as to what type and degree of expectancy can and should be communicated to offenders who express interest in or are mandated for sexual offender treatment; an emphasis on collaboration; the relevance of the offender's motivation to be open, to learn, and to enact life changes; and an agreement by the psychotherapist to work empathically, respectfully, and collaboratively with the offender should provide an appropriate framework for potentially effective treatment. However, these practices need to be guided by scientifically informed data and then the clinical needs and responsivity issues of particular offender clients. In the absence of scientifically informed forensic/clinical practice, several questions exist for practicing clinicians who provide psychotherapy for sexual offenders. Harris et al. (1998) advocated as follows:

> The best option in these circumstances of relative ignorance is to adopt treatments that (a) fit with what is known about the treatment of offenders in general, (b) have a convincing theoretical rationale in that they are motivated by what we know about the characteristics of sex offenders, (c) have been demonstrated to produce proximal changes in theoretically relevant measures, (d) are feasible in terms of acceptability to offenders and clinicians, cost, and ethical standards, (e) are described in sufficient detail that program integrity can be measured, and (f) can be integrated into existing institutional regimens and supervisory procedures. (p. 104)

Similarly, Langstrom et al. (2013) wrote "Without specific guidelines for treating individuals at risk, the most ethically defensible position would be to assess the presence of treatable risk factors for sexual abuse of children, including concurrent psychiatric disorder, and offer individualised treatment" (p. 4). As with other presenting problems that lack of demonstrated effective interventions, offering psychotherapy should continue to be offered to offenders who appear genuinely and intrinsically motivated for such interventions. However, as forensic therapy, with the community as a significant "client" or "interested party," honest and accurate representations about the existing empirical evidence for such psychotherapies must be acknowledged; related concerns exist about who should bear the cost of unproven interventions. A related practical and ethical question concerns what practitioners can and do communicate to sexual offenders about the possible benefits of sexual offender treatment. Should offenders be provided with an accurate "likely no effect" or an "optimized" perspective on the likely effectiveness of such psychosocial interventions relative to their

expectancies of potential change? Is it ethical to induce a heightened positive expectancy for sexual offender treatment via motivational interviewing or other preparation in light of both the failure to demonstrate treatment effectiveness and the lack of empirical evidence that such theoretical notions themselves actually affect sexual offender treatment outcome? As with other presenting problems lacking demonstrated effective interventions, offering psychotherapy should continue to be offered to offenders who appear genuinely and intrinsically motivated for such interventions and for whom resources are available to fund their treatment. However, as forensic therapy, with the community as a significant "client" or "interested party," honest and accurate representations about the existing empirical evidence for such interventions must be provided; the failure to demonstrate efficacy of psychotherapies for enacting personal change in sexual offenders and decreases in sexual offense recidivism must be acknowledged so that policy makers and the public are informed about the potential value of resource allocation and the degree of community safety such resources might provide.

From a public policy perspective, the lack of an empirical demonstration of the efficacy of sexual offender treatment, particularly as forensic psychotherapy, raises several significant questions. Should treatment be mandated in the absence of clear demonstrations that sexual offender treatment "works?" Regarding the study of criminal behavior, Andrews and Bonta (2006) wrote: "…it views a reduction of the costs of both crime and criminal justice processing as highly desirable. We are particularly interested in reducing the costs of crime by reducing criminal victimization in the first place" (p. 3). To the extent that much of sexual offender treatment is provided by way of public funding for institutionalized offenders or social service benefits (and to a lesser degree by insurance funding), should demonstrated effectiveness be necessary to justify such funding? In the absence of objective evidence, should offenders themselves bear the costs of funding sexual offender treatment, given providers belief that such intervention is hypothesized to impact their lives in a positive manner? In addition, if, at best, such interventions can only offer some small degree of "harm reduction" in reducing the frequency and severity of sexual offending, is that a sufficient goal for public safety and for justification of the use of public funds to provide such interventions? To what degree does society have a right to demand evidence of a large effect for sexual offender treatment—a high degree of empirically demonstrated persisting change on the part of sexual offenders? Another perspective would suggest that if sexual offender treatment cannot currently be strongly relied on to clearly and consistently reduce sexual offense recidivism, then the management of sexual offenders should shift to other alternative practices. Over a decade ago, Harris et al. (1998) noted that, to the extent that treatment fails to reduce recidivism (the current state of science), "…supervision (including denial of community access) has to take its place" (p. 104). In addition to more intensive and long-lasting community management, other options to a reliance on psychotherapy as a primary management tool for sexual offenders might include utilizing insurance programs for sexual offenders to obtain coverage for liability relative to their risk for future sexual offending (e.g., similar to motor vehicle or malpractice insurance) or extend or indeterminate sentences for offenders with prior sexual offending history and so on.

All can agree that for all stakeholders, the prioritization for the prevention of sexual violence requires, even demands, increased time and resources be devoted to studying and innovating programs for reducing future acts of sexual offending by identified sexual offenders. Given the degree of public concern about sexual offending expressed by society and political entities, there should be no question that substantially increased funding of psychotherapy outcome studies for sexual offenders should occur, just as such expanded funding has increased for other identified public health problems which effect far fewer members of the community. The *potential* for psychosocial interventions to play a central role in facilitating understanding and change in sexual offenders clearly exists. However, only by *accepting* the reality of the current status of the field of sexual offender treatment can the scientific and larger public community *commit* to a reasonable process prioritizing and funding theorizing, testing, and refining treatment models, strategies, and tactics that might be shown to effectively assist sexual offenders in modifying their personal characteristics and social contexts in such ways that their risk for future sexual offending is eliminated or substantially reduced. Following the principles of EBP, it is critical that researchers and policy makers collaborate to develop, test, and assign resources to sexual offender treatment and that researchers and sexual offender treatment programs work collectively to execute standardized research studies that clarify the role that such interventions can play in the management of sexual offenders. Sexual offender treatment clinicians and program managers must be fully informed on the existing and evolving scientific research regarding the outcome and implementation of sexual offender treatment and be educated, committed to, and supervised in implementing best practices in clinical work with sexual offender clients. At the same, as with other presenting problems lacking demonstrated effective interventions, it is reasonable to continue to provide psychotherapy to offenders who appear genuinely and intrinsically motivated for such interventions; however, without demonstrated efficacy, funding responsibility may and perhaps should shift to sexual offenders themselves. For sexual offender treatment as forensic psychotherapy, with the community as a significant "client" or "interested party," honest and accurate representations about the existing empirical evidence for such interventions must be provided. The failure, to date, to demonstrate efficacy of

psychotherapies for enacting personal change in sexual offenders and decreases in sexual offense recidivism must be acknowledged so that policy makers and the large community are informed about the potential value of resource allocation. Finally, given its role as almost exclusively forensic psychotherapy, advocates of sexual offender treatment must be transparent about what is known about its efficacy so that realistic notions of its role in public safety (as well as personal change) can be taken into consideration relative to its role in the management of sexual offenders.

Forensic Psychotherapy for Sexual Offenders: Likely Factors Contributing to Its Apparent Ineffectiveness

Harry M. Hoberman

Introduction

The key social policy question regarding providing psychotherapy for sexual offenders is simply does such treatment itself specifically lead to a significant and meaningful reduction in sexual offense recidivism? If such a finding has been scientifically demonstrated and replicated by independent researchers, then such a psychosocial interventions should play a central role in the management of sexual offenders. However, if not, until empirical evidence of its clear efficacy exists, very careful consideration should be applied to the role of sex offender treatment as a significant component in the containment of potential sexual dangerousness for sexual offenders. Instead, other alternatives to effectively reduce sexual offense recidivism must necessarily take on a more prominent role in the overall management of sexual offenders. Unfortunately, to date, psychotherapies have not been scientifically demonstrated to reduce sexual offense recidivism for sexual offenders as a group (Hoberman, 2015a). By 2010, the problematic status of psychosocial interventions for sexual offenders had become a significant enough issue that the Executive Board of the Association for the Treatment of Sexual Abusers (ATSA; 2010) proclaimed: "After 50 years, the field of sex offender treatment cannot, using generally accepted scientific standards, demonstrate conclusively that effective treatments are available for adult sex offenders." The goal of sex offender treatment is almost universally viewed as the reduction or elimination of sexual offense recidivism for public safety. Such treatment must almost always be considered "justice involved" or *forensic therapy*, that is, for the purpose of public safety, most commonly required by the legal system and typically funded by the public. As Prentky, Gabriel, and Coward (2011) wrote: "…the most compelling reason for treating sex offenders is reducing the likelihood that those offenders will reoffend and create additional victims. The primary goal of sex offender treatment is not to cure sexual offenders or to make them feel better but (a) to reduce the risk that they will reoffend, and (b) to assist with the optimal management of those sexual offenders who are in the community" (p. 117). In reviewing the results of both systematic reviews and meta-analyses, the most optimistic perspective that can be gleaned from the existing studies is that the sexual recidivism of select, lower-risk sexual offenders may be slightly lowered when they are treated in community settings; the available results could also be interpreted to mean that regardless of treatment, lower-risk sexual offenders, particularly those truly disturbed by their offending and motivated not to reoffend, generally are characterized by lower rates of sexual reoffending (not surprisingly). In contrast, for higher-risk sexual offenders who are treated in correctional and other institutional settings, there is no scientific evidence from controlled studies of psychotherapy to suggest that such interventions lead to a desired reduction in sex offense recidivism. In addition, it remains unclear if sex offender treatment is effective for different types of sexual offender and what, if any; elements of psychotherapy are particularly useful in impacting sexual offenders and sex offense recidivism rates (e.g., see Hoberman, 2015b).

While writers often cite short-term recidivism rates for sexual offenders as approximately 10–13 % for 5-year follow-up periods, scientific perspectives on long-term sexual offense recidivism indicate that *detected* sexual reoffending increases over longer follow-up periods to at least 40 % (e.g., Hanson, Morton, & Harris, 2003; Harris & Hanson, 2004; Harris & Rice, 2007). Further, such rates do not reflect the established finding that many or most acts of sexual offending are actually not detected or adjudicated as sexual offenses (e.g. reported to authorities, processed through the legal system or accurately characterized as sexual offenses

by that system), whether committed against strangers or acquaintances. In addition, repeated victimizations of particular individuals by the same perpetrator are often counted as "one" offense. Thus, the probable or true likelihood of sexual reoffending appears relatively high, for persons already identified as having already committed a sexual offense. In addition, the consequences of attempted or enacted sexual offenses on both child and adult victims can be profound and long lasting. Given that there has been some demonstrated success in psychological interventions for general criminality and for select severe psychosocial problems (e.g., eating disorders, substance abuse), the fact that for most sexual offenders psychotherapeutic programs have not been shown to be effective indicates that psychotherapy cannot yet be considered a necessary let alone a sufficient component of sexual offender management. Thus, the current inability to demonstrate that psychosocial interventions can meaningfully reduce sexual offense recidivism among identified sexual offenders must be viewed as critical public health issue. In addition, given the advocacy for endorsing psychotherapy as a central management component of public policy for sexual offenders, it offers further "fuel" for the general public, funding agencies, and public policy-makers regarding the potential utility of psychological science generally and, more specifically, the value of psychotherapy.

The purpose of this chapter is to develop a perspective as to the variety of possible reasons why sexual offender treatment has yet to demonstrate its efficacy; various aspects of sexual offenders as clients, characteristics of clinicians who provide therapeutic services to such offenders, and the nature and delivery of psychotherapy for sexual offenders. In addition, findings that many or most of the specific components [e.g. strategies or tactics (skills)] of psychotherapeutic interventions that typically comprise the core of sexual offender treatments have no or little basis in scientific evidence has clear and pointed implications for the inability to rely on psychosocial interventions to reduce sexual reoffending the nature and first, the available psychotherapy literature generally and that for sexual offenders is reviewed. From this, it is apparent that most psychotherapies appear to be generally effective interventions for persons with mood and anxiety problems but less effective for persons with more chronic, entrenched behavioral problems. Client variables are identified as accounting for the largest portion of variance in general psychotherapy outcome. Further, most recent reviews [summarized by Hoberman (2015b) and others] indicate the efficacy of sex offender treatment has yet to be demonstrated by accepted empirical means; thus, to date, no or little scientific evidence exists that psychosocial interventions affect sexual reoffending among sexual offenders let alone produce meaningful personal change in such offenders. Second, a historical perspective is considered on the largely non-theoretical or nonempirical nature by which sexual offender treatment developed in North America. A historical review provides an important context for understanding problematic aspects of the development of and implementation of almost all current programs of sex offender treatment. Finally, a critical analysis of the client, therapist process, and specific treatment components of forensic sex offender treatment is provided identifying the striking degree to which few aspects of conventional and contemporary programs of sex offender treatment have been demonstrated to have any relationship to reductions in sexual offense recidivism. That is, the available evidence would suggest that, in particular, client characteristics and treatment components would either increase or have no effect on the likelihood of future sexual offending. Finally, the implications of the current state of affairs regarding the apparent failure to develop and demonstrate the efficacy of specific intervention programs are discussed and future directions are identified.

Summary of Psychotherapy Outcome and Sexual Offender Treatment Outcome

The three primary methodological components of psychotherapy outcome research generally referenced in that literature are the use of one or more control groups (relative to the treatment of interest), the random assignment of similar individuals to the specific treatment proposed and the control groups, and considering outcome for all persons assigned to the treatment condition (such as dropouts or treatment refusers) whether they terminate or complete treatment. First, one or more control groups are utilized with the expectation that a successful treatment approach will be distinguished in outcome from persons who did not receive the treatment of interest. Random assignment offers the potential for controlling the influence of any preexisting (known or unknown) differences that exist between comparison groups, given the possibility that pretreatment client characteristics might influence or determine the results of the study. Such a procedure provides the best means of reducing selection effects; such randomization represents a best practice for eliminating or reducing the possible influence of such extraneous factors, from demographic factors to problem severity. In that way, if differences between treatment and comparison groups are found, one can be much more certain that those differences have to do with the intervention and not some other factor. Only persons motivated for treatment and willing to be randomly assigned to a specific treatment of interest or control group(s) are included for a controlled study that employs random assignment. Such studies are designated as randomized control trials (RCTs), and they are the type of study that is relied on by various professional and administrative groups [e.g., the Federal Drug Administration (FDA) or the Center for Disease Control (CDC)] to determine if a proposed treatment is effective.

In addition, a third methodological dimension involves intent-to-treat analysis; the experimental or treatment groups consist of *all* persons originally assigned to that group, whether or not they complete the intervention. This third issue which relates to the degree to which persons are retained in and complete the assigned treatment is considered an important aspect of the outcome or results of the treatment comparison; a treatment that loses a significant number of participants but succeeds for some would not necessarily be considered a successful or effective intervention. Thus, for a number of pharmacological studies, persons assigned to an active drug condition may drop out because of undesirable experiences such as side effects. However, individuals who drop out of or are terminated from a treatment group are typically counted as part of the intervention group since that is considered a meaningful measure of the relative results of a particular intervention (what is referred to as intent-to-treat analyses, counting individuals who in effect reject the treatment). Generally psychotherapy treatment outcome studies are first conducted with relatively pure groups of motivated clients; consequently, persons with comorbid psychiatric conditions, particularly low intellectual ability, and other characteristics are initially excluded from study. The basic notion is to first conduct a simple test of a proposed psychosocial intervention to provide the best chance of it being successful, with the notion that later studies can examine the effects of potential moderating or mediating factors. As Howard et al. (1996) wrote given the high degree of experimental controls imposed by RCT design: "…it is quite rare that a randomized experiment fails to conclude that the experimental treatment works" (p. 1059). In contrast, in several domains of psychological problems, RCTs were not initially utilized, and positive effects of intervention were first reported (e.g., arthroscopic knee surgery for meniscal repair or crisis debriefing). However, once RCTs were applied, either no effect of the interventions or even negative effects were identified (e.g., Rice & Harris, 2012).

An enormous literature on psychotherapy outcome in general has accumulated and the current results can be summarized. Relative to control conditions, psychotherapy has been found moderately beneficial for persons motivated for change in their lives, particularly for persons who seek treatment primarily because they themselves are disturbed by moderate to high degrees of emotional distress (e.g., they "feel badly"). For many persons who seek psychotherapy for anxiety or depression, the effects of treatment appear to be somewhat enduring (e.g., albeit these have typically been relatively "pure" clients by virtue of exclusion criteria that screen out significant—and typical—comorbidity). In contrast, for persons seeking treatment to address more complex behavioral problems or with comorbid psychiatric conditions, there is little to some evidence for the relative effectiveness of psychotherapy typically for particular features of those conditions. In general, greater problem severity and chronicity, comorbid psychiatric conditions (and in particular, maladaptive personality traits), and functional impairment in everyday life were each associated with decreased response to psychosocial treatments. Researcher allegiance accounts for a significant amount of variance in outcome; those invested in a particular intervention are more likely to find it effective. There is *decreasing* evidence that *specific types* of psychotherapy produce differential degrees of improvement, including the treatment of emotional distress. Thus, most interventions are equally effective for persons with emotional distress; common or nonspecific factors appear to have a very significant effect on whether clients' "feel better" or are "satisfied" as a result of psychotherapy (e.g., positive expectancies for change, acceptance, therapist credibility). Conversely, there is a lack of specific evidence that decreased distress is mediated cognitively as cognitive-behavioral therapy (CBT) would suggest. Little superiority of CBT or other psychotherapies has been demonstrated for more severe and/or behavioral conditions or persons with multiple, comorbid psychiatric conditions. To be effective, psychotherapy needs to be provided in a sufficient dose relative to the severity of the individual's presenting problem; a greater number of and/or more severe problems require more intense and/or higher doses of psychotherapy. Clearly, client characteristics have the most significant influence on the outcome or benefit realized in psychotherapy. Therapist characteristics also impact the outcome of psychosocial treatment for common presenting problems, with particular personal qualities and professional practices more strongly related to outcome; in addition, some clinicians appear to be much more effective with clients than other therapists. As Lambert (2013) recently suggested, improvement from psychotherapy is a function of the following four factors to the indicated degree: client/life situation (40 %), common factors (30 %), client expectancy (15 %), and (specific) techniques (15 %).

Summary of Reviews of the Effectiveness of Sexual Offender Treatment

Hoberman (2015b) reviewed the various systematic reviews (SR) and meta-analyses (MA) of adult sexual offender treatment studies in the scientific literature. The majority of studies available in the sexual offender treatment outcome literature relied on nonrandom assignment of very select groups of subjects who were preselected to be low or moderate risk. Further, the great majority of such studies that utilized control groups relied on "incidental assignment" or assumed equivalence as control groups for treatment groups and contained a high percentage of higher-risk offenders. Effectively, only two RCTs were available for adult sexual

offender to provide a systematic evaluation of the efficacy of particular treatment programs or approaches.

In his meta-analysis, Hall (1995) found a "small" statistically significant effect for sexual offender treatment but that such treatments might be less effective with the more "severe" sexual offenders. He found that outpatient sexual offender treatment appeared more effective. Like Hall, Hanson et al. (2002) concluded from their meta-analysis that there was a "modest" advantage for the treated versus the untreated offenders and this finding was statistically significant. They also found that if only those studies that utilized random assignment of sexual offenders to treatment were examined, then no treatment effect was apparent. Hanson et al. (2002) noted that the treatment effects on sexual recidivism were smaller in the good-quality studies than in the weak studies. In addition, Hanson et al. identified a "robust" finding that sexual offenders referred to sexual offender treatment based on "perceived need" (e.g., higher-risk sexual offenders) had higher sexual offense recidivism rates than those with less need; they were less responsive to sexual offender treatment. The investigators concluded that "We believe the balance of available evidence suggest that current treatments reduce recidivism, but that firm conclusions await more and better research" (p. 186). However, in examining only the RCT studies, Hanson et al. (2002) found that no empirical support for treatment effectiveness for adult sexual offenders could be drawn from those studies.

Losel and Schmucker (2005; Schmucker & Losel, 2008) also "cautiously" concluded from their meta-analysis of *both* biological and psychosocial treatments that treatment studies suggested a small-to-moderate positive effect for sexual offender treatment. However, they noted that only 6 of 69 studies available were considered to meet the Maryland level 5 (highest) standard and that most of the studies included in their meta-analysis were of poor methodological quality. Losel and Schmucker (2005), Schmucker & Losel (2008) showed that larger effects of treatment were found more frequently in studies with small sample sizes and were strongly influenced by allegiance effects. In addition, they reported that the largest treatment effect was found for Maryland level 3 studies in which the equivalence of comparisons groups was assumed (e.g., lower-quality studies such as quasi-experimental designs). Their results were similar to those of the Hanson et al. meta-analysis where only incidental assignment ("assumed equivalence") showed an effect for sexual offender treatment. Schmucker and Losel (2008) found: "Restricting the analysis to a few randomized trials shows a comparable mean effect but it does not render it statistically significant" (p. 17). Similar to Hanson et al. (2002), Losel and Schmucker found that "obligatory" or "mandatory" participation in treatment resulted in no treatment effect; both meta-analyses found that "apparent" voluntary treatment was more likely to have positive results.[1] In contrast to Hanson et al. (2002), Losel and Schmucker found no differences between "current" and older sexual offender treatment programs. Another contrast between the Hanson et al. (2002) and the larger Losel and Schmucker (2005) meta-analyses was that the latter identified a trend for lower effectiveness in institution-based programs, whereas the former did not. Losel and Schmucker's (2005) finding was similar to what Polizzi, MacKenzie, and Hickman (1999) had concluded previously, namely, that "…the evidence is not strong enough to support a conclusion that [prison-based programs] are effective" (p. 357). They concluded "Bearing the methodological problems in mind, one should draw very cautious conclusions from our meta-analysis" (p. 135). Similar to Losel and Schmucker, Hanson, Bourgon, Helmus & Hodgson et al. (2008; Hanson, Bourgon, Helmus & Hodgson et al. 2009) found that approximately 80 % of included studies were characterized by weak research designs and that more positive results were associated with more methodologically flawed studies. They concluded that if only higher-quality studies were considered, it would be reasonable to conclude that there was no evidence that psychosocial treatment decreases sexual offense recidivism. The Institute of Health Economics (Corabian, Opsina, & Harstall, 2010) interpreted the available data to suggest that sexual offense treatment had been shown to provide "small" reductions in sexual offense recidivism. However, the SBU found that the scientific evidence was insufficient for determining whether that such treatment could reduce sexual offending. Finally, one of the most recent, most rigorous reviews of treatment, for both CBT and psychodynamic interventions with meaningful follow-up data, Dennis et al. (2012) noted that "…neither showed any benefit for the intervention. Thus, neither… appeared to reduce sexual recidivism" (p. 35). This finding was similarly confirmed by Langstrom et al. (2013). All of the systematic reviews and meta-analyses to date have concluded and emphasized that the field of sexual offender treatment has been characterized almost exclusively by poor-quality methodology (including lack of RCTs and small numbers of subjects), that the little information was provided about program integrity or about which elements of sexual offender treatment contributed to the outcome of the intervention, and that there remained a need for more research of higher scientific rigor. While some analyses/reviews suggested a positive effect for psychosocial sexual offender treatment, in all cases the effect was "small" and

[1] It should be noted that the criteria for definition of "voluntary" participation were not specified in either study. This is notable given the data that the majority of "voluntary" sexual offenders are likely to be under a legal mandate to obtain sex offender treatment either during or after incarceration.

the words utilized to describe the limited positive results for sexual offender treatments were "cautious" or "tentative". As Rice and Harris (2012) put it, "no one has seriously argued that the effects of [sexual offender] treatment are large" (p. 17). Further, as Kirsch and Becker (2006) noted, "…between 10 % and 30 % of treated offenders sexually reoffend within 5 years of their release" (p. 211). Regarding sex offender treatment, Prentky et al. (2011) stated: "Application of an evidence-based metric to assess treatment of sex offenders in prison yields underwhelming results …" (p. 128); they noted that the "evidence" part of evidence-based treatment is lacking.

Several issues qualify the poor results of the available SRs and MAs. The primary basis for an inability to demonstrate persuasive effectiveness for sexual offender treatment was the fact that, effectively, only two RCTs are available in the field. Only one of these RCTs—that conducted by Marques, Wiederanders, Day, Nelson, and Ommeren (2005) known as the Sexual Offender Treatment and Evaluation Project (SOTEP)—was recent and included CBT, relapse prevention strategies, and aftercare. [Obviously, neither of the two prominently referenced meta-analyses of psychotherapies for sexual offender treatment (e.g. Hanson et al., 2002, Losel & Schmucker, 2005) referenced this seminal study.] The remaining controlled studies did not randomly assign similar and motivated subjects to treatment and comparison groups. Rather, as noted, most available treatment outcome studies for sexual offenders relied on so-called incidental assignment, which as applied has not typically produced equivalent treatment and control groups (e.g., such control groups typically have contained sexual offenders who, a priori, were likely to be at higher risk for sexual offense recidivism such as a high percentage of potential treatment refusers or dropouts).

Methodological issues in sexual offender treatment literature include limitations of meta-analysis; inadequate length and methods of follow-up of subjects, including failure to utilize survival analysis in outcome measurements; posttreatment experiences such as probation and additional services; allegiance effects; extreme exclusion or restriction of subjects studied; and the failure to utilize random assignment of motivated subjects in well-controlled designs. Thus, at best, if one considers quasi-experimental research studies, a relatively small effect relative to decreased recidivism is demonstrated for treating low- to moderate-risk sexual offenders. However, if only higher-quality research studies (such as those involving RCTs) are considered, from an empirical perspective, no definitive scientific evidence has yet been presented that when sexual offenders are provided with psychotherapy those interventions associated with any reduction of sexual offense recidivism.

The largest problem with existing sexual offender treatment outcome studies is the failure to utilize RCTs. This has several components to it. To begin with, while in general RCTs, the subject sample includes persons motivated for the treatment of interest, in the sexual offender treatment field, at least two factors influence the nature of the offenders studied. First, many or most sexual offenders are not even offered the possibility of treatment. As Hoberman (2015b) reviewed, a number of the available studies have excluded various types of sexual offenders the opportunity to participate in the outcome study, including those deemed most "severe," more significant criminal history, persons who denied their sexual offenses, and other comorbid conditions (e.g., low intellectual ability). Effectively, it is very likely that the most high-risk sexual offenders are screened out and not even eligible for inclusion in sexual offender treatment outcome studies. Additionally, by only accepting persons willing to volunteer for sexual offender treatment, studies further excluded those sexual offenders unmotivated for psychotherapy, most of whom might also be regarded as high risk. Harris et al. (1998) have strongly argued that the utilization of persons who volunteer for and persist with treatment effectively screens out more higher-risk sexual offenders. As a result, sexual offenders who do "volunteer" for sexual offender treatment appear to be an unusual group of sexual offenders in some ways that have been identified and others that remain unknown. The available evidence demonstrates that sexual offenders who choose or self-select to participate in sexual offender treatment are a different group of sexual offenders from those who choose not to participate or those who are excluded from participating (despite the fact that many of those may be under some mandate to complete sex offender treatment at some point). Finally, almost all existing studies of sexual offender treatment excluded treatment dropouts from their treatment group (e.g., contrary intent-to-treat principles). In short, as a group, participants in sexual offender treatment outcome studies appear to be a distinct group, both at lower risk and perhaps more genuinely motivated for treatment. As writers (e.g., Marshall & Marshall, 2007) suggested, such exclusionary criteria should bias controlled outcome studies *in favor* of finding a treatment effect.

In contrast, the compositions of incidental comparison groups are in the opposite direction, namely, a greater proportion of higher-risk sexual offenders. Thus, in Hall's meta-analysis, several studies included offenders who either refused or quit sexual offender treatment. In the existing incidental assignment studies, researchers have resorted to various groups of offenders to serve as a "control" condition including identified treatment refusers, treatment dropouts, persons selected from a general group of sexual offenders, and/or general sexual offenders matched to a treatment group on one or more variables. Obviously, treatment dropouts and refusers reflect higher-risk groups for comparisons. However, it has been demonstrated that other incidental comparison groups are also problematic for determining if the treatment condition for sexual offenders is actually effective. If 2/3 or

5/6 of the general pool of sexual offenders do not volunteer for sexual offender treatment, that means the group of sexual offenders potentially available to participate in control groups is biased; they are much more likely to be unmotivated and higher risk. Consequently, when investigators select their comparison group from some set of sexual offenders, that comparison group will necessarily contain a significant portion of offenders who would be deemed higher-risk/more severe offenders, have multiple problems or comorbid conditions, would/did not volunteer for possible inclusion in a treatment study, would refuse treatment if included and assigned treatment, and/or would drop out from treatment—all subsets of sexual offenders who would likely carry a higher risk for sexual offender recidivism. Thus, a priori, even before the results were calculated, the comparison group(s) would be highly likely to be characterized by higher probabilities of sexual reoffending. In addition, Rice and Harris (2003) have pointed out that in several studies included in "incidental assignment," a *double error* was committed: offenders who refused treatment were not counted as part of the treatment condition (decreasing likely recidivism) but were counted as part of the control group (increasing recidivism). In effect, the "small" or "tentative" positive results sometimes attributed to reviews of sex offender treatment research studies are largely due to the fact that both initial (and probably truly or meaningfully) seeking and volunteering for sex offender treatment (e.g., not being mandated to obtain such intervention in relation to a criminal justice or other legal order) and persisting in such treatment serve as significant screen against the inclusion of higher-risk sexual offenders and in favor of lower-risk offenders. Consequently, sex offender treatment efficacy will be grossly overstated if those who do not volunteer for treatment, those who actively refuse treatment, and those would likely refuse if asked or dropped out of psychosocial interventions are not accounted for in study design and data analysis.

Summarizing the state of the scientific literature at the time, Rice and Harris (2003) concluded: "In our opinion, few useful scientific data on effectiveness can come from studies contrasting treatment completers with sex offenders not offered treatment because such contrasts almost inevitably entail non-comparable groups…The current empirical support suggesting beneficial effects of treatment rests on the use of non-comparable groups in which control subjects were of higher *a priori* risk." (p. 432, 437) In a later analysis some nine years later, Rice and Harris (2012) again concluded: "The most parsimonious interpretation of finding from weaker designs is that pre-treatment differences and other forms of selection bias are responsible for apparent treatment effects" (p. 22). Thus, even prior to implementing treatment, in incidental studies that find "small" differences between treated and untreated offenders, such differences should be expected based simply on the *likely preexisting differences in sexual offense recidivism rates* between those selected into treatment and "control" groups. That is, the preexisting risk-related differences between sexual offenders who volunteer for and complete sex offender treatment would lead to a reduced rate of sexual offense recidivism particularly when those volunteer/completers were compared to groups that included sexual offenders not offered such treatment (often for specific reasons related to presumed severity of pre-existing characteristics), who refused such treatment or who dropped out from such treatment. Given the selection factors in the SOTEP study were in favor of finding a positive result for the treatment group as suggested, it becomes even more significant that no finding of an effect for sexual offender treatment was obtained. Given the totality and coherence of the available information about sexual offender treatment, the most reasonable conclusion is that sexual offender treatment *does not* lower the rate of sexual offense recidivism below that of the average sexual offender, but rather that rates of sexual offense recidivism for *persons used as comparison groups are significantly higher than the average sexual offender*. Thus, the differences between treatment and control groups are not due to psychosocial treatment but *rather preexisting risk status*. Further, numerous studies have demonstrated that pretreatment assessments of sexual offenders are more predictive than posttreatment assessments relative to sexual offense recidivism, suggesting that little meaningful or substantive intraindividual change occurs for participants in sexual offender treatment. As Prentky et al. (2011) stated regarding the general results of sex offender treatment research and the specific findings of SOTEP: "Ignoring what is generally regarded as the gold standard is hazardous…We would argue that it is pointless to debate the superiority of the RCT design in the abstract without acknowledging the reliable findings on efficacy of prison-based sex offender treatment are compromised by innumerable methodological problems…the California Treatment Project was far more rigorously controlled and run and closer to expectation of how treatment in general should be delivered…" (p. 120).

Thus, unlike many presenting problems addressed with psychosocial interventions by mental health professionals, many sexual offenders apparently do not reduce their risk of sexual reoffending via participation in psychotherapy and, perhaps relatedly, do not evidence valid personal change. That is, psychotherapies are generally somewhat effective for persons with anxiety and depressive problems, and, while less effective, such treatments do appear to result in reductions in core signs and symptoms that are maintained over time of serious treatment refractory conditions such as eating disorders and alcohol and drug dependence. Given the status of the outcome literature regarding sexual offender treatment and its potential importance to offenders, the community,

and policy-makers, it seems useful to consider why this collective set of approaches have resulted in such limited results. A multitude of factors can be identified that appear to provide particular clarity for the failure to demonstrate the efficacy of psychotherapy with the group of individuals who commit sexual offenses.

History of Development of Sexual Offender Treatment

The manner in which the general principles and practices of sexual offender treatment were identified and implemented has important implications for its current status and bears consideration. Several authors have provided perspectives on the development of programs of sexual offender treatment or "rehabilitation" over the past 50 years (e.g., Laws & Marshall, 2003; Marshall & Laws, 2003; Marshall, Marshall, Serran, & O'Brien, 2011; Schwartz, 2003). As these writings make clear, it is particularly notable that much of what constitutes the elements and practices of sexual offender treatment was developed not from theory per se (e.g., a model of "why" individuals commit sexual offenses). Rather, it seems more correct to state that specific clinical strategies were "borrowed" from clinical applications already being implemented with other behavioral problems; those developers of sexual offender treatment largely emulated the current practices of treatment and applied them to sexual offenders. Alternately, when intervention strategies were derived from more theoretical perspectives, they were often not empirically demonstrated before being applied with enthusiasm. In addition, the histories of sexual offender treatment indicate that such interventions initially developed following the lead of institutional programs for other behavioral problems and only later, over time, were influenced by particular research efforts.

Schwartz (2003) noted that in the United States, most sexual offender treatment programs were initially developed and delivered in institutional settings and that "the treatment of sexual offenders has largely emulated the treatment approaches that were popular for the general population at that specific time" (p. 360). She reported that in the East Coast, the predominant interest in psychodynamic approaches focused on the exploration of early dynamics such as one's own traumas. In contrast, institutional programs on the West Coast developed highly confrontational group approaches that focused on breaking down denial and "resistive personality dynamics" as a means of accepting responsibility for one's behavior. In addition, Schwartz noted that West Coast models of institutional treatment of sexual offenders (e.g., Western State Hospital's sexual psychopath program in Washington State) were also characterized by a "structured self-help" model, which relied heavily on groups that were largely operated by the patients themselves (with therapists' roles ones of monitoring or facilitating the group process). Schwartz also noted that such group treatments of sexual offenders were influenced by the confrontational style common to substance abuse treatment programs at the time. As a result of these different perspectives, sexual offender treatment was initially implemented quite differently depending on the region of the country in which a program was located, and these differences continued up to the 1990s. In addition, Schwartz also noted that the Oregon State Hospital sexual offender treatment program established in the 1980s (for sexual offenders from the Department of Corrections who voluntarily transferred to the state hospital) also introduced the use of psychoeducational approaches, the penile plethysmograph, and behavioral techniques to institutional treatment programs. In short, the early institutional treatments for sexual offenders were largely group treatments (often of a confrontational nature), with an emphasis on "self-help" from fellow group members, supplemented by psychoeducational experiences.

A particularly interesting point made by Schwartz (2003) was that in Washington State and in Massachusetts, staff emerged from the first generation of institutional programs for involuntarily committed sexual offenders to establish private practices and community-based programs for sexual offenders.[2] Thus, Schwartz suggested that general sexual offender treatment in the United States effectively evolved from institutional programs developed for those offenders perceived to have more extreme problem behavior (e.g., those who were involuntarily civilly committed or serving lengthy criminal sentences) and then were applied to a more diverse population of sexual offenders who received treatment in varied community settings. However, according to Schwartz, key differences emerged in the delivery of treatment to sexual offenders in the community. While institutionally based programs historically devoted considerable time to direct treatment (10–12 hours per week) which was supplemented by a variety of other therapeutic activities, outpatient sexual offender treatment was often limited to one or two 1–2 hour sessions per week. As Schwartz pointed out:

> With up to 12 individuals in a group, there is little time for anything other than monitoring how participants have coped with risky situations during the past week. If one individual is in crisis, other members may have trouble finding any time to comment on their adjustment. There is also little time for formal skills training or teaching new members how to prepare a relapse prevention plan. (p. 365)

[2]It should be noted that most states eliminated these programs in the 1970s and 1980s because of the conclusion (primarily by psychiatrists) that sexual offenders committed to these programs were either "untreatable" or "not amenable to treatment" and should received disposition in the criminal justice system and not the mental health system.

One important element of sexual offender treatment did arise from a theoretical perspective. An important early and influential article was that by McGuire, Carlisle, and Young (1965). They suggested that "sexual deviations" were the product of accidental early sexual experiences that resulted in the later pairing of masturbatory activity and sexual fantasy, which in turn resulted in one or more sexual preferences. Further, they suggested that sexual fantasies might lose their potency (reinforcement potential) over time and result in the use of (increasingly) greater "deviance" in such fantasies to enhance sexual arousal. Per Laws and Marshall (2003), "the hypothesis was so appealing that it was rapidly accepted as doctrine and is still widely embraced nearly 40 years later. Acceptance of this theory demanded that the focus of treatment be directed at eliminating deviant sexual preferences" (p. 84). Consequently, a variety of aversion therapies for treating "sexual deviance" were developed involving administering a highly aversive stimulus in conjunction with stimuli depicting deviant sexual behavior or inappropriate sexual behavior itself. Bancroft (1974) reviewed various efforts to "decondition" deviant sexual behavior through pairing the experience of deviant sexual interests with various aversive stimuli (e.g., electrical shock, nausea-inducing drugs); he concluded that such tactics were effective in reducing deviant sexual arousal and behavior. Per early reviews, a belief developed that changing deviant sexual interests would "automatically" both eliminate such interests and result in the emergence of "appropriate" sexual behavior. However, Marquis (1970) advocated "orgasmic reconditioning," a process that involved having an offender masturbate to orgasm while either watching or fantasizing about normative sexual behavior with appropriate adult partners. He proposed that atypical sexual interests could not simply be eliminated but that individuals with such interests needed to have their sexual interests in appropriate objects encouraged and otherwise reinforced. Thus, an early emphasis from research settings but based on early behavioral therapy models suggested that the primary means of treating sexual offenders was through modifying what was viewed as ubiquitous presence of deviant sexual arousal.

Later in the 1970s, per Marshall's various writings, paralleling changes in the more general behavioral treatment of various disorders, there was an increased emphasis on cognitive aspects of treatment for sexual offenders. In one of the first uses of cognitive procedures, Cautela (1967, 1970) advocated the use of covert sensitization and reinforcement; thus, he suggested that "deconditioning" could be affected in the "head" of an offender by the "experience" of pairing deviant sexual images with aversive cognitive stimuli (e.g., embarrassing or negative imagery). Maletzky (1973) modified this procedure via "assisted" covert sensitization where noxious odors were added to the presumed aversive images that offenders reported pairing with deviant fantasies or images. "Satiation therapy" was developed as a procedure in which an identified "inappropriate response" (e.g., deviant sexual behavior or arousal) is eliminated by repeatedly eliciting that response until the desire for the stimulus itself is presumably eliminated via boredom. Marshall (e.g., 1979) reported controlled single-case experimental demonstrations for the effectiveness of a procedure identified as satiation therapy. This procedure involved the offender continuing to masturbate during the refractory period post-orgasm while asked to repeatedly experience his deviant sexual fantasies. The expectation was that the experience of boredom and/or a lack of arousal might "decondition" the association of deviant sexual arousal and reinforcement, thus leading to a potential reduction or even extinction of arousal to deviant sexual images and, subsequently a potential decrease in masturbating to such images. Per Marshall, O'Brien & Marshall (2009), the procedure was subsequently modified to one involving "verbal satiation" where clients would verbalize aloud "every variant they can create on their deviant images for no more than 10 minutes after 2 minutes post-orgasm" (p. 323).

In a significant expansion of sexual offender treatment, Marshall (1971) proposed that sexual offenders might lack critical social skills and recommended the expansion of intervention to include the teaching of such skills; Becker, Abel, Blanchard, Murphy, and Coleman (1978) later made similar suggestions. In addition, following after Meichenbaum (1974) and Beck (1975), treatment of sexual offenders began to address the hypothesized mediating role of cognitions such as attitudes and beliefs. Thus, over time, case studies and theoretical articles began to emphasize the inclusion of treatment targets such as social and assertiveness skills, empathy for victims, self-esteem of offenders, social cognitions, and "distorted" cognitions that might be related to offending. Additional behavioral targets presumed to be linked to sexual offending such as anger, substance abuse, and social skills deficits also became common intervention components of more comprehensive, multi-target CBT interventions. Based, in part, on broader *conceptualizations* that thoughts, emotional states, and behaviors hypothesized to be related to sexual offending, sexual offender treatment evolved to encompass teaching sexual offenders multiple cognitive and behavioral skills to identify and modify their sexually and otherwise deviant behaviors. Similar to other behavioral disorders or psychological conditions, the primary treatment of sexual offenders developed into "integrated" or "multifaceted" programs that included both cognitive and behavioral modules that were either presumed or theorized to reduce propensities for sexual offending (e.g., Becker et al., 1978; Brownell, 1980; Marshall, Earls, Segal, & Darke, 1983; Marshall & Williams, 1975). However, little or no primary scientific study of the actual effects of these various specific cognitive and behavioral modules on specific or general aspects of sexual offenders was conducted to serve as base

for incorporating such elements of interventions. That is, social skills training or cognitive modifications were not demonstrated to affect sustained changed in the thinking or social relations of sexual offenders. Thus, with almost no empirical foundation, primarily behavioral sexual offender treatment programs became cognitive-behavioral therapy (CBT) programs. That is, little basic research on the etiology or maintenance of theorized elements of sexual offending was available or initiated. Consequently, largely generic theories of possible etiological factors related to sexual offending guided the development of sexual offender treatment in the 1970s and 1980s. In turn, Marshall and Barbaree (1984) developed a thoughtful and more comprehensive model of the etiology of sexual offending. This particular perspective effectively provided further endorsement of CBT approaches as the treatment of choice for sexual offenders (e.g., Marshall, Jones, Ward, Johnston, & Barbaree, 1991).

Both Schwartz and Marshall and his coauthors have identified that "There can be little doubt that the most significant innovation of the 1980s was the adaptation from the addictions field of the relapse prevention model" (Marshall & Laws, 2003, p. 98). Marlatt's (1982) the relapse prevention (RP) model for the management of addictive behaviors was based on the observation that after the end of formal treatment, relapse rates among substance abusers approached 80 % within the first 12 months posttreatment. The theory was that for addictive and other presumed impulse control disorders, persons encounter "high-risk" situations and must be taught how to self-manage high-risk situations (e.g., so lapses into high-risk behavior did not become relapses). RP interventions offered substance abusers specific training in the identification of potential relapse signs and coping methods to interrupt a hypothesized chain of events (high-risk situations, leading to distress leading to failed coping) which lead to lapses or relapses of substance use. Per Marlatt and George (1984):

> RP is a self-control program designed to teach individuals who are trying to change their behavior how to anticipate an cope with the problem of relapse…[which] refers to a breakdown or failure in a person's attempt to change or modify any target behavior…Based on social cognitive principles, RP has a psychoeducational thrust that combines behavior skill-training procedures with cognitive intervention techniques. (p. 2)

Thus, RP was originally conceptualized as a *maintenance strategy* after a treatment program—to sustain the effects of a primary, efficacious treatment program—and *not* as a primary treatment. Based on the possibility that sexual offenders were similar to persons with addictive conditions, Pithers, Marques, Gibat, and Marlatt (1983) provided the first description of how Marlatt's RP model for management of addictive behaviors might be applied to the treatment of sexual offenders. It was hypothesized that if an offender learned self-management strategies to deal with risks or threats to maintaining abstinence (e.g., potential offense precursors), then sexual offense recidivism could be obtained. Of note, the success of RP was effectively contingent on a presumption that "successful" primary treatment had occurred for a sexual offender. As Kirsch and Becker (2006) noted, "RP assumes that sexual offending follows a predicable part in which covert planning and a series of seemingly irrelevant decisions set sexual offender up for risk for reoffending" (p. 210). However, they noted that at the time of its adoption, there was no theory or scientific evidence that particularly pathways were identified for sexual offenders.

At the time that RP was first applied to sexual offenders, no empirical studies of the RP model applied to sexual offenders existed. Rather, it appears that "face validity" of the model and ease of implementation guided the widespread adoption of the RP model. Thus, select state institutional treatment programs (e.g., in Vermont and California) made RP the centerpiece of multidimensional cognitive-behavioral programs for sexual offenders. Effectively, in those programs, sexual offender intervention became cognitive-behavioral relapse prevention (CBT-RP). In turn, the vast majority of institutional- and community-based sexual offender treatment programs relatively quickly and uniformly adopted the RP model as the center of their intervention programs. In 1996, Marshall suggested that the addition of RP was the most significant innovation in the treatment of sexual offenders. However, as Marshall and Anderson (1996) emphasized the implementation of RP, they also noted that its implementation was actually marked by differences and inconsistencies in programs said to be based on the RP model.

In Canada, general criminological principles have had a significant influence on the treatment of sexual offenders. Relying on the results of meta-analyses, Andrews and Bonta (1994, 2006) advocated for a model of intervention for general criminal offenders that has become known as the risk-needs-responsivity (R-N-R) model. This model proposed that interventions were most effective when they were directed at offenders with the highest risk and the greatest set of criminogenic needs in a manner responsive to the nature of the offenders. That is, providing the most intensive and broadest treatments to high-risk offenders, by means of targeting criminogenic needs (those functionally related to criminal offending), is viewed as particularly effective. In addition, it was argued that interventions be provided in a style and mode that is responsive to the offender's learning style and ability (typically CBT). Reviewing the extant literature,[3] Andrews and Bonta found that the more that interventions incorporated R-N-R principles, the greater the

[3]However, that extant literature was and continues to be based predominantly on quasi-experimental studies (not RCTs) and includes almost no studies with follow-up periods longer than 2 years.

later reduction in criminal recidivism. Hanson, Bourgon, Helmus & Hodgson et al. (2009) in a MA found statistically significant support for interventions for sexual offenders based on need and/or responsivity but not for risk; they could not identify any studies that utilized all three processes. Of note, Losel and Schmucker (2005) found that general interventions developed for general criminal offenders had no effect on sexual offense recidivism; rather, they found that only sex offender-specific treatments provided any positive results on such recidivism.

Wheeler and Covell (2013) developed recidivism reduction therapy (3RT) in response to their identification of the limitations of relapse prevention approaches and to incorporate what they viewed as "best practices" that have been identified by more recent clinical research. 3RT was developed to accomplish the following goals: (1) to address identified limitations of the popular—but insufficient—RP model for sexual offense treatment; (2) to explicitly incorporate the "doing what works" approach to sexual offense treatment (specifically the R-N-R model); (3) to employ dynamic risk assessment as the dominant conceptual framework for treatment planning and implementation; and (4) to utilize other existing empirically based practices and apply these to the behavioral, emotional, and cognitive deficits that are associated with sexual offense behavior. Viewing RP as based on the presumption that sexual offending was based on an avoidance-based coping strategy (e.g., to avoid negative emotional states) be ignored the rewarding dimensions of sexual behavior, 3RT includes increased emphasis on "approach-based sexual offending." It is one of the few contemporary models that is primarily directed at presumed skills deficits of sexual offenders and recommends contemporary CBT approaches to remediate those deficits.

A related set of developments in the theory and practice of sexual offender treatment occurred in the past decade as Yates (2014, 2015) has described. Both the self-regulation or pathways model (SRM; Ward & Hudson, 2000) and the good lives model (GLM; Ward & Gannon, 2006; Ward & Stewart, 2003) were originally proposed as complementary approaches to address problems inherent in the traditional RP approach. Recently, the GLM and SRM were themselves integrated into a comprehensive treatment approach (Ward & Gannon, 2006; Yates, Prescott, & Ward, 2010; Yates & Ward, 2008), and it has been claimed that the GLM and SRM offer a superior approach to interventions based on the R-N-R principles of Andrews and Bonta (2006). The GLM is based on an "approach" model that offers "a positive view of both the character and future responsibilities of sexual offenders" and suggests "…sex offender treatment should aim to identify and seek to achieve for each client a personalized good life" (Marshall et al., 2009, p. 11). The thesis of the GLM is that identifying and improving skills, attitudes, and behaviors that lead to a "good life" for a sexual offender (generally speaking) will necessarily ameliorate criminogenic needs.

Similarly, Marshall et al. (2011) offered a "strength-based approach" as another "positive" approach to treating sexual offenders. Per the authors: "Treatment…should develop or enhance the prosocial skills of sexual offenders so they will be equipped to pursue productive relationships and all the other features of a good life" (p. 25). Marshall et al. (2009) suggested:

> One of the major inferences we have drawn from the positive psychology movement for the treatment of sexual offenders concerns a shift in therapeutic attention (a) from the focus on the details of past offenses to the identification of areas of functioning that need to be enhanced; (b) from an exclusive concern about clients' deficits to a more strength-based emphasis; (c) from an elaborate detailing of potential future risks to the generation of future possibilities for a better life; and (d) from the production of an extensive lilts of situations, thoughts, feelings and behaviors to be avoided in the future to the development of approach behaviors that will enhance their life. (p. 19)

Collectively, these approaches share several values or perspectives: that sexual offenders are heterogeneous and have committed sexual offenses in the pursuit of different offense-related goals; that sexual offenders have the capacity to change; that sexual offenders can cultivate and develop strengths, a focus on what the offender will gain from treatment, particularly in terms of finding alternate means of reaching general goals; and that sexual offender treatment should be differentiated to address the particular offense pathway(s) of a sexual offender and the manner or degree to which sexual offending provides a means to obtain his particular goals and needs. Overall, these approaches as a group take a holistic and humanist perspective on psychotherapy with sexual offenders. They aim to provide sexual offenders with the skills, attitudes, and beliefs that will allow them to achieve greater life satisfaction by identifying goals and taking the steps needed to achieve them. However, to date, while there has been an extraordinary proliferation of professional writing on the purported value of GLM and strength-based approaches, there has been virtually a complete absence of traditional scientific evaluation of such theoretical models of treatment. In the one study that directly compared a GLM and an RP approach to the treatment of sexual offenders on probation—despite utilizing a variety of methods to measure change—Barnett, Mandeville-Nordin, and Rakestrow (2014) found "there is no great difference between the two types of program approach, in effecting change in those who, prior to treatment, are dysfunctional in various dynamic risk factors" (p. 30). They summarized their results: "The groups were compared on their level of psychometric change over treatment on individual measures, on measures grouped by dynamic risk domain, and on overall psychometric change,

using a variety of analyses, including examination of clinically significant change. There were no differences in amount of change over treatment or, for those deemed as requiring change, clinically significant change, by program approach, for the majority of the measures examined" (p. 3). This despite the GLM group was found to be less dysfunctional than the RP group. Further, there was no difference in attrition rates between the treatments despite the hypothesis that GLM treatment would be more engaging and motivating for sexual offender participants. Barnett et al. concluded that their study found "…there is no great difference between the two types of program approach, in effecting change in those who, prior to treatment, are dysfunctional in various dynamic risk factors. It appears that the GL approach may be better at helping those already functional before treatment, to sustain their functionality…" (p. 30).

More broadly, not one of these models have yet to be tested via RCT, so there is no rigorous empirical evidence that any of the newer, proposed theories of sexual offender treatment "work" or are effective at affecting change in sexual offenders, particularly in reducing future sexual offending.

Possible Factors Related to the Lack of Evidence of Effectiveness for Sexual Offender Treatment

The extant data suggests, at best, "small effects" of sexual offender treatment for low- to moderate-risk sexual offenders in nonrandomized controlled studies. In contrast, in the only relatively contemporary RCT study of sexual offenders, the aforementioned SOTEP (Marques et al., 2005) produced no significant differences for low- to moderate-risk sexual offenders. More broadly, per all recent systematic reviews (e.g., Dennis et al., 2012; Langstrom et al., 2013; Rice & Harris, 2012), given the absence of rigorous scientific studies available, the problematic nature of interpreting results of non-controlled studies, and the failure to demonstrate treatment efficacy in the only RCT, it seems clear that there is no empirical evidence that sexual offender treatment "works" for the typical sexual offender; sexual offender treatment as practiced appears to have few or no effects in terms of meaningful personal change for sexual offenders and/or reduced sexual offense recidivism. Nonetheless, sex offender treatment continues to be offered to stakeholders as a primary means for community safety; increasingly the value of such treatment is being advocated as the appropriate mechanism for improving dysfunctional aspects of the lives of sexual offenders. Given the rather dismal research findings for such a uniquely important group of criminal offenders, it is worth considering those findings and issues which appear most likely to contribute to the apparent ineffectiveness of sexual offender treatment to date as a means of both general behavioral change and reducing sexual offense recidivism. A substantial set of identifiable factors might be related to the failure to demonstrate efficacy for psychotherapy for sexual offenders.

Client Characteristics in Relationship to Psychosocial Treatment

Heterogeneity of Type and Severity of Predisposing Conditions for Sexual Offending: High Risk, Multiple Needs, and Varying Pathways to Sexual Offending

As noted earlier, the largest amount of variance in or contribution to general psychotherapy outcome in general is related to client characteristics; in their review, Bohar and Wade (2013) indicated that between 30 % and 87 % of the variance in general psychotherapy outcome is identified as related to the client. They suggested that rather than argued over whether or not "therapy works," the appropriate questions regarding treatment outcome is whether "the client works." It is important to acknowledge that sexual offenders as a group are ubiquitously characterized as heterogeneous, in terms of variability in their criminal history and the nature and degree of primary criminogenic needs (e.g., deviant sexual interests, antisocial and other maladaptive personality characteristics, and social relations). Some sexual offenders are identified by the known target or type of their sexual offense or sexual offenses (e.g., as rapists, child molesters, incest offenders, non-contact offenders, statutory rapists, and persons possessing child pornography). However, there is also significant crossover in sexual offending among a large minority of sexual offenders, so that a sizeable proportion of sexual offenders engage in multiple sexually deviant behaviors (Abel et al., 1988; Heil, Simons, & Ahlmeyer, 2003; Weinrott & Saylor, 1991). There is a subgroup of sexual offenders who would be described as having one or more paraphilic disorders (characterized by recurrent, intense sexual fantasies, urges, or behaviors involving something other than "sexual interest in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners" (American Psychiatric Association, 2013) that causes distress to the individual or harm to the person or others). A significant issue is that, apparently, a number of sexual offenders' sexual offenses are not predominantly the result of strongly or uniquely deviant sexual interests (or that current research methods have failed to accurately assess and identify the presence of deviant sexual interests). Consequently, at least per studies of sexual recidivists (e.g.,

Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004, 2005), there are apparently a relatively large group of sexual offenders who are characterized by a variety of personality and related conditions that singly or in combination result in sexual offenses, including repeated patterns of such offending. A large proportion of this second group is considered to be motivated by largely antisocial, unstable, narcissistic, or social personality characteristics (see Hoberman (2015a) for a discussion of nonsexual personality and other conditions related to sexual offending). Yet another group is a "mixed" group whose sexual offending is likely a function of interactions of deviant sexual interests and antisocial/psychopathic characteristics. In addition, most research indicates that a significant number of sexual offenders may be characterized by a high degree of psychiatric comorbidity (e.g., depression, anxiety, varied and multiple maladaptive personality traits, as well as intellectual limitations and learning disorders).

Conventionally, psychosocial treatments are directed at risk factors presumed to be causally related to the development and maintenance of a biopsychosocial problem; such factors have been identified by reviews of available retrospective data evaluation and field study of persons who have committed sexual offenses; they are derived largely from convenience samples. Relative to sexual offenders, there are no prospective studies of initiating etiological factors but only studies of risk factors for sexual offense recidivism that can provide some guidance toward relevant treatment targets; consequently, little, if nothing, is known about risk factors for initiating sexual offending. In addition, information exists about only those risk factors theorized to be related and measured that provide some basis for inferring that they are risk factors. Variables that were theoretically excluded or inadequately measured would not emerge as identified risk factors and/or criminogenic needs. Based upon the available scientific literature, particularly the three meta-analyses conducted by Hanson and associates (e.g., Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2005; Mann, Hanson, & Thornton, 2010), there is no one risk factor that is uniquely and strongly associated with sexual offending. Rather, there are two predominant (relatively primary) sets of risk factors, deviant sexual interests/sexual preoccupation and nonsexual predisposing conditions, primarily antisociality, that are, relatively, most strongly predictive of future sexual offender. However, neither of these factors measured on its own accounts for a very large portion of the variance in sexual offense recidivism. In addition, there are other psychosocial risk factors that are predictive of future sexual offending but to a lesser degree. Consequently, at this time, it appears that sexual offending is the result of various accumulations of multiple predisposing factors, which presumably interact with one another in various ways to potentiate and mitigate their risk qualities. In addition, situational factors are also likely important, given the "if then" or "behavioral signature" nature of psychological-related risk factors (e.g., Mischel & Shoda, 1995, 1998; Mischel, 2004). Yates (2007) following Ward and Hudson (2000) has called attention to the limitations of traditional CBT-RP relative to the potential diversity of pathways to sexual offending, particularly offenders characterized by explicit approach goals, active planning of offending, and/or the active pursuit of deviant sexual interests. In a recent article, Kingston, Yates, and Firestone (2011) reported that so-called approach-automatic or approach-explicit pathways characterized approximately 64 % of sexual offenders. In short, while there are probably some commonalities of combinations of risk factors associated with sexual offending, in addition to likely differing across subgroups of sexual offenders (e.g., rapists, child molesters), they may also differ in potency/primacy at different times and situations; they may also differ both generally and across offenses in their "pathway" to sexual offending. Thus, the potential treatment targets for sexual offenders may differ significantly across types of offenders and within types of offenders. At best, only crude attempts have been made to differentiate potential subtypes and pathways of sexual offending.

In addition, it can also be argued that much remains to be learned about the etiology of the maintenance and repetition of sexual offending. To date, there are no meaningful prospective studies that have been conducted to identify risk factors for the initiation of sexual offending. It can be argued that, from a scientific perspective, virtually nothing is known about why particular individuals initiate sexual offending. Existing empirically studies have focused on sexual offense recidivism (repeated sexual offending) after detection and sanction for one or more sexual offenses. Thus, the three meta-analyses of risk factors for sexual offense *reoffending* are those of Hanson and Bussiere (1998), Hanson and Morton-Bourgon (2004), and Mann et al. (2010). Further, these studies individually and collectively indicate that no one risk factor or predisposing condition is determinative of sexual offense recidivism. Rather, maximum associations or correlations of identified risk factors are typically .30 or less and individually account for some small degree of variance (albeit similar to identified risk factors for other mental health conditions). To date, few studies have looked at cumulative sets of risk factors and their association with sexual offense recidivism and the degree of variance in sexual reoffending they account for. Consequently, empirically, while primary dimensions of sexual offense recidivism have been consistently identified, they do not yet provide a relatively comprehensive perspective on the primary main effects and/or interactions among multiple risk factors that underlie sexual reoffending. This degree of scientific impoverishment clearly

constitutes at least one obstacle toward developing an empirically based model or practice of sex offender treatment.

Empirically identified predisposing conditions or risk factors (criminogenic needs) and relative risk to reoffend are overlapping but also independent factors related to sexual offender recidivism. A key issue in the inability to demonstrate the effectiveness of sexual offender treatment may be that a significant proportion of sexual offenders are characterized by multiple cumulative or interacting risk factors such that many sexual offenders manifest a considerable and complex density of predisposing conditions that per models such as those of Malamuth and Knight exacerbate one another or function synergistically. Moreover, the nature of both the sexual dimensions of sexual offending (e.g., paraphilias and paraphilic disorder) and the nonsexual predisposing conditions as described by Hoberman (2015a) is such that they may be extremely difficult to change or modify; central motivators and multiple dimensions of disinhibition may represent conditions that, to date, are relatively impermeable to short-term change via time-limited psychosocial interventions and, if modified or managed temporarily, are highly likely to rebound from a modified to a risk-inducing state. The combination of constitutional or physiologically based conditions, conditions related to early adversity, and other personal elements that provide profound rewards and significant gratification may create very significant obstacles for changes as with other presenting problems. Several studies have now demonstrated that measures of criminogenic needs interact with and add incremental validity to measures of largely static risk factors (Hanson, Andrew, Harris, Scott, & Helmus, 2007; Knight & Thornton, 2007; Olver, Wong, Nicholaichuk, & Gordon, 2007); per Ward and Beech (2006), the types and set of variables measured by these instruments would reflect the current "state" status of more dispositional risk factors. A key difference between the current literature regarding psychosocial programs to reduce criminal recidivism and sexual offense recidivism is that for the former group, programs targeted at high-risk offenders are more effective than others, while per Hanson, Bourgon, Helmus & Hodgson et al. (2009), the risk principle was not demonstrated in their meta-analysis of sexual offender treatments. It is known that the presence of relative psychopathy and deviant sexual interests significantly increases risk for sexual offender recidivism (e.g., Hawes, Boccaccini, & Murrie, 2012); it is not known the degree to which the presence of the so-called dynamic duo affects the outcome of treatment. More generally, it is unknown what effect varied combinations of pretreatment predisposing conditions or risk factors (criminogenic needs) relate to sexual offender treatment outcome. As noted, Kingston et al. (2011) reported that approximately 64 % of sexual offenders were characterized by the so-called approach-automatic or approach-explicit pathways; their results also showed that offenders characterized by approach pathways scored approximately four times higher on a risk assessment measure and significantly higher on measures of dynamic risk factors. Yates et al. noted that offenders characterized by approach pathways would likely require different treatment approaches than those who showed more avoidant pathways and that even the two groups of offenders characterized by approach pathways would likely benefit from different treatment experiences.

In short, there appears to be one group of sexual offenders whose offending may be a one-time event or a time-limited episode with a particular child. However, a significant number of sexual offenders (e.g., as many as 40 % per Hanson et al., 2003; Harris & Rice, 2007) are identified as recidivists and offend against multiple and frequently diverse victims of different ages, gender, and relationship to the offender. To date, research has not identified a single predominant risk factor related to sexual offending but rather has consistently found that sexual offenses appear to be the product of an accumulation of multiple risk factors mediated by situational factors. In addition to predisposing risk conditions, offenders and temporal and situational factors also appear to manifest themselves in diverse "pathways" leading to particular or patterned forms of sexual offending. Thus, from several perspectives, there is a striking diversity and complexity among sexual offenders that, on its face, would create significant problems in developing a standardized treatment program that would adequately focus on the particularly psychologically meaningful risk factors of particular sexual offenders in relationship to the nature and diversity of their sexual offending.

General psychosocial interventions appear to be most effective for clients characterized by emotional concerns and less for those with serious behavioral problems. As the review of psychotherapy in general indicated, psychosocial interventions have a clear but small-to-moderate and time-limited effect for the majority of help-seeking clients, most of whom actively *seek* treatment for relief from negative affect and emotional distress or as a result of perceived impairment in important areas of their lives. For such individuals, many or most interventions, including attention-control conditions, have some positive effect, and most such clients are satisfied with the treatment that they receive. In contrast, the effectiveness of psychotherapy seems much less than the case for persons characterized by more severe and chronic problems, including those that involve maladaptive interpersonal behavior. The evidence reviewed for general psychotherapy indicates that both immediate and more distal outcomes after psychotherapy are considerably reduced by the presence of personality disorders or high levels of maladaptive character traits as well as by overall problem severity and chronicity and social impairment or dysfunction.

The Limitations of Effectiveness of Psychotherapy for Persons with Personality Disorders or Significantly Maladaptive Personality Traits

While CBT has been demonstrated to be at least as effective as other specific forms of psychotherapy in RCTs for mild-moderate depression and anxiety disorders, it has not fared as well with disorders of greater severity or chronicity. Lynch, Laws, and McKenna (2010) in a meta-analysis of well-controlled RCTs found that CBT was not effective in reducing symptoms or preventing relapse for schizophrenia or in reducing relapse in major depression or bipolar disorder. Even in the treatment of major depression, they found that the effect size for reducing symptoms was small. Similar results have been found for persons with comorbid psychiatric conditions and/or high symptom severity. In a Cochrane Review, Hunt, Siegfried, Morley, Sitharthan, and Cleary (2013) included 32 RCTs and found no compelling evidence to support any one psychosocial treatment over another for clients to remain in treatment, to reduce substance use, or to improve mental state in people with serious mental illnesses. In their review, Bohar and Wade (2013) concluded that empirical evidence indicated that severity of symptoms, comorbid diagnoses (largely personality disorders), and functional impairment led to poorer prognosis for treatment outcome. Similarly, previous reviews of Lambert and Ogles (2004) and Clarkin and Levy (2003) had also reported that persons with primary or secondary characterological issues or personality disorders showed less enduring change and were at higher likelihood of relapse. Similarly, Tyrer and Mulder (2006) has pointed out that the "complexity" and severity of a personality disorder (the former defined in terms of meeting criteria for more than one personality disorder and the latter in terms of the possibility of severe disruption to both individual and to many in society) were robust predictors of negative outcome. Thus, in general, the presence of significant maladaptive personality traits or personality disorders is consistently identified as psychotherapy interfering and psychotherapy-effectiveness threatening condition.

Given the repeated findings that personality disorders, particularly antisocial personality disorder, are the second most prominent risk factor or criminogenic need for sexual offenders (e.g., Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004; Mann et al., 2010), such results suggest that the presence of such conditions limits or qualifies the potential for strong effects of psychotherapy with sexual offenders. In 2007, Duggan reviewed treatment for criminal offenders and concluded that such interventions were not informed by relevant scientific findings…. "We have very limited scientific evidence for effective interventions in offenders with Anti-Social Personality Disorder from the mental health field" (p. 2610). A National Institute for Health and Clinical Excellence (NICE) review of "Interventions for People with Anti-Social Personality Disorder" was published in 2009. It identified that "The evidence for the treatment of the constructs of antisocial personality disorder is extremely limited and does not support the development of any recommendations" (p. 177). This NICE report noted that psychological interventions for such persons "were poorly researched and direct evidence on the treatment of this population is scarce." The NICE report also pointed out that previous reviews had failed to identify any high-quality evidence for people receiving treatment for antisocial personality disorder (e.g., Duggan, Huband, Smailagic, Ferriter, & Adams, 2007; Salekin, 2002; Warren, McGauley, & Norton, 2003). The NICE review was a relatively broad review that considered not only interventions that targeted ASPD itself but also those that targeted symptoms or behaviors associated with the diagnosis (such as anger, impulsivity, and aggression) as well as interventions for offenders regardless of diagnosis. Thus, the NICE review suggested that there was limited support for "the use of group-based cognitive and behavioural interventions for non-offending populations with antisocial personality disorder in the community" (p. 190). They also found that psychological interventions for drug abuse (e.g., opioid dependence) indicated that substance abusers with comorbid antisocial personality disorder could benefit from treatment, particularly through the use of contingency management. The NICE review concluded that there "appears to be modest evidence of the effectiveness of group-based cognitive-behavioural skills interventions, delivered in the community and institutional settings, in reducing offending for adults in the criminal justice system" (p. 181). The review noted that such programs have a "small but positive effect" on general recidivism but also identified that younger adult offenders do not appear to respond to such interventions.

More recently, Gibbon et al. (2010) conducted a Cochrane Review of psychological interventions for antisocial personality disorder. They examined 11 studies involving 471 participants but noted that data were available from only five studies involving 276 participants with antisocial personality disorder; only two studies focused solely on an ASPD sample. Each of the 11 studies utilized different psychological interventions, and only two studies reported on reconviction and one on aggression. They concluded that they

> were unable to draw any firm conclusion from the evidence available. Although several studies looked at treatments to reduce drug or alcohol misuse in people with Anti-Social Personality Disorder, few studies focused on treating the disorder itself. Only three studies reported outcome measures that were originally defined in the review protocol as being of

> particular importance in this disorder (reconviction and aggression). Nonetheless, there was some evidence that a type of treatment known as contingency management (which provides rewards for progress in treatment) could help people with anti-social personality disorder to reduce their misuse of drugs or alcohol. Further research is urgently needed to clarify which psychological treatments are effective for people with this disorder. This research is best carried out using carefully designed clinical trials. Such trials should focus on the key features of Anti-Social Personality Disorder. To be informative, they need to be carried out with samples of participants of sufficient size. (p. 2)

Per Gibbon et al: "The current review concluded that good quality evidence favoring any psychological intervention for ASPD is virtually non-existent…The results of this review are that there is insufficient trial evidence to justify using any psychological intervention for those with a diagnosis of ASPD" (p. 35). Gibbon et al. noted that persons with ASPD were "a notoriously difficult group to retain in treatment, as they tend to be treatment-rejecting rather than treatment seeking" (p. 35). Most recently, Gibbon et al. (2011) reported on their analyses and noted that there were few studies of psychotherapy with ASPD that focused on outcomes such as reconviction, aggressive acts, or other rule breaking and that "No effect was found on these behavioral manifestations of the disorder in any of the psychological trials…" (p. 57).

Several reviews of treatments for adults with borderline personality disorder (BPD) found somewhat similar results. First, Binks et al. (2006) conducted a review of both clinical and cost-effectiveness; they concluded:

> The overall efficacy of psychological therapies is promising; however, at this stage the evidence is inconclusive. The cost-effectiveness of the intervention in six RCTs examined, however, does not support the cost-effectiveness of DBT although potential is suggested. There is a need for considerable research in this area. This research should involve appropriately powered head-to-head RCTs of psychological therapies…. (p. iii)

A Cochrane Review (2006) of psychotherapeutic interventions for BPD (Binks et al., 2006) concluded: "There were generally too few studies to allow firm conclusions to be drawn about the value of all the other kinds of psychotherapeutic interventions evaluated. However, single studies show encouraging findings for each treatment that was investigated, both 'comprehensive' and 'non-comprehensive' types. More research is needed" (p. 2). Second, a NICE review (2009) examined seven RCTs of dialectical behavior therapy (DBT; e.g., Linehan, 1993) and found that treatment "showed some effect on anxiety, depression and symptoms of borderline personality disorder, although the evidence quality was moderate" (p. 154). In addition, treatment showed some benefit on the rate of self-harm and suicidal ideation and service utilization. They pointed out that DBT retained clients in treatment compared to treatment as usual. The NICE review found: "There is very little evidence for the efficacy of individual psychological interventions in the treatment of people with borderline personality disorder because almost all studies are uncontrolled" (p. 141). Overall, the review found weak evidence of cost-effectiveness for psychosocial treatment of persons with BPD, stating that the available data did not allow for a firm conclusion. Binks et al. (2006) concluded: "This review suggest that some of the problems frequently encountered by people with Borderline Personality Disorder may be amenable to talking/behavioural treatments but all therapies remain experimental and the studies are too few and small to inspire full confidence in their results. These findings require replication in larger 'real world' studies" (p. 1). Brazier et al. (2006), in a systematic review on the cost-effectiveness of psychological therapies based on RCTs, concluded: "The mixture of results for the four trials of DBT, plus the high levels of uncertainty and the limitations of the analyses, do not support the cost-effectiveness of DBT, although they suggest that it could have the potential to be cost-effective. The results for [Mentalization Partial Hospitalization] are promising, although again surrounded by a high degree of uncertainty, and for [Manual Assisted Cognitive Behavioral Therapy], the analysis suggests that the intervention is unlikely to be cost-effective. There is a need for considerable research in this area. Of note, client centered therapy was not effective, suggesting that the simple application of common factors of psychotherapy was not sufficient for persons with significant maladaptive personality characteristics." Kliem, Kröger, and Kosfelder (2010) conducted a meta-analysis of DBT, including both RCTs (5) and other methods of evaluation ($n=2$); they included only those studies that included the four required components of DBT: individual therapy, group format training, consultation team, and telephone or staff coaching. Of approximately 500 subjects, 25 % dropped out before the end of treatment. They found small positive effects when DBT was compared to other specific treatments for BPD and larger effects for comparisons with treatment as usual; however, the global effects of DBT decreased at follow-up suggesting that more research is needed to improve the transfer to daily life. Further, no control was available across studies for the impact of utilization of psychiatric interventions (e.g., medications) or of other psychosocial treatment in parallel to DDBT or during the follow-up period. Stoffers et al. (2012) in the most recent Cochrane Review concluded that there are "indications of beneficial effects" for both comprehensive psychotherapies and non-comprehensive psychotherapeutic interventions for BPD core pathology and associated general psychopathology. Some modes of therapy were better at reducing select symptoms such as anger and suicidal behavior, while others were better at keeping clients in treatment. However, Stoffers et al. noted that none of the treatments had a very robust evidence base, and there are some concerns

regarding the quality of individual studies. They suggested that the current findings support a potentially important role for psychotherapy in the treatment of people with BPD but clearly indicated a need for replication

Given the poor findings of psychosocial interventions on adults with PDs, it should be noted that the available evidence concerning the psychosocial treatment of general criminal offending in adults is mixed. Various writers (e.g., Andrews & Bonta, 2006; Andrews, Bonta, & Hoge, 1990; McGuire, 2004) have claimed that CBT-based criminogenic treatment programs have a positive effect in reducing future reoffending. Although there are a limited number of RCTs with longer-term follow-ups, Andrews and Bonta (2006) showed that the relative short-term success of interventions reported for general criminal offenders had a *small-effect size*, which approximately doubled when incorporating all three elements of the R-N-R model. Recent meta-analyses by Landenberger and Lipsey (2005) and Latessa and Lowenkamp (2006) of broadly defined moderate-intensity CBT programs for general criminal offenders claimed clear evidence of effectiveness in terms of general criminal recidivism. Similar to the earlier meta-analyses, they found that it was CBT programs set up for research or demonstration (as compared to "real-world" practice programs) that produced larger reductions in recidivism. However, several significant methodological issues regarding the findings by Landenberger and Lipsey were acknowledged by the authors: a relatively small number of the included studies utilized a RCT design, the typical length of follow-up was *short term* (e.g., 78 % had just 12 months and *only* 7 % were even 2–3-year follow-ups), and treatment dropouts or refusers were not "counted." In addition, no information about additional posttreatment factors that might have influenced outcome, particularly intensive supervision or additional prosocial programming, was noted. For *short-term follow-up* (and not necessarily involving survival analysis), Landenberger and Lipsey found that CBT reduced recidivism; however, when they studied intent-to-treat analyses and treatment dropouts were included in outcome recidivism, the effect size of treatment was diminished. Further, while Landenberger and Lipsey concluded that while CBT is capable of producing reductions in general recidivism, "The amount of high quality research on CBT in representative correctional practice is not yet large enough to determine whether the impressive effects on recidivism found in this meta-analysis can be routinely attained under everyday circumstances" (p. 14). In addition, Latessa and Lowenkamp (2006) have also noted that the "integrity" with which psychosocial intervention programs are implemented for criminal offender is as important as the R-N-R dimensions; they have emphasized that a significant portion of psychosocial interventions for criminality are poorly implemented by inadequately trained and supervised staff. Thus, while a number of writers have suggested that the potentially positive findings of psychosocial interventions for general criminals might apply to sexual offenders, those findings are not overwhelming in and of themselves and lack generalizability. In particular, they are characterized by the same methodological weaknesses thought to plague the sexual offender outcome literature. To be clear, despite claims that CBT R-N-R treatment reduces criminal recidivism, there are few RCTs generally and fewer RCTs that have significant follow-up of reoffending (e.g., more than 12 months); there is an absence of definitive evidence that psychosocial interventions have long-term effects on reducing general criminal recidivism. Both from the perspective of theory and from the differential findings for the efficacy of sex offender treatment, valid arguments can be made that, most, many or a substantial group of sexual offenders might well represent a unique subgroup of criminal offenders who do not respond meaningfully to time-limited CBT interventions. This might be related to the potentially elevated presence of sexual preoccupation or deviant sexual arousal or other elevated dimensions of predisposing nonsexual conditions related to sexual offending.

In subgroups of criminal behavior that share some commonalities with sexual offenders, the results of the meta-analyses are not impressive in the reduction of symptomatic behavior and/or recidivism. Regarding drug treatment of incarcerated criminals, in their meta-analysis, Mitchell, Wilson, and MacKenzie (2012) found:

> Seventy-four evaluations met our eligibility criteria. The overall average effect of these programs was approximately a 15 to 17 % reduction in recidivism and drug relapse. The effectiveness of such programs, however, varied by program type. Therapeutic communities had relatively consistent but modest reductions in recidivism and drug relapse. Counseling and narcotic maintenance programs had mixed effects. Specifically, counseling programs on average reduced recidivism but not drug relapse, narcotic maintenance programs had sizeable reductions in drug relapse but not recidivism, and boot camps had negligible effect s on both recidivism and drug relapse. (p. 6)

However, Mitchell et al. noted methodological weaknesses characterized studies with more positive results (including publication bias in the studies of therapeutic communities), some evidence that aftercare was useful in maintaining treatment gains when they occurred, and that voluntary participation was associated with greater gains. They also concluded: "there is a lack of understanding concerning which particular components of treatment programs are most important, and which combination of components are most effective. Further, the general methodological weakness of this area of research leaves findings vulnerable to alternative explanations (i.e., reductions in recidivism could be due to factors other than the intervention)" (p. 30).

Babcock, Green, and Robie (2004), in a meta-analysis of male batterers or domestic violence perpetrators, reported:

> This meta-analytic review examines the findings of 22 studies evaluating treatment efficacy for domestically violent males. The outcome literature of controlled quasi-experimental and experimental studies was reviewed to test the relative impact of Duluth model, cognitive-behavioral therapy (CBT), and other types of treatment on subsequent recidivism of violence. Study design and type of treatment were tested as moderators. Treatment design tended to have a small influence on effect size. There were no differences in effect sizes in comparing Duluth model vs. CBT-type interventions. Overall, effects due to treatment were in the small range, meaning that the current interventions have a minimal impact on reducing recidivism beyond the effect of being arrested. (p. 1023)

Similarly, in a systematic review of court-mandated batter intervention programs, Feder and Wilson (2005) found that mean effect for victim reported outcomes was zero (compared to "official reports") and that where positive results for interventions were obtained, methodological problems were manifest (e.g., comparisons of an intervention with dropout group) in studies that found more positive results. They concluded that the results of their review "raise concerns regarding official reports. The findings, we believe, raise doubts about the effectiveness of court-mandated batterer intervention programs" (p. 239).

Finally, Hockenhull et al. (2012) looked broadly at intervention strategies for populations at high risk of engaging in violent behavior. While they noted some short-term evidence for effectiveness of psychosocial interventions in the context of high heterogeneity of results, they concluded: "Improvements are needed in the design quality of future research studies. Of particular note is the relative dearth of RCTs, especially in the evaluation of non-pharmacological interventions. Furthermore, RCTs themselves should be improved by extending the study follow-up period wherever possible." They also noted: "Design quality overall also remains relatively low and reflects the dominance of a pragmatic approach. Until the research effort becomes more homogeneous and well designed, any results from pooling studies will be limited in the robustness of results" (p. 5).

Specifically, writers have also raised issues regarding the implications of providing sexual offender treatment for persons with high or even elevated levels of psychopathic traits. Per Hare (2003), the mean score on the Psychopathy Checklist Revised (PCL-R; 2003) for a criminal offender is approximately 22, approximately three times the rate of the average male in the community; thus, while not all sexual offenders exceed the various cutoffs for being designated as a "psychopath," the great majority are characterized by a degree of psychopathic traits much higher than the average individual in the community. Hemphill, Hare, and Wong (1998) and Hemphill, Templeman, Wong, and Hare (1998) found that psychopathy as measured by the PCL-R contributed to the risk of criminal and violent recidivism when utilized as a continuous measure. In fact, surprisingly, survival analyses for persons rated either "medium" or "high" on the PCL-R were not clearly differentiated from one another; both of these groups showed similar recidivism rates and patterns. Thus, a moderate degree of psychopathy has significant implications for personality and predisposition for violent behavior; it also has implications for treatment. Nonspecific factors on the part of a person particularly the capacity for some degree of social bonding and intimacy are of particular importance in the initiation and maintenance of psychotherapy. Sexual offenders, particularly those with some degree of psychopathy, may be relatively unaffected by social bonds and intimacy. They may not view their sexual offending as a problem (except that they were detected and received consequences), and their distress is primarily with their condition of confinement or restrictions. Thornton and Blud (2007) identified a set of other issues that would likely compromise the effective treatment of more psychopathic sexual offenders: failing to give accurate, personally relevant accounts of the past history and functioning (motivated by "duping delight" and indifference to deceit); having bogus intentions (using language to manipulate others, easily agree to change their future behavior); disrupting group processes; experiencing treatment as just another opportunity to con or dominate; for those more psychopathic persons with "fragile narcissism," the likelihood that contemplation of being in need of personal change would be deeply threatening; inability or reluctance to taking responsibility for their own actions manifests as lack of insight into identifying aspects of themselves that might need to change; inability or difficulties in bonding to therapists or other group members; boredom proneness, impulsivity and disregarding commitments; and complaisance with rules and group expectations. Skeem, Polaschek, and Manchak (2009) identified that a higher degree of psychopathy was associated with a slower response to treatment, required more intensive treatment (but typically received less for various reasons), and show short treatment duration and premature termination. They also pointed to one of their studies that showed that "treating psychopaths is painful for treatment providers…and clinician's perceptions that offenders had made limited progress in mastering the skills need to overcome drug problems" (p. 370). However, they found that PCL-R scores did not relate to ratings of offender status at the end of treatment or did not moderate the effect of the intensity of treatment on general recidivism. Relative to the earlier findings that treatment might make persons with elevated psychopathic traits worse, Skeem et al. (2009) wrote: "In our opinion, the results are more likely to mean that subjecting high-risk offenders to intensive, radical, involuntary treatment makes them more likely to recidivate violently than leaving the alone. They stated: 'In sum, these studies indicate that psychopathic individuals are difficult to treat and often do not receive much treatment-points that few would contest'" (p. 366). Their review did find that more psychopathic offenders required more intensive,

higher doses of treatment and pointed to research that showed similar findings. However, Skeem et al. noted that none of the available studies of the effect of psychopathy on treatment outcome were RCTs and that with both general and high-risk criminal offenders, there was a pronounced gap in knowledge about the mechanisms by which appropriate treatment works. They also called attention to the issue of generalizability of psychosocial interventions with high-risk sexual offenders. They noted that, more generally, offenders with mental disorders "are particularly likely to fail community supervision, even when provided with 'state-of-the-art' mental health treatment…" (p. 376), thus raising the question as to whether even validated correctional treatment programs can reduce recidivism rates per se. They summarized the extant literature, stating first "In conclusion, little is known about whether intensive programs targeting high-risk violent offenders can reduce risk" (p. 375). They continued, "Yet even with general offenders, knowledge of the mechanisms involved in rehabilitative change, risk reduction and desistance remain largely unknown. With high-risk offenders, there is simply a need for more carefully designed program outcome studies, and as with general offenders, investigations must follow of what changes and how. There is much still to do" (p. 380).

Thus, for those sexual offenders with significant characterological traits, personality disorders, and/or elevated psychopathy, such characteristics are generally associated with a diminished treatment response, and a lack of effectiveness of sexual offender treatment fits with the larger treatment literature. The available evidence is that it appears very difficult to change well-entrenched attitudes, cognitions, and behaviors, particularly when those mentally/emotionally driven behaviors are particularly rewarding from both an immediate sexual nature and more general psychological nature.

Motivation for Sexual Offender Treatment or Not

In general, very few individuals enter treatment unless they perceive an advantage to themselves (e.g., relief of intense distress, everyday impairments, and so on) and without the expectation that an intervention will benefit them. The research literature on self-control, executive functioning, and self-regulation all highlight that both general ability and motivation are critical for purposeful, goal-oriented behavior, particularly other-oriented behavior or more abstract social goals; self-regulation fails more for "have to" behaviors than for "want to" ones (e.g., Hoberman, 2015a). Bohar and Wade's (2013) review of client characteristic and psychotherapy suggested that client involvement and engagement are particularly strongly associated with treatment outcome and that persons who are more internally motivated for personal change are those clients who are most likely to change. Thus, per Bohar and Wade's (2013) review, studies have shown that high levels of personal distress may be the best predictor of psychotherapy outcome; the less satisfied with one's "life," the greater the degree of change is to be expected from treatment. In addition, even among persons who make active, voluntary choices to participate in psychosocial treatment, the issue of reluctance or resistance to enact personal change has been and remains a prominent phenomenon that clinicians, particularly forensic clinicians, must acknowledge and address. Mahoney (1991) identified five perspectives on such "resistance" to psychological change in psychotherapy among persons who "choose" to engage in such treatment: (1) motivated avoidance as out-of-consciousness conflict between desire for change and desire for the status quo; (2) motivational deficits (as identified in many theories of learning) due to insufficient incentives and/or inadequate reinforcement available for change; (3) ambivalent choice as a result of variation in immediate and delayed consequences (e.g., the consequences of hard work may be aversive or even just neutral but ultimate effects may be highly positive); (4) psychological reactance involving perceptions that freedom to change exists but reactance results when that perceived freedom is eliminated or threatened; and (5) normative self-protection in the sense that resistance to change may reflect often "out-of-awareness" comfort with one's identity or life conditions and/or anxiety about the challenge and unknowns of enacting personal change. In short, there are numerous perspectives and bases for "ordinary" persons who chose psychotherapy but are characterized by mixed feelings, some conscious and others not perhaps, about the idea and process of changing and the uncertainty of what may result from possible change.

Consequently, the motivation and various aspects of resistance of sexual offenders to seek and participate in sexual offender treatment might be expected to play a significant role in the outcome of interventions. Yet, at best, it is unclear if sexual offenders are truly distressed by their sexual offending behavior and/or "want" sexual offender treatment. To what degree are sexual offenders troubled by the effects of their offending behavior on others and/or intrinsic (self-generated or "internalized") motivation to seek personal change or management strategies to prevent future sexual offending? Do sexual offenders seek treatment on a truly voluntary basis because they themselves are distressed by their sexual offending or impaired by their thoughts, feelings, or behaviors? Is the primary motivation for a significant subset of sexual offenders to relieve the upset caused by dispositions involving limits on their personal freedom? In reviewing the available studies of sexual offender treatment, it seems clear that a very significant number of sexual offenders do not evidence clear motivation both before and after sexual offender treatment; that is, they appear disinterested, reluctant, or unwilling to initially engage in treatment; even persons who

complete sexual offender treatment often manifest low motivation and compliance when that treatment ends. In an early review of sexual offender treatment in Canada, Wormith and Hanson (1992) noted, "Previous studies have indicated that between 40 % and 70 % of sex offenders do not consider themselves in need of treatment" (p. 193). Levenson and D'Amora (2005) acknowledged: "It is true that researchers and practitioners recognize that many sex offenders will not seek treatment voluntarily *because they enjoy what they are doing and do not want to stop*" (p. (referring to sexual offending, p. 147), emphasis added). That is, it appears that for a significant number of sexual offenders, general criminal as well as specific sexual offending is ego-syntonic; they do not experience significant or any distress with their behavior and do not view it as problematic (e.g., except regarding the consequences for themselves when they are detected and punished). From a "common sense" perspective, it is hard to understand why someone who feels comfortable with their maladaptive behavior, does not view their behavior as "wrong" relative to its effects on others and is not distressed by their offending behavior per se would experience much meaningful, self-generated motivation for change. Regarding sexual offenders, Marshall et al. (2009) wrote: "It is now acknowledged that offenders cannot be assumed to be intrinsically motivated to change when they enter a treatment programme. They may well be entering treatment for extrinsic reasons only, particularly if the programme is located in a penal institution, or if attendance is mandated as part of parole" (p. 335). Later, Marshall et al. (2011) opined: "Very few of these men are self-referred; most have gone through a lengthy process of being reported, investigated, charged with an offense, tried in court sentenced, and then imprisoned or court-ordered to treatment" (p. 40). It is notable that in a generally well-regard study involving a comparison of specialized sex offender treatment to nonspecialized treatment, the authors indicated that higher-risk sexual offenders appeared more likely to choose the less demanding treatment option (McGrath, Hoke, & Vojtisek, 1998).

This raises specific questions about the motivation of sexual offenders as well as more general questions about why persons characterized by various problematic behaviors don't change. Ultimately, as Levenson and D'Amora (2005) point out, mandated interventions create opportunities for change and ultimately the offender must choose whether or not to engage in treatment and make a commitment to personal change. Yet, similar to Mahoney, Arkowitz and Lilienfeld (2007) noted that resistance to self-change in the face of personal distress or impairment or potential harm to others may be relatively common. They pointed to significant portions of the general population who repeatedly resist changing behaviors that are potentially harmful to themselves (e.g., smoking, overeating) and/or others (binge drinking). Further, they highlight that even when people have sought and received treatment for medical problems, as many as 50–60 % do not subsequently follow their treatment regimen. Arkowitz and Lilienfeld suggest that many people are pulled in two directions, with motivation both to change and to maintain the status quo. They also identify that faulty beliefs about the possibility of change or the degree of change possible and the multiple psychological functions that undesirable behaviors may serve all may act as forces that interfere with self-change. In a related manner, Tyrer et al. (2003) have suggested that persons with personality disorders may be divided into those who are "treatment rejectors" as opposed to "treatment seekers." In fact, McMurran, Huband, and Overton (2010) provided a systematic review of non-completion of personality disorder treatments. In 25 studies, they found that the median non-completion rate was 37 % (range 15–80 %); non-completion was associated with adverse outcomes. They found that client "needs" associated with non-completion included narcissism, "complexity" of personality disorder traits, impulsivity, low depression, substance abuse, and lower levels of problem-solving and general functioning.

However, historically, as reviewed by Tierney and McCabe (2002) and as Marshall et al. (2011) indicated, both data and the perception of sexual offender treatment professionals is that a uniquely significant proportion of sexual offenders are essentially unmotivated for change. Studies such as Grubin and Gunn (1990) found that in one sample most sexual offender did not wish to participate in treatment; for rapists, 73 % indicated that they did not want or need treatment. Prentky et al. (2011) noted that expressed motivation of treatment among incarcerated sexual offender began to decline in the 1980s and has continued into the 2000s; they cited research that only half of sexual offenders surveyed indicated a desire for treatment. However, the general psychotherapy literature indicates that motivation is best understood as a complex and systemic issue involving interactions between personal, environmental, and temporal factors; motivation has been conceptualized and measured in various manners. As Tierney and McCabe pointed out, decisions to participate in sexual offender treatment can be related to avoiding incarceration, to presenting oneself in a positive light for the benefit of probation and parole decisions, or simply to obtain some personally valued outcome (as opposed to for the protection of others). Alternatively, they note that some treatment programs target the most motivated sexual offenders for treatment because they are considered to be the most likely to attempt to change their behavior. Tierney and McCabe opined:

> …It is potentially dangerous to assume that a high level of motivation necessarily results in a change in sexual offending behavior. While motivation is a necessary condition for treatment participation, treatment completion and behavior change, it is not a sufficient condition for change. (p. 122)

Prentky et al. (2011) stated that, in contrast to standard mental health treatment, "…it is most often the case that sexual offenders have not freely chosen to be in treatment. They are placed in treatment by the court as part of an agreement to avoid going to prison, as part of a prison-based treatment program or civil commitment program, or as part of a release condition after serving their sentence. Although offenders may 'volunteer' for a prison-based treatment program, with the understanding that such participation will be looked up favorably by the court and/or the paroled board, such participation is often prompted by motives other the desire to be in treatment. The net result is that sexual offenders are a captive population of 'clients' who, for the most part, enter treatment with little or no desire to be there" (p. 118).

Among studies that have examined sexual offender's motivation for treatment (e.g., Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988; Miner & Dwyer, 1995), dropout rates from 35 to 54 % from voluntary outpatient sexual offender treatment programs have been reported; such high dropout rates have implications for offender motivation for change. Kaplan (1990) reported that 50 % of incarcerated child molesters were not motivated to seek counseling for their sexual offense during their stay in prison, and while under parole supervision; 80 % believed that counseling was not needed. As Marques et al. (2005) found, initially only approximately 1/3 of the eligible inmates who were incarcerated for a sexual offense even volunteered to participate in the interview for the project. Later, an additional 21 % of those who had volunteered for sexual offender treatment withdrew prior to the beginning of treatment. Further, Marques et al. also found that 18 % of the small group of sexual offenders that did volunteer for and were assigned to receive sexual offender treatment did not complete program (27 voluntarily withdrew and 10 were demitted because they presented as "severe management problems in the hospital"). Shaw et al. (1995) found a poor relationship between expressed willingness to participate in sexual offender treatment and treatment success. Of 114 offenders accepted into sexual offender treatment, only 16 completed the program with "a good prognosis." They found that 86 % of offenders admitted to a correctional treatment program were either terminated during the evaluation stage for unwillingness to cooperate during treatment or discharged for incompletion of treatment modules or inappropriate behavior. They concluded willingness to participate in treatment was not necessarily predictive of a good treatment outcome. Further, Marques et al. (2005) also noted that they had "some participants were quite comfortable just 'programming,' attending treatment activities but not really making the commitment to change that is important to the RP model…" (p. 100). Thus, in SOTEP, a considerable number of sexual offenders offered treatment refused, others who were assigned to such treatment dropped out or were demitted, and additional others remained in treatment but made little commitment to change. All of these types of sexual offenders must raise significant questions about the role of motivation to pursue or complete sexual offender treatment. More recently, in their review, Larochelle et al. (2011) indicate that between 15 % and 86 % of sexual offenders who enter sexual offender treatment do not complete it, either as a result of dropping out, expulsion, or another arrest or conviction. Relative to results from SOTEP, Mann and Marshall (2009) wrote: "It is now acknowledged that offenders cannot be assumed to be intrinsically motivated to change when they enter a treatment programme. They may well be entering treatment for extrinsic reasons only, particularly if the programme is located in a penal institution, or if attendance is mandated as part of parole" (p. 325).

The issue of motivation for sexual offenders in relation to treatment is confounded by various factors; external mandates and recommendations and administrative selection are operative, and the former interacts with self-selection for sexual offender treatment. Jones, Pellissier, and Klein-Saffran (2006) found that important predictors of "self-selection" into a correctional sexual offender treatment program included higher scores on motivation, previous sexual offender treatment, a greater number of sex-related victims, and a greater number of sex-related convictions. However, the best predictor of volunteering for treatment was if a judge had recommended sexual offender treatment. Thus, self-selection or "volunteering" for treatment was strongly associated with a judge's recommendation. They concluded that a judge's recommendation at sentencing was a key factor in persons entering sexual offender treatment. However, while self-reported motivation was a predictor of treatment entry, it was unclear what the determinants of this factor were. A key construct may be reactance—persons who are particularly sensitive to interpreting external direction as a threat. Beutler et al. (2011) in a meta-analysis found that clients who were high in reactance did poorly in treatments that were more directive (e.g., CBT). Another treatment-related consideration related to motivation is the degree of denial which characterizes sexual offenders; Marshall, Eccles, and Barbaree (1993) wrote: "Well over half the sexual offenders in Canadian penitentiaries deny, upon entry to the system, that they committed the offense for which they are incarcerated. Many of the respondents minimize the nature of their offenses" (p. 447). They also noted that even among those who admitted their offenses, a number claim that simply having been adjudicated will be sufficient to prevent sexual reoffending. A few years later, Marshall (1999) indicated that more than 60 % of potential sexual offenders in their setting would be excluded from treatment if they denied or minimized their offending history, "among whom are the most dangerous" (p. 230).

Empirically, both meta-analyses of risk factors for sexual offense recidivism (e.g., Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004) found that measured offender motivation was unrelated to sexual reoffending per se. A question may be raised about motivation during and after treatment for sexual offenders. Barrett, Wilson, and Long (2003) found that per clinician records, sexual offenders' motivation in treatment "increased" from entry to end of institutional treatment; however, subsequently "motivation decreased for all types of sexual offenders upon community release" (p. 279). They reported "preliminary evidence" that an underlying paraphilic motivation to commit sexual offense against children might affect a sexual offender's motivation to change his sexual behavior. In their follow-up of reoffenders in the SOTEP study, Marques, Nelson, Alarcon, and Day (2000) reported that almost no individuals admitted to making a commitment to abstinence regarding sexual offender; all of them reported that they had been very motivated to change when they began treatment "but most were unable to sustain their motivation over time." This accords with Stirpe, Wilson, and Long (2001) who found that sexual offenders, particularly higher-risk ones, reported greater difficulty maintaining motivation for personal change and against sexual reoffending when returned to the community.

Almost no studies have examined any sexual offender's intrinsic or self-reported motivation to seek treatment. There are no known investigations of the reasons sexual offenders might be willing to participate in sexual offender treatment and/or change their behavior related to sexual offending nor are there studies of the relationship between "expressed" or "perceived" motivation to change sexual offending behavior and actual behavior change. The issue of motivation for involvement in sexual offender treatment and commitment to significant change remains an important issue to understand particularly in light of the question about treatment effectiveness. Knowing that an offender had technically "completed" sexual offender treatment provided no additional information to risk assessment by an actuarial measure.

Mandated or Coerced Treatment

Beyond individual sexual offenders' self-assessment and self-motivation for treatment, a related and highly relevant issue for the lack of demonstrated effectiveness of sexual offender treatment is the degree to which such interventions are mandated or coerced. The issue of the effect of mandated treatment has been somewhat controversial. It seems clear that many or most sexual offenders seek treatment under some condition of external pressure or contingencies: per a court order, as an alternative to incarceration, as a condition of parole or probation, and as a condition of child protective services or from family pressure, among others. Generally speaking, all of these conditions provide "external" or extrinsic motivation to seek treatment; there is a secondary reward or gain for pursuing intervention. As noted, Marshall et al. (2009) wrote that a significant portion of sexual offenders entered treatment "for extrinsic reasons only particularly if the programme is located in a penal institution, or if attendance is mandated as part of parole" (p. 335). Terry and Mitchell (2001) suggested that sexual offender treatment is largely characterized by "indirect coercion," where the belief is there is no choice to enter a treatment program because without the treatment there will be adverse consequences. That is, it would appear in almost all instances of sexual offenders participating in sexual offender treatment, there is indirect coercion where significant portions of treatment-participating sexual offenders believe that to reject treatment will result in adverse consequences. Thus, as Jones et al. (2006) showed, judicial recommendation for sexual offender treatment was strongly associated with sexual offenders "volunteering" for treatment. Obviously, mandated treatment does not only occur for sexual offenders. Rather, persons with severe and chronic presenting problems of serious harm to self (e.g., suicidal clients or persons with eating disorders) are also mandated for treatment, including hospitalization, for stabilization; however, such clients appear to respond much more favorably both acutely and over time to treatment mandates.

As previously noted, Losel and Schmucker (2005; Schmucker & Losel, 2008) found that only sexual offender treatment programs involving some type of "voluntary" participation showed a significant effect; programs that involved "a more or less coerced treatment" did *not* show an effect. Relative to correctional samples more generally, Parhar, Wormith, Derkzen, and Beauregard (2008) conducted a meta-analysis of 129 studies regarding the degree of offender coercion in treatment and its relationship to treatment effectiveness. They reported: "In general, mandated treatment was found to be ineffective in several analyses, particularly when the treatment was located in custodial settings, whereas voluntary treatment produced significant treatment effect seizes regardless of setting" (p. 1109). Further, "This implies that if offenders are being required by courts to attend treatment in custody settings the treatment is likely to have no effect and cost the criminal justice system and the courts both time and money" (p. 1127). They found that both mandated (ordered) and coerced (negative consequences if not done) treatments did not lead to effective interventions. In contrast, for specific recidivism (including sexual offender recidivism), voluntary (non-mandated, non-coerced) treatment in the community was associated with positive effects. In contrast, for specific recidivism, the greater the degree of mandated and/or coerced treatment, the smaller the treatment effect. Parhar et al. raised the question of whether it is ethical to insist that offenders participate in interventions

that have not been demonstrated to be effective. The Parhar et al. study suggests that any correctional sexual offender treatment program that consists of largely mandated and/or coerced offenders will not likely be effective.

As Levenson and D'Amora (2005) pointed out: "Ultimately, clients always have a choice about whether or not to enroll or participate in treatment, and the court not the treatment program, imposes the consequences of those choices" (p. 146). Since many sexual offenders who do pursue sexual offender treatment do so only under explicit or implicit judicial or similar pressure, it seems reasonable that such participants in sexual offender treatment might actually be disinterested in (unmotivated for) sexual offender treatment and either pursue treatment for secondary gain or wish to drop out of treatment. However, since "formally" dropping out of sexual offender treatment may result in sanctions or loss of desired opportunities, sexual offenders who attend treatment may not formally dropout bur rather passively attend to "completion." Rather, like Marques et al.'s (2005) participants, they may elect to sit through treatment but with little genuine commitment to the proximal or distal goals of sexual offender treatment.

Therapist Issues

As in more general psychotherapy outcome studies, the experience and skills of therapists may be a critical variable in sexual offender treatment. Marshall (e.g., Marshall, 2005; Marshall et al., 2009) has suggested that the influence of the therapist accounted for between 40 and 60 % of the benefits of treatment with sexual offenders, at least based on incidental assignment or non-controlled studies. In particular, he has suggested the tone of the treatment or therapists to offenders is critical to positive outcomes. As noted, Schwartz pointed to the sexual offender treatment field's adoption of a confrontational approach common to substance abuse programming in the 1970s. Marshall et al. (2011) have criticized the role of confrontation in sexual offender treatment; Marshall, Fernandez, Serran, Mulloy, and Thornton et al. (2003) reported that various therapist characteristics such as empathy; warmth; respectfulness; a positive, rewarding style; and a challenging or direct approach are associated with greater treatment change. However, Sandhu and Rose (2012) reported: "Due to methodological limitations of the studies, no conclusive evidence was found for the contribution of therapist characteristics to treatment efficacy" (p. 269). However, they did find the evidence suggesting those therapist characteristics "seem likely" to have an important impact on the process and outcome of sexual offender treatment. They indicated that the clinical challenge was to determine how therapist factors interacted with offender characteristics and "particularly, factors related to individual offending dynamics" (p. 281). It seems beyond dispute that sexual offenders would and do prefer positive attitudes and behaviors on the part of their therapists; however, the specific links and mechanisms by which those dimensions are related to subsequently reducing sexual reoffending or stable personal change among sexual offenders remain unclear.

In his more recent writings, Marshall has also emphasized the importance of the therapeutic alliance, typically citing relatively older studies in the general psychotherapy literature. Kozar and Day (2012) concluded there was currently insufficient evidence to support the view that the therapeutic alliance impacts "either directly or indirectly on treatment outcomes" for violent offenders (including sexual offenders); Beyko and Wong (2005) found no significant relationship between sexual offender treatment non-completion and therapeutic alliance in a small sample. Per Lambert and Ogles (2004), the importance of the alliance is a necessary but not sufficient condition for change in general psychotherapy. Similar to Marshall, they view the therapeutic alliance as a manifestation of the critical role of common factors in effective psychotherapy. However, based on their review of the current research literature, they determined "…we simply do not know enough yet about the therapist factor to specify when and how it makes a difference, nor when it matters more than technique" (p. 168). Similarly, Crits-Christoph, Johnson, Connolly Gibbons, and Gallop (2013) concluded: "Despite extant research, there are mixed reviews on the importance of the therapeutic alliance in treatment outcome;" they pointed to a recent meta-analysis that found a "small to moderate relationship between the [therapeutic] alliance and therapeutic outcome (r =. 27)" (p. 302). Challenging the conventional view of the role of the therapist-client relationship, Crits-Christoph et al. pointed to research that suggests that early positive change in symptoms is the *cause* of an improved "therapeutic alliance" as opposed to the converse process. Somewhat similarly, per Bohar and Wade's (2013) review, successful therapeutic alliances may be more driven by client behavior, so that clients who were motivated, engaged, and "present" in therapy elicited similar qualities in response from clinicians. They noted that studies have shown that successful clients were active in building rapport with therapists via their own prosocial behaviors (e.g., being appreciative and accommodating of their therapist) and that client contributions to the alliance were significantly correlated with outcome as opposed to therapists' contributions. In short, Bohar and Wade's review of client characteristics clearly showed that the nature of the client and the quality of a client's participations in treatment—and its effect on the therapist—played the most important role in making psychotherapy effective and leading to positive outcomes. For many reasons, the nature and characteristics of sexual offender treatment client and therapist would seem especially important in sexual offender

treatment, even more important than in general psychotherapy. To date, no RCT study has been conducted regarding the nature and role of the therapeutic alliance in relationship to sexual offender treatment—let alone for any therapist variable—in interventions for sexual offenders. Consequently, no rigorous empirical data has been collected to support or direct the role of therapist behavior and/or therapist-client relationships in sexual offender treatment.

Several writers have raised issues about the dilemma of developing dual relationships in mandated treatment that include almost all sexual offender treatment programs (e.g., Gannon & Ward, 2014; Ward, 2014). In both of these commentaries, it is noted that a dual relationship exists for therapists in forensic or "justice involved" treatment programs: such clinicians are presumed to balance the needs and interest of the offender client and the potential future possible harm to the community. Such a problem is framed as an important ethical problem. Among other areas, Gannon and Ward (2014) argue that collaboration, exploration, reflection, and supportiveness of the offender client are key aspects of developing a therapeutic alliance and that the role of contemporary correctional (or like) mental health practitioners threatens or undermines the potential potency of the therapeutic alliance because of their involvement in security-management and punishment-focused tasks. They appear to suggest that unless there is a clear situation of threat to another's imminent safety, the protection of the alliance is relatively paramount. A more general concern for mental health professionals providing "justice involved" sexual offender treatment is that the focus and accurate record-keeping of an offender-client's work and disclosures in treatment necessarily raises concerns about the ability to be honest and transparent when such behavior may lead to undesired consequences such as elevated risk assessments and/or extended detention. Such dual relationships are not unique to sexual offender treatment; similar situations exist in other court-mandated treatment experiences such as repeated alcohol-related infraction programs and domestic violence/batterer programs as well as court-ordered treatment for parents, children, and families in the course of a high-conflict divorce. In each of those cases, the protection of others and/or the best interests of children govern the nature and degree of disclosure of what emerges in therapeutic encounters. Hanson (2014) too has minimized the significance of the dual role for therapists treating sexual offenders in conventional treatment programs, stating: "The therapists' dual rule (as authority and helper) is explicit and, I would add, largely unproblematic, likening the role to other dual functions in society such as 'boss–employee, teacher–student, and most basically, parent–child'" (p. 4). Along these same lines, relative to the issue of court-ordered child protection and custody-related psychotherapy—what they term "forensically informed treatment"—Greenberg and Gould (2001) elaborated on the "treating expert," writing: "The psychologist is mindful of the limitations and biases that may be present in data generated in treatment and interprets and communicates such information conservatively. The psychologist may track clients' behavior and response over time and use such information to guide treatment or communicate it to the forensic evaluator or other professionals" (p. 477). Thus, dual relationships are not uncommon in other areas of court-related treatment in the context of potential or likely dispositional evaluations. Thus, there appear to be no simple solutions to the dual relationship in forensic psychotherapy where the primary goal (and typically the basis for funding the treatment) is increased and enduring public safety by means of facilitating the offender-client to be open and transparent about their general personal experiences and criminogenic needs and the degree to which such offenders are motivated and able to make substantive and valid cognitive, affective, interpersonal, and other behavioral changes.

Several issues concerning those who provide psychotherapy to sexual offenders raise questions about the potential for effectiveness of treatment. Per McGrath, Cumming, Burchard, Zeoli, and Ellerby (2009), as many as 38 % of residential programs for adult sexual offenders in the United States had clinical services provided by persons with bachelor's degrees or less level of formal education and 45 % by persons with master's degrees. It is unclear what type of training in the research and clinical literature such providers possessed. Anecdotally, in institutions, persons serving as therapists often lack extensive general and sexual offender treatment-specific training, and there appears to be a striking instability in treatment personnel, in both community and institutional settings. Yet as Skeem et al. (2009) note, given the findings that intervention programs in correctional settings are frequently or commonly delivered in a manner not in conformance with the stated treatment principles or protocol, there appear to be significant issues with treatment integrity and the quality of psychosocial treatment provided.

A related issue is the degree to which sexual offender treatment program clinicians know and follow the currently available scientific information about sexual offenders and sexual offender treatment. Generally speaking, based on their use of risk assessment measures, clinicians in the sexual offender field appear to have accepted the scientific evidence that actuarial measures are empirically more accurate than clinical judgment (e.g., that science is superior to clinical intuition); they have relatively adamantly rejected the lack of scientific evidence about psychosocial sexual offender intervention. For psychotherapists in general, Ogilvie, Abreu, and Safran (2005) showed that 86 % rated their ongoing experience with their clients as "most helpful," while only 29 % reported "research publications/presentations" as most helpful. Thus, these therapists greatly valued their own perceived experience as of much greater utility than available research

on psychotherapy. Studies show that sexual offender treatment psychotherapists believe in the efficacy of sexual offender treatment at a rate far disproportional to the science reviewed above. Thus, 80–90 % of such clinicians believe that treatment in outpatient or prison treatment "would be effective in reducing child sexual abuse" (e.g., Fortney, Baker, & Levenson, 2009). Given the state of research reviews and the ATSA statement, it is striking that it appears the great majority of sex offender treatment clinicians believe relatively strongly that psychosocial treatments for sexual offenders "work." In contrasting the ready acceptance of the empirically demonstrated risk assessment instruments, this strong convictions regarding sex offender treatment would seem to be a prime example of cognitive dissonance (e.g., Festinger, 1957) and confirmation bias: privileging (even seeking out) beliefs that are in accord with preexisting beliefs while selectively ignoring or devaluing the disconfirming scientific data that continues to accumulate. Further, there has been a consistent finding in the general treatment outcome literature that researcher/therapist allegiance accounts for a significant amount of the perceived outcome in treatment studies that find particular interventions effective. Thus, the inadequacy of the methods of intervention and the inability of clinicians to meaningfully gauge the quality of learning, internalization of constructs, and application in often artificial settings may also compromise any potential that current sexual offender treatment interventions have to offer, particularly with offenders participating in treatment under mandated and/or coerced conditions.

In addition, to being misinformed about the degree to which treatment reduces risk of sexual offense recidivism, one must also wonder about the degree to which clinicians providing sexual offender treatment view their own capabilities at affecting change in their clients. Regarding self-perceived efficacy, in general, clinicians overestimate their capabilities in the treatment role relative to other psychotherapists. As in other professions, Walfish et al. (2012) found that 25 % of mental health professionals rated their skills to be at the 90th percentile when compared to their peers and none viewed themselves as below average. They also showed, as per similar studies, that clinicians tended to overestimate their rates of client improvement. This is a general phenomenon among psychotherapists. Chevron and Rounsaville (1983) conducted an evaluation of different methods of assessing psychotherapy skills and found poor agreement among different assessments of therapist skills based on varied data sources. They also noted important aspects of treatment sessions may be distorted by therapists' reports. Their study found that only supervisor's ratings of therapists were associated with client outcome and that therapist's self-ratings were not. This becomes even more problematic in the context of how psychotherapists guide their actual work in treatment with clients. Castonguay et al. (2010) found little overlap in the types of treatment-related activities reported as helpful by client and therapists; the results suggested that what therapists believe to be useful with regard to change may be substantially different than what clients believe or experience such that clinicians, generally, may not fully understand their client's experience of psychotherapy. In a related manner, citing a variety of earlier studies, Hanson and Harris (2000) noted: "Experienced clinicians are frequently unable to differentiate between sexual offenders who benefited from treatment and those who did not…" (p. 7). Yet Ogilvie et al. (2005) showed that therapists rated their "ongoing experience with clients" as most helpful (e.g., 86 %) relative to research publications and presentations (e.g., 29 %). That is, in general, psychotherapists are much more likely to rely on their own beliefs about psychotherapy and their perception of their history of providing treatment than what scientific study has demonstrated to be related to effective or efficacious psychosocial interventions. However, if psychotherapists of sexual offenders are not able to differentiate those sexual offenders who are actually benefiting from psychosocial interventions from those who are not, then relying on their own perceptions of ongoing experience with those clients may be profoundly significant both in the actual accomplishment of personal change and/or the nature of mistaken presumptions of reduced propensities for sexual offender recidivism.

Further, increasingly questions arise about the relative proficiency or competency of persons employed in therapeutic roles in forensic treatment settings and the importance of therapeutic expertise. Gannon and Ward (2014) make a strong argument that "psychological expertise is becoming frequently overlooked within correctional services…" (due in large part to economic pressures and limited resources) leading to the use of paraprofessionals or relatively inexperienced clinicians (e.g., trainees or unlicensed practitioners). However, Gannon and Ward note:

> Research clearly indicates that effective treatment outcome is related to the skills and competencies of the treatment provider…Consequently, it is hard to see how those with little or even no psychological training hold the technical and interpersonal expertise required to engage in the series of complex and dynamic tasks required to implement flexible, cognizant, and reflective EBP treatment that is matched to client need and grounded in knowledge of the research evidence base pertaining to assessment, formulation, treatment strategies, and ethical decision making. Most notably, the employment of some staff in psychological programing (i.e., correctional officers) may even make one aspect underpinning EBP—that is, the development of a trusting therapeutic relationship-extremely difficult. (p. 441)

Relative to psychotherapy in general, Lambert and Ogles (2004) opined, "It is conceivable that therapists with appropriate styles or skill should improve the outcome for severe cases considerably" (p. 177). They suggested that more experienced and well-supervised therapists might have

greater impact on clients with personality disorders and other more severe disorders. Similarly, Marshall et al. (2011) noted that it should be obvious that some clinicians are more effective than others, stating: "Effective therapists need to have a strong foundation in the empirical literature as well as to possess a specific set of characteristics that have been found to embody a good therapist" (p. 63). Consequently, without clinicians with demonstrated personal qualities, knowledge, and skills and demonstrated effectiveness across various dimensions (similar to state-of-the-art risk assessment measures), the potential outcome of sexual offender treatment may be significantly compromised. In this light, it is notable that more generally, Krause, Lutz, and Saunders (2007) suggested that rather than specific treatments, specific therapists should be "empirically certified" as effective in their actual practice. Additional factors, beyond inexperience and inadequate training and professional experience, concern the apparent high rate of turnover among "justice involved" treatment programs, both those that provide more intermediate and more extended sexual offender treatment.

In short, while therapist variables may be significant in the potential efficacy of sexual offender treatment, there are also many concerns that therapists are not adequately educated, trained, or informed about sexual offender treatment specifically or psychotherapy generally which might significantly undermine the potential influence of sexual offender treatment programming. Sexual offenders as a group may represent a group of clients that is particularly heterogeneous, complex, and characterized by multiple problems and needs, many of which appear to be relatively enduring or persistent. Contrary to what others have suggested, it may well be the case that a substantial subset of sexual offenders are distinctly different from the general criminal offender and not responsive (in terms of reduced sexual offense recidivism) to the standard R-N-R model of intervention. Given the degree of diagnostic comorbidity and the frequent density, persistence, and range of criminogenic needs, it seems quite reasonable to conclude that sexual offenders constitute a particularly difficult group to provide effective treatment for and that the potential for effective treatment may lie in funding highly competent, experienced clinicians who have the requisite competence/expertise and are appropriately compensated to remain in their positions for more extended periods of time.

Nature of Treatment Delivery

Increasingly sexual offender treatment is provided through CBT the use of relatively standardized intervention programs as in other areas of "mental health" or "behavioral problems", CBT is the dominant model of intervention. CBT targets emotions by providing the means to changing cognitions (thoughts) and behaviors that are contributing to the presenting problems. Via self-monitoring exercises, CBT initially emphasizes increasing awareness of how situations, thoughts, and feelings interact and lead to problems. Further, largely based on a premise of skills deficits or misapplication, CBT focuses on understanding, learning, and building (developing) sets of skills that allow an offender to change their behavior, thinking, and feelings as a means of managing their presenting problem.

In sexual offender treatment, the presentation of "packages" of "skill" or "topic" modules of largely manualized CBT interventions is clearly the normative practice. Various agencies and individuals have developed and marketed treatment manuals or workbooks that provided relatively prescriptive programs of intervention strategies; it appears that many community- and institutional-based programs center their treatment for sexual offenders on such manuals and workbooks, with the notion that participants filling out the worksheets and verbalizing the information that they have received and their "feelings" and "insights" groups represent meaningful intervention. CBT-RP is typically delivered in a group format and as a structured treatment package (e.g., often with a specified numbers of sessions for a particular module or treatment strategy). It can be argued that in applying these manuals, given the psychoeducational thrust of CBT-RP for sexual offenders, treatment may be a matter of group leaders telling offenders what the treatment concept or skill is, having group members write down their version of the treatment concept in a workbook/worksheet (and perhaps apply it to themselves), and then taking turns in group to verbalize the treatment concept. Such verbal statements and repetition provide little in the way of establishing understanding, internalization, or ability to apply the concept or skill; there appear to be no studies linking the nature of verbalized information and feelings in treatment settings either to behavior outside of the therapeutic environment, let alone the community; there are no studies demonstrating that any of these behaviors or their quality or nature is related to reduced sexual offense recidivism. As Schwartz pointed out, after between session updates or persona crises, "There is also little time for formal skills training or teaching new members how to prepare a relapse prevention plan" (p. 365). In addition, many sexual offenders appear to possess low levels of psychological mindedness, namely, the capacity for self-monitoring, self-reflection, introspection, and personal/interpersonal insight; they are often generally alexithymic or have a relative inability to identify and describe their feelings or internal motivations (often except anger). As noted, they may experience their maladaptive personality characteristics and other predisposing conditions as well as their sexual offending as ego-syntonic. Consequently, the initial element of CBT, identifying relevant thoughts and feelings, may be a challenge for sexual offenders to begin with.

In addition, to the apparent degree that sexual offenders may be characterized by a variety of skills deficits related to coping with negative affect, prosocial, intimate interpersonal relations, and distorted thinking or problematic schema, psychotherapy may represent a considerable challenge to understand and effectively practice multiple new skills. For criminal offenders generally, Andrews and Bonta (2006) reported that treatment methods most useful involve training and modeling of appropriate skills by therapists, graduated behavioral practice, behavioral rehearsal (role playing), extensive coaching and feedback (from therapists and/or group members), and positive reinforcement of skills that appear to become more successful. Generally, CBT emphasizes the repeated practice of these skills both in and outside of therapy. Per MA, homework assignments and compliance both show effect sizes equal to or greater than that for psychotherapy generally (e.g., Kazantzis, Deane, & Ronan, 2000). However, both in institutional- and community-based treatment, real-time limits may limit skills acquisition and practice (particularly the latter) so that skills are neither well learned let alone mastered. As noted, little or no information exists to validate that such skills are truly learned, generalized, or related to sexual reoffending. Consequently, the time necessary for effective skills acquisition and practice across all the relevant treatment needs of persons with multiple criminogenic needs or risk predisposing conditions may be quite extensive and require frequent and lengthy treatment sessions, particularly if conducted via group treatment. Marshall et al. (2009) have emphasized that, generally, interventions for sexual offenders should have a strong skills-building focus. "More time and energy should be devoted to developing skills than to simply raising awareness of risk factors" (p. 335). They also stress the importance of attempting to generalize newly acquired skills to situations outside of therapy rooms. In particular, Fernandez, Shingler, and Marshall (2009) have emphasized the need to "put behavior back" into CBT to facilitate the potential acquisition and maximal generalization of treatment gains. Other criticism of manualized treatment focuses on the limits such methods place on a clinician's ability to provide individualized treatment geared toward a particular offender's unique psychologically meaningful risk factors and/or long-term risk vulnerabilities. Further, along somewhat related lines, in contrast to presenting problems of emotional distress or "problems in living," time-limited, modularized psychoeducational, or worksheet-based approaches for sexual offender treatment may be particularly inadequate interventions for moderate- and high-need sexual offenders relative to their ability to attend to, meaningfully comprehend, and repeatedly practice novel, alternative ways of dealing with themselves and the world over sufficient period of time that the new behaviors become validly adopted and well consolidated and acquire habit strength. They may also be problematic for those offenders with significant issues in social relationships (e.g., both anxiety and dominance). In addition, from a behavioral or CBT perspective, skills training and meaningful acquisition for persons with significant and broad deficits will always represent a considerable challenge and require considerable time.

Consequently, particularly structured treatment programs (particularly those delivered in groups)—"one size fits all"—may be inappropriate for the heterogeneity of sexual offenders found in both community and residential settings. However, Mann (2009) has strongly advocated for the flexible use of treatment manuals, arguing that they enhance treatment integrity and fidelity, keep intervention focused on relevant (e.g., criminogenic) goals, and limit the effects of biases and knowledge deficits associated with "therapeutic artistry." While treatment manuals may be an important component of outcome research, Mann noted that manualized treatment can be applied in a more flexible, individualized manner within a given treatment protocol and that flexibility can itself be manualized. However, it is unclear to what degree this has happened in extant sexual offender treatment outcome studies. Mann has argued that evidence base supporting treatment manuals in correctional programs is "convincing" and that the possible disadvantages can be remedied. Given the psychological complexity of a significant number of sexual offenders and the multiple, cumulative predisposing conditions that lead to particular sexual offending, it is possible that more individually tailored interventions might produce larger positive outcomes. It may be the case that sexual offender treatment has rarely been delivered in a manner that was optimized to particular sexual offender "needs" to the point of an individual actually mastering an understanding of and application of particular intervention elements. Clearly, the standardization of interventions is both significant and necessary if treatment elements or programs are to be funded, studied, and adopted by third-party payers. However, to date, there is no RCT comparison of manualized treatment versus individualized or even "treatment as usual" by clinicians for sexual offenders.

In part, a primary aim of manualization, both in research and clinical settings, is to ensure some uniformity and quality to treatment, in part by reducing idiosyncratic therapist effects, and to "correct" for inadvertent therapist omissions. In such manners, treatment manuals can serve to promote treatment integrity and fidelity and, as a result, overall quality in treatment provision, in much the same way that structured risk assessment measures serve to correct for the limitations of pure clinical judgment. Skeem et al. (2009), in writing about interventions for criminal offenders, noted that the quality of treatment as measured by provider training, implementation monitoring, and provision of treatment in research settings has been found to be associated with

reduced recidivism. Program integrity appears to be associated with program effectiveness in terms of outcome. However, they also noted that the vast majority of correctional programs lack program integrity and may amount to little more than "correctional quackery." Skeem et al. indicated that there was credibility to the concern that most programs as the implemented were unlikely to be effective. Relative to sexual offender treatment, as with general criminal offender treatment, to date, there has been little to no study of treatment fidelity or integrity; it is actually unclear as to whether treatment programs are being implemented as "intended" or prescribed. This poses another issue that may well relate to the finding that sexual offender treatment efficacy has yet to be demonstrated.

Beyond the primary use of manualized or otherwise standardized treatment programs, over 90 % of community and residential programs rely primarily on group treatment, primarily for cost-effectiveness. Consequently, there are limits to how individualized treatment can be relative to sexual offenders with different sets of criminogenic needs or risk factors; it is argued that this is particularly true for manualized treatment programs. Sexual offender treatment is typically provided in a group format of mixed sexual offenders, meaning persons who have offended against minors and those who have offended against adults are treated in the same groups. Individual therapy is relatively infrequent outside of private practice settings. Of 112 studies, only two were reviewed by Hanson et al. (2002), and Losel and Schmucker (2005) found only eight studies that utilized exclusively individual therapy and another eight that used primarily individual treatment program. While some writers have suggested that group treatment can instill hope and provide social support (e.g., Harkins & Beech, 2007), arguments have been made that group treatment can lead to less individualized treatment, particularly for mixed groups of offenders and those which rely on treatment manuals (e.g., Marshall & Marshall, 2007). Unfortunately, no direct RCT comparisons apparently exist of group versus individual sexual offender treatment programs or more or less manualized interventions.

It is also unclear as to how much time sexual offender treatment programs devote to didactic elements (e.g., teaching) as opposed to open group discussion of either offender—generated issues or topics/issues related to the particular focus of the treatment session are on a given date. As Schwartz (2003) pointed out:

> With up to 12 individuals in a group, there is little time for anything other than monitoring how participants have coped with risky situations during the past week. If one individual is in crisis, other members may have trouble finding any time to comment on their adjustment. There is also little time for formal skills training or teaching new members how to prepare a relapse prevention plan. (p. 365)

There are no RCTs comparing group versus individual treatment, either with or without a manualized approach to intervention. In addition, it is left for group leaders to decide (or not) whether or not individual group members had learned or mastered a treatment construct. Largely, in typical clinical practice, "outcome measurement" appears to be confined to therapists determining "acceptable" responses in workbooks/assignments and the relative ability of the sexual offender to articulate some understanding of the concepts in group interaction and/or crudely apply those generic concepts to their stated versions of their sexual offending history or sometimes just their most recent offense. Generally, research has shown that therapists' ratings of clients' progress are significantly greater than what their clients report or what is reported by client's significant others (e.g., Hill & Lambert, 2004); this is likely to be even more pronounced in forensic therapy settings, where there is significant potential secondary gain for sexual offenders who present as reflecting positive treatment behavior and apparent treatment gains. Further, in their review, Hill and Lambert concluded that therapist ratings of treatment outcome and global ratings of change are associated with the "perception of greater effectiveness" of treatment compared to more specific measures and more distal measures.

Clearly, the dose of psychotherapy is likely an important factor. Per McGrath et al. (2009), the typical community sexual offender treatment program in 2009 reported program length of 24 months (albeit with a large standard deviation of 14 months). In contrast, residential programs reported program length of 29 months (with a remarkably large standard deviation of 28 months and a median of 18 months). As Schwartz (2003) noted, the likelihood of significant cognitive, emotional, and behavioral change is unlikely when interventions are brief, the exposure to substantive content is limited, and the opportunities for experiential practice are inadequate. Particularly for sexual offenders with entrenched cognitions, attitudes, behavior patterns, and/or atypical sexual interests, affecting changes in those domains may take a substantial amount and intensity of clinical time over an extended period of time. In contrast, interventions with limited sessions over several months may provide very inadequate exposure for all but the most low-risk/low-need sexual offender. In 2003, Schwartz called attention to key differences between institutional and community programs relative to the factor of time or dose of treatment. She noted that community-based outpatient groups typically consisted of one 90-minute session once a week often with as many as 12 participants in the group. She notes that, practically speaking, such may leave "little time for anything other than monitoring how participants have coped with risky situations during the past week" (p. 365) or addressing specific crises. Further, Schwartz commented

that with such limited contact time, there is typically little opportunity for meaningful intensive skills training or for teaching new members how to prepare a relapse prevention plan. In contrast, she noted that institutionally based programs might be in a position to devote much more time to treatment, offering "between 6 and 10 hours of direct treatment supplemented by a variety of other therapeutic activities" (p. 365). McGrath et al. (2009) confirmed that most community programs met once per week, while residential programs had approximately four sessions per week. The median number of hours to complete sexual offender treatment was 140 and 316, respectively, in community and residential programs. Thus, in providing largely group treatments, the amount of time available for individual participants in sexual offender treatment may be quite limited given the limited weekly hours, the size of the groups, and the variety and severity of individual's issues and problems that characterize a sizeable number of sexual offender treatment participants. The disparity of treatment time and dosage between community and residential types of treatment (e.g., increased) raises questions about the findings from several SRs and meta-analyses that institutional programs have worse outcomes in terms of sexual offense recidivism rates. This raises significant questions about the requisite duration and dosage of time necessary for moderate- and high-risk sexual offenders to meaningfully change. Further, in contrast to general criminal offenders, Hanson, Bourgon, Helmus & Hodgson et al. (2009) found that the risk principle (e.g., more intense services to high-risk offenders) did not lead to more positive outcomes. As Harkins and Beech (2007) noted, "little work has been conducted on the relationship between dosage of sexual offender treatment according to risk level and recidivism" (p. 624).

Little Evidence Exists That the Specific Components of Sexual Offender Treatment Are Efficacious

Perhaps the most significant factor in the failure to demonstrate efficacy of psychosocial sexual offender treatment is that little or no empirical evidence exists that most of the specific core targets and the component tactics, strategies, and methods employed in such interventions are themselves effective. The historical perspective on the development of sex offender treatment and the results of the most recent survey of sex offender treatment programs (McGrath et al., 2009) both indicate that currently, the great majority of such programs consist of multicomponent elements that target specific areas believed or assumed to be related to sexual offending. Consequently, the effectiveness of these programs must strongly rely on whether or not these areas are related to sexual offending and/or whether the specific interventions have an actual effect on the select targets; by actual effect, there should be scientific evidence affirming that these treatment components have an intended (or even unintended) effect on sexual offenders that leads to a reduced likelihood of sexual offense recidivism. If this were not true, then there would be little basis to expect that sex offender treatment would be effective, except perhaps for effects from the so-called common factors. As Baker, McFall, and Shoham (2009) point out:

> Scientific plausibility refers to the extent to which an intervention makes sense on substantive bases and whether there is formal evidence regarding its mechanism…the absence of a demonstrated or plausible specific mechanism of action, especially for a psychosocial intervention, leaves open the possibility that the intervention may merely be capitalizing on nonspecific credible, ritual, or placebo effects. (p. 72)

Unfortunately, virtually all available evidence suggests that little or no most current treatment targets or intervention strategies have any empirically demonstrated basis; that is, little or no evidence indicates that these components of sex offender treatment programs have a clear, defined, and lasting effect on sexual offenders and/or if they are actually associated with decreased sexual offense recidivism. Given the lack of scientific evidence for the effectiveness of sexual offender treatment, both the common treatment targets and methods of such treatments may be "off target" or irrelevant to the goal of reducing sexual offense recidivism (as opposed to just inadequately implemented).

Historically, almost all sexual offender treatment programs have been institutional (primarily correctional) or community agency based in nature; the available data indicates that very few sexual offenders receive psychotherapy in private practice settings. Per a recent survey (McGrath et al., 2009), 92 % of sex offender treatment program for adult males identified cognitive-behavioral therapy (CBT) as one of their top three influences; relapse prevention (RP) was the next most common selection.[4] Approximately 50 % of both residential- and community-based programs endorsed psychoeducational methods as a primary model, which was a decrease from previous surveys. Thus, most current sex offender treatment programs in North America utilize CBT and RP for sexual offenders (e.g., Marshall, 1999; McGrath et al., 2009). McGrath et al. (2009) identified the common treatment targets and treatment methods of sex offender treatment found in most community and residential sex offender treatment programs in the United States. They are listed in Tables 1 and 2. In addition, the Center for Sexual

[4]In recent years, sex offender treatment programs have increasingly endorsed some use of the GLM and/or SR models of treatment, but no empirical studies of the outcome of these models have been conducted.

Table 1 Most common core treatment *targets* for residential and community programs (McGrath et al., 2009)

Core treatment targets	Adult males (%)
Residential programs	
Offense responsibility	91
Social skills training	91
Victim awareness and empathy	87
Intimacy and relationship skills	84
Problem solving	79
Emotional regulation	64
Arousal control	59
Offense-supportive attitudes	54
Self-monitoring	49
Family support networks	47
Community programs	
Victim awareness and empathy	93
Offense responsibility	92
Intimacy and relationship skills	91
Social skills training	88
Problem solving	80
Arousal control	69
Emotional regulation	66
Self-monitoring	56
Offense-supportive attitudes	54

Table 2 Most common *components* of sex offender treatment in the United States (from McGrath et al., 2009)

Core treatment components	Adult males (%)
Residential programs	
Relapse prevention	92
Assault cycle or offense chain	92
Cognitive restructuring	91
Sex education	72
Motivational interviewing	61
Client's victimization/trauma	60
Therapeutic community	47
Victim clarification	39
Schema therapy	9
Community programs	
Relapse prevention	96
Assault cycle or offense chain	92
Cognitive restructuring	90
Client's victimization/trauma	78
Sex education	74
Victim clarification	69
Motivational interviewing	46
Therapeutic community	14
Schema therapy	9

Offender Management (CSOM, 2008) of the US Department of Justice presents an online curriculum for the "Elements of Sex Offender-Specific Treatment."[5] The curriculum is based on an early survey of sex offender treatment program conducted by McGrath et al. from 2003. It provides

> a framework for thinking about sex offender–specific treatment. It particularly deals directly with a topic of great interest to those involved in community supervision—addressing offender denial. It also covers techniques for addressing cognitive distortions with respect to consent to sexual activity, and speaks to increasing victimization awareness and the steps that follow disclosure of a full sexual history. Additionally, participants are introduced to the four domains of treatment: sexual interests, distorted attitudes, interpersonal functioning, and behavior management.

However, as the systematic review of treatment for adult sexual offenders by the Institute of Health Economics (IHE) in Canada (e.g., Corabian et al., 2010) noted: "There also remains much disagreement concerning what are the most useful components and elements of sex offender treatment program that would ensure meaningful rehabilitation for convicted adult male sex offenders and limit the number of future victims" (p. 39). It can be argued that currently, minimal empirical evidence exists to support either the core treatment targets or the methods involved in sex offender treatment. It is important to recall that much of what is identified as sex offender treatment was either "borrowed" from existing treatment models or practices for other behavioral problems (e.g., modification of cognitive distortions, social skills training, relapse prevention) or theoretically based on early behavioral conceptions of the potential etiology of deviant sexual interests. Unlike other problems targeted by or addressed by psychotherapy, there was little scientific investigation (or demonstration) that specific interventions had particular short- or long-term effects on sexual offenders and/or that scientifically demonstrated interventions were then incorporated into sex offender treatment programs.

Rice and Harris (2003) opined:

> …we suspect all would agree that very little knowledge has accumulated about several crucial matters. Thus, there is no information about what aspects of treatment (teaching social skills, versus exploring the offense chain, versus practicing relapse preventions strategies) might produce reductions in recidivism. Anyone attempting to start a treatment program would find little or no empirical foundation from the sex offender treatment literature. This dearth of knowledge about sex offender treatment contrast sharply with the rapid expansion of knowledge in other areas. (p. 437)

[5] http://www.csom.org/train/treatment/long/index.html

In fact, Hanson, in his series of meta-analyses of risk factors for sex offense recidivism, has demonstrated that various components of CBT-RP sex offender treatment programs (at least as measured) *do not* appear to empirically be related to sexual offense recidivism. Initially, Hanson and Bussiere (1998) examined the role of "clinical presentations" to sex offender recidivism. They found that motivation for sex offender treatment, denial of the adjudicated sex offense, degree of empathy for victims, and length of treatment showed no relationship to later sexual reoffending. Later, in their updated meta-analysis, Hanson and Morton-Bourgon (2005) similarly found that similar variables of clinical presentation were unrelated to sex offender treatment outcome; (low) motivation for sex offender treatment, denial of the adjudicated sex offense, degree of empathy for victims, loneliness, and low self-esteem were also found to have no relationship to later sexual reoffending. In addition, poor progress in sex offender treatment, measured at the end of such intervention, was unrelated to sex offender treatment outcome. Hanson and Morton-Bourgon stated: "…most [sex offender treatment] programs direct considerable resources toward characteristics that have little or no relationship with recidivism (e.g., offense responsibility, victim awareness, and empathy)" (p. 1159). In a later meta-analysis of sex offender treatment, Hanson, Bourgon, Helmus & Hodgson et al. (2009) continued to emphasize:

> Many of the factors targeted in contemporary treatment programs do not [target criminogenic needs]. Offence responsibility, social skills training, and victim empathy are targets in more than 80 % of sexual offender treatment programs…yet none of these have been found to predict sexual recidivism…. (p. 886)

Thus, Hanson and Morton-Bourgon wondered: "An important question is whether programs that target the major predictors of sex offender recidivism (e.g. lifestyle instability, deviant sexual interests, or sexual preoccupations) are more effective than programs that target" (p. 1159). Hanson, Bourgon, Helmus & Hodgson et al. (2009) emphasized that attention to the need principle would motivate the largest changes in interventions currently given to sexual offenders, such that an empirical association with sex offense recidivism would be a minimum criterion for a factor to be considered a criminogenic need. They suggested that without a focus on empirically identified criminogenic needs, psychotherapies for sex offenders might not be effective interventions.

It should be noted that the shift to more multidimensional, multicomponent cognitive and behavioral treatment strategies (e.g., targets) and tactics (for optimal implementation) in the treatment of sexual offenders was not based particularly strongly in either theory or scientific evidence. Rather, it reflected both a more general change in treatment methods for a variety of mental health conditions and/or social problems from the CBT perspective (providing a broad "shotgun" set of therapeutic components) and a non-empirically rooted belief that particular treatment targets might be related to sexual offense recidivism for most sexual offenders. Consequently, it is perhaps not so surprising how little science exists to support particular goals (targets) and methods (components) common to sex offender treatment programs. With virtually no exceptions, the available research finds almost no scientific research specifically linking a specific treatment area or method commonly utilized in sex offender treatment to changes in its psychosocial target.

Concerning the acceptance of responsibility of an offender's history of detected sexual offenses, Marshall (1994) found that 32 % of a sample of sexual offenders significantly minimized elements of their sexual offending, while another 31 % completely denied having sexually offended. Thus, well over 60 % of those sexual offenders, to a large degree, started treatment without accepting responsibility for having sexually offended. Prentky et al. (2011) reported that acceptance of responsibility for adjudicated sexual offending has actually decreased significantly over time; acceptance of responsibility dropped from 90 % of sexual offenders receiving treatment in the 1960s to only 50 % in the 2000s. Consequently, for most sexual offender treatment programs, offense responsibility (involving sexual offending disclosure and accountability) has been a primary aspect of sex offender treatment programs; per McGrath et al. (2009), approximately 90 % of sex offender treatment programs identified this as a key and most common treatment target. They found that over 1/3 required an offense disclosure "very consistent with official records" and over 40 % required an offense disclosure "reasonably consistent with official records" (p. 66). Per CSOM's Web-based treatment curriculum overview:

> Denial is a major concern because most sex offender treatment is predicated on the offender's admission that he committed sexual assaults and that these behaviors are a problem for him… If a convicted sex offender assumes the position in treatment that he did not commit any sex crimes, then whenever issues are discussed in treatment group meetings, such as cognitive distortions, deviant arousal, and offense cycles, the denying offender simply states that these concepts don't apply to him. This precludes his addressing his problems, and often interrupts the therapeutic process for the other sex offenders in the group who are admitting their sex offense histories. A corollary concept related to the importance of sex offenders' taking responsibility for committing sexual assaults is that by implicitly acknowledging that they chose to commit sexual assaults, they can make other choices, namely not to commit future sexual assaults. Sex offender treatment emphasizes that people can change; failure to admit problems provides no impetus to change…Therefore, before sex offender treatment can be effective, the offender must admit his offense history, at least in part…We view treatment of denial essentially as pre-treatment; not all sex offenders need it. However, those who do must substantially abandon their denial in order to benefit fully from sex offender treatment.

However, as noted, the Hanson et al. risk factor meta-analyses in 1998, 2004, and 2005 each found that denial

(albeit, measured in various ways) was not correlated with sexual offense recidivism. However, Levenson and Macgowan (2004) found denial to be inversely related to engagement in treatment.

Ware and Mann (2012) raised questions about the necessity of offense disclosure and focused on denial and minimization as the opposite of such offense responsibility. They argued that there was no well-articulated model of change for taking responsibility for one's sexual offending and that denial and excuse-making could be viewed as normal behavior. They also indicated that a lack of acceptance of responsibility for sexual offending was implicated in particularly high rates of treatment attrition, noting that there might be significant "costs" to the offender relative to self-esteem and loss of social support for such "confessions." Conversely, several reasons support that sexual offenders provide a full and detailed disclosure of their history of sexual offending. It is difficult to conceptualize many psychotherapy situations where individuals enter treatment but do not acknowledge that they have a "problem." To the degree that such persons deny that a problem exists (e.g., persons with eating disorders or substance abuse/dependence which are ego-syntonic), the initial focus of treatment is addressing that "resistance" so that treatment toward a healthier lifestyle can begin. This would seem particularly significant for forensic therapy, where a client is also the community interested in the protection of the client or society at large. Given the diversity and crossover for a significant number of sexual offenders, a full disclosure of sexual offending history can elucidate the range and dynamics of sexual offending.

From a CBT-RP perspective, full disclosure of sexual offending allows the development of "offense *chains*" and the potential *variety* of behavioral signatures of sexual offending for a particular offender (especially given the demonstrated crossover and overlap of significant numbers of sexual offenders' victims and/or offense type). In many respects, such offense chains are similar to the products of self-monitoring of presenting problems where clients are expected to create a behavioral analysis of situations and associated cognition, emotions, and behaviors that lead to particular behaviors or other consequences. Such a self-monitoring promotes awareness of the predisposing and situational factors related to a presenting problem. As noted, in sex offender treatment, offenders are typically expected to develop a detailed analysis of the sequence of events leading up to one or more sexual offenses, including associated thoughts, feelings, and behaviors and to examine the chains and their components to determine what set of conditions were "high risk" for them. Such offense chains provide a basis for creating an individualized focus of treatment for the sexual offender (including identifying components critical to relapse prevention efforts, situational cues/antecedents, motivational factors, and historical and potential consequences of sexual offending). Such a focus seems necessary as a key means to identify a relatively complete set of criminogenic needs to be addressed in treatment. Even Ware and Mann "suggest…that therapists focus on using disclosure of offenses as an information gathering strategy that ultimately informs case conceptualization" (p. 286) so that factors related to sexual offending can be identified as treatment targets (e.g., criminogenic needs) and provide the basis for what they identify as "active responsibility" toward future life change. Further, from both a forensic and public safety perspective, obtaining a relatively correct and comprehensive history of an individual's sexual offending seems quite necessary in order for a comprehensive, individualized risk assessment and related management strategies; sexual offending history has consistently been identified as one of the best predictors of sexual offense recidivism per the various meta-analyses of risk factors for sexual reoffending. In addition, studies have demonstrated that the inclusion of self-reported sexual offense history is an independent predictor of such recidivism (e.g., Hanson, Steffy, & Gauthier, 1993). Thus, from the perspective of forensic psychotherapy, with its strong emphasis on community safety and decreased future sexual offending, complete disclosure and acceptance of responsibility by offenders regarding the scope and variety of sexual offenses appears necessary to understand the nature of their risk for recidivism and to provide meaningful information to direct the specifics of psychosocial interventions. It also provides a metric for sexual offenders to come to terms with the need and nature of sex offender treatment and for their actual self-motivation relative to commitment to personal change for the sake of community protection.

As noted, the one key area of sex offender treatment that was theoretically derived was the belief that deviant sexual arousal represented a conditioned association that paired a past event or mental representation (typically accidentally) with a state of sexual arousal (e.g., McGuire et al., 1965); the mental representation when experienced then became sufficient to produce a state of sexual arousal which would be reinforced via masturbation to that cognition. Deviant sexual fantasies, urges, and even behavior were thus believed to be derived from or originate from previously "learned" sexual interest in acts or memories that came to be associated (via conditioning) with sexual arousal. As a result, the original treatments for sexual offenders were primarily applied behavioral techniques that attempted to alter or "modify" deviant sexual interests by either eliminating the reinforcing aspect of the deviant fantasy/arousal (and to "normalizing" or changing the deviant fantasies or arousal to more "appropriate" stimuli). As Rice, Harris, and Quinsey (2001) noted, reconditioning of deviant sexual arousal was the one element common for virtually all psychosocial treatments for sexual offenders. Even more recently, such techniques (broadly identified as arousal control or modification) have been

central, substantive components of current CBT treatment for sexual offender (per McGrath et al., found in approximately 60–70 % of US treatment programs in 2009). However, the relevance of conditioning (as the cause of sexual offending) and behavioral modification of sexual interests and arousal patterns (as an intervention for sexual offending) has been questioned. O'Donohue and Plaud (1994) concluded that, due to the methodological problems of available studies, the basis was "tenuous" for asserting the existence of relationships between habituation, sensitization, classical conditioning, operant conditioning, and sexual behavior. Laws and Marshall (2003) observed that while the theory that sexual preference (e.g., deviant sexual interest) developed via behavioral conditioning was an appealing one, it had never been supported by more than anecdotal evidence. Marshall himself (1971) had first pointed out that even eliminating deviant sexual interests and adding procedures to enhance appropriate sexual interests was not likely to guarantee the development of nondeviant sexual interests. Relative to the various methods proposed to alter deviant sexual interests (e.g., masturbatory reconditioning, aversive therapy, covert sensitization), Laws and Marshall (2003) noted that "there was limited evidence on the long-term effects on overt behavior of these techniques…there was, and continues to be no evidence of enduring changes in sexual preferences as a result of these simple behavioral approaches…" (pp. 86–87).

In a review of the available studies of arousal control, one finds that almost all were case studies, few if any involved comparison treatment conditions or no treatment groups, and none followed "treated" sexual offenders for any significant length of time. Almost all studies relied on the self-report of the sexual offender that his deviant sexual interests had changed as a result of intervention. Thus, even early proponents of such interventions such as Laws and Marshall (1990) stated that the evidence advanced in support of most methods of masturbatory reconditioning was then "weak" and Marshall and Pithers (1994) noted that most strategies to alter deviant sexual interests had limited empirical support.

Covert desensitization or covert sensitization has been and continues to be the most popular approach used in an attempt to modify deviant sexual arousal (e.g., McGrath et al., 2009). This procedure involves having a client imagine enacting preferred deviant sexual behavior and then immediately imagine a very undesirable or aversive consequence or image. However, per Marshall et al. (2009), it is noted that clients report that after repeating imagery consequences several times, the aversiveness of that stimuli dissipates or is lost. Further, Marshall et al. noted that despite its popularity, "there is little in the way of supportive evidence for the covert sensitization" (p. 321). At the same time, Marshall in various forums (e.g., Marshall et al., 2009, 2011) has continued to advocate for the technique of masturbatory satiation as efficacious. However, a review of the available research literature would indicate that little empirical evidence, let alone robust scientific evidence, exists to substantiate this intervention strategy as particularly effective, certainly based on controlled studies utilizing a meaningful follow-up period. Even Marshall et al. (2009) wrote: "What is most clear from this review of behavioural procedures is that far more research is needed to generate confidence in their utility. This is particularly pressing given that so many programmes employ these techniques. It is time that clinicians made the effort to collect data in their use of behavioural procedures aimed at enhancing appropriate sexual al interests and decreasing deviant interests" (p. 324). Overall, no RCTs or other types of controlled studies have demonstrated enduring or long-term change in deviant sexual interests as a function of any masturbatory reconditioning. To date, at best, the value of such treatment components is unknown.

Social skills training also became an important component of sex offender treatment. Marshall (1971) is credited for advocating that simply reducing deviant sexual arousal was insufficient as treatment and that it was important to facilitate the acquisition of social skills to enable offenders to obtain the capabilities for age-appropriate sexual partners. Similarly, Abel, Blanchard, and Becker (1978) included social skills training as part of a comprehensive approach to treating sexual offenders and conducted limited research into social skills in relation to sexual offenders (e.g., Barlow, Abel, Blanchard, Bristow, & Young, 1977). McFall (1990) also discussed enhancing social skills as a component in the treatment of sexual offenders. Per CSOM,

> Generally speaking, the belief is that if offenders can learn to live more functionally in the world of adults, they will find life more satisfying, thereby diminishing their likelihood of reoffending. This is not to suggest that a lack of social skills is either the primary reason why people commit sexual assaults, or even that poor social skills have been associated with sex offender reoffense risk. However, intimacy deficits and conflicts in intimate relationships have in fact been found to predict sexual recidivism. Thus…the case for criminogenic needs in the area of social skills training for sex offenders is less clear.

However, little useful research exists regarding social skills deficits or issues related to sexual offending in general.

Stermac, Segal, and Gillis (1990) in their review of the available research at the time concluded: "Although a number of controlled studies have examined the social skills and interactions abilities of sexual offenders, a clear pattern of deficits has not emerged for either rapist or child molesters… It is clear…that further work in the area of social skills and social perception needs to be carried out" (p. 155). Mann et al. (2010) found that social skills, as measured, were not

empirically associated with future sexual offending. Regarding social skills, Marshall and Eccles (1991) noted that while such components had been a part of sex offender treatment for 20 years, "the evidence for such deficits is rather thin" (p. 72). Hanson et al. (1993) found that enhanced social skills did not show a positive association with treatment. More recently, Ward, Polaschek, and Beech (2006) reported: "as yet there is no evidence that social skills training can, on its own, reduce sexual offender' risk" (p. 184).

Following Beck (1975), Abel et al. (1978) began assessing and targeting so-called cognitive distortions as part of a treatment package for child molesters. Segal and Stermac (1990) and Murphy (1990) also discussed the role of cognition and modifying cognitive distortions in sexual offenders. At that time, the term cognitive distortions included a variety of references, including beliefs about potential victims, denial, minimization, and justification for sexual offending. Salter (1988) strongly advocated the value of strongly confronting "cognitive distortions, rationalizations and excuses for offending" (p. 114). It notable that even then Murphy reported on research that indicated that sexual offender's cognitive distortions appeared to change as the result of other components of treatment. More recently, Maruna and Mann (2006) have argued that there are many different views of cognitive distortions regarding sexual offender and that most phenomena regarded as distortions (e.g., denial, excuses, justifications) may not have a causal role in sexual offending.

In addition, Shingler (2009) reviewed studies that showed that "thought monitoring" or "thought suppression" appears to be *problem-exacerbating* for sexual offenders, both by priming thinking and *increasing* targeted intrusive thoughts (e.g., rebound thinking). Per Mann and Marshall (2010) and Marshall et al. (2009), recommendations are to target schema-related beliefs and offense-supportive attitudes as filters on processing confirming and disconfirming evidence about potential victims. However, generally, there is little evidence that schema change actually occurs as a result of cognitive therapy and that only minor cognitive changes typically follow "experimental" behavioral changes that result in disconfirming "evidence." Longmore and Worrell's (2007) review of CBT generally reported: "…these findings reveal a worrying lack of empirical support for some of the fundamental tenets of CBT. There is a paucity of evidence that cognitive interventions forming the core procedural aspects of CBT are differentially effective in reducing distress. Further, there is a lack of evidence that their effectiveness, such as it is, is mediated cognitively…" (p. 185). If cognitive therapy does not provide the mechanism of change for depressed or anxious clients, is it reasonable to expect it to serve as a powerful means of reshaping sexual offender's offense-supportive attitudes and self- and other schema? Clearly, there is no meaningful data on the actual change in sexual offender's information processing, cognitive distortions (automatic thoughts), or (meta) cognitive schemas as a result of treatment (e.g., in a controlled manner), whether such changes are enduring and in what manner they are related to sexual offense recidivism.

A related issue concerns victim empathy (VE); most sex offender treatment programs emphasize the significance of offenders either gaining or, at least, learning about VE. Mann and Marshall (2009) review various studies and concerns regarding VE. They note that empathy has a number of components and is a multidimensional construct. Further, they point to a lack of research support (including the Hanson meta-analyses) that sexual offenders, as a group, actually lack empathy. Finally, they also noted that offenders often indicate that they possess empathy for others in general but not for their specific victims. However, they also indicate that anecdotally both clinicians and offenders often report that empathy interventions can be a critical aspect of sex offender treatment. Mann and Marshall recommend that "Empathy work should…be a very specific, targeted activity for each offender…" (p. 333). Brown, Harkins, and Beech (2012) noted that research linking empathy to sexual offending and/or to treatment outcome has produced mixed findings. In their study, they found that victim-specific empathy improved from pretreatment to posttreatment and related to overall treatment change. A small group of offenders, whose victim empathy scores deteriorated from pretreatment to posttreatment, had higher rates of sexual recidivism compared with the rest of the sample. However, Brown et al. found that generally there was no reliable pretreatment to posttreatment changes noted on general empathy scores nor was any relationship found to sexual recidivism. This study found limited sexual offense recidivism, so it is unclear what self-reported victim-specific empathy score change scores have to sexual offense recidivism. Generally, it is unclear as to whether empathy-target interventions are actually related to self-reported empathy scores or that the various forms of general or victim empathy, as measured to date, show little or no relationship to sex offender recidivism.

RP is directly premised on the notion that high-risk situations and/or negative emotional experiences/stresses trigger sexual reoffending. Both independently and in conjunction with RP, it has been theorized that sexual offending might be a coping strategy for experiencing the range of negative affect or that sexual arousal might be related to such affect such that sexual offending represented a means of coping with experienced distress (e.g., Cortoni & Marshall, 2001; Serran & Marshall, 2006). Coping strategies of various types have been utilized in sex offender treatment as a means of providing skills in managing negative affect. However, McCoy and Fremouw (2010) reviewed the evidence for an association between negative affect and aspects of sexual offending and found that the available studies do not support such relationships (in part due to methodological limitations). Both

approach pathways of the SR model are predicated on offenders pursuing sexual offenses with purpose and, in many cases, anticipation of pleasure and sexual gratification (e.g., Yates & Kingston, 2006). Serran and Marshall (2006) reported: "… research remains unclear as to the processes that move offenders from affect states and poor coping to abusive acts" (p. 121). In a related manner, Nezu, Dudek, Peacock, and Stoll (2005) found that social problem-solving skills were unrelated to sexual offending, at least among offenders identified as child molesters There are few or no direct tests that coping or problem-solving skills of sexual offenders change as a result of sex offender treatment or that related changes are associated with sexual offense recidivism. Again, no direct tests of sex offender treatment approaches involving coping strategies or problem-solving skills relative to other approaches or control conditions have been conducted, let alone any other controlled investigations. Thus, it is unknown if encouraging the development of coping skills is advantageous or even meaningfully adopted by sexual offenders. More generally, a meta-analysis of problem-solving therapy showed that such interventions were relatively effective for various mental health problems compared to placebo but demonstrated no specific effectiveness relative to other bona fide treatments; in addition, it was unclear if such interventions lead to solving more real-life problems over time (Malouff, Thorsteinsson, & Schutte, 2007), suggesting that such interventions have generic effects and lack ecologically valid results.

As noted, at one point in time, RP was considered the most significant advance in the field of sex offender treatment. RP typically involves the identification of "high-risk conditions" (e.g., situations, feelings, expectancies) presumed to be associated with a reoccurrence of a particular problem behavior and the specific challenges for a specific individual relative to refraining from the behavior; individuals are subsequently taught a range of coping strategies specific to their sexual offending history to decrease the probability of "relapsing by attempting to commit another sexual offense." RP, by nature, should be a largely idiographic process directed by a careful case-formulation of a particular sexual offender's available history of prior sexual offenses. However, RP per se was never systematically scientifically investigated as a stand-alone or even as an added component for a sex offender treatment program. The emphasis or inclusion of RP in sex offender treatment has been criticized on a number of grounds and by various authorities. Ward, Hudson, and Siegert (1995) first criticized the redefinition of a lapse, and incorporating the issues of the "problem of immediate gratification" into the RP model created theoretical confusion and was not supported by then existing research. Ten years later, Wheeler, George, and Marlatt (2006) argued that the modifications of formulations and application of RP "have generally failed to characterize sexual offense relapse cycles accurately and comprehensively" (p. 233), noting that in particular the modifications failed to specify the nature of the abstinence violation effect's occurrence and influence in the offense cycle. They pointed out that available data collected from sexual offenders "indicate that the current model of RP for sexual offenders is indeed incomplete if not inaccurate" (p. 245).

Irvin, Bowers, Dunn, and Wang (1999) conducted a MA of RP, almost all of which dealt with substance abuse. Their results indicated treatment effects were strong and reliable for alcohol and drug abuse (but not smoking), particularly as measured by participants' self-report. Of note, RP appeared to have more impact on improving psychosocial function than actually reducing substance/alcohol use. In addition, their measured effectiveness was greatest at the end of intervention and weaker at more distal points following intervention. More specifically, the explicit RP treatment and aftercare program of SOTEP can be viewed as strong evidence that RP may not be an effective element in sex offender treatment. Marshall et al. (2011) stated, "[The] rejections of RP now seem justified given the clear failure of a well-designed evaluation of a model RP program" (p. 11), referring to SOTEP. [Per the most recent Cochrane Reviews, a similar finding was reported regarding the treatment of bulimia nervosa and related eating disorders as well (e.g., Hay et al., 2009).]

Marshall et al. (2009) have argued that the weakness of RP interventions is that offenders are required to generate potentially long "lists" of avoidance plans at the expense of expanding their behavioral repertoire to "fulfilling" or "enjoyable" behavior. Marshall et al. suggested that RP is essentially an avoidance model (offenders are taught to avoid stimulating situations that might provoke or elicit sexual reoffending) and CBT is largely framed as a deficit model where missing cognitive and behavioral skills are introduced and practiced as a means of addressing presenting problem behaviors (e.g., Marshall et al., 2003, 2011). He and his collaborators have suggested that sexual offenders are more likely to actively participate in sex offender treatment when provided approach goals as opposed to avoidance goals. They pointed to a study by Mann, Webster, Schofield, and Marshall (2004) where two groups of offenders were compared: those treated in programs that emphasized the RP (avoidance plans) approach and those who were focused on generating individualized approach goals. This latter group was seen as more engaged and open in treatment, as well as more motivated to avoid reoffending. Intuitively, the notion of offering primarily or exclusively "approach" goals is appealing, from the perspective of both clinicians and sexual offender clients. However, given the available evidence about the presentation of denial/minimization and general lack of motivation for self-change and sex offender treatment among sexual offenders, a basic but unanswered question is

to what degree sexual offenders generally are interested in approaching some goals and what those might be (beyond liberty). An additional question would be, assuming that approach goals were developed and through some psychological means and methods secured, to what degree would it make a significant difference to sexual offender recidivism and broader prosocial change. There is evidence that offenders prefer treatment that affects an orientation toward the GLM but no evidence that a GLM orientation toward treatment results in different outcomes for offenders exposed to it as opposed to CBT "as usual." Thus, Barnett et al. (2014) compared GLM to a traditional RP program in the community. While offenders appeared to prefer the GLM model, "There were no differences in the amount of change over treatment or…clinically significant change" (p. 1). Harkins, Flak, Beech, and Woodhams (2012) had reported similar findings. To date, there is no demonstrated scientific evidence demonstrating that any of the more novel treatment approaches "work" in terms of reducing sexual offense recidivism and offer evidenced benefit for either the sexual offender or society.

In short, when commonly identified components of a comprehensive sexual offender treatment program are considered, a review of the available scientific literature provides little support for the likely efficacy of these specific components to impact presumed treatment targets. Thus, little empirical evidence of the general or sexual offender-specific effectiveness of offense disclosure, modification of deviant sexual arousal, social skills training, changes in cognitions, affective training (e.g., victim empathy), and relapse prevention can be found in the available research literature regarding psychosocial interventions.

Further, as Hoberman (2015b) noted in his review of treatment efficacy of sex offender treatment, published scientific studies to date have almost never shown that posttreatment scores or change scores in most measures of treatment targets are associated with a decrease in sexual offense recidivism. In the general psychotherapy literature, specific components or programs of intervention appear to have similar results for treatment outcome (e.g., Lambert & Ogles, 2004; Wampold, 2001); however, they have similar positive results, particularly in modifying affective states. Wampold (2001) has repeatedly called attention to the common elements of psychotherapy as associated with positive changes in outcome measures for most persons who choose to enter such interventions. As Lambert and Archer (2006) concluded: "Psychotherapy can be efficient, especially for patients who are not severely disturbed" (p. 126). In contrast, no specific or nonspecific component of sex offender treatment has been established to have a demonstrable effect on personal change or reducing sexual offense recidivism. Rice and Harris (2003, 2012) noted available data regarding the nature of sexual offender treatment has shown little or no detectable specific effect on outcome. Similarly, Marshall et al. (2011) noted that "…there is presently a dearth of studies showing that specific treatment procedures aimed at modifying criminogenic features…actually achieve the sought-after goals… There is, then, an urgent need for more thorough detailed evaluations of the effectiveness of treatment to change specific criminogenic features across most clients and to determine which of these changes is essential to reduce future reoffending" (p. 45). Further, most sex offender treatments emphasize skills education and skills training. However, without considering motivational and other responsivity issues, there appears to be no empirical data regarding the length of time that is necessary for offenders to actually learn and understand those skills and practice those skills to proficiency within a therapy situation, let alone to consistently generalize such skills outside the therapy or classroom. As Marques et al. (2000) indicated:

> It is easy to write down 'I would recognize and defeat that cognitive distortion by telling myself it is wrong to think about a child that way.' It does not follow, however, that the individual could do that quickly and effectively in a high-risk situation. There was a strong consensus among SOTEP clinicians that more actual practice of identified coping skills was needed. (p. 327)

Finally, Marshall et al. (2009) stated "…it is…irresponsible to continue with irrelevant goals or involve counterproductive approaches…" (p. 342).

Are Treatment Targets Accurate or Understood in Sexual Offender Treatment?

A significant reason that treatment components (and their package into sexual offender treatment programs) may not be particularly successful with sexual offenders might be that they do not meaningfully address those factors that either "cause" and/or maintain sexual offending. That is, current sexual offender treatment targets may not appropriately or adequately represent those conditions that are the basis for sexual offending. Hanson and Harris (2000) wrote: "When the specific goal is to prevent sexual offense recidivism there is almost no empirical foundation for identifying treatment targets or determining whether interventions have been successful…" (p. 6). Treatment targets must be identifiable and mutable—they must be subject to potential change via one or more specific interventions or manageable within particular contexts. Typically, treatment targets are hypothesized to be related to causal risk factors (e.g., Elwood, 2009; Kraemer et al., 1997); they must not just be associated or correlated with an outcome such as sexual offending but precede the event, show some significant strength of a connection, and, typically, exist on a gradient where the greater the presence of the risk factor, the more likely the outcome of interest (e.g., sexual offending). Hypothesized risk factors can be

identified on a theoretical basis and on an empirical basis. Regarding the latter, effectively, no prospective studies have been conducted to examine psychosocial and other characteristics that might be related to the onset of sexual offending. However, at least three meta-analyses of empirically identified risk factors for sexual reoffending have been conducted (Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2005; Mann et al., 2010). Of note, no specific risk factor has been demonstrated to correlate more than approximately .30 with sexual reoffending, suggesting that such variables do not account for more than 9 % of the total variance in their association with sexual offender recidivism. The so-called dynamic duo—deviant sexual interests and antisocial history/status—are the two primary psychosocial clusters predictive of sexual offense recidivism, apparently with both of those dimensions representing "motivators" toward sexual offending and the latter also representing varied dimensions of disinhibition (e.g., Hoberman, 2015a). However, based on available empirical evidence, even those persons identified as high on both of those dimensions are not necessarily detected for future sexual offending.

The finding that risk factors consistently identified via scientific study do not show an expected strength of association (either individually or in combination) may have its roots in several things. First, while an extensive history of theories about sexual offending exists (e.g., Ward et al., 2006 for a review of such theories), to date, no empirical evidence has been collected to validate one or more specific theories. Consequently, the field of sexual offending is currently based on and working with unvalidated theories. There has been a progressive movement to broader and more comprehensive theories of sexual offending to best capture the heterogeneity of sexual offenders. Ward and Beech (2006) identified genetic determinants and neurobiological functioning, in interaction with environmental contexts, as leading to three compromised systems of neuropsychological functioning: motivational emotional, action selection and control, and perception and memory. When dysfunctional, these systems of neuropsychological functioning are viewed as manifesting themselves as "clinical states" or exemplars (e.g., Ward & Beech, 2015). Somewhat similarly, Mann et al. (2010) used the term "psychologically meaningful risk factors" (PMRF) to refer to individual's *propensities* that become manifest in particular situations or contexts, such that risk factors for sexual offending may only become observable when and after a potential sexual offender encounters particular environments/situations and triggering cues. *If* the offender with underlying PMRF—underlying causal predispositions or propensities—encounters particular stimuli, *then* sexual offending may be more likely to occur.

In their most recent publication, Ward and Beech (2015) criticized Mann et al. and the larger domain of dynamic risk factors (e.g., presumably changeable ones; see Hoberman, 2015). They made the distinction between the descriptive aspect of identifying the so-called dynamic risk factors and the explanatory or etiological aspect of causal risk factors. Ward and Beech argued that such examples or exemplars do not necessarily provide a clear *explanatory* model that delineates sets of interactions among the key psychological, social, and biological constructs and the common trajectories of such constructs and problem clusters. They stressed the importance of an etiological model, which provides "guidance concerning how the causal aspects of dynamic risk factors interact to actually generate observed clinical features and subsequent sexual offending…" (p. 10). Ward and Beech raised concerns that, in effect, lists of identified correlates or even prospective risk factors do not, in and of themselves, provide causal explanations of the diversity of sexual offending. They stated:

> In summary, we have argued that in the current state of research dynamic risk factors are really hybrid concepts containing "symptom" or phenomena aspects and etiological aspects. In our view, the conflation of the descriptive and explanatory elements within a single concept is confusing and runs the danger of derailing research and practice into dead ends. We have argued that viewing the descriptive aspects of dynamic risk factors as attributes of an exemplar(s) and introducing a separate explanatory phase of research that concentrates on developing causal explanations of the exemplar and its associated phenomena and course are ways forward. (p. 12)

Thus, Ward and Beech recommend that beyond just identifying clinical phenomena that are effects of presumed causal processes (e.g., risk proclivities), it is necessary to *explain* the occurrence of such phenomena (e.g., clinical attributes) and their interrelationships for sexual offending for an individual and/or subgroups of sexual offenders. In short, Ward and Beech caution against assuming that presumed risk factors may be only descriptive and not necessarily explanatory relative to the underlying processes that lead to sexual offending. Thus, one potential issue is that the putative risk factors for sexual offending are inadequately conceptualized or operationalized despite the empirical association identified by the meta-analyses.

Another related issue concerning potential targets for sexual offender treatment interventions has to do with, in effect, measurement issues. Available methods of quantifying risk factor do not "capture" its presence or the degree of it presence. For example, while deviant sexual interest may be inferred from behavior or identified by self-report by an offender, some or many sexual offenders may not choose to share the range and degree of atypical sexual interests for various reasons, including social desirability. No consistently reliable and valid means exists to determine the actual nature of an individual's potentially diverse sexual thoughts, fantasies, or urges. Similarly, likely antisocial attitudes may

be problematic to accurately assess because such cognitive-affective characteristics are not easily measured, particularly by self-report; persons who are not psychologically minded or for whom those attitudes are ego-syntonic may not be likely to endorse such attitudes or social desirability may affect accurate self-disclosure. Similar factors may compromise the ability or willingness of individuals to identify dysfunctional or deficient problem-solving, emotional-management capacities, or the multiple social schema that impact their ability or willingness to engage in more intimate social relationships. More broadly, if, as Mann et al. (2010) have suggested, psychologically meaningful risk factors are enduring propensities that are "activated" by particular stimuli or contexts, then individuals may manifest decreased awareness of those propensities or fail to perceive the contextual nature of their own predispositions. Finally, it is worth emphasizing that the findings that certain psychosocial conditions have not, to date, been empirically identified as risk or causal factors for sexual offending may not mean that such conditions do not matter relative to sexual offending. Rather, they or their functional elements may simply be difficult to measure by observation and/or reliant upon accurate self-report by individuals, who for various reasons are unable or unwilling to identify the presence or degree to which they are characterized by conditions.

A final consideration for treatment targets for reducing sexual recidivism regarding has to do with presumed "malleability" of so-called dynamic risk factors, conditions believed to be causal risk factor that are capable of change or modification. If, in fact, some, many, or most causal risk factors are not capable of being modified or are limited in the degree to which they might be affected via psychological or social means, then psychotherapies as interventions will be largely ineffective if behavioral change is the criteria by which they are evaluated. Certainly, the literature reviewed regarding the limited change in persons with personality disorders as a result of psychotherapy and the various failed attempts to modify sexual orientation raise serious questions about the degree to which key aspects of persons are subject to. [By analogy, even surgical procedures or medications (e.g., castration, antiandrogens) do not consistently reduce sexual interest and/or preoccupation.] To date, there is minimal empirical evidence that intraindividual (as opposed to group) characteristics change as a result of change. As Hoberman (2015b) reviewed, with few exceptions (e.g., Beggs & Grace, 2010; Olver, Beggs Christofferson, Grace, & Wong, 2013), most studies have found that pretreatment scores and ratings—and not posttreatment or change scores—are most strongly associated with sexual offender recidivism. Such general findings raise significant questions as to whether offenders do change as a result of sexual offender treatment or simply report or appear as if they have changed to therapists and observers.

Summary and Conclusion

In almost all respects, it is not particularly surprising that no scientific evidence yet exists that moderate- to high-risk sexual offenders may benefit from psychotherapeutic interventions. Generally, psychotherapies as a group appear most efficacious for presenting problems involving personal distress, and there is minimal evidence that specific types, models, or "strategies" of psychotherapy affect the likelihood of general outcome for such problems. While most types of psychosocial interventions are beneficial for some conditions such as general anxiety or depression, their improvements are relative (e.g., varying reductions in experienced distress, quality of life, and "life problems"). In contrast, empirical studies of psychotherapies to date show that they are much less efficacious for a variety of more severe conditions, including "behavioral" problems, maladaptive personality traits/personality disorders, and persons with comorbid psychopathology. To be sure, for many persons, their involvement in psychotherapy may be perceived as a useful and even valued experience, but actual behavior changes typically appear slow, incomplete, and not necessarily persistent over time. As noted earlier, Lambert (2013) summarized the extant research and concluded that improvement from psychotherapy is a function of the following four factors to the indicated degree: client/life situation (40 %), common factors (30 %), client expectancy (15 %), and (specific) techniques (15 %). From that perspective, it seems evident that psychosocial sexual offender treatments might not be particularly effective in affecting either personal change or sexual offender recidivism rates for the majority of the very heterogeneous set of persons who are identified as sexual offenders.

Given the identified importance of client variables relative to outcome from psychotherapy in general, based on the knowledge of empirically identified risk factors, there are many aspects of sexual offenders that would also likely impact on their potential response to psychotherapy, certainly relative to "typical" psychotherapy clients or even nonsexual offending clients with personality disorders, substance abuse, or general criminality. Further, sexual offenders are clearly a very heterogeneous group, with a number characterized by multiple and cumulative well-entrenched and persisting predisposing conditions including paraphilias and personality disorders as well as varied and multiple motivational issues and deficits in disinhibition. Little evidence of any sort indicates that fundamental sexual interests (perhaps largely akin to sexual orientations) and robust biologically influenced personality dimensions (that are effectively self-perpetuating) can be modified via psychosocial experiences, even targeted ones via such treatments. As a group, sexual offenders are characterized by a large, varied set of potentially cumulative, interacting, and persisting

criminogenic needs or psychologically meaningful risk factors. A subset of sexual offenders clearly appear to be "high risk," in that they are characterized by a much higher density and degree of criminogenic needs or risk factors. Several different pathways to sexual offending may also characterize sexual offending. Some limited evidence that psychosocial interventions (particularly forms of CBT) appear to "work" with general criminal offenders relative to reducing general criminal recidivism at least a small degree over brief follow-up periods and this does not appear to be the case for sexual offenders (as a somewhat "more specialized" group of criminal offenders) over longer follow-up periods, it seems quite reasonable to consider that the group of persons who engage in repeated sexual offending are significantly different from general criminals and likely in multiple ways that have yet to be identified, let alone understood.

In addition, prior to even entering sex offender treatment, the available evidence indicates that sexual offenders are largely characterized by a striking lack of motivation to seek or pursue psychotherapy, either before or after they have enacted sexual offenses. Various aspects of their overall psychological status and their predisposing conditions may well be ego-syntonic, and the same or other factors may limit and interfere with their ability or capacity to recognize that they have engaged in behavior that was harmful to others. Thus, significant dispositional reasons exist as to why they may not seek psychotherapy, such as lack of psychological mindedness, empathic deficits, and/or a resistance to authority or "assistance." Nonetheless, despite an apparent lack of identifiable or apparently genuine motivation for psychosocial treatment, a significant number of sexual offenders are mandated or effectively coerced by the criminal justice system to enter sex offender treatment programs (e.g., the best predictor of why a sexual offender is recommended for or placed in sex offender treatment). Such mandates are thus being imposed on a significant portion of sexual offenders who are unmotivated for treatment generally and/or are somewhat or extremely antisocial; not uncommonly, some of these offenders have pronounced or long-standing issues with authority, which might likely include such mandated psychotherapy. Thus, various client characteristics are likely to be ones that have a significant potential to limit or eliminate the potential effectiveness of sex offender treatment.

Relative to the issue of motivation and desire for personal change, recently there has been an increased emphasis on treatment preparation and motivational interview interventions for sexual offenders in various settings as a means to address potential resistance of sexual offenders to self-change (e.g., Marshall & Marshall, 2007; Prescott, 2009, 2011). Intuitively, such therapeutic activities make sense, particularly given the client characteristics of this population, and they appear to have great appeal to forensic clinicians working with such offenders. Motivational interviewing (MI) has been described as blending relationship building and a client's stage of change. Per Burke, Arkowitz, and Menchola (2003), therapists are careful not to explicitly advocate for change, resistance is viewed as an interpersonal phenomenon, and therapists are advised not to challenge the client's resistance directly. A client's readiness to change is viewed as related to the importance of change for the client and the confidence of the client about successfully making personal changes. In a MA, Burke et al. (2003) showed that MI was quite effective in general, when the prototypical MI component consisted of approximately 100 minutes of that intervention technique over two sessions. As with other therapeutic strategies, significant allegiance effects were found, with effects 2–3 times larger produced in the developer of MI's own clinical studies. In addition, MI was more effective in diet and exercise studies (e.g., self-desired or health-promoting domains) than in the treatment of clients with alcohol and drug problems (e.g., more behavioral and personally hedonic domains). However, the MA indicated that the studies were of weak methodological quality, with few attempts to identify alternative explanations for differential results. Per Burke et al., "…there is little evidence to suggest that AMIs actually work by enhancing motivation or readiness for change…[and] did not appear to differentially increase readiness for change in comparison to alternative interventions or controls" (p. 859). More recently, Lundahl, Kunz, Brownell, Tollefson, and Burke (2010) conducted another MA of MI; they found that judged against weak comparison groups, MI produced statistically significant durable results in the small-effect range but judged against specific treatments produced nonsignificant results. These results were found for alcohol and drug abuse. Despite these findings, Lundahl et al. concluded that MI is able to promote healthy behavioral change across various problem areas but is more potent in some situations compared to others and does not work in all cases. They also opined that MI did increase client's engagement in treatment and their intention to change although the basis for that conclusion was unclear. Thus, there is mixed evidence regarding the scientific evidence of MI, but results suggest positive effects for some individuals with some types of presenting problems. To date, there are no RCTs involving either weak or strong comparison groups so the empirical evidence for MI (or other treatment readiness interventions) remains unknown. Consequently, while such interventions offer hope or the possibility of enhanced sex offender treatment results, one cannot conclude that they do.

Therapist or common factors' characteristics are the second most significant category relative to outcome for general psychosocial interventions. It appears that the same types of so-called common factors associated with positive therapist behavior matter in the treatment of sexual offenders in some similar ways as they do to general psychotherapy

clients. As Marshall et al. (2011) reported on their own earlier research: "The four most important therapist features to emerge were warmth, empathy, rewardingness and directiveness" (p. 74). Marshall and colleagues also noted that other studies for that for sexual offender "Effective therapists were those who were seen to be honest and respectful, caring, noncritical and nonjudgmental" (p. 74). More broadly, Skeem et al. (2009) reviewed literature on both general and "high-risk" criminal offenders and suggested that therapist behaviors predictive of positive outcome included enthusiasm, warmth, respectfulness, defining clear rules, exerting authority without being authoritarian, fairness, and structuring learning into concrete, guided steps. Certainly, some, perhaps many, therapists who provide psychotherapy for sexual offenders treatment are characterized by such positive clinical styles. However, given the general literature on therapist characteristics and the more specific state of sexual offender treatment, it may also be that a number of clinicians who provide psychotherapy for sexual offenders may be characterized by inflated beliefs about their own competence, relatively untrained in the scientific evidence regarding sexual offenders (or misguided by the lack of detailed, comprehensive models of sexual offending), significantly uninformed about the absence of scientific information about the efficacy of sex offender treatment, relatively inexperienced as clinicians, and inadequately supervised. Conversely, one wonders as to the degree to which sex offender treatment psychotherapists believe or expect that their efforts are likely to impact their offender clients; as forensic clinicians, they are placed in an awkward position relative to "helping" their clients relative to socially and legally defined goals such as reduced sexual offense recidivism. However, it seems particularly notable that a number of studies have found that therapist's judgment of their sexual offenders' treatment progress is unrelated to sexual reoffending or, in fact, their judgment of positive progress is actually predictive of higher rates of sexual offense recidivism (e.g., Quinsey, Khanna, & Malcolm, 1998; Seto & Barbaree, 1999). This may be simply a de facto practitioners' "allegiance" effect, but it may also suggest that many sex offender treatment providers misperceive their clients' status while in treatment and consequently do not intervene adequately relative to the information provided by an offender, their stated insight or "knowledge" of treatment issues, and/or their enactment of therapeutic skills. As a result, perhaps some sexual offenders leave sexual offender treatment with a false confidence that they have internalized new beliefs and have actually acquired the capacity for behavioral change in the community. As Marshall et al. (2011) point out, therapists' perceptions of themselves do not always match the way that they are viewed by their clients; it seems likely that therapists' perceptions of themselves do not always match the way that they are viewed by others (e.g., supervisors or external evaluators) as well. In any case, as with other presenting problems and/or treatment modalities, a necessary step at this point is to study the various preliminary findings (e.g., both favorable and unfavorable) in a controlled manner (e.g., via RCT) and by various investigators to control for potential allegiance effects.

Further, relative to the current failure to demonstrate effectiveness of sexual offender treatment, there may be significant issues in the common delivery of sexual offender treatment. Aspects of clinical services such as the duration, intensity, treatment integrity, feedback to clinicians, and other qualitative aspects of therapy may also impact the lack of apparent outcome in psychosocial interventions for sexual offenders. As Skeem et al. (2009) noted, the quality of psychosocial treatment (indexed by features such as provider training, implementation of more careful monitoring and supervision of clinicians, and provision of treatment in research context) was strongly associated with lower recidivism rates. They concluded that program quality and integrity related substantially to program effectiveness and that the vast majority of correctional programs lack such qualities and procedures. Thus, once models or theories of sex offender treatment are empirically demonstrated, particular therapists with a commitment to evidence-based procedures, well-trained, carefully supervised, and provided ongoing feedback, appear most likely to be effective at delivering such programs. It should be remembered that there are ongoing issues and no empirical evidence about the specific manner in which sex offender treatment is provided to offenders: in groups as opposed to individual therapy, via psychoeducational methods or other manualized programs, without regular checks and feedback about treatment integrity or fidelity, and/or the appropriate dose of psychotherapy necessary for moderate- to high-risk sexual offenders.

Perhaps most importantly, there is little evidence that the particular intervention components or elements common to sex offender treatment programs at the present time have been demonstrated to be effective in either personal change (generally or with sexual offenders) or decreasing sex offender recidivism. This is a striking finding. While specificity of treatment methods has been demonstrated to carry a smaller load of the variance than expected in general psychotherapy for various presenting problems, nonetheless it contributes something, and as an "implementation" of psychotherapy, all methods seem to have demonstrated effectiveness for a great variety of emotional and even some behavioral disorders. However, the various elements of sex offender treatment have failed to demonstrate effectiveness for sexual offenders at all, either separately or as part of comprehensive packages of interventions. It is quite likely that this failure of efficacy of specific intervention strategies interacts with more delivery issues and/or with therapist effects, but it also may have even more to do with the 40 % of treatment variance that is associated with client variables, in this case the particular nature of many or most sexual offenders.

Finally, from both a theoretical and empirical perspective, it remains unclear as to what risk factors and what interactions among risk factors are related to the onset and maintenance of sexual offending. The field of sexual offending continues to lack a well-developed understanding of how sexual offenses come to occur and why particular individuals commit such offenses at particular times. Further, given what is currently understood, significant uncertainty exists as to if and how putative risk factors and processes can be changed.

It is striking that so many practitioners in the sexual offense treatment field zealously persist in continuing to provide psychosocial interventions that lack empirical demonstration of effectiveness for either meaningful personal change or sexual offense recidivism. Clearly, for many clinicians in the sexual offender treatment field, there appears to be a strong commitment to the hope or wish that their offender clients will be changed by their practices. Since there is no or little existing empirical evidence that this is true, it appears to be a form of cognitive dissonance and confirmation bias; to feel efficacious and meaningful in their work, clinicians ignore data (or the lack of data) that otherwise would threaten their sense of purpose and seek out. Moreover, rather than confront the apparent ineffectiveness of current treatment programs, many sexual offender treatment clinicians attend to the writings, mostly theoretical, that propose novel, albeit still untested approaches to treatment. As Rice and Harris (2012) stated:

> Over the past sixty years, the field of sexual offender intervention exhibits change where there should be stability—instead of a well-established foundation of effective therapeutic techniques, particular treatments go in and out of fashion in the absence of acceptable evidence as to efficacy. And the field exhibits stasis where progress should have occurred… Hypotheses, suggestions, and advice aside, essentially nothing is known (in the sense of empirically verified) about which therapeutic or supervisory techniques are effective for which targets in which types of sexual offenders. (p. 23)

However, sex offender treatment clinicians, as other psychotherapists working with particular types of presenting problems, must soon, even rapidly, come to terms with the implications of the lack of scientific evidence for current psychosocial interventions for their clients. Within the mental health field generally, sex offender treatment is typically left out of handbooks on psychological treatments for specific disorders and does not appear on any list of evidence-practice guidelines. While it is encouraging that new models of treatment and potentially useful clinical strategies continue to be developed and enthusiastically embraced by practicing sexual offender treatment clinicians, these methods remain scientifically untested in terms of their efficacy and may achieve the same limited results of older treatment approaches. The persistence in empirically unfounded interventions stands in stark contrast to the area of risk assessment where most practitioners in the sex offender treatment field have readily adopted more empirically based actuarial approaches and rejected unstructured clinical judgment based on scientific evidence. In the sex offender treatment field, clinicians appear to continue to rely on elements of programming that individually and collectively have demonstrated little relationship to the goal of reducing sex offender recidivism or more general personal change. In fact as multiple authorities have pointed out, there is little evidence that most of what constitutes "the content" of sex offender treatment programming appears related to reducing risk for sexual reoffending: victim empathy, social skills training, emotional regulation, techniques to reduce deviant sexual arousal, modifying cognitive distortions, and/or relapse prevention have not been individually or collectively demonstrated to reduce sex offender recidivism, let alone produce persisting change in offenders. The relative value of approach goals versus avoidance goals or remediation of any skills deficits has not been shown to be effective components of sex offender treatment relative to substantive personal change or reduced sexual reoffending.

Given the apparent dark portrait of the lack of efficacy of sex offender treatment and the multiple factors which are likely active in that failure, the sex offender treatment field should be regarded as wide open to increased attempts to think critically and creatively about theories of sexual offending and what methods and elements of psychotherapies might meaningfully impact sexual offender's personal change and/or lead to reduced sex offender recidivism. Anecdotally, DBT has been incorporated in various ways into many sexual offender treatment programs, albeit typically not following the specific model proposed by Linehan, Armstrong, Suarez, Allmon, and Heard (1991); however, no RCTs (let alone uncontrolled studies) have been conducted of its potential value to outcomes such as reducing sexual offender recidivism. One can view the GLM, Marshall's strength-based approach, and 3RT (examples of more contemporary treatment models for sexual offenders) as potentially inspiring models or programs that their proponents have the opportunity to demonstrate that they can make a fundamental difference in the role that psychotherapy can play as part of a large program of sexual offender management. Similarly, motivational interviewing (Prescott, 2009, 2011) and/or other treatment preparatory programs (e.g., Marshall & Marshall, 2009) might well lead to sexual offenders more motivated to enter and engage in meaningful psychotherapy; before such innovations become standard practice, however, they must be demonstrated to have some significant relationship to desired outcomes with sexual offenders.

Further, it may be time to apply approaches that have demonstrated some efficacy with significant and severe

problems number of recent RCTs have demonstrated successful outcomes with clients with more severe presenting problems; for borderline personality disorder, schema-focused therapy has been shown to be effective over a 3-year period of (Bamelis, Evers, Spinhoven, & Arntz, 2014; Giesen-Bloo et al., 2006), while several meta-analyses of psychodynamic psychotherapy have shown short- and long-term effectiveness more generally in the treatment of personality disorders and other complex mental disorders (e.g., Leichsenring & Rabung, 2011; Shedler, 2010). Other interventions that might have applicability are ones such as modified dynamic group therapy (e.g., Khantzian et al., 1990, 1992) and schema therapy for aggressive offenders with personality disorders (Keulen-de Vos, Bernstein, & Arntz, 2014). In addition, as Hoberman (2015b) suggested, it makes sense to develop, incorporate, and assess interventions that target particular sexually criminogenic dimensions, mechanisms, or predisposing conditions than specific "mental disorders" or the problem of "sexual offending" and to provide more individualized, but comprehensive, treatment for sexual offenders with multiple predisposing conditions and comorbid issues and problems.

Given the relative social importance of containing identified sexual offenders from committing more offenses (and to a lesser degree providing some means for offenders to engage in substantive change from a particular criminal lifestyle), it will be essential for both the individual elements and the programs based on the identified treatment models as well as any yet identified models to be subjected to rigorous scientific evaluation through RCTs and other contemporary procedures to gauge effective treatment outcome. As Marshall et al. (2009) indicated, it is "inadvisable to introduce new procedures on the basis of untested theory…" (p. 342). Given the length of time already passed without strong evidence of successful psychotherapeutic treatment of sexual offenders and the degree of concern about the occurrence and consequences of sexual offending, the field of sexual offender treatment has little room to fail in persuading society that it has something of value to offer as part of sexual offender management policy. To the degree that little evidence exists that psychosocial treatments have yet been demonstrated to be effective interventions for personal change and reducing sexual offense recidivism for the typical sexual offender, some shift in public policy should occur. While psychosocial treatment efforts may affect change on particular individuals, until clear efficacy of such approaches is demonstrated for sexual offenders in general and high-risk/high-need sexual offenders, it may be appropriate to shift reliance on alternative aspects of containment. To this end, an increased emphasis on comprehensive risk assessment, intensive supervision, variations in detention dispositions, and primary prevention may be the necessary means to reduce sexual reoffending.

The Containment Approach: A Strategy for the Community Management of Sex Offenders

Kim English, Peggy Heil, and Greig Veeder

Introduction

We begin this chapter with a reminder that all research related to sex offenders suffers from what criminologists point to as "the dark figure" of crime (Sellin & Wolfgang, 1964). The dark figure refers to crimes that are never discovered or reported. While this measurement problem affects research on all types of crime, it especially haunts research on sex offenders because these are the least likely crimes to be discovered or reported. For this reason, it complicates the management of sex offenders. Lack of information about past and current sexually abusive behavior can leave professionals at a considerable disadvantage, operating without the knowledge required to make the most effective case management decisions. The hidden nature of these crimes can mask the risk and treatment needs of individual offenders. Obtaining and sharing knowledge, including information about individual offenders, is among the fundamental reasons that the containment approach emerged in the 1980s, and it is why containment remains an important method for managing sex offenders and protecting victims and potential victims.

Background

The findings from a federally funded, nationally focused research study identified and documented the five-part containment approach for managing adult sex offenders (English, Pullen, & Jones, 1996; English, Pullen, & Jones, 1997; English, 1998, 2004). Small groups of professionals in jurisdictions in Oregon, Washington, Arizona, Minnesota, Wisconsin, Texas, and Colorado were implementing variations of the containment approach described here. The efforts involved therapists, probation and parole officers, judges, victims' advocates and therapists, child services workers, defense and prosecuting attorneys, and law enforcement. These collaborations created a multidisciplinary, cross-agency perspective that focused on the protection of victims and the humane treatment of offenders. Motivated by the secret nature of the offense and the considerable harm done by the crime, professionals were working together to identify and reform official agency practices and policies that created barriers to the safe management of known sex offenders.

It seems difficult to imagine today, but in the 1980s and early 1990s the most consistent problem voiced by professionals was that the criminal justice system managed sex offenders as if they were the same as other offenders (English et al., 1996). Many professionals who were working directly with convicted sex offenders reported that they struggled to convince their fellow professionals—their supervisors, their agency administrators, their colleagues in other agencies, and sometimes their colleagues across the cubical divide—that this population did significant damage to victims even when overt violence was not involved in the crime (see Johnson (2011) for an important discussion of psychological force). These offenders—both violent and nonviolent—operated in secret, were usually manipulative, blamed others, and groomed victims deliberately and skillfully. Safely managing these offenders in the community required special conditions of supervision and surveillance methods.

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_30

It was common in the 1980s and even in the early 1990s for therapists to provide conventional psychotherapy to sex offenders in treatment, reflecting a considerable lack of knowledge of the literature on sex offender treatment. In fact, it was not uncommon for sex offenders in the 1980s to be court-ordered to participate in therapy at the local mental health center where they received counseling on stress management. Often both the offender and the victim were considered to share culpability, even when victims were quite young. Usually convicted offenders were either allowed to continue living with their victims or the victim was placed in foster care while the offender's life was undisrupted.

But many professionals suspected that these crimes were not one-time events. When perpetrators had access to family members, they often abused them for years before getting arrested. Those who continued to have access to their victims frequently abused them again while they were under correctional supervision. Those who were arrested for new sex crimes while under correctional supervision were often sent to prison on technical violations without incurring a new sex crime conviction, thus distorting recidivism statistics.

The containment approach grew out of the frustration of probation and parole officers who were constrained by ineffective policies and procedures resulting from social attitudes that minimized the crime. In the same way that intoxication was once viewed by the court as a mitigating rather than aggravating circumstance, sexual abuse was seen as a family problem or a simple misstep by the perpetrator. Even Prentky and Quinsey's (1988) statement about adult sex offenders was thought to apply only to the few offenders who used overt violence: "This is a distinct correctional population, a group whose crimes involve a dangerous interaction of sex and power" (page).

It was within a social and judicial context of remarkable apathy that the containment approach developed. Professionals from multiple agencies gather ED together in grassroots efforts, educating each other, raising awareness, and seeking to reform existing sex offender supervision and treatment strategies. They needed to change policies, practices, and common attitudes that minimized all but the most violent sex crimes. These early innovators were clear that their common interest was to prevent known sex offenders from harming again. They wanted those who perpetrated sex crimes to be held accountable by the criminal justice system, and to prevent further offenses while being offered every opportunity to change the behaviors that victimized others.

This chapter details the five-part strategy for managing adult sex offenders in the criminal justice system and reviews research that may provide a fresh understanding of containment. The focus of this chapter is #3 below, the use of a variety of containment strategies, particularly the polygraph examination, since it is the most likely aspect of containment to be misunderstood. Despite that focus here, each of the five parts represents a fundamental element of an effective sex offender containment approach. All five must be present and integrated to maximize the effects of risk management efforts by criminal justice professionals and treatment providers. These are the five components of the containment approach first described in English et al. (1996) which are discussed in detail in this chapter:

1. A clearly articulated community safety/victim-oriented mission;
2. The coordinated activity of many well-informed, multidisciplinary, intra- and interagency collaborative teams;
3. The use of a variety of containment strategies;
4. Consistent, informed public policies; and
5. Resources dedicated to state and local quality control efforts.

Component 1: Victim and Public Safety-Centered Philosophy

The Jackson County, Oregon, sex offender management process incorporated the phrase "making the victim whole" (English et al., 1996, pp. 2–7). The sex offender treatment program at the Colorado Department of Corrections has a mission statement that reads "No More Victims." The Colorado Sex Offender Management Board has among its guiding principles these statements: "Community safety is paramount" and "Victims have a right to safety and self-determination." This focus on victim and community safety is intended to confront the apathy, cultural denial, and lack of knowledge of the trauma associated with sexual victimization. It is critical to remain vigilant about this aspect of the containment approach because the purpose of managing sex offenders differently from other offenders is rooted in understanding the prevalence rates and impact of sexual abuse victimization.

Millions of individuals are victims of sexual abuse because many sex offenders commit an untold number of sex crimes: 1 of 6 U.S. women and 1 of 33 U.S. men have been victims of a completed or attempted rape in their lifetime, and many are raped more than once (Tjaden & Thonnes, 2000, using a definition of forced oral, anal, or vaginal penetration). This prevalence rate reflects a high frequency of sexually abusive behavior, much greater than official arrest records would suggest. In fact, Ahlmeyer, Heil, McKee, and English (2000) found a ratio of 100 self-reported contact and noncontact sex crimes for every crime recorded in official records (page). This pattern has held constant since researchers began to actively study prevalence rates. In 1988, Abel, Becker, Cunningham-Rathner, Mittelman, and Rouleau interviewed paraphiliacs under conditions of guaranteed confidentiality and found that only 3.3 % of the paraphiliacs'

self-admitted hands-on sex offenses, such as rape and child molestation, resulted in an arrest. The numbers of victims along with the numbers of offenses are difficult to conceptualize. Even harder is quantifying the effect that this level of abuse has on a society and culture that values personal safety.

Studies have found that the consequences of these crimes can be brutal and long-lasting (see Wyatt & Powell, 1988). Sexual assault victims compared to non-rape victims are at significantly higher risk to abuse alcohol and drugs, to suffer from depression, anxiety, nightmares and social isolation, and to attempt suicide (Kilpatrick, Edmunds, & Seymour, 1992; Peters, 1988; Briere & Runtz, 1988). Because most sexual assaults occur in the context of an established relationship, experts explain that this trust violation causes great confusion and nearly unbearable trauma to the victim (Herman, 1992). Summit (1988) is one of the few to discuss the psychological damage inherent not only in rape but in touching: "Sexual touching, so often trivialized by words such as fondling or molestation (annoyance), is only the physical expression of a climate of invasion, isolation and abandonment" (page). The victim-centered philosophy of the containment approach assumes that every sexual assault, from a violent stranger-rape to voyeurism by a family member, represents a significant act resulting in fear and a sense of betrayal. The victim's need for safety and empowerment thus becomes a priority in the management of the offender's case.

If the societal or criminal justice system response to an attack is to place the victim at fault, the trauma is magnified and recovery may be delayed (Hindman, 1989). Finkelhor (1988) describes how important it is for agency officials to respond appropriately: "Clinicians have often observed that the harm of some sexual abuse experiences lies less in the actual sexual contact than in the process of disclosure or even in the process of intervention" (pages 77–78). This point is fundamental to the containment approach. The power and authority of police officers, lawyers, judges, and social workers can weigh as heavily on the victim as on the perpetrator. Laws seeking to hold offenders accountable, but that are not mindful of the complex nature of victimization, particularly when the victim is a child and the perpetrator is a family member, can profoundly affect the victim. For example, community notification laws and Internet postings of offenders' addresses or pictures may have a devastating effect on the victim if the perpetrator is a family member. In an effective containment approach, the healthy recovery of the victim and the well-being of the community guide policy development, program implementation, and the actions of law makers and professionals working with both sexual assault victims and perpetrators.

Adopting a victim-centered philosophy sometimes requires a significant shift in agency values, as every case management decision will require considering the risk the offender presents to past and potential victims. Probation and parole agencies may be challenged to dissolve usual job and agency boundaries so that risk management decisions can be made quickly and in an ongoing fashion.

Reporting Rates

The victim-centered focus of the containment approach becomes especially important when those in the justice system have few opportunities to protect and empower victims of sexual assault. Most victims never report the crime to authorities and so cannot participate in a criminal case. Of course, many crimes go unreported. In fact, the 2011 National Crime Victimization Survey found that only 39 % of property crimes and 49 % of violent crimes were reported to law enforcement; 27 % of sexual assaults were reported (Truman & Planty, 2012, page). Importantly, this survey omits crime victims under the age of 12. Tjaden and Thoennes (2006) surveyed 16,000 adults and found that 22 % of women and 48 % of men who experienced a completed or attempted rape were under age 12 at the time of the assault (page).

Young victims are least likely to report assault. Diane Russell (1983) conducted face-to-face interviews with 930 randomly selected adult females in San Francisco and found that 5 % of extrafamilial sexual abuse and 2 % of incestual abuse were reported to law enforcement. Smith et al. (2000) found that reporting was delayed when the victim was young or knew the perpetrator, which was most of the time: only 11 % were raped by strangers. Smith et al.'s study of over 3,200 women reported that 28 % of the respondents had never told anyone about the rape until the researcher asked. Of those who told, 47 % did not do so for 5 or more years after the assault, making prosecution unlikely. A particularly discouraging finding in a study by Roesler and Wind (1994) found that one-third of incest victims disclosed the abuse prior to age 18, most commonly to a parent, but in 52 % of disclosures the abuse continued for at least another year. The women in this sample who disclosed as children said they were likely to be met with disbelief or blame rather than with support, validation, and protection. See Pipe, Lamb, Orbach, and Cederborg (2007) for more information about childhood disclosure of sexual abuse.

Older victims report at slightly higher rates. Kilpatrick, Saunders, and Smith (2003) found that 14 % of adolescents who were sexually assaulted reported the crime to law enforcement; 74 % knew their perpetrators. Tjaden and Thoennes (2006) found 19 % of women and 13 % of men who were raped since their 18th birthday said their rape was reported to the police. Only 17 % of marital/intimate rape was reported to law enforcement.

Arrest, Prosecution, and Conviction Rates

While the literature is replete with data substantiating the lack of reporting by victims of sexual abuse, less is known about what happens next. Tjaden and Thoennes (2006) surveyed 8,000 women and 8,000 men and found that 18% of *adult* rape victims reported the crime to police. Of these, 43 % resulted in an arrest. This figure drops precipitously when the victim is a child. Howard (2000) found that 27 % of reported sex crimes against children resulted in arrest.

Tjaden and Thoennes (2006) found that 18 % of the adult rapes that were reported to law enforcement resulted in prosecution, and one-third of those were convicted. Overall, Tjaden and Thoennes (2006) found that, of adult female rapes, 19 % were reported to law enforcement, 7.8 % were prosecuted, 3.3 % resulted in convictions, and 2.2 % resulted in incarceration (p.34).

Why are these rates important? First, every effort should be made to develop policies and practices that protect children and empower adults whose victimizations come to the attention of authorities. How victims are treated can affect reporting rates. Many victims want their privacy protected and fear being blamed for the offense (Kilpatrick et al., 1992, page). In fact, 99 % of those in Kilpatrick et al. (1992) said that public education about acquaintance rape would increase reporting rates, suggesting that holding sex offenders accountable regardless of their relationship to the victim would empower some to report the crime, along with efforts to move the blame away from the victim and on to the perpetrator. Still, many victims are reluctant to report abuse by a trusted person upon whom the victim may be emotionally or financially dependent. These low reporting rates reflect the complicated nature of this crime, since in most cases the victim knows the perpetrator.

Second, these figures should serve as a sober reminder that we know very little about this crime; it occurs in secret and remains almost entirely hidden from researchers and others trying to develop and implement prevention and containment methods. It affects our ability to assess immediate and long-term risk for offenders. The assessment of long-term risk is especially plagued by underreporting, since actuarial scales that rely on official record data will underestimate risk of actual (as opposed to recorded) reoffense. Underreporting will be discussed later in the chapter.

Finally, even those offenders who come to the attention of the criminal justice system due to a sexual assault may have incomplete information in their official records. Frequently, these crimes are plea bargained to another classification and so may not result in a sex crime conviction. Of felony sexual assault cases filed in Colorado in 2008, 76 % were convicted of sexual assault, 20 % were convicted of a nonsexual, nonviolent crime, and 4 % were convicted of a nonsexual violent crime (Colorado Division of Criminal Justice, 2011). For those individuals who actually committed a sexual offense, the factual basis of the crime is usually lost in this bargaining process. This masks the true offending history as recorded by official records and can distort our understanding of risk for individual offenders.

Component 2: The Coordinated Activity of Many Well-Informed, Multidisciplinary, Intra- and Interagency Collaborative Teams

Various teams form and work together as cases proceed through the criminal justice system and the child protection system. These teams contribute to the development of consistent policies focusing on victim protection and offender accountability. Representatives from these organizations also train staff in other organizations to ensure an integrated approach. These teams can overcome the fragmentation that naturally arises from the multilayered nature of the criminal justice system, and the communication barriers that often exist across agencies. The team approach minimizes duplication of effort and maximizes resources. It also strengthens both the motivation and the effectiveness of individual workers. These teams frequently provide an important support network for coping with frustration, stress, and the burnout often experienced by those who work with sex offenders (English et al., 1997; Edmunds, 1997; Kadambi & Truscott, 2003; Thorpe, Righthand, & Kubik, 2001; English and Heil, 2006).

Members of intra-agency, multiagency, and multidisciplinary teams typically include representatives from law enforcement, child protection, rape crisis centers, prosecutor's offices, defense attorneys, probation and parole, hospital emergency room staff, treatment providers, polygraph services, school counselors, crime victim advocates, and child victim advocates. The teams develop policies, procedures, and protocols for managing sex offenders and monitor their own implementation of these practices. Assembling professionals with different areas of expertise creates a rich pool of information and perspectives to improve the management of sex offenders. State and local sexual assault organizations representing victim concerns are an important resource to those involved in defining and implementing a containment approach. In fact, a major litmus test of any specific containment practice, as well as the overall management approach, should be support from victim service organizations.

A strategy that commonly emerges within this context is job specialization. Specialization is the assignment of one or more workers to specifically handle sex offense cases. It

may take the form of a unit, as is typical in law enforcement, or a single professional designated to manage all sex assault cases. The effect of specialization is to greatly increase the expertise of professionals, in turn enhancing the ability of team members to educate each other. With specialization, case experience is multiplied and agencies can target training resources. These teams and job specialists, then, are responsible for understanding and incorporating into their work very specific issues associated with sex offender case management such as victim trauma, investigation methods, interview techniques for victims and perpetrators, medical assessments, dynamics of offending, offender denial, local policies and procedures related to sex offender management, and professional burnout. These teams can play an important role by improving each others' understanding; cross-training allows physicians to learn the evidentiary issues prosecutors face, law enforcement officers and prosecutors learn about common reactions to trauma from rape crisis counselors, and victim advocates learn more about the criminal justice system so they can better help victims prepare for court (Epstein and Langenbahn, 1994, p.85).

Interagency and multidisciplinary collaboration can occur in many ways. In Colorado, for example, a state-level Sex Offender Management Board with multidisciplinary membership is defined in legislation and meets monthly. The Board developed guidelines for the evaluation, treatment, and behavioral monitoring of adult sex offenders, including sex offenders with developmental disabilities. It also developed release criteria for sex offenders serving lifetime probation or parole sentences, a sentencing strategy undertaken in lieu of civil commitment. Smaller multidisciplinary groups meet regularly within judicial districts. The State Division of Probation Services regularly convenes two groups, the officers who specialize in juvenile sex crime cases and those who manage adult caseloads. In Oregon, quarterly meetings were held for all the probation and parole officers from across the state that specialized in the supervision of adult sex offenders, and law enforcement and treatment providers also attended these meetings. In Alaska, the Department of Corrections regularly gathered stakeholders within the agency to develop policies related to sex offender management. In Ohio, a parole officer initiated a meeting with colleagues working in the local police department's sex crime unit, and they subsequently worked together to solve cases. Frequently, line staff forges these types of relationships, with one committed professional seeking out the expertise of another. Regular meetings and communication ensue. These small acts of collaboration continue to change the way this work gets done in many jurisdictions across the country (English, 2004, page).

Component 3: The Use of a Variety of Containment Strategies

Case processing and case management in a containment approach must be tailored to the *individual sex offender* and his or her patterns of sexual offending. This focus on the individual is a fundamental aspect of containment. In fact, we return to this point many times in this chapter. Not only is this individual focus central to the containment approach, but individualized assessment and treatment is a basic tenet of evidence-based correctional practices, specifically the Risk-Needs-Responsivity Model (Andrews & Bonta, 2010; Wolff, 2008; Andrews, Bonta and Wormith, 2011) that promotes the development and use of a very specific treatment plan based on a thorough assessment of specific treatment needs. Sex offender treatment experts also promote this approach (for example, Heil & Simons, 2008; Ward & Stewart, 2003a), which should also include an assessment of cognitive deficits that require special programming (Haaven & Coleman, 2000, page). Ward and Brown (2003) emphasize that individuals who are assessed as low risk may display high needs requiring intervention, so needs and not risk should drive treatment in this event. This is especially true for offenders convicted of sex crimes who score low risk on actuarial scales. Typically, actuarial scales are heavily weighted by incomplete official record data. Additional offense history is frequently disclosed when offenders proceed in treatment with polygraph testing, further illuminating the seriousness, frequency, and range of deviant behaviors, reflecting new levels of needs and risk and an associated need for more intensive, long-term treatment.

Containment Strategies

Individualized case management incorporates multiple tools that become part of containment. These include confidentiality waivers, collateral contacts, home visits, employment restrictions, Internet restrictions, family reunification policies, positive informed support, urinalysis testing, law enforcement registration, conditions of supervision, and leisure time monitoring for the offender. Additional strategies include professional cross-training, surveillance officers, victim services, and multidisciplinary teams. The core strategy, which is a focus of this chapter, is the formation of a containment team consisting of a specially trained treatment provider, a supervising officer (including the probation or parole officer in the community and the correctional staff prison), and a polygraph examiner. Some jurisdictions include a victim advocate as part of the team, operationalizing the victim

orientation described in Component 1 above. Including a victim representative on the team ensures that the victim's perspective is routinely incorporated into case management decisions.

In fact, to be most effective in these collaborations, victim organizations must provide support and sometimes training to staff to ensure that they have sufficient confidence to keep treatment providers, supervising officers, and other practitioners and policymakers focused on public safety. For example, when offenders reach the end of time-limited probation or parole terms, often professionals develop family reunification plans even for offenders who have not made meaningful life changes because the offender is "going home anyway." The individual may still present a significant risk to the community and potentially specific family members, despite the presence of a reunification plan. Scott (2011) notes that in a 3-year period in Maricopa County (Phoenix), half the reoffenses for sex crimes occurred because family members allowed their children to be in contact with offenders, even though they had been appropriately informed.

The containment approach depends on obtaining and sharing key pieces of information about the abuser with the containment team: "The criminal justice supervision activity is informed and improved by the information obtained in sex-offender-specific therapy, and therapy is informed and improved by the information obtained during well-conducted post-conviction polygraph examinations" (English, 1998, p.225). Each anchor must be perceived by the offender as separate-yet-aligned with the other.

The containment team must be prepared to consistently respond to shared information in order to minimize the offender's access to victims and high-risk situations. This additional information allows professionals to develop meaningful treatment and supervision plans. It also means that professionals obtain much more information about offenders' violations of these plans. It is this aspect of containment that is one of the most difficult to implement: increasing the information on each case requires significantly more time on the part of both the treatment provider and the supervising officer. This additional information can multiply the amount of case time required.

Sharing information requires that the supervising officer, treatment provider, and polygraph examiner establish common and clear public safety goals and consistent responses to new information disclosed by the offender during the course of treatment and supervision. In poorly functioning containment teams, members sometimes withhold information disclosed by offenders that may result in greater containment (such as curfews or GPS monitoring) or criminal justice sanctions, usually for the purpose of protecting the offender. Team members who withhold information about the offender are either feeling conflicted in their role or are being successfully groomed by the offender, or both. The value of working together as a team is to obtain feedback from fellow professionals. Sharing information and respectfully giving and receiving feedback are necessary to create the transparency required to safely manage this population of offenders. Working well as a team is reflected by this information sharing, and it models the honest and open lifestyle that is the goal for the offender.

The core containment strategy—polygraph, treatment, and correctional supervision—is discussed in detail below, beginning with the polygraph examination since its use informs and frames treatment and supervision.

Post-conviction Polygraphs

The post-conviction polygraph is the only type of polygraph exam used in containment, and its regular use is fully integrated into treatment and supervision. Understanding how the information disclosed during the polygraph exam is integrated into case management is essential to successful implementation of the containment approach.

The greatest value of the polygraph examination is that its use facilitates the offender's progress in treatment (Knapp, 1996; Grubin, Madsen, Parsons, Sosnowski, & Warberg, 2004). Clients know that they will be regularly polygraphed as part of the treatment process and are encouraged from the onset to fully disclose those aspects of their lives that they have traditionally kept secret. Preparation for the polygraph examination includes clarifying behaviors that are abusive. This is often educational for clients who are expected to disclose their history of offending so that an appropriate treatment and supervision plan can be developed and implemented. We discuss the accuracy of the polygraph later in the chapter, but it is this important process of disclosing harmful behaviors that helps move the offender through denial and early resistance to treatment where the polygraph proves it mettle.

In addition to verifying the accuracy and completeness of self-reported sexual history information gained in treatment, the polygraph exam is also used periodically (preferably at least every 6 months) to corroborate the offender's compliance with criminal justice and treatment conditions. This information about compliance is a critical component of public safety because it taps the offender's actual life behaviors, going beyond how one behaves during therapy. It is a relatively simple task for offenders to learn the language of treatment and to assess and respond to the expectations of the containment team. In fact, many sex offenders can easily employ elsewhere the skills developed in the service of manipulating victims. Grooming therapists and supervising officers should be expected; feigning engagement in treatment should also be expected. Assessing behavior change *outside* of treatment using the polygraph exam and other

monitoring methods, then, is a critical barometer for managing this population of offenders safely.

Safe management means every effort is under way to prevent a new sex crime by a known sex offender. The polygraph examination is an essential component of the containment approach because its use reveals much necessary information about the offender. Its use is also critically valuable in determining those for whom this is their only sex crime and who, therefore, may be at low risk of offending again.

One objective of containment is to improve public safety by obtaining information that will prevent known offenders from harming again. The polygraph targets behaviors actually engaged in, not sexual interest or sexual arousal. This occurs primarily through the synergistic effect of combining sex-offense-specific treatment, criminal justice supervision, and post-conviction testing. Working together, these strategies can facilitate the offender's compliance and increase the information he or she discloses, thereby increasing the effectiveness of treatment and supervision. The effective use of the polygraph depends in large part on how a treatment provider reacts to newly disclosed information. We return to this issue later in the chapter.

Types of Polygraph Exams

The post-conviction polygraph examination gathers information after the individual has been convicted of a sex crime. In containment, sex offenders are tested for three time periods: sex crimes that occurred prior to the current criminal event, the time between arrest and treatment onset, and abusive and other noncompliant behavior during treatment. Each of these time periods provides different sets of information for different purposes. Questions covering the time period prior to arrest or conviction for the current crime uncover age of onset, duration, frequency, and variation (types of victims and assaultive behaviors) which are critical elements of therapeutic and risk assessment (Heil & Simons, 2008, page). The time between arrest or conviction and sentencing or the onset of treatment can be a very active period for some offenders and indicates how they might behave under stress, while polygraph testing while the offender is under supervision and in treatment provides information about the extent to which the offender is responding to external controls and applying the tools learned in treatment.

The Colorado *Standards and Guidelines* (2011) specify five types of polygraph examinations. Four of these are discussed here (the fifth type, the child contact assessment polygraph, is used specifically to assess the individual's risk to their own children, and will not be discussed here). Although the polygraph procedure itself remains the same, the questions and consequences for deception vary depending on the time period involved and the seriousness of the information withheld or disclosed.

The *sexual history examination* is used to thoroughly investigate the person's lifetime history, including the identification of victim age/gender/relationship and victim selection behaviors. The sexual history addresses age of onset, frequency, seriousness, and variety of past sexually abusive behavior. Revealing this information allows the offender the opportunity to be accepted by the therapist despite the level of harm he or she has caused others. It reveals to the therapist how entrenched the deviant behavior may be and begins to clarify the true risk the offender presents to the community. This information should inform the therapist on the intensity and duration of treatment needed to effectively address the offender's issues, and the number and type of containment strategies that might be necessary to safely manage the person in the community, such as GPS tracking, curfews, daily phone calls, and using a "buddy system" with other members of treatment programs. Therapists and supervising officers must also determine who, if anyone, needs to be warned given the information learned during the course of treatment and polygraph examinations.

The sexual history polygraph examination requires that the offender has completed in treatment a written sexual history disclosure journal prior to the examination. The Colorado *Standards* require that the therapist provide the sex history material to the examiner in advance of the exam, and the examiner is required to read the information in the packet before preparing for the examination. Both the supervising officer and the treatment provider must work together to prepare the offender to take the sexual history examination. Effective preparation, according to polygraph examiners, improves an offender's ability to resolve questions and issues of concern. Preparation for the examination in therapy should *not* include a review of possible test questions, but rather should involve discussing the examination process, expectations regarding honesty, and the need to disclose—in treatment rather than the polygraph office—noncompliant behaviors and risk concerns. The focus should remain on treatment and supervision compliance, risk and need factors, cognitive distortions, and the "stuff" of therapy.

The maintenance/monitoring polygraph examination is first used within 90 days of treatment onset and then at least semiannually. It should be used more frequently for those who present high-risk behaviors, who recently experienced a life change (such as changing their residence or starting to date), or who have previously unresolved examination results, and it can be used as frequently as weekly. This examination investigates the offender's compliance with supervision and treatment, and many offenders anecdotally report to polygraph examiners that it has a deterrent effect on their behavior. In a small study of only 28 offenders who were guaranteed confidentiality, Harrison and Kirkpatrick

(2000) found that over half reported that they altered their behavior in anticipation of the polygraph examination. Specifically, more than half reported a decrease in grooming behavior, 43 % reported a decrease in probation violations, 36 % reported reduced substance use, and 27 % reported decreased sexual touching of children. Grubin et al. (2004) also found polygraph testing to have a deterrent effect on high-risk behaviors in a small sample of sex offenders voluntarily participating in polygraph exams: 20 out of 21 offenders reported that they thought the polygraph examination helped them avoid reoffending. The average number of high-risk behaviors reported by sex offenders significantly decreased between the first polygraph test and the second, suggesting that polygraphy was effective in decreasing these behaviors. At the same time, disclosures of high-risk behaviors to treatment providers and supervising officers increased. Grubin et al. (2004) concluded that the polygraph might be better considered a truth facilitator rather than a lie detector (page). Abrams and Ogard (1986) also studied the deterrent effect of polygraph testing on probationers and determined that 69 % of offenders who received polygraph testing with supervision successfully completed probation as opposed to only 26 % of offenders who received supervision alone.

The *event-specific* polygraph examination is used to investigate the details of a person's specific involvement in a known or alleged incident, or to resolve discrepancies or inconsistencies in the offender's account of a specific event. Polygraphs should not be conducted on active criminal investigations unless law enforcement officials agree to the procedure. The *child contact assessment*, mentioned above, is used in Colorado to assist the containment team in making a recommendation about the offender's contact with his or her own children who are not already known to be victims as well as siblings of victims. The event-specific polygraph examination is used in situations of unknown risk to identify possible risk based on past behaviors and inform decision makers regarding the offender's potential risk to the children.

The event-specific examination may be used when offenders deny the instant offense or aspects of it. Nannetti and Greer (1996) noted that common defenses for child sex offenders include (1) the touching was not sexually motivated or was accidental or innocent, (2) the victim's graphic description is based on prior knowledge, (3) the alleged abuse is a fantasy; the child wants attention, and (4) the identification of the perpetrator is inaccurate (page). Offenders of adult victims may maintain that the sexual contact occurred with the victim's consent. These issues can be addressed with a careful interview that includes the definition of terms to be used during the examination, and targeting questions specific to the behaviors of concern. Strate, Jones, Pullen, and English (1996) describe the value of these examinations to help the offender take responsibility for his or her damaging behavior, moving them forward in the treatment process. Additionally, details of the instant offense are often incomplete. Polygraph examiners report that, upon questioning, clients will often disclose the use of force or violence that was not recorded in the police report or other descriptions of the offense. Victims of sex crimes are often reluctant to disclose the use of aggression, especially if they are acquainted with the offender.

The Polygraph Test

The polygraph exam is a verification of the offender's self-reported information about his past and current behaviors. Its focus is actual behavior undertaken by the client, not feelings, thoughts, motivations, interest, or attraction. The polygraph examination lasts approximately 90 min; most of this time is spent discussing the exam process and the potential questions, calibrating the equipment, and interviewing the client. Each examination can test on only three or 4 questions. These few questions reflect the need to identify the offender's patterns of behavior and immediate risk concerns. This question limit reveals that the polygraph can never substitute for the combination of therapy and supervision. In fact, it is possible that the questions asked could completely miss a part of the offender's life that is teetering out of control. This is a sober reminder that the use of the polygraph cannot replace the vigilance required of a supervising officer and a treatment provider to continually look for cues that the offender may be slipping into dangerous patterns of behavior.

Question construction is a critical dimension of the polygraph examination. There can be no surprise or trick questions, and they must elicit only a yes or no response. Questions must be concise, well-defined, and easy to understand. Broad and vague questions such as "does your written sex history journal include every victim?" are likely to generate an anxious response whether or not someone is intentionally withholding information. Instead, questions should be discussed and completely defined in advance of the test procedure, during the pretest interview between the examiner and the client. The American Polygraph Association's *Model Policy for Post-Conviction Sex Offender Testing* (2009) reads: "Before proceeding to the test phase of an examination, the examiner should review and explain all test questions to the examinee. The examiner should not proceed until satisfied with the examinee's understanding of and response to each issue of concern" (181).

The polygraph examiner focuses on the technical and physiological requirements of the exam itself, the threats to validity, careful construction of questions, a methodical execution of the pretest (where every question is reviewed with the offender), the test itself (measuring heart rate, blood pressure, respiration, and perspiration), and the posttest

Table 1 The polygraph, supervision, and treatment work together to identify behavior problems

How violation was discovered	Total
Self-disclosure during polygraph examination	15.6 % (77)
Probation officer found out (including self-report)	14.0 % (69)
Treatment provider found out (including self-report)	12.1 % (60)
Lab result (UA)	11.3 % (56)
Fail to appear for treatment	9.7 % (48)
Probation officer (PO) did home visit	8.1 % (40)
Fail to appear for probation appt.	7.3 % (36)
Law enforcement	5.5 % (27)
Roommate called PO or treatment provider	4.3 % (21)
Group member called PO or treatment provider	2.8 % (14)
Both PO and treatment provider found out (including self-report)	2.0 % (10)
GPS/EHM	1.4 % (7)
PO called or visited employer	1.2 % (6)
Sex offender's friend called PO	1.2 % (6)
Victim advocate called PO	1.0 % (5)
PO called residence	0.8 % (4)
Computer surveillance	0.8 % (4)
Employer called PO	0.4 % (2)
PO called nonresident family member	0.4 % (2)
TOTAL	100 % (494)

interview (review of test results with the offender). Well-trained examiners who actively participate in workshops and educational experiences and are open to quality control reviews by their colleagues are important members of the containment team.

The synergy of containment—polygraph exams, treatment, and supervision—can be seen in the data presented below. In a study of 130 mostly high-risk sex offenders during the first 15 months of community supervision in Colorado, 443 violations of probation were recorded in the probation files of 103 offenders. Most of these violations did not result in revocations; they do, however, reflect the large amount of information that became available to the containment team in the course of their work with individuals in the sample.

Table 1 displays how the violations were discovered. Note that the violation could be discovered by multiple sources. The polygraph examination identified 77 (15.6 %) of the violations, the probation officer discovered 69 (14.0 %), and the treatment provider reported 60 (12.1 %). These violations were revealed primarily by the sex offenders in the study who self-reported the information. Of course, it is possible and even likely that many of these violations would have been discovered without the polygraph; however, the important point is that the three leading sources of detected violations were from the three components of the containment approach.

In this study, 15 new sex crimes were committed by 13 offenders in a 15-month period. All of these were noncontact crimes, and 11 were disclosed during polygraph examinations. In two cases, a treatment group member phoned a probation officer, 1 offender self-reported to the treatment provider, and law enforcement detected one crime (Colorado Sex Offender Management Board, 2004).

Violations and Stages of Change

The number of violations detected in the study referenced above underscores the difficulty of working with this population. Sex offenders are almost always an involuntary treatment client. In a meta-analysis of 125 studies of therapy retention, Wierzbicki and Pekarik (1993) found 50 % of clients dropped out of treatment—and the study did not differentiate between voluntary and involuntary clients. In a study of proactive recruitment, Lichtenstein and Hollis (1992) investigated a program where physicians spent time with every smoker to persuade them to sign up for a state-of-the-art, action-oriented clinic. If that failed, nurses spent up to 10 min more, followed by 12 min with a health educator and, finally, a counselor's call to the home. The result was a base-rate participation of 1 %. Note that, with smoking, there is no social stigma associated with getting help.

Most therapists are aware of Prochaska and DiClemente's (1982) groundbreaking work which identified the processes involved in producing individual change. It is a process that unfolds over time and involves a progression through six stages: precontemplation, contemplation, preparation, action, maintenance, and termination. Termination occurs when individuals experience zero temptation and complete self-efficacy: they are confident that they will not return to their old unhealthy pattern of behavior. In fact, it is as if they never experienced the problem or acquired the pattern in the first place. Snow, Prochaska, and Rossi (1992) found that this stage was reached by less than 20 % of smokers and alcoholics. Prochaska (2001) reported on a study of the stages of change by Rossi (1992) of 15 unhealthy behaviors in 20,000 HMO members. Rossy reported that 40 % were in precontemplation (people are not intending to change or may take action "in the next 6 months"), 40 % were in contemplation (people intend to change in the next 6 months), and 20 % were in the state of preparation, meaning they have a plan for action such as consulting a counselor. Again, involuntary treatment was not studied, so these figures are likely less optimistic with court-ordered clients.

Prochaska (2001) discusses how individuals who begin to contemplate acting seriously vacillate between the costs and

benefits of change: "There is no 'free change." The balance between the costs and benefits of changing can provoke profound ambivalence. This ambivalence can keep people immobilized in this stage for long periods. We often characterize this phenomenon as chronic contemplation or behavioral procrastination" (231). And it might be expressed by sex offenders as behaviors that violate the conditions of supervision and treatment.

Sex offender ambivalence regarding personal change contributes to significant treatment attrition and community supervision revocation rates. Treatment providers and supervisory agents must attempt to motivate offenders' investment in the change process through the use of Motivational Interviewing (Miller & Rollnick, 2002, page), appropriate therapeutic relationships such as promoting offenders' hope for change, supporting offenders' change efforts, and respectfully holding offenders accountable to change. Motivating change also occurs through the use of behavioral monitoring, incentives, and sanctions. While therapists cannot instill hope or will in the offender, they can provide logic and delineate the benefits of behavioral change. It is understandable that court-ordered clients may find it difficult to become self-motivated or remain self-motivated about the difficult work that change requires. Yet, allowing unmotivated offenders to remain in group treatment without being held accountable for completing homework and applying what they are learning rewards negative behavior and undermines those who *are* engaged in the change process. Change is not absorbed by passive participation in treatment. Rather, it requires active and sometimes painful work. In Colorado, termination from community treatment can result in a prison sentence if the individual does not reconsider and recommit to the process of change. The decision to terminate treatment should be made by the containment team or, in the case of prison treatment, the treatment team. This ensures multiple perspectives consider the offender's stage of change, ambivalence, and level of motivation.

Therapist Response to the Polygraph Information

Often, therapists find the information disclosed by the offender during the polygraph examination difficult to absorb. Some therapists experience a dissonance between the reality described in the polygraph report and their hopes for the client. Therapists enter the profession to positively influence the lives of their clients, and the information generated via the polygraph examination is often disappointing, especially when it indicates that the offender is continuing to engage in risky or abusive behavior. Frequently, the first reaction of the therapist is to doubt the polygraph results rather than doubt the progress the offender has made (or not) in treatment. If the therapist does not move past these impulses and recognize them as rooted in personal disappointment, the successful containment of the offender is seriously jeopardized. In this situation, the therapist values his or her image of the offender over the potential harm the offender may present to the community. It is this reason that the containment approach requires a victim orientation and a public safety mission. Learning that the revelation of secrets and risk behaviors is a goal of treatment and supervision, and that public safety is the ultimate outcome, is how professionals guide and support behavioral change that is helpful to the client.

Containment is rooted in the humane management of sex offenders (English et al., 1996, page). Containment professionals who cannot hold offenders accountable for the risks they pose as revealed by self-reported information may allow the offender to be in high-risk situations, such as living with family members or children. New victimizations may result in very long prison sentences for the client. Those who consistently struggle with recognizing and managing their disappointment with court-ordered clients may be more suited to working with a noncriminal population.

It's About Honesty

The treatment provider and the supervising officer need to set the expectation that the offender will be found nondeceptive on the examination. That is, honesty is expected and with appropriate preparation in therapy, the client will "pass" the examination because they are willing to be honest. Some treatment programs work with the correctional agency to specify, in advance, written consequences for deceptive results and incentives for nondeceptive results that indicate the offender is engaged in the change process. This clarity provides support for changes the offender may find difficult to undertake, and it promotes understanding and a common goal: for the offender to succeed in therapy.

In fact, research conducted at the sex offender treatment program at the Colorado Department of Corrections found that the proportion of successful (nondeceptive) polygraph examinations varied considerably over time based on variables such as the reluctance of the treatment staff to support the use of the polygraph combined with consistent application of sanctions related to polygraph test findings. When sanctions were poorly implemented for nondeceptive exams, 37 % of the tests were nondeceptive (over a 1-year period); when staff were reluctant to use the information from the polygraph examination, 51 % of exams were found nondeceptive. However, when staff attitudes changed and sanctions were consistently implemented, 63 % were found nondeceptive, a statistically significant difference (Simons, Heil, & English, 2004).

For those who have not worked with the polygraph examination, it may be helpful to know that the polygraph examination itself is relatively proscriptive and predictable. The American Polygraph Association has detailed standards of practice (APA, 2009). It is not a mysterious instrument or process so it should not distract from the work of treatment. Nevertheless, all members of the containment team, including the examiner, require special training to be effective with this population. The skill of the examiner should build confidence in the offender: honest clients worry that the examiner is unskilled, and dishonest clients worry that the examiner is very skilled.

Polygraph Controversies

Donald Krapohl (2007), former president of the American Polygraph Association and member of the Defense Academy for Credibility Assessment Department (formerly the Department of Defense Polygraph Institute), has comprehensively summarized the controversies concerning the use of the post-conviction sex offender test (PSCOT). Polygraph critics cite concerns about accuracy, the lack of research, the possibility of false accusations, and the possibility of mistreatment of offenders as an outgrowth of the examination process. Proponents point out that traditional methods of detecting or deterring sex crimes by known offenders are inadequate, and identifying precursor behaviors is critical to protection of vulnerable victims. Both camps agree that more research is needed.

The value of the polygraph in the containment approach is its ability to facilitate self-reporting of the frequency and variety of sexually abusive behaviors. The information obtained using the combination of treatment and polygraph testing seems to be reluctantly disclosed, rendering it all the more important because of the value it holds to the offender. The self-reported information should be used to improve treatment, supervision, and public safety, and new crimes admitted during supervision should be subject to further investigation and, if verified, prosecuted. It should be viewed as one tool in the toolbox of sex offender management and should not be overly relied upon. A nondeceptive examination may be the result of targeting the wrong behaviors, so clearly its use should never displace active supervision by the criminal justice agency. Polygraph screening combined with skilled interviewing techniques produces high value information that would be nearly impossible to uncover by other methods, according to Krapohl (2007) who discusses PSCOT along with the use of the polygraph in U.S. counterintelligence agencies.

Amid the controversies outlined by Krapohl (2007), two valuable outcomes result from the consistent use of the polygraph in the containment approach. First, it takes the onus of responsibility for disclosing sex crimes off the victim and places it on the offender (English, 1998). Even after reporting a crime, and even after that crime has resulted in a conviction, victims may withhold important but embarrassing or humiliating aspects of the crime. Victims who know the offender are often uncomfortable reporting acts of violence or threats, or prior assaults, yet this information is vital for the assessment of risk and treatment needs. The offender is in the best position to report on his or her behavior, and disclosing details of the current crime places responsibility for our knowledge on the offender and not on the victim.

Second, the polygraph has significant value for identifying the one-time, low-risk sex offender. Individuals with one or few offenses will be easily identified. This narrows the field of questioning and increases the rate of accuracy. Most examiners report that they do, indeed, identify first-time offenders while conducting sexual history examinations. Low-risk offenders should be separated from medium- and high-risk offenders in treatment and supervision planning. Given the incomplete nature of official record data, this is a significant and often-overlooked benefit provided by the polygraph examination.

Polygraph Accuracy

Critics of the use of the polygraph in sex offender management often question the accuracy of the instrument. It is important to remember that the reliability and validity of the polygraph exam is not in question when the offender self-reports additional or new victims prior to or after the examination. These self-reports are similar to self-reports during other circumstances. The National Academy of Sciences (2003) explored the use of the polygraph in the detection of espionage and, despite criticizing the paucity of well-controlled research on the instrument, concluded "specific incident polygraph tests can discriminate lying from truth telling at rates well above chance, though well below perfection. Because the studies of acceptable quality all focus on specific incidents, generalization from them to uses for screening is not justified" (4). The NAS concluded its accuracy investigation with the determination that specific incident polygraph testing had a median accuracy rate of 86 %. Indeed, accuracy declines as the test moves toward multiple issue testing, and this speaks to the need to focus on each offender's specific vulnerabilities: drinking, driving "aimlessly," masturbating to inappropriate sexual fantasies, and other types of specific precursor behaviors such as stalking (English & Heil, 2006).

Krapohl and Stern (2003) compared counterintelligence testing with post-conviction sex offender testing. In espionage testing, the assumption is that there may be one out of

1,000 or 10,000 tested subjects who engaged in espionage. However, in sex offender testing, the situation is reversed: it is likely that 500 or 800 or 950 offenders out of 1,000 are hiding important information (the base rate depends on many factors [Simons, Heil & English, 2004]). Krapohl and Stern (2003) estimated a conservative accuracy rate of 80 % (page). This rate can increase or decrease with the skill of the examiner, but on average 760 of the 1,000 sex offenders will be correctly identified as deceptive on the exam. Many of these offenders will disclose important risk-related information to the polygraph examiner during the course of the examination. The disclosures may not be complete, but significantly more information now exists for treatment and supervision purposes. However, the overall error rate along with the fact that the test questions are limited in number (and so may miss areas of concern) underscores the need for ongoing intensive supervision and vigilance on the part of the treatment provider and supervising officer.

Krapohl (2007) makes an important recommendation about the problem of false positives—calling a person deceptive who is telling the truth. Since polygraph decisions are based on scores that the examiner assigns to the polygraph data, he suggests altering the polygraph decision rules such that false-positive errors are less likely to occur. This, of course, increases the incidence of false negatives, classifying deceptive individuals as nondeceptive. In addition, recognizing that multiple-issue screening tests have lower accuracy than do single-issue criminal tests, Krapohl (2007) recommends a successive hurdles approach (Meehl & Rosen, 1955). Applicable to most medical and psychological diagnostic tools, this principle refers those who produce a "positive" finding on a screening to a subsequent, more focused test. The examiner explores the issues with the examinee, seeking resolution of the positive result. This is followed by another test with more focused questions. This is an iterative process, and successive tests can involve resetting the scoring cutoffs to correct for the reduction in false positives, discussed above.

This approach requires research to better understand its affect on decision accuracy. Nevertheless, the successive hurdles strategy is recommended in the *Model Policy for Post-Conviction Sex Offender Testing* (American Polygraph Association, 2009). Containment teams should ensure that examiners are following the APA's model policy, are members of their local polygraph association, and receive frequent training to improve their testing and interviewing skills.

Self-incrimination is discussed in greater detail in English and Heil (2006), but it is somewhat less of a concern today than in the early days of post-conviction testing. In January 2005, in *U.S. v. Antelope,* 05 CDOS 745, the 9th U.S. Circuit Court of Appeals ruled that Antelope had been unjustly denied his Constitutional right against self-incrimination when a Montana district court judge required that he undergo treatment and disclose past crimes as a condition of probation supervision. The court found that Antelope could not be forced to participate in treatment unless he was promised that he would not be prosecuted for past crimes. This ruling, while applicable only to the jurisdiction covered by the 9th Circuit Court, marks the critical need to clarify with offenders and the containment team exactly how the information obtained during therapy and polygraph examinations will be used. This case codified the need to develop a specific strategy that precludes professionals from obtaining crime details necessary for prosecution: the name of victim, the geographic location, and date and time of offense. Should victims come forward independently and report the sex crime to law enforcement, prosecutors may choose to pursue criminal charges.

Despite the *Antelope* decision, some programs continue to obtain full details, including the name of the victim and their current location if this is known by the offender. These programs operate on the assumption that this information is critically necessary to provide the potential for counseling to child victims or to be included in the client's exclusionary zones on GPS. Newly revealed victims are reported to the supervising agency; however, this information is rarely used for prosecution or a change in sentence.

The Polygraph and Therapeutic Alliance

A commonly expressed criticism about the use of the polygraph is that it may negatively affect the therapeutic alliance since it communicates distrust of the client (for example, McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2010). However, its use is analogous to the urinalysis testing during substance abuse treatment, a strategy recommended by the National Institute on Drug Abuse (2006): "Monitoring drug use through urinalysis or other objective methods, as part of treatment or criminal justice supervision, provides a basis for assessing and providing feedback on the participant's treatment progress" (3). Substance abuse treatment providers routinely overcome the problem of monitoring behavior and therapeutic alignment.

Nevertheless, the therapeutic relationship is one of the foundations of psychotherapy outcome and individual change (Hubble, Duncan, & Miller, 1999). Lambert and Barley (2001) summarize the research on the therapeutic relationship, and they define the therapeutic alliance as a condition that includes both the therapist's skills and the client's contributions to the relationship (page). This means that the client is also responsible for building therapeutic alliance, and few would argue that the client's honesty is important in this regard.

Lambert and Barley (2001) caution therapists to "watch for a reduction in their ability to empathize and relate to clients that can indicate professional stress or burnout" (page). Certainly, all containment team members must strive to encourage and support offenders' change efforts while holding them accountable because of the challenges presented by this population. In fact, Lambert and Barley (2001) close their discussion of the therapeutic relationship with these words: "It is clear that some therapists are better than others, at least with some clients. This is probably related to the therapist's contribution to the therapeutic alliance, especially in working with severe cases" (359).

Ackerman and Hilsenroth (2003) reviewed therapist characteristics and the therapeutic alliance and suggested that clients who perceive the treatment relationship to be a collaborative effort are more likely to invest in the therapy process and, in turn, experience greater therapeutic gains (page). Lambert and Barley (2001) refer to Bordin's (1976) classic work and describe the therapeutic alliance as having three parts: tasks, goals, and bonds (359). *Tasks* are behaviors and processes within the therapy session that constitute the actual work of therapy. Both the therapist and the client need to view these tasks as important and appropriate for a strong therapeutic alliance to exist. The *goals* of therapy are the objectives that both the client and therapist endorse. *Bonds* are the positive interpersonal attachment between a therapist and client of "mutual trust, confidence, and acceptance." It is important to remember here that court-ordered, offense-specific treatment means that the client has been found responsible for a crime. Involuntary treatment requires a shift in the burden of producing the therapeutic alliance: the client must prove willing to engage in treatment because it is a condition of supervision and therapy. This inherently requires that the offender demonstrate behavioral changes, making them in large part responsible for the therapeutic alliance. Additionally, the use of the polygraph examination, collateral contacts with family members and roommates, urinalysis testing, driving logs, sex history journals, leisure time logs, and other therapeutic tools are not mutually exclusive from building a strong therapeutic alliance. In fact, offenders who have the experience of feeling understood, accepted, and valued when the truth about them is known (and continually verified) are in a strong position to make use of the new skills and attitudes that accompany successful cognitive-behavioral therapy.

Understanding the sex offender client means that therapists should expect most of these individuals to struggle with honesty. Therapists should look for signs of the offender's use of manipulation in the service of keeping secrets. Because the secrets can lead to significant harm, the therapist's continual and reality-based skepticism benefits the client. Experienced offense-specific therapists explain this dynamic as a critical safety-oriented perspective. Part of the therapeutic interaction that makes use of the alliance is *reframing*. Reframing involves reflecting back to the client what he has said and putting it in a new light; it is not simply to agree with the client but to offer new interpretations. Polygraphs and other tools can be part of this process. Developing a positive therapeutic alliance will be challenging regardless of the containment tools involved in treatment because the tasks, goals, and bonds—the essence of the alliance—may be faced with considerable ambivalence and even hostility by the involuntary client. The client can positively affect the alliance by learning to view the containment tools as beneficial to himself and the community.

The polygraph examination can be framed simply as a tool to verify the offender's self-reported information and to clarify the person's immediate level of risk and compliance, much like the use of urinanalysis testing for substance abusing clients. Skilled therapists present it to the client as a helpful tool, while acknowledging the offender's anxiety about its use. Therapists help the client understand that the use of the polygraph helps unveil many secrets that lead to hurting people, and it is the offender's responsibility to stop these behaviors, including the precursor behaviors that lead up to the assault. The polygraph is just one tool to assist in this aspect of the change process. Rather than focusing on the examination, therapists focus on the value of honesty and openness during the treatment process.

Sex Offense-Specific Treatment

Sex offender treatment uses cognitive-behavioral therapy to target the thoughts, feelings, attitudes, reasoning, and problem-solving that contribute to sex offending behavior along with denial, minimizations, motivations, and justifications (see for example, Marshall & Serran, 2000; Terry, 2000; Ward, Hudson, Johnston, & Marshall, 1997). Lipsey (1992) found that programs that were classified as being structured, cognitively and behaviorally oriented, multimodal, and which were directed at building concrete skills had significantly better outcomes than other programs (Cooke & Philip, 2001). Fernandez, Shingler, and Marshall (2006) discuss the need for treatment goals to be based on individual needs, deficits and strengths, and the use of "shaping" to reward and reinforce small steps toward prosocial behavior change (page).

Schwartz (2011) discusses reasons group therapy is preferred over individual therapy. The common characteristics of guilt, denial, and secrecy "make sex offenders especially difficult to treat in individual therapy. Because these offenders often lie, minimize and rationalize their behavior, it is quite a task for a lone therapist to muster the strength or the evidence to confront their defenses" (page). Moreover, Schwartz suggests that individual therapy can replicate the dynamics

of the sexual assault because the therapist and offender "are in a 'secret' (confidential) relationship" and offenders can more easily, in private, exercise power and control in the relationship (Schwartz, 2011, 24).

Sex-offense-specific treatment begins with assessments and planning that take into account the duration, frequency, variety, and intensity of the client's sexually abusive behavior. Many convicted sex offenders have extensive sexually abusive histories beginning when the person was young. Heil and Simons (2008, page table is located on) summarized the following information. Wilcox, Sosnowski, Warberg, and Beech (2005) found the mean age of onset was 13; Freeman-Longo and Blanchard (1998) reported ages 18 for rapists and 15 for child molesters; Simons, Heil and English (2004) reported age 12; and English, Jones, Patrick, Pasini-Hill, and Cooley-Towell (2000) reported age 11 for those convicted of incest and 13 for non-incest offenders. Wilcox et al. (2005) found the average age from onset to detection to be 14 years; Freeman-Longo and Blanchard (1998) found 6 years for rapists and 13 years for child molesters; Simons, Wurtele, and Durham (2004) reported 16 years; and English et al. (2000) estimated 10 years.

Lengthy and intense treatment may be required for many sex offenders, particularly since these behaviors are likely to result from the interaction of biology and social learning (Ward & Beech, 2008). Abel, Becker, Cunningham-Rathner, Mittelman, and Rouleau (1988) and others (Abel & Rouleau, 1992; Ahlmeyer et al., 2000; English, Jones, Patrick, & Pasini-Hill, 2003a, 2003b, English, Jones, & Patrick, 2003b; Heil, Ahlmeyer, & Simons, 2003; O'Connell, 1998, Simons et al., 2004; Wilcox et al., 2005) have documented the presence of multiple paraphilias. Abel et al. (1988) discussed a "wave effect" in some offenders with multiple paraphilias where preferences changed over time and the intensity of one behavior rose while others subsided but sometimes overlapped (page).

Additional treatment needs may become apparent after the full pattern of sex offending is identified. The offender generally discloses information incrementally over the course of treatment, with careful integration of the polygraph test and treatment; much of the offending pattern and history can be discerned within 12–15 months. During this period, issues such as compulsivity, impulsivity, and hypersexuality often become evident. The experience of childhood trauma may also be revealed: "For some offenders, their own childhood victimization has been so severe and traumatizing that several years of [therapy] work are needed before they can work through issues blocking their progress" (Scott, 2011, pp. 27–11). Therapists may consider psychiatric referrals for medication (e.g., SSRIs) as an adjunct to cognitive-behavioral treatment when necessary; monitoring medication use then becomes an important component of containment. To be relevant to the offender and to be effective in terms of public safety, comprehensive individualized treatment plans and relapse prevention/community safety plans should also be based on more complete information. These plans are thus revised and made more specific over time.

The offenders' officially recorded crimes may not reflect their most serious sex offending behaviors. There is little utility to a relapse prevention or risk management plan that is only designed to prevent sex offenses identified in the official record without addressing the actual range of sex offending behavior. For example, a relapse prevention plan for a rapist may permit him to reside with his children based on an assumption from the official record that he does not pose a risk to children. However, as revealed in studies with guaranteed confidentiality or treatment with polygraph, approximately 50 to 65 % of rapists have committed child sexual abuse (Abel et al., 1988; English et al., 2000; Heil, Ahlmeyer, & Simons, 2003; O'Connell, 1998; Wilcox et al., 2005). Therefore, determining whether the rapist has a history of child molestation becomes an important consideration in developing an effective relapse prevention or community safety plan. In addition, comprehensive sexual history information may help therapists assess sex offending motivations and risky lifestyle patterns. This will lead to the identification of alternative skills that the offender may need to develop in order to decrease opportunities to reoffend. Skill development consists of assistance in building a new lifestyle that includes productive leisure time, satisfying vocational skills, and authentic relationships.

Treatment and Disclosures

The victimization data discussed earlier suggests that the majority of sex crimes are never disclosed or recorded in official records. And for those that are in the criminal justice system, "Once an individual has been arrested…he stops talking about the kind of behavior he has been involved in" (Abel, 2012,D-4). The hidden nature of the behavior for which the offender seeks treatment means that the therapist can best care for the client by uncovering the extent of his or her deviant sexual history. Treatment providers help the offender to disclose the full extent of his or her deviant sexual history because this is necessary to develop an individualized treatment plan that addresses his or her full scope of issues and needs. As previously stated, age of onset, duration of offending, frequency of offending, and the variety of behaviors the offender engaged in must be understood in order to develop a meaningful treatment plan. In addition, allowing the offender to hold on to powerful secrets about their past abusive behavior is not therapeutic and if allowed by the therapist may perpetuate the secrecy at the core of the offender's lifestyle. Marshall (1994) describes procedures for overcoming denial and reducing minimization and

clarifies a critical part of the disclosure process: people are most likely to take the risk to admit to acts that they believe others view as repugnant if they know they are not going to be rejected and if they are assured that support and help will continue (page). This idea is a foundation of the containment approach.

In containment, the treatment provider and the supervising officer work closely together in a collaborative team. To participate in community treatment, the offender agrees and consents to a waiver of confidentiality to permit information sharing among containment team members, including the polygraph examiner and law enforcement. An essential role of treatment in the containment approach is to obtain details about each individual's offending history, patterns, and precursor behaviors necessary for criminal justice officials to develop risk management plans. The information is verified using a polygraph examination as discussed above.

Uncovering the Offender's M.O.

Specific information about a sex offender's *modus operandi* is obtained though sex offense-specific treatment and validated and expanded by post-conviction polygraph examinations performed by specially trained examiners. Pithers' (1990) description of the assault pattern is a reminder of the need to be alert to what may, at first, appear to be accidental or occasional victim access: "Many aggressors, seeking to minimize their responsibility for offenses, would also have us believe their behaviors are the product of irresistible impulses overwhelming their self-control....In reality, many offenders carefully plan offenses so that they appear to occur without forethought" (334). Amir (1971) found that 75 % of rapes involved some degree of planning, while Pithers et al. (1988) reported that 90 % of their sample of sex offenders reported experiencing specific, strong, emotional states before reoffending. Hudson, Ward, and McCormack (1999:179) stated that "much of the optimism that has pervaded the treatment of sexual offenders in the last 15 years has come from the notion that the processes that these men follow are comprehensible and, therefore, under ideal circumstances, at least controllable" (179).

This idea is central to the containment approach. This attention to planning increases the likelihood that each offender's MO can be identified, allowing the supervising officer and the treatment provider to apply appropriate restrictions to reduce the likelihood of reoffense. Some examples of pre-assaultive behavior include stalking a victim prior to an assault, standing beneath a stairway to view underwear, going to children's movies or toy stores, purchasing toys and child-friendly videos, secretly watching family members, engaging in substance abuse, and jogging through neighborhoods at night. Having knowledge of these pre-assaultive behaviors can allow supervising officers to intervene before a sexual assault occurs. For example, one offender, who described in his sex history journal his use of shelter dogs to get the attention of child victims, was prohibited from owning a dog when released on parole. During his first home visit, his parole officer found a newly purchased dog collar, and the offender was revoked to prison. In another example, an offender with a pattern of stalking victims can be asked on a polygraph examination questions specific to stalking. The very specific nature of the question increases accuracy, and failing on a very specific question related to the offending pattern should result in an immediate response by the criminal justice system. This can include law enforcement surveillance, but it can also include changing the individual's living situation, requiring the individual to team up in a buddy system with other members of the (milieu-oriented) treatment program, using GPS monitoring, and alerting at-risk individuals in the offender's life.

As previously described (see also English, 1998, 2004; English et al. 2000; English et al. 2003b), early in the treatment process, the offender will be assigned the job of writing a sex history journal detailing past sexual activity, consenting and nonconsenting (since sometimes what appears to be consenting to the client is actually coercive), a description of the victim (age, gender, general relationship to offender), and the circumstances surrounding the assault. In this extensive exercise, the offender reveals the range and frequency of sexually abusive behavior. This information, typically not otherwise disclosed by the client, will be used to manage current and future risk, and to ensure that the offender's treatment plan is appropriately directed at real patterns of behavior. Because many individuals have early onset of sexually abusive behaviors, information about the duration of the offending history can inform the treatment plan. Abel and Rouleau (1990) found that over 50 % of his sample of more than 500 noncriminal justice-involved men reported they were below the age of 18 when they began sexually abusive behaviors (page); English et al. (2000) found an average age of onset of 12 (11 for those convicted of incest) for contact and noncontact behaviors in their study of offenders on probation and parole in three states (page). This early onset, particularly when combined with frequent offending, suggests a need for intensive, long-term treatment, supervision, and positive support to change what is apt to be a deeply entrenched lifestyle.

Once the client's sex history information is provided to the polygraph examiner, the therapist and the supervising officer work with the examiner to construct monitoring questions specific to that offender's MO, such as "Since you were released from prison on January 15, have you stalked anyone?" (The word *stalk* will have been carefully defined by both the examiner and the offender before the polygraph examination began). Deceptive findings on the exam should be followed by a subsequent and more narrowly focused exam at a later date.

Challenges for Therapists

Many of those providing treatment services to sex offenders believe their skills can overcome the client's patterns of secrecy and denial and are surprised to learn that many offenders still withhold information that is only revealed during the polygraph testing process. Moreover, many professionals can be deeply affected by the full scope of harm the offender has inflicted on victims. These issues present significant challenges to treatment providers who require specialized training and support from their colleagues to learn how to integrate polygraph assessments as a therapeutic tool.

It becomes easier to incorporate polygraph-related information into the treatment and supervision process when the containment team members prioritize public safety. The full details about the offender's past behaviors and dynamic risk factors that are revealed through the sex history journal and ongoing polygraph examinations often leave therapists feeling negatively about their clients. Ward and Fisher (2006) discuss the need for clinicians to have a "mixed view of human nature," meaning that those who work with sex offenders should believe that "individuals have innate tendencies to behave both altruistically and aggressively or selfishly toward their fellow human beings" (155). The therapist must use the information gathered through the polygraph testing process to manage risk and also engage the offender in the process of change. Managing the information obtained by using the containment approach, especially the polygraph, is part of the necessary challenge for professionals.

Avoiding information can lead to serious gaps in containment and real gaps in public safety. English et al. (2000) collected detailed data by hand from the treatment and polygraph files of 180 convicted sex offenders on probation or parole in jurisdictions in three states. The information provided below shows what information was available in the official records prior to the onset of treatment/polygraph and afterward. Nearly all the individuals were convicted of crimes against children, and 80 were convicted of sex crimes against their own children; 31 were preparing for the polygraph examination; self-report data were collected just prior to their first exam.

Table 2 shows the proportion of the sample admitting to sex offenses committed as an adult against victims in specific age/gender categories. Before treatment and polygraph, 4.4 % reported sexually assaulting a boy younger than 6 years old, and afterward, 10.3 % of the sample admitted assaults against this age and gender group. This information tells both treatment providers and supervising officers what specific groups of potential victims offenders must avoid and suggests that multiple MOs may be involved when a wide range of age groups is targeted. When multiple MOs are involved, this must be carefully addressed in the relapse prevention/community safety plan. Also, 95 % of the sample was convicted of a crime against a child or adolescent, but 36.7 % reported a history of sexually assaulting adult women and 7.2 % reported assaulting adult men. Abuse of multiple age groups may reflect the need to assess compulsivity or hypersexuality. Also, an expanded evaluation targeting a wide range of thinking distortions, beliefs about consent, hostility, and entitlement may be necessary to ensure that the treatment approach is comprehensive enough. According to Heil and Simons (2008) "multiple paraphilias are difficult to detect, monitor and treat" (542). The greater the range of problems, and the more engrained the belief system, the more likely the need for intense treatment and monitoring of sufficient duration to allow the offender to make sustainable changes and begin to experience the benefit of a prosocial lifestyle.

Table 3 shows a larger proportion of the sample disclosing the listed assaultive behaviors after treatment with polygraph examinations. The proportion of the group reporting

Table 2 Percent offenders admitting to victims in each age and gender category before and after the polygraph

Age and gender categories of victims	Total ($n=180$) Represents sexual offenses committed as an adult	
	% before	% after
Males 0–5	4.4	10.3
Females 0–5	11.1	23.9
Males 6–9	7.2	10.6
Females 6–9	22.8	30.6
Males 10–13	5.6	11.1
Females 10–13	38.9	44.4
Males 14–17	5.0	11.1

Bestiality	5.3	47.4	3.2	45.2	9.7	19.4

these behaviors increased substantially "after" treatment/ polygraph. For example, excessive aggression nearly tripled. Over one-third of the group reported engaging in bestiality as an adult, suggesting that the supervision plan should disallow access to animals. Learning that an offender has engaged in bestiality presents a significant opportunity to learn more about the secrecy and likely shame associated with this behavior. The treatment provider may want to address this behavior in individual sessions when the therapist can ask very specific questions about intimacy and violence with the animal. Gene Abel, M.D. (2007) describes bestiality as "very relevant: these individuals are adept at ignoring many things, including fur, feces, and the animal trying to get away from you" (page). Abel believes this behavior signifies "deep denial that leads to the idea that having sex with a child is no big deal" (page). In addition, it is noteworthy that nearly half of those in Sites A and B reported engaging in bestiality. Others have studied the prevalence of bestiality among convicted sex offenders. Heil and Simons (2008) found 59 % of child sexual abusers engaged in bestiality compared to 30 % of rapists (page). In the same study, 81 % of those who assaulted both children and adults reported bestiality. Simons, Wurtele, and Durham (2004) found that those who had abused animals were at significant risk to children (page). Without the combination treatment/polygraph, this important marker for dangerousness—assaulting another species—may remain unknown and therefore not a focus of treatment or supervision.

Of particular interest are the noncontact sex crimes of exhibitionism and voyeurism, which seem to be especially underreported initially. These behaviors may occur early in the offending cycle or fuel compulsive behavior. Both are therefore important in terms of risk assessment; understanding the role of hands-off crimes in the assault cycle can alert both the offender and the containment team to the need for an immediate increase in external structure (which may include house arrest), supervision, and support to provide the containment necessary to avert the progression to a hands-on sex crime.

While the information in Tables 2 and 3 may seem alarming, it is consistent with the groundbreaking work of Abel et al. (1988) and Abel et al. (1987) using federal certificates of confidentiality and other polygraph studies (see Heil & Simons 2008 for a review). Further, the findings presented here are likely to be underestimates because many of the examination results were deceptive. Additional polygraph examinations result in a greater proportion of nondeceptive examinations and, correspondingly, additional disclosures as reported by Heil et al. (2003). Note that the consistent application of sanctions and incentives increases disclosures and nondeceptive findings on the polygraph examination (Ahlmeyer, Heil, McKee, & English, 2000).

To underscore the need for the polygraph to be well integrated with treatment and supervision, Table 4 shows differences across the sites where data were collected. Site A had containment teams that were well established and closely coordinated. Site B was composed of experienced professionals who considered themselves to be working in containment teams but in fact communicated infrequently. Consequently, treatment services and supervision strategies were not well integrated and in practice did not consistently incorporate the additional information obtained during polygraph exams. Site C had just implemented the polygraph into treatment and supervision only months prior to the study, and offenders had not yet received pressure from the containment team to fully disclose. Harrison and Kirkpatrick (2000) found that offenders tend to think they can "beat the

polygraph" prior to their first examination, suggesting they might not be forthcoming with complete information early in the treatment/polygraph process. Finally, in none of the sites were there consistent consequences for lack of disclosure.

Longer implementation and greater containment team cohesion were generally correlated with higher rates of nondeceptive responses: 66 %, 49 %, and 30 %, as shown in Table 3. Greater rates of disclosure were found generally in the first two sites compared to Site C. This supports the assumption that the information in Tables 1 and 2 underreports the actual frequency of engaging in these specific sexually abuse behaviors, and it underscores the need for those implementing the containment approach to work together closely. Of course, some unknown portion of the variation across sites may also reflect actual differences in behavior.

Over half (57.8 %) of the study cases disclosed sexually assaulting family victims in addition to the current victim (data not displayed). Of these, 34.8 % self-reported assaulting strangers and 56.7 % said they also had victimized another from "a position of trust." This "relationship crossover" is important for both treatment providers and supervising officers because it reveals the range of the preferred and expanded victim pool. Twenty-nine percent reported assaulting both males and females (data not presented). Abel et al. (1988) found that 23 % of his sample offended against both family and nonfamily victims and, of those who raped adult women, 50.6 % admitted to also molesting children (page). Twenty-percent reported assaults against both males and females. Ahlmeyer et al. (2000) found 50 % of the adult rapists also admitted sexually abusing children, and 82 % of the child molesters reported sexually assaulting adults (page). Even those convicted of "hands-off" crimes require careful assessment: Abel et al. (1988) found that exhibitionists were highly likely to engage in additional sexually assaultive behaviors: 46 % had assaulted young girls, 22 % had assaulted young boys, and 25 % admitted raping an adult (page). Based on this information, Abel and Rouleau (1990:10) said: "Therapists need valid, reliable information from the sex offender. Without this, the treatment is less likely to identify the precise treatment needs and to quantify treatment's long term effects" (page).

This analysis of multiple targets begins to reveal information about offending frequency. Among those who started offending before the age of 18, Abel and Rouleau (1990) reported an average of 380 contact and noncontact sex crimes by the time the men reached adulthood (page). In a small sample of inmates, Ahlmeyer et al. (2000) found that inmates reported an average of more than 500 contact and noncontact sex offenses and an average of 184 victims. Freeman-Longo and Blanchard (1998) studied 23 rapists and found that this small group reported 319 incidents of child sexual abuse. Heil et al. (2003) studied 233 inmates who reported an average of 137 sex offenses committed against an average of 18 victims. Emerick & Dutton (1993), Simons et al. (2004), Weinrott & Saylor (1991), and Wilcox et al. (2005) report similar findings.

Containment in Prison

Although there are more external controls and supports in prison, there are many opportunities for inmates to sexually act out (Heil et al. 2009, page). This is important risk and treatment information, so there is value in using the containment approach, including the polygraph examination, in prison. Since containment is about using multiple strategies to obtain information from the offender that can be shared for the sake of enhancing public safety, prison is an excellent environment to implement containment strategies. Prison treatment staff can establish relationships with law enforcement, engage in collateral contacts including working with families, provide intense treatment, and prepare offenders to release into containment when they are placed on parole supervision. Preparing offenders for community-based containment can greatly enhance their likelihood of success, as shown in Table 5, along with their longer term outcomes, as shown in Table 6.

The Sex Offender Treatment and Management Program at Arrowhead Correctional Center in Colorado has been using the polygraph exam in treatment for over 15 years. It is well integrated into the program (for a full description of the program and recidivism outcomes, see Lowden et al. 2003). Because the program is unusually comprehensive compared to what is available to offenders serving community sentences in Colorado (where 90 min group therapy once or twice per week is typical), and because program evaluation outcomes were positive (See Tables 5 and 6), a brief description of the program is included here.

Phase I is a time-limited therapy group that includes an initial curriculum on criminal thinking errors, anger management, and stress management. Some of the sex-offense-specific issues and areas that are addressed include characteristics of sex offenders, development of victim impact, cognitive restructuring, sex offense cycles, relapse prevention, healthy sexuality, social skills, and relationship skills. The program lasts 6 months and offenders participate in group treatment for 2 h/day, 4 days/week. Phase 1 does not include the use of the polygraph examination. Lowden et al. (2003) found that the average length of time in Phase 1 approached 9 months because some offenders were terminated for nonparticipation and were required to start at the beginning when they reentered the program (page if available). Phase 1 operates in five facilities, including the women's prison; two facilities accommodate low functioning inmates, one accommodates the hearing impaired and one accommodates Spanish-speaking inmates. All those who complete Phase 1 are eligible to participate in Phase 2. Phase 2 is a modified therapeutic community where offenders live and work together. Polygraph testing is part of the Phase 2 program. Lowden et al.'s (2003:31) description of Phase 2 remains consistent with current operations:

> To participate in the TC, inmates must be motivated to work toward eliminating sexual assault behavior and they must accept responsibility for changing their destructive actions. The TC program addresses offenders' life skills and their understanding of the world, others, and themselves. It also seeks to teach offenders to develop socially appropriate and non-sexually aggressive responses to their problems. Treatment topics include relapse cycle and prevention, cognitive restructuring, sexuality, social skills, and levels of denial (page).

Phase 2 offers 15 different types of therapy groups, including a probation group for those who have been placed on treatment probation for lack of progress. The average time in treatment for Phase 2 participants is more than 12 months. To be recommended for parole by the treatment program, inmates must meet the following criteria:

- Actively participating in treatment and is applying what he or she is learning
- Completed a nondeceptive polygraph assessment of his/her deviant sexual history; any recent monitoring polygraph exams must also be nondeceptive
- Practicing relapse prevention with no incidents of institutional acting out within the past year
- Defined and documented his or her sexual offense cycle
- Reviewed and received a therapist-approved copy of the sexual offense cycle
- Identified at least one approved support person who has attended support education
- Compliant with any psychiatric recommendations for medication that may enhance his or her ability to benefit from treatment and/or reduce his/her risk of reoffense
- Benefited from treatment and/or reduced his/her risk of reoffense
- Able to be supervised in the community without presenting an undue threat

Resources limit the number of inmates served. In 2009, there were approximately 2,500 sex offenders serving time in the Colorado Department of Corrections; 172 offenders participated in Phase 1 and 100 participated in Phase 2.

The use of the containment approach in prison can improve success rates in the community, enhancing public safety. Parole officers reported that parolees who had participated in the prison treatment program understood what was expected of them in community containment (Lowden et al., 2003, page) and more easily transitioned into community residences. The structure offered by containment on parole seemed valuable to offenders: 70 % of the Phase 1 participants successfully completed parole, and 84 % of the Phase 2 participants successfully completed parole, compared to 52 % of sex offenders (in an unmatched comparison group) who did not participate in treatment.

Apart from providing treatment and containment services to inmates, a program mission is to enhance knowledge and understanding of this offender population. Table 7 shows the results of a study of offenders in Phase 2 sex offender treatment at the Colorado Department of Corrections who were found nondeceptive on their sexual history polygraph examination. The table shows self-reported "hands-on" sex abuse histories of 408 individuals who participated in Phase Two. It excludes noncontact behaviors such as exhibitionism, voyeurism, and Internet sex crimes. The findings show that 2 %, or 9 people, reported only one offense and were found to be nondeceptive on the polygraph examination. For these individuals, this single victim and crime represented the crime

Table 7 Frequency of contact sex crimes: nondeceptive polygraph findings ($n=408$)

One victim	5 % (19)
One sex offense	2 % (9, 8 were violent with force/weapon)
Number of victims (median/mean)	14/23
Number of offenses (median/mean)	42/263

for which the inmate was imprisoned. Eight of those with a single offense were convicted of violent sex crimes. The remainder of the inmates, 98 %, reported more than one offense. The nondeceptive program participants reported a median of 14 victims (mean of 23) and a median of 42 (mean of 263) contact offenses.

Assessment is Ongoing

The information obtained using the combination of treatment and polygraph shows that offenders with multiple paraphilias, multiple victims and offenses, and early age of onset are not unusual. Rather, many of the offenders who come to the attention of the criminal justice system seem to have these complicated patterns of behavior. Yet, there are important differences among offenders that must be identified to individualize the treatment intervention. Simons, Wurtele, and Durham (2004) found that offenders who were primarily child sexual abusers (i.e., those who reported that at least 80 % of their victims were children) had child sexual abuse histories, earlier onset of masturbation, early exposure to pornography, and sexual activities with animals (page). Heil and Simons (2008) discuss these findings in terms of social learning theory and the need for treatment to help the offender resolve childhood trauma as it relates to sexual abuse. Simons et al. (2004) found that sex offenders who were primarily adult rapists had childhood experiences involving physical abuse, parental violence, emotional abuse, and cruelty to animals. These individuals tended to respond to emotionally charged situations with aggression and violence. Finally, those offenders who Simons et al. (2004) labeled "indiscriminant" because they did not meet the 80 % threshold for rape or child molestation had childhood experiences with both heightened sexuality and violence. Discussing the issue of multiple paraphilias, Heil and Simons (2008:542) state that these individuals "have structured their lives to gain access to sexual outlets, and consequently they may have developed few other interests and social contacts" (page). They recommend that treatment providers use information gained from polygraph examinations to evaluate for multiple paraphilias and evaluate for trauma and attachment issues, attention-deficit/hyperactivity disorder (ADHD), depression, and social phobia. Comprehensive treatment for multiple paraphilias includes cognitive-behavioral treatment, pharmacology, trauma therapy, attachment interventions, and containment.

In sum, information about patterns of sex crime behavior—age of onset, duration of offending, frequency, seriousness, and variety—routinely provided by offenders in the written sexual history journal described above and verified polygraph examinations can provide relevant information about the risk offenders present to individual victim groups, and illuminate treatment needs and patterns of dangerous behavior. The containment approach involves using knowledge of these behaviors to develop relapse prevention/community safety plans that account for preferred targets while helping the offender learn to replace destructive patterns with prosocial behaviors. Offenders have a range of criminogenic needs that must be targeted in offense-specific treatment. Offenders can learn to avoid new criminal behavior while learning to build a "good life" (Ward & Stewart, 2003b; Ward & Marshall, 2004; Yates, 2004; Ward and Fisher, 2006). However, the polygraph data used in the containment approach suggest that many sex offenders in the criminal justice system have multiple paraphilias. This information may not be available early in the assessment and treatment process, suggesting that assessment should be an ongoing part of treatment. The prevalence of multiple paraphilias in the sex offender population suggests that treatment, to be effective, must be intense, frequent, and long term.

The Impact of the Polygraph on Therapists

As addressed above and referred to elsewhere (English & Heil, 2006), the information disclosed during the polygraph examination can be alarming. Reflective of the disquieting effect of information disclosed during the polygraph examination, examiners and supervising officers frequently reported to us during dozens of interviews that some therapists were resistant to the examination findings (English et al., 2000, page). In these cases, therapists often did not return phone calls from the examiner and, when they did speak on the phone, the therapist was skeptical rather than feeling relief at getting information previously withheld by the offender. Clearly, some therapists struggle with reconciling their perceptions of the offender's treatment progress with the new information obtained from the polygraph process (Grubin et al., 2004, page). Once the information is revealed, the therapists and team members must reevaluate their treatment and supervision plans to develop appropriate responses to the information. The polygraph testing procedure becomes less useful without this response. Research at the prison sex offender treatment program in Colorado found that participants were significantly more likely to fail polygraphs when the therapist was rated as ambivalent about the use of the polygraph (Simon, Heil, and English, 2004, page). The therapist's commitment to the use of the polygraph is a critical aspect of its successful implementation.

Nevertheless, its use is challenging. The polygraph examination results can be especially concerning when certain clients, thought to be progressing well in treatment, are found deceptive on the polygraph test. Sometimes these exams involve disclosures by the offender of high-risk or

actual offending behaviors. When the offender fails to disclose new information—and sometimes when he does—the situation can give rise to professionals' concerns that the polygraph is not accurate or the examiner is not competent. Sometimes this leads to significant conflict between the therapist and the supervising officer, who may act on the information by increasing surveillance and restricting the offender's lifestyle. If the offender discloses new criminal behavior, the officer may pursue an arrest.

This series of events can create considerable tension among the examiner, officer, therapist, and offender. All containment team members need to remain mindful that they can be groomed by the offender to disregard concerns. Since addressing manipulation is an inevitable aspect of treatment and containment, the polygraph is a helpful tool. The development of policies, protocols, and agreements regarding the use of the information learned from the polygraph exam will be especially helpful at this time. Additionally, there is no substitute for enthusiasm and purposefulness about this work. Understanding the value of working with sex offenders may be the most important antidote for the difficulty of the work itself.

As we have discussed before (English and Heil, 2006), it may be helpful to those who find themselves uncomfortable with the polygraph process to consider that the examination is intended to help prevent the offender from harming again. This is a humane undertaking. Offenders reluctantly report that the use of the polygraph is valuable, even though they dislike taking the exam. Therapists who dislike the use of the polygraph may benefit from visiting the examiner at his office, observing an exam via short circuit television or videotape, talking with other therapists who use the polygraph, and obtaining training that specifically focuses on how best to use post-conviction polygraph results.

The polygraph examination should only be used in conjunction with sex offense-specific treatment. These two components, acting together and consistently, provide a powerful incentive for an offender to be truthful and to refrain from behavior that puts the community at risk while helping the offender adopt prosocial thinking and behavior. Without the use of the polygraph examination process, the information necessary to manage the risk of offenders is significantly incomplete, and the offender's risk to the community remains uncertain.

Risk and treatment plans may need to be adjusted when more complete information is obtained. Thus, low risk on sex offender actuarial scales should be questioned later when the offender discloses a more serious offending history. In fact, comprehensive treatment with a consistent focus toward new, potentially risk-related information necessarily moves the management team to focus on a case-by-case basis. To maintain a public and victim-safety perspective, it is necessary to move away from cookie-cutter interventions and toward individualized treatment based on learning information that an offender may be trying to hide. This specific focus on each offender means that a centerpiece of community-based containment is the use of technical violations as one option to preventing new sex crimes.

Criminal Justice Supervision

It is imperative that community supervision within the containment approach be well implemented, since most sex offenders serve all or part of their sentences in the community. In Colorado, in fiscal year 2012, one out of three adults (37 %) convicted of a sex offense received a direct sentence to prison. The remainder were sentenced to probation or a combination of probation and jail.

The supervising officer is empowered primarily by the authority of the criminal justice system, which can exercise its containment powers a number of ways. These include specialized conditions of supervision, longer probation and parole sentences, restrictions on high-risk behaviors, restrictions on contact with children, random home visits, urinalysis testing, and verified law enforcement registration. Computer and Internet monitoring of sex offenders (Bullens, 2004) and GPS and electronic monitoring (Padgett, Bales, and Blomberg, 2006) are also important containment tools.

Supervising officers should be familiar with the stages of change (Prochaska et al. 1992, page) and understand that personal change is hard. A supervising officer in Colorado works with offenders to develop a life plan, which starts with him/her asking new clients to make a list of (prosocial) activities they would like to accomplish. Developing this list is usually an exercise that takes several visits with the officer. One offender expressed a wish to attend college, and the officer helped the offender access financial aid to accomplish this. Involvement in college courses also had the advantage of removing the offender from his negative peer group and involving him with prosocial others. This is an excellent example of a supervising officer proactively assisting the offender with the change process. In the containment approach, supervising officers are obligated to help the offender succeed while recognizing the difficulties involved in the change process. Indeed, officers should be aware of each offender's preferences, strengths, competencies, and resources: "This crucially involves identifying the internal and external conditions necessary to implement the [treatment] plan and designing a rehabilitation strategy to equip the individual with these required skills, resources and opportunities" (Ward & Fisher, 2006, 154). The supervising officer should work closely with the treatment provider to support and reinforce the work of therapy (see Scott, 2011).

Among the most important of containment tools is the relationship between the supervision officer and the client.

Recent research has underscored this often-overlooked aspect of supervision: Skeem et al. (2003) state that the relationship between the officer and the offender can be "a pivotal source of influence on the implementation of treatment mandates" (see Alexander et al. 2008). Skeem et al. (2007) found that relationship quality involves caring, fairness, trust, and an authoritative not authoritarian style (page). The content of the conversation between the supervising officer and the offender also matters. Emerging research in Canada suggests that focusing on the offender's criminogenic needs during the supervision meeting rather than the conditions of supervision reduces recidivism (Bonta et al. 2010, page).

The supervising officer represents the criminal justice agency responsible for the offender, and so he or she generally convenes the containment team. In prison treatment, the therapist often plays both roles, although correctional officers, especially work supervisors, can be trained to assist in the containment process. Supervising officers depend on a variety of information tools including collateral contacts with an offender's family members, roommates, employer, and the victim's therapist, for example.

Officials can define the behavioral changes required of sex offenders as they move through stages of treatment and show themselves to be managing their own risk. The Colorado Sex Offender Management Board (*Standards and Guidelines,* 2011), at the request of the state's General Assembly, documented the behaviors necessary to show successful progress through offense-specific treatment and completion of treatment. The behaviors can be monitored by the supervising officer and used to set clear expectations for supervision and treatment compliance. The following is a list of some common behavioral compliance expectations.

The offender:

- is, and consistently has been, in compliance with all recommended prescribed psychiatric medications used to reduce arousal or manage behaviors related to risk
- can identify objectification and inappropriate sexual gratification in relationships and is developing skills to address them
- is addressing any domestic violence history with appropriate domestic violence treatment and has not engaged in domestic violence
- is addressing drug and alcohol programs in treatment and is maintaining abstinence if recommended
- the offender demonstrates control over arousal and interest through plethysmograph or Abel Screen "improvement"
- the offender consistently completes nondeceptive polygraph examinations regarding high-risk and precursor behaviors and masturbation to deviant arousal fantasies
- the offender consistently demonstrates self-motivated use of a relapse prevention and safety plan and has distributed written copies of the plan to any cohabiters and significant others
- the offender consistently demonstrates self-motivated use of treatment techniques for identifying and correcting cognitive distortions

These are just a few examples of the specific behavioral requirements of sex offenders under supervision and in treatment in Colorado. For more information, refer to the Colorado Sex Offender Management Board's *Standards and Guidelines* (2011).

Leverage and Sanctions

Criminal justice systems can encourage, even leverage, the offender to engage in treatment. This is a long-valued role in the substance abuse treatment community. The National Institute on Drug Abuse (2012) lists the following as "Principle 8" in its description of substance abuse treatment with criminal justice populations: "The coordination of drug abuse treatment with correctional planning can encourage participation in drug abuse treatment and can help treatment providers incorporate correctional requirements as treatment goals" (3).

Consequences for failure to follow the directives of treatment and supervision can take a variety of forms. At a minimum, surveillance can be increased (house arrest, electronic monitoring, additional home visits by the supervising officer, requirements to phone the officer or others with location information) and orders for additional treatment sessions or homework can be imposed. Intermediate sanctions include community service activities, short-term jail sentences, or placement in a halfway house for sex offenders. At the extreme end of the sanction continuum is revocation of the community sentence and placement in prison. But prison sentences are not the end of risk management concerns, since most prisoners eventually are released into the community whereupon the containment approach should be reinstated.

Consequences can be clearly spelled out because this clarity promotes consistency and communicates what is expected of an offender. Sometimes this takes the form of a lengthy and explicit treatment contract. Members of the Colorado Department of Corrections sex offender treatment team and parole officers joined with local treatment providers to develop a "decisions grid" specific to polygraph testing (see Fig. 1) although other types of grids can be valuable. Low-level sanctions included starting regular urinalysis testing, restricting community activities, requiring additional treatment homework, and imposing a curfew or geographic restrictions. Medium-level sanctions included withdrawing driving privileges and travel permits for vacation, more visits

	Admissions Prior to Polygraph Examinations	Admissions During Polygraph Pretest	Admission to Non-deception findings at Posttest	Admissions to Deception Posttest	No Admissions to Deception
Past offenses & High Risk Behaviors					
Behavioral Lapses & Basic Rule Violations					
Serious Treatment Rule Violations					
Offenses & High Risk Behaviors					

Fig. 1 Decisions grid provides clarity

with supervising officers, frequent searching of the residence, and prohibiting community activities. High-level sanctions included moving the offender to intensive supervision status, contacting law enforcement for surveillance, requiring community service, and imposing a curfew with daily scheduled call-ins to the officer. All sanctions included increased supervision. Incentives for treatment progress and nondeceptive results were also included. The decisions grid is discussed with every offender and is attached to a form that requires the signatures of the therapist, supervising officer, and offender. The grid is an excellent example of coordination and collaboration among stakeholders who wanted to be clear and consistent regarding the use of sanctions.

The use of sanctions in the containment approach is consistent with substance abuse treatment as recommended by the National Institute on Drug Abuse (2012), "Rewards and sanctions are most likely to change behavior when they are certain to follow the targeted behavior, when they follow swiftly, and when they are perceived as fair" (21). Many treatment providers have reported that without the leverage of the criminal justice system's consequences for noncompliance, they could not engage sex offenders in the treatment process (English et al., 1996, page). When the offender engages in a long-term process to change what is often a deeply entrenched pattern of behaviors, motivation to change can be expected to ebb at times. Sanctions, including treatment termination and revocation, provide important public safety leverage because ambivalence is part of the nonlinear change process (Prochaska, DiClemente, & Norcross, 1992, page). Personal change is difficult, and many sex offenders enter treatment without a complete understanding of the full extent of their abusive behavior and the psychological difficulty associated with acknowledging the extent of the harm they have done. Treatment must address these issues early on, while providing the offender the tools to learn to rebuild their lives in a healthy way.

Nevertheless, it is important to recognize the dangerousness presented by an offender's inconsistent effort to change. Without external pressure on the offender to adhere to the behavioral expectations detailed in the conditions of supervision and treatment contract, community safety depends on the offender's good will alone. In this way, community supervision and sex-offense-specific treatment are continuously linked, providing the greatest opportunity for the offender to experience the leverage that is often necessary to engage in the difficult change process. Even so, revocation rates are high for failure to comply with treatment requirements, often above 50 %. This should not come as a surprise, however. As mentioned above, Wierzbicki & Pekarik (1993) conducted a meta-analysis of 125 treatment studies and found nearly 50 % of clients dropped out of psychotherapy (page). Prochaska (2001:235) calls this fact a "skeleton in the

therapy closet" (page). In containment, individuals are expected to participate in the therapeutic process because without going through the change process, the risk looms that the client will victimize others with continued sexual offending. Failure to participate in treatment after multiple efforts are made to engage the client will likely eventually result in revocation to prison. Prochaska (2001) reviews studies he conducted with colleagues that focused on clients involved in therapy for substance abuse, smoking, obesity, and a broad spectrum of psychiatric disorders and found that those who quickly and prematurely dropped out of treatment were in the precontemplation stage of change. Precontemplation is defined as the stage in which people are not intending to change or take action in the near future (usually measured as "the next 6 months") (Prochaska, 2001, page). It is not uncommon for treatment programs to offer "deniers' groups" that last up to 6 months; some jurisdictions offer psychoeducational classes in place of deniers' groups (English et al., 1996, page). Marshall and Moulden (2006) report encouraging results from "preparatory programs" that are designed to enhance the effects of subsequent treatment (page).

Case-specific supervision requires planning, documentation, and visits to the offender's home and work. Often, safety considerations require that fieldwork be conducted in teams of two officers. Ongoing training is also necessary to keep professionals at the top of their game. Probation and parole officers should have caseloads limited to 20 or 25 sex offenders, and they should have flexibility in work hours to monitor the offender's activities at night and on weekends (English, 2004, page). Burrell (2006) recommends a caseload of 20 for high-risk offenders (page).

Component 4: Informed and Consistent Public Policies

Clear policies facilitate containment. As described most recently in English (2004), the fourth component of a sex offender containment approach requires local criminal justice practitioners to develop public policies at all levels of government that institutionalize and codify the containment approach (page). Harris and Lurigio (2010:478) reflect on the need to move toward evidence-based public policy and note that "a significant and widening gap exists between the effective practices that are employed by criminal justice and clinical practitioners and the policies that have been created by state and federal legislators" (page). Indeed, local agency policies can be most responsive to the needs of their workers, and the expertise of these workers along with research should be the driving factor behind policy development.

Sex offender policies should hold offenders accountable and, to be effectively implemented in the field, must empower those who work closely with these cases. Policies must define and structure the discretion authorities need to manage each offender individually. Criminal justice practitioners must organize and document local and agreed-upon practices that support a victim-oriented approach to sex offender risk management. English et al. (1996) provide examples of areas that require written guidelines for uniformly managing sexual assault including the following: The weight given in sentencing to an offender's denial of the crime, the use of polygraph information, family reunification assessment protocols, presentence investigation report information, failure to progress in treatment, revocation procedures, third-party liability/duty to warn potential victims, and employment and leisure time restrictions for sex offenders under criminal justice supervision; and the use and limitations of actuarial risk assessment instruments.

Ideally in the containment approach, policies are based on research and best practices. Policies should focus on addressing gaps in risk management activities and empowering the ability of the supervising officer to quickly respond to offender behaviors that are out of compliance with treatment requirements and supervision conditions.

Written policies and procedures are an essential part of the justice process. An offender deserves to know what is expected of him or her and what to expect from the criminal justice and mental health systems. Often, behavioral expectations are spelled out in lengthy treatment contracts. Clear expectations will help keep the focus on the offender "working the program" rather than complaining about the system. Additionally, some policies undermine sex offender containment and minimize the seriousness of the crime. Policies that undermine sex offender containment include allowing plea bargains to lesser charges, to non-sex crimes, or to misdemeanor sex crimes when the evidence exists to fully prosecute the case. Lowering the charge, granting diversion, or issuing a deferred judgment minimizes the case to the offender ("it wasn't that bad, I won't do it again") and the victim ("I'm not important to the court"). When sex crimes are disposed as assaults or trespassing—outside the family of sex crimes—the sexual assault is eliminated in the official record. Aiding in the minimization process will ultimately make it harder for the offender to begin and sustain the lifelong changes required to ensure public safety.

Prosecutors and judges who specialize in sex crimes and receive regular training from national entities understand the power of the court to set in motion the healing process, referred to as therapeutic jurisprudence (see LaFond and Winick, 2004). Evidence-based sentencing practices to reduce recidivism suggest increasing the discretion of the judge so he or she can make decisions based on the risks and needs of each individual and the treatment necessary to reduce the likelihood of reoffending (Wolff, 2008, page).

Clear, consistent, and documented agreements on sex offender polices, developed in a spirit of cooperation among agencies responsible for managing sex offenders, enable the successful implementation of the containment process outlined here. The range of activities that require such documentation is quite large, but primary among them is the need for open communication and information sharing at all stages of the process of managing sex offenders in the community.

Risk Assessment and the Limits of Actuarial Scales

New information about the offender's risk to reoffend is frequently revealed in the first months and years of supervision and treatment. In fact, risk is essentially unknown in the early stages of treatment. It is imperative, then, that intervention strategies and policies encourage an elastic response to risk. Although most sex offenders do not have an extensive arrest or conviction record, much of the research reviewed in this chapter indicates that many have a long history of hurting different types of victims.

Having a sex crime conviction is the most powerful predictor of risk of future sex crime. An often overlooked fact in the Bureau of Justice Statistics study is that a 5.3 % sex crime rearrest rate over 3 years among over 9,600 offenders released from prison means that the convicted sex offenders were four times more likely to be rearrested for another sex crime compared to other offenders (Langan, Schmitt, & Durose, 2003, page). Many reoffended quickly, too: 40 % were rearrested within a year of release from prison. Harris and Hanson (2004) reviewed 10 recidivism studies and found 37 % of sex offenders with a prior sex crime were rearrested within 5–6 years (page). After reviewing the literature on sex offender risk scales and recidivism rates, Doren (2002:150) reported "lifetime sexual recidivism by previously convicted sex offenders is not a statistically 'rare event.' ….[L]ong-term recidivism statistics approach 50 %." (page).

The lack of officially recorded crimes can cloud risk assessments conducted with actuarial scales since these usually depend on past arrests or convictions for sex offenses. Additionally, actuarial scales place individuals into groups with certain statistical probabilities to reoffend and thus do not measure individual-level specific and immediate risk. Policies should reflect the limitations of actuarial instruments to predict short-term risk and to predict unreported sex crime events. Treatment providers, evaluators, judges, and supervising officers need to consider additional information along with actuarial scores when considering risk to the public.

Component 5: Quality Control

Quality control is a fundamental tenet of evidence-based correctional practice (Cohen 2002; Latessa et al. 2002). Program monitoring and evaluation activities combined with professional standards of practice ensure that victim safety and the humane treatment of offenders are not compromised (Przybylski and English, 1996, page).

As addressed in English et al. (1996) and English (2004), the containment approach requires broad discretion on the part of the criminal justice system professionals, treatment providers, polygraph examiners, and others collaborating to protect public safety. This discretion allows for individualized treatment and supervision plans, and quick responses to the ongoing assessment of risk and progress. It also recognizes that these cases often involve complicated relationships between the perpetrator and the victim. Such discretion must be systematically monitored to ensure fairness, justice, and the humane treatment of offenders. For this reason, quality control is fundamental to the administration of any sex offender management program, project, or system-wide process. Quality control activities should include, at a minimum:

- Monthly, multi-agency case review meetings to ensure that prescribed policies and practices are implemented as planned
- The requirement of annual training on the topics of sexual assault, conflict resolution, teaming, victimization, trauma, family reunification, treatment efficacy, and research related to each of these
- Developing and tracking performance measures associated with the policies and procedures specified in the jurisdiction
- Videotaping of all polygraph examinations to avoid recanted statements and to facilitate periodic review of examinations (including chart reviews) by a quality control team
- The collection of case data describing the characteristics of offenders who fail in treatment or commit new sex crimes so gaps in containment can be identified and closed

Sexual abuse cases are difficult to manage, and offenders frequently attempt to manipulate the management system just as they did their victim(s). Containment professionals can burn out, get soft, miss "red flags," become cynical, and otherwise become ineffective. Empathy toward victims and repeated exposure to traumatic material can also result in *compassion fatigue* (Figely, 1995; Stamm, 1995). Police, firefighters, and other emergency workers report that they are most vulnerable to compassion fatigue when dealing

with the pain of children (Beaton and Murphy 1993, page). In addition, "trauma is contagious" (Herman, 1992,180). Compassion fatigue, a near certainty in this work, presents a significant threat to the quality of the program and the well-being of the dedicated professionals who are working to make our communities safer. Ongoing training, flexible hours, a supportive environment, and safe working conditions are important ways that administrators can help fight compassion fatigue.

A final aspect of quality control consists of clearly defined and agreed-upon measures of success. It is challenging to identify measures of detection, detention, and revocation that target offenders *before* the commission of a new assault. Addressing these issues requires the allocation of resources for monitoring and evaluation. Indeed, resource allocation is a key component of quality control.

Effectiveness of the Containment Approach

Lowden, et al. (2003) conducted a comprehensive process and outcome evaluation of the sex offender treatment program at the Colorado Department of Corrections. This program, described earlier in this chapter, employed the containment approach in the institution, including intense treatment with polygraph testing. When paroled, the offenders participated in treatment, supervision, and polygraph testing in the community.

Researchers found that 84 % of the offenders who participated in the therapeutic community component of sex offender treatment in the institution successfully completed parole, versus 52 % of the sex offenders who had not participated in institutional treatment. By the third year following parole discharge, 21 % of the offenders who had participated in institutional treatment had been arrested for any type of crime versus 42 % of the offenders who had not participated in treatment. Treatment and supervision effects lasted for the duration of the outcome period, nearly 8 years. However, over time, individuals in both the treatment and comparison groups continued to fail. After nearly 8 years, 40 % of those who had participated in the therapeutic community were rearrested for any type of crime; 50 % of those who participated in Phase 1 were rearrested, and 62 % of sex offenders who had not participated in treatment were rearrested. These findings may provide the most compelling argument for the value of containment—treatment combined with polygraph examinations and specialized supervision—but the fact that the effect of treatment eroded over time is an equally important finding. Few offenders in Colorado receive the intensity of treatment available to them in prison, yet only half in the prison study remained arrest free after nearly 8 years. Given the lack of reporting by sexual assault victims, actual reoffending rates are likely higher. This suggests the need for ongoing containment for many convicted sex offenders. In a discussion of child pornography offenders, Abel testified to the U.S. Sentencing Commission in 2012 that treatment and follow-up "maintenance" should range from 5 to 10 years and, for some offenders, lifetime maintenance is required (U.S.S.C. 2012)

Other studies also reveal the value of the containment approach. A preliminary study of the containment approach in the Framingham, Massachusetts, parole agency also produced promising results (Walsh, 2005, page). Of the 152 sex offenders managed under containment between 1996 and 2005, 15 were still actively under parole supervision, 81 had successfully completed supervision, and 58 had returned to custody. Eight offenders had been arrested for new crimes, none of which were sex offenses.

A study of the Jackson County (OR) probation and parole program also found support for the containment approach. Comparing outcome data on offenders in the Jackson County program with a comparison group from a nearby county, researchers found that offenders who stayed in treatment/containment for at least 1 year were 40 % less likely than those in the comparison group to be convicted of a new felony (England-Aytes et al. 2001, page). The Jackson County program dates back to 1980 and was featured in English et al. (1996).

The Maricopa County (AZ) Adult Probation Department has been using the containment approach since 1986. An evaluation by Hepburn and Griffin (2002) of the program involving 419 probationers with an average 36-month follow-up period found 2.2% of the offenders were arrested for a new sexual offense and 13.1 % were arrested for a new criminal offense. This appears to compare favorably to Losel and Schmucker's (2005) meta-analysis which found average sexual recidivism rates of 11.1 % and criminal recidivism rates of 22.4 % for treated offenders over an average 5-year follow-up, but the differences in time-at-risk are important.

Stalans (2004) conducted a comprehensive study of probation sex offender programs in three counties in Illinois that were implementing the containment approach. Stalans (2004) concluded that "…all specialized probation programs should be based on the containment approach and should include (a) at least three unannounced random field visits per offender every month, (b) a full-disclosure polygraph and a maintenance polygraph exams every 6 months, and (c) a tight partnership between probation officers and treatment providers that includes probation officers appearing at random times at the treatment site to check on offenders' attendance" (599).

The Virginia Department of Corrections conducted a study of 1,753 sex offenders in three probation and parole regions; 583 were assigned to one of nine containment programs and the remainder were assigned to non-containment units (Boone et al. 2006, page). The new crime rates after an

average of 4.5 years were comparable at 4.5 % (non-containment) and 4.6 % (containment). More than half of those who returned to prison did so due to technical violations, and those who were in containment programs had a 30 % higher technical violation rate than the non-containment group. The researchers stated the following about the higher rate of technical violations: "Higher technical violations are to be expected in containment units as the purpose of the increased supervision is to deter new crime and detect patterns of relapse before the offender engages in a new crime" (Boone et al., 2006, 40). The authors concluded:

> Sex offender containment models modify recidivism rates in different and opposite directions. The first impact is that offenders who violate conditions of their probation will be detected with greater frequency, thus inflating the recidivism rate. The second impact is that sex offender containment models reduce the likelihood that individuals will engage in new crimes by a combination of deterrence (increased supervision) and treatment (sex offender therapy). Non-containment units with similar rates of recidivism cannot be classified as doing just as well as a containment unit based solely on similar recidivism rates. Non-containment units may in fact be missing, due to reduced supervision and the absence of polygraphs, offenders who are committing new crimes, while less intensive treatment may be increasing their likelihood of re-offense (Boone et al., 2006, p. 40)

Finally, published results of a longitudinal, randomized control group study of the treatment program operating at the Atascadero (CA) State Hospital that compared outcomes of treated sex offenders with those of two untreated control groups: treatment volunteers and treatment refusers. Although the authors point out that the random assignment did not produce equivalent groups—the treated group had higher risk scores, a higher number of offenders previously committed for treatment as mentally disordered sex offenders, and a higher number of unmarried offenders—the program was considered state of the art. The Atascadero program used cognitive-behavioral treatment, relapse prevention, and 1 year of aftercare in the community. The evaluation found that the program was ineffective in reducing recidivism. It is important that the authors note that the treatment program differed in some respects from most current treatment programs. To reduce treatment attrition, offenders were not required to fully participate or progress in treatment to remain in the program. Consequently, the offender's sentence determined program discharge and was unrelated to treatment progress or assessed risk. In addition, these offenders did not participate in polygraph testing. After summarizing these issues, the authors conclude:

> Although it has not been rigorously tested, this "containment approach" (English, 1998) represents the current thinking in the field (Association for the Treatment of Sexual Abusers (ATSA), 2004; California Coalition on Sexual Offending, 2001; Center for Sex Offender Management, 2000; Colorado Sex Offender Management Board, 1999). As we learned in interviews with our treatment failures, a number of RP participants were facing high-risk situations soon after entering the community (Marques et al., 2000). It is possible that added surveillance and teamwork could have prevented some of these early failures (Marques et al., 2005, pp. 101–102)

Indeed, the Atascadero program lacked important aspects of the containment approach, including the use of the polygraph, the consistent application of sanctions—including termination from treatment for nonparticipation—and containment upon release from the institution. Requiring that individuals disclose their assault patterns, develop and implement plans to avoid high-risk environments, develop a positive support system, fully engage in treatment upon release, and acknowledge and manage their ongoing risk—that is, take full responsibility for the risk he or she presents to the community—are key components of the containment approach and were not part of the Atascadero program.

Conclusion

In sum, the containment approach is victim-safety focused, multi-agency, and collaborative. This chapter has focused closely on the containment strategy that involves the treatment provider, the supervising officer, and the polygraph examiner. Since the officer represents the criminal justice agency responsible for the offender, he or she generally convenes the case management team, and our research found that the officer and the treatment provider often go beyond the traditional boundaries of their job descriptions to implement containment (English et al., 1996, page). In other words, they show a particular kind of dedication to public safety, making time for the necessary collaborations, teaming, information sharing, training, and surveillance required to manage this population in the community. Supervising officers and treatment providers depend on a variety of information tools including "collateral contacts" with an offender's family members, employer and victim representatives, home visits, electronic monitoring, and urinalysis testing for drug use. While polygraph testing is one technology in a varied set of tools that are used to improve the management of sex offenders, the integration of polygraph testing with treatment and supervision remains at the core of the case management component of the containment approach.

This description, and certainly the practice of actual containment, is consistent with what Lisbeth B. Schorr called "critical attributes of effective intervention" (year, page). In this important paper, Schorr (1999) states that interventions that are most likely to change the lives of children and families in high-risk circumstances share certain attributes. They are (1) are comprehensive, flexible, and responsive, (2) see children [or victims and offenders] in the context of families, and families in the context of communities, (2) have a long-term orien-

tation with an understanding that deep-rooted problems are unlikely to respond to quick-fixes, (3) are managed and staffed by people who believe in what they are doing, (4) operate with intensity and perseverance to achieve a clear, coherent mission, (5) recognize the limits of a single strategy, and (6) encourage staff to build strong relationships based on mutual trust and respect, often going well beyond the boundaries of their job descriptions. Communities where the containment approach is implemented benefit from its focus on public safety.

Finally, the containment approach should be implemented in the context of emerging research in the field. This includes incorporating the risk-need-responsivity model (Andrews, Bonta & Wormith, 2011, p. 738) which includes respecting the client and providing services "in an ethical, legal, just, moral, humane, and decent manner" (page). Equally important is the research that underscores the importance of the relationship between the supervising officer and the offender in the change process (Skeem, Encandela, and Eno Louden, 2003; Skeem, Eno Louden, Polaschek, & Camp, 2007). Likewise, therapists must have a positive attitude toward the offender (Ward and Fisher, 2006, page) and seek to build a strong therapeutic alliance built on honesty, respectfulness, warmth, interest, and openness (Ackerman and Hilsenroth, 2003, page). Fundamentally, this approach seeks to manage risk and hold offenders accountable; this must occur in ways that are compatible with the humane application of containment.

Circles of Support & Accountability: The Role of the Community in Effective Sexual Offender Risk Management

Robin J. Wilson and Andrew J. McWhinnie

Ask yourself: How many people are there in your daily life who are not paid to be there? Now ask yourself, "How successful am I as a person, lover, spouse (maybe), a parent, a friend, or a member of an extended family?" These two questions are almost inextricably related, right? The first you may recognize as a question similar to one found in many assessment tools measuring stable dynamic predictors of risk for sexual reoffending (see Hanson, Harris, Scott, and Helmus, 2007) exploring significant social relationships. Indeed, such instruments consider quite a number of areas that, translated into common parlance, explore a person's connection to and ability to function in a community setting of noncriminal associates (e.g., relationship stability, general social rejection, lack of concern for others, impulsivity, poor problem-solving skills). The need for "community" in anyone's life is extensive, and no less so for the person struggling to cope with issues related to criminal sexual behavior. In fact, poor social functioning and social isolation are well known and commonly observed factors among those who engage in deviant sexual behavior (Finkelhor, 1984; Finkelhor & Araji, 1986; Hanson et al., 2007; Hudson & Ward, 1997; Malloy & Marshall, 1999; Marshall, 1989; Marshall, Barbaree, & Fernandez, 1995; Miner et al., 2010; Pacht & Cowen, 1974; Segal & Marshall, 1986; Ward, Laws, & Hudson, 2003).

As a family physician and clinician working in one of Canada's most impoverished communities—the Downtown Eastside of Vancouver, British Columbia—Dr. Gabor Maté reflects on his experience: "We shouldn't underestimate how desperate a chronically lonely person is to escape the prison of solitude. It's not a matter of common shyness but of a deep psychological sense of isolation experienced from early childhood by people who felt rejected by everyone, beginning with their caregivers" (Maté, 2008).

So, are people who have committed sexual offenses simply social isolates, lonely, and in need of a friend? Yes, in some ways, though it is not quite that simple. Treatment models for various types of sexual offending patterns have been, and continue to be, developed that address some of the more pernicious issues a clinician will ever confront (e.g., fantasies of sexually abusing children, acts of sexual violence, general social deviance). But, if treatment is to be successful and if change in treatment is to be maintained, then having a few good friends really helps, especially friends who understand and can help a person stay safe, live safe, and develop the human bonds that failed to develop in the first place when they were growing up. These friends are needed to continually talk about and model appropriate adult relationships. The obvious human need for appropriate intimacy suggests that these sorts of friends are worth their weight in any currency, and, as radical as it may seem, this is a role in managing risk that can *only* be fulfilled by members of a willing and knowledgeable community.

Canada has over 20 years of experience of doing just that—pairing ordinary citizens with high-risk sexual offenders. Citizens have been visiting offenders in jail forever. But, being alongside as a person leaves prison and enters the mean streets of a hostile community rife with both temptation and scorn—this is an unusual experience. This is where the proverbial rubber meets the road for offenders returning from "paying the price." This is where the "price" is actually "paid." We are talking about engaging nonprofessionals—ordinary citizens who are not paid to be with the returning offender, who are aware of the dynamics of sexual offending behavior and the offense histories of the persons involved, and who are still willing to try being a friend to a high-risk sexual offender in his bid to live safely in the community with no more victims.

Put into clinical terminology, the research literature on effective interventions tells us that we should provide offenders with human service opportunities that match intensity to risk, specifically target assessed areas of criminogenic need, and which promote motivation to change and consider the idiosyncratic nature of the clientele (Andrews & Bonta, 2010). This is the essence of the risk-need-responsivity (RNR) model that underpins many of the correctional rehabilitation programs across North America and some international jurisdictions. A related literature thread tells us that programs should not just focus on risk, need, and responsivity, but that they should also promote the development of lifestyle balance and self-determinism (Curtiss & Warren, 1973)—all in the quest for a "good life" (Wilson & Yates, 2009; Yates, Prescott, & Ward, 2010). But what do most "good lives" have? A solid social network—even if it is just a small one—of reliable and concerned friends.

The majority of persons who sexually offend (and get caught) receive determinate sentences, meaning that they will 1 day return to society. In the best case scenario, all sexual offenders will have had an opportunity, while incarcerated or under supervision, to complete some degree of evidence-based treatment or counseling, hopefully adhering to the RNR principles noted above. However, there are still many instances in which this does not occur. For instance, what happens when the person in need of an effective intervention does not have access to one? What happens when the offender fails to appreciate that he/she needed one and, as such, did not take advantage of the opportunity when it was presented? Scenarios like these lead to some being released to the community as "untreated sexual offenders." Whether deservedly or not, these are the sorts of folks who cause real concern for law enforcement personnel and members of the community.

Let us also, for a moment, consider those offenders who do have access to good treatment while institutionalized and who undertake that treatment, but their risk is still not sufficiently ameliorated prior to release. Truth be told, this happens frequently. Part of the reason for this is that, as noted above, most sexual offenders receive determinate sentences—that is, the Department of Corrections must let them go at the end of their time. In some US states (less than half), there are civil commitment programs that will indefinitely hold certain sexual offenders while they receive additional treatment and risk management instruction. However, even this is not fail-safe. There are many occasions when the judicial system will "release" someone from civil commitment for reasons unrelated to clinically assisted reductions in risk to reoffend. Simply put, sometimes offenders at risk make it back to the community before we have a chance to fully address that risk.

So, where does that leave the community? It would be unreasonable to expect that the criminal justice system will be able to ensure that the totality of risk to the community can be managed. As a field, we are simply not able to predict—with full accuracy—who will and who will not reoffend sexually upon release to the community. With the advent of actuarial risk assessment tools (e.g., Static-99R; Helmus, 2009) and measures of community reintegration (i.e., dynamic risk potential—see Hanson et al., 2007), we are a lot better at distinguishing these two groups, but there is more to be accomplished.

Perhaps one of the areas with greatest potential for growth is in regard to community engagement of the collaborative risk management endeavor. Many jurisdictions now favor "containment" approaches to managing risk in the community (see English, Pullen, and Jones, 1998). In such models, treatment, supervision, and monitoring occur in concert; however, all of these services/measures are offered by the "official control" sector—probation/parole, law enforcement, paid professionals, etc. Silverman and Wilson (2002) suggested that a viable solution to community violence is found in community engagement with the criminal justice system. Research in support of this assertion includes findings that social support led to reductions in violent recidivism among mentally ill patients as well as violent sexual offenders (Estroff, Zimmer, Lachicotte, & Benoit, 1994; Gutiérrez-Lobos et al., 2001). Further, stable housing, as well as social support, has shown a relationship to reduced sexual recidivism and general criminality among both child molesters and rapists (Grubin, 1997; Lane Council of Governments, 2003; Willis & Grace, 2008, 2009). It would be our submission that while containment models provide a clear "law and order" accountability framework for statutory agencies and released offenders alike, the sort of caring and warm human regard available from endeavors like Circles of Support and Accountability (CoSA; Wilson & McWhinnie, 2013) is critical to ensuring long-term social and community integration.

Community Risk Management: The Birth of Circles of Support and Accountability

In the summer of 1994, congregants of a small Mennonite community church had no idea that they were about to change the way people considered "high risk" were received in Canadian communities and internationally. A man named Charlie—a repeat offender who had spent the majority of his life incarcerated for molesting more than 20 children—was about to be released from an Ontario prison.[1] Convicted of

[1]While in the institution, an assessment report composed using an early version of the Sex Offender Risk Appraisal Guide (SORAG—see Quinsey, Harris, Rice, and Cormier, 2006) had put Charlie's risk potential at 100 % chance of sexual or violent reoffending in 7 years.

multiple sexual offenses involving young boys, this was not good news for the residents of Hamilton, Ontario, where Charlie was planning to reside.

Bill Palmer, a psychologist with the Correctional Service of Canada (CSC) was Charlie's therapist in prison. No one knew the risks Charlie posed better than he. Palmer also knew that once Charlie was released, both he and CSC would be powerless to do anything about the risks Charlie posed. Palmer contacted community-based corrections personnel working in Toronto, Ontario, including the primary author (Wilson) and the District Chaplain, Rev. Hugh Kirkegaard. Palmer wanted to know, was there anything that could be done? Without appropriate supports and supervision, the probability that Charlie would harm another child was high. Wilson's response was less than heartening. In essence, the criminal justice system had more or less run out of options in Charlie's case. His release was imminent, there were no services for him, and, apart from police surveillance, there was little the community could offer Charlie. To Palmer, something—anything—that would help Charlie stay safe in the community was needed. But what? To whom could he turn?

Rev. Kirkegaard hoped that the answer would ultimately come from volunteers who had assisted Charlie during the last time he had been out, specifically, from the Reverend Harry Nigh and his congregants at the Welcome Inn, a Mennonite church. Harry Nigh knew Charlie from his experience with a person-to-person outreach to prisoners, called "M2W2" (Man to Man, Woman to Woman—see Yantzi, 1998). Further, people, who had known Charlie the last time he had been released and who were still visiting him in prison, had been exploring ways of supporting Charlie this time around. Restorative justice adherent Ed Vandenberg, for instance, was intrigued by a "circling" process used successfully in the past with mental health patients. Bill Palmer contacted Reverend Nigh and facilitated a meeting at the penitentiary to plan for Charlie's release. It was there that the idea of a "circle of ongoing support" was brought up—"a Charlie's Angels group" as Harry referred to it in his minutes. This concept has deep roots in Canadian Aboriginal traditions. However, the idea in this case was also influenced by other work with which this Charlie's Angels group had been experimenting in supporting other ex-prisoners. The goal was to assist ex-prisoners in living offense-free. As part of the basis for their optimism, these folks knew that an even earlier, similar initiative had proven successful in supporting people with disabilities to live independently in the community.

In hindsight, Reverend Nigh recalls a sense of foreboding. He knew he could also have simply said there was nothing he or his church community could do, and that Charlie, in fact, posed too great a risk for their small community to take on. Instead, Harry gathered several members of his Hamilton congregation and, together, they fashioned a response of "circling" people like Charlie to provide support for them as they worked at establishing themselves in the community. Members of this faith community responded by welcoming Charlie in their midst, but Charlie presented many challenges to this first circle, including poor problem-solving skills, institutionalization, and a sort of entrenched social orneriness. They soon realized that the circle needed to have an accountability component to go along with its supportive work. With that realization, the first of what has now become "Circles of Support and Accountability" (CoSA) was established.

With the assistance of his "circle" (Reverend Nigh and his associates), Charlie began to settle into a life in the community. Days turned to months, months turned to years, and Charlie did not reoffend. Indeed, on the strength of Charlie's apparent success, other faith groups began engaging in similar processes, assisting additional high-risk sexual offenders who were being released to the community with little or nothing in the way of a formal risk management framework. This was the birth of a Circles of Support and Accountability movement that now stretches across Canada, into the United States, and across both the Atlantic and Pacific Oceans.

From that first experience in Ontario until the present time nearly 20 years later and west to British Columbia (one of now 16 CoSA projects in Canada), Linda Rathjen—a BC CoSA volunteer—talks about working with "Arthur," a man in many ways similar to Charlie:

> When asked what his highlight was after his first month out of prison, [Arthur] emphatically stated that it was having found his CoSA group, his six friends. His greatest fear was losing them. So the signing of the covenant, where we committed to being his Circle for at least a year, meant the world to Arthur. It guaranteed the safety of our relationship with him, and helped reduce his fear of abandonment. It symbolized community to him in a tangible and real way, and he was more than eager to abide by the terms of the covenant. I believe my community is safer because of CoSA. When Arthur was asked on his anniversary as to why he has been successful in the community this time as opposed to other times, he replied, "I've never had good friends before. How could I ever do anything that would hurt these people?" So, when the phone rings, and I see that it's Arthur, and I don't feel like talking with him AGAIN, I am reminded that this could be the phone call that he needs to prevent him from slipping back into his crime cycle, and how could I do less than give him those few minutes of my time in exchange for the safety of my community?

Circle Mechanics

In the generally accepted model, each Circle is comprised of a Core Member (the ex-offender) and four to six community volunteers—citizens who have pledged personal time to assist the Core Member in the community. Community members who volunteer their time to CoSA are trained to ensure that they understand the roles and responsibilities

associated with assisting and holding accountable high-risk sexual offenders in the community (Correctional Service of Canada, 2002a; Wilson, Cortoni, & McWhinnie, 2009; Wilson, McWhinnie, Picheca, Prinzo, & Cortoni, 2007). In addition, community volunteers in almost all Canadian CoSA projects have access to an advisory committee comprised of professionals from law enforcement, corrections, clinical services, and business who also volunteer their services. Most, if not all, CoSA projects also have a paid "staff" person who serves as the local coordinator and provides operational support to the Circles running in their project.

In the initial phase of the Circle (typically 60–90 days following release), at least one volunteer is designated as the primary contact and meets with the Core Member on a more or less daily basis. Other Circle volunteers are also in contact with the Core Member, at a minimum, on a weekly basis during this initial phase. In addition to these individual meetings, the full Circle meets on a weekly basis. A CoSA is a relationship scheme based on friendship and accountability for behavior. As is expected in any friendly relationship, openness among all members is key and is seen as the method by which accountability is most likely to be maintained.

Offenders targeted for CoSA are usually those who have long histories of offending, have typically failed in treatment, have displayed intractable antisocial values and attitudes, and are likely to be held until sentence completion due to high levels of risk and criminogenic need. Upon release, these offenders face significant reintegration challenges, and involvement in CoSA assists greatly in helping them make good choices regarding the acquisition of valued goals consistent with the tenets of the currently popular good lives model (GLM—see Wilson and Yates, 2009; Yates et al., 2010). Briefly, the GLM posits that all people seek to attain human goods that include, among others, relatedness/intimacy, agency/autonomy, and emotional equilibrium. In short, human goods are associated with general well-being, and the sort of balanced, self-determinism also argued in the life skills model (Curtiss & Warren, 1973). Through involvement in CoSA, released offenders have access to "prosocial guides" who will assist them in meeting their needs in ways that promote personal efficacy and well-being and decrease propensity to reoffend. Those released without benefit of participation in CoSA are presumably less able to meet their needs in prosocial ways and are, therefore, less likely to reintegrate successfully in the community.

With its focus on support, CoSA provides positive social influences, concrete help with cognitive and other problem-solving, and helps counteract the social isolation and feelings of loneliness and rejection associated with sexual reoffending. Further, with its concurrent focus on accountability on the part of the offender, it targets issues related to distorted cognitions that support offending and minimize risk, including cooperation with supervision and the need to maintain a balanced, self-determined lifestyle. The CoSA approach is therefore fully in line with the risk and need elements of the principles of effective interventions (Andrews & Bonta, 2010; Wilson & Yates, 2009).

A Two-Ring Circle

A CoSA is actually two circles—an inner circle consisting of community volunteers and the Core Member and an outer circle consisting of professionals who have volunteered their expertise to support the inner circle (see Fig. 1). The inner circle manages the day-to-day aspects of the Core Member's community reentry, while more difficult or complicated issues (e.g., breach of conditions, treatment concerns, and

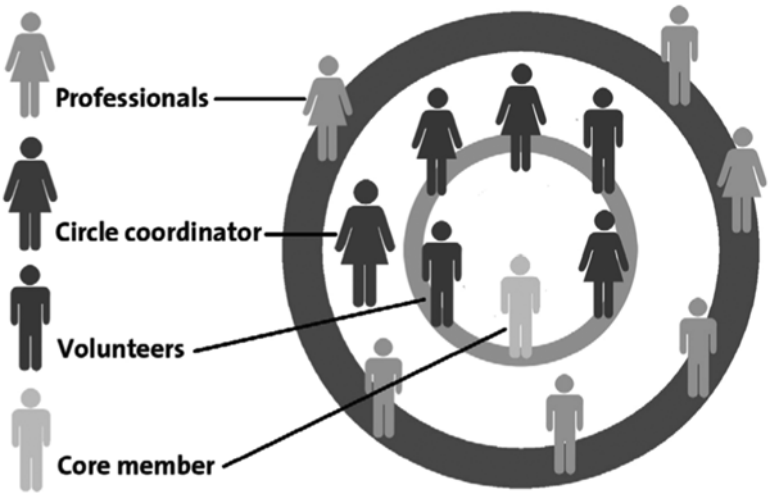

Fig. 1 Graphic representation of CoSA model (adapted from Wilson and Picheca (2005), Wilson et al. 2007b, c)

reports to law enforcement or child protection) are addressed with the assistance of the outer circle, comprised of professionals and other representatives of official stakeholder groups (e.g., probation, law enforcement, treatment professionals). In our experience, a realistic circle size is now five volunteers for each Core Member.

Training and Support of Volunteers

It is essential that volunteers are supported, monitored, and held accountable for the work they are undertaking. This supervision needs to be undertaken by a coordinator (i.e., the paid staff member noted above) who not only understands the issues related to risk management but who also understands the needs of the volunteers. The challenge is to find a balance wherein the volunteers feel supported but are not wholly dependent on that support to work effectively. It is important to understand that when undertaking something new, this something new is approached from a point of naïveté. Both advice and guidance are needed until experience consolidates sound judgment. The Circles coordinator provides this guidance and advice both formally and informally. The personal well-being of volunteers is paramount and, as such, they are invited to attend quarterly reviews in which they can explore their experience of Circles work. The coordinator will also ensure that each Circle as a whole is regularly reviewed.

Evidence-Based Practice

There are many different practices currently employed, each of which claims to help ameliorate the risk that sexual offenders pose to the community. On the surface, many of these practices appear to make sense. However, in today's world, it is not enough to have what psychologists call face validity ("makes sense"), you have to underscore your claims of efficacy with program evaluation research. And, even when you do this, there still may be criticism from other professionals or the community that your evaluation has flaws or other elements that might serve to lessen the strength of your claims.

From the very beginning, we realized that if we were ever going to be able to claim that CoSA had a measurable effect on the risk to the community posed by Core Members, we were going to have to build in a research component. Having been involved from the beginning, the first author was careful to start building a database of variables and factors that would, at some point in the future, require revisiting to be sure that CoSA was having its intended effect on safety. We also realized that it would be important to conduct this research in keeping with other developments in the field, so we were careful to use tools and methods that other programs and projects were using. In short, it was important that we not allow any potential benefits of CoSA involvement to be dismissed simply because we had not conducted scientifically rigorous investigation of those potential benefits.

As the numbers of persons coming into the project as Core Members grew, we approached a point where it was possible to start speaking with others about what we were doing and to start evaluating outcomes. The very first presentation on the mechanics of the CoSA model was made at the annual conference of the Association for the Treatment of Sexual Abusers (ATSA) in Arlington, Virginia, in the fall of 1997 (Heise, Kirkegaard, & Wilson, 1997). However, discussion of actual data did not come until 3 years later (Wilson & Prinzo, 2000), when a preliminary comparison of 30 Core Members and 30 matched comparison subjects was presented. A few years later, we were able to double these samples, and the first peer-reviewed evaluation of CoSA was published (see Wilson, McWhinnie et al., 2007; Wilson, Picheca, & Prinzo, 2007a, 2007b). A national replication study followed soon after (Wilson et al., 2009), demonstrating very similar results.

As soon as we started conducting comparisons of men who had been in a Circle with similar men who had not, we were surprised by the outcomes. Contemporaneously, other studies were then starting to emerge regarding the relative rates of reoffending observed after offenders had completed one or another treatment intervention compared to those who had not completed treatment. Most studies were reporting modest (but significant) reductions in reoffending, purportedly as a consequence of being involved in "sexual offender-specific" treatment. However, CoSA was never intended to be a treatment program; these were nonprofessional, community volunteers assisting high-risk offenders, post-release, in the process of community integration. Yet, the differences in reoffending between men in Circles and matched comparison subjects not in Circles were striking.

In a meta-analytic review, Hanson and colleagues (Hanson, Bourgon, Helmus, & Hodgson, 2009) presented data from 23 sexual offender treatment efficacy studies meeting certain basic criteria for study quality (including our first CoSA evaluation—Wilson, Picheca, et al., 2007b). Average sexual reoffense rates for those offenders completing treatment was 10.9 %, while those offenders who did not complete treatment reoffended at a rate of 19.2 %, for an odds ratio of .568. In the first evaluation of CoSA (see Wilson, Picheca, et al., 2007b), the rates of sexual reoffending over an average of approximately 4½ years were 5 % for 60 CoSA participants and 16.67 % for 60 matched comparison subjects who were not involved in a Circle, for an odds ratio of .299. In a recently published replication study (see Wilson et al., 2009), the respective differences in sexual reoffending were 2.3 % and 13.7 %, for an odds ratio of .168 (mean follow-up time was approximately 3 years).

In many respects, it would appear that the value added for offenders involved in CoSA surpasses that available through involvement in treatment. However, this may not be an entirely fair comparison. In the aforementioned meta-analysis of treatment outcome studies, Hanson et al. (2009) assigned a rating to included studies based on how well they adhered to the elements of the Andrews and Bonta (2010) RNR model. Hanson et al. assigned a rating of "2" to the first CoSA evaluation (Wilson, Picheca, et al., 2007b), stating that the model met the "risk" and "responsivity" tenets, but not "need." In this chapter, we would like to correct Dr. Hanson and his colleagues, in suggesting that the acute attention paid by Circle volunteers to elements of criminogenic need may be precisely what has given CoSA an edge over other attempts at community-based risk management. Indeed, one of the unique benefits of CoSA is found in the nature of the relationships formed between volunteers and Core Members. In this model, attention to criminogenic need is accomplished through methods that are responsive to offender needs in ways that professionals generally cannot offer.

As an outcome of their ambitious Dynamic Supervision Project research, Hanson and associates (Hanson et al., 2007) updated their scales for assessing stable and acute dynamic risk factors. The resultant scale for stable dynamic factors (Stable-2007) essentially outlines 13 variables in 5 categories that are important to consider in community risk management and the development of ongoing treatment. Most sexual offender aftercare (i.e., post-release) programs are informed by the Stable-2007 or other similar schemes (e.g., Thornton's Structured Risk Assessment [SRA] protocol—Thornton, 2002). The five domains in the Stable-2007 are:

1. Significant social influences
2. Intimacy deficits
3. General self-regulation
4. Sexual self-regulation
5. Cooperation with supervision

However, most programs have only the ability to teach skills theoretically linked to the reduction of difficulties in these target areas. Probation and parole staff must then send offenders back out into the community to put those new skills into practice, while staff essentially "wait and see." CoSA takes a somewhat different approach to this. Unlike correctional and other similar personnel, CoSA volunteers are able to engage with offenders in ways that might otherwise be characterized as a breach of professional boundaries (e.g., buying the Core Member lunch, inviting him to your home, giving him your personal phone number—of course, all with safety considered in advance). Volunteers can provide intensive mentoring and virtual hand-holding as the Core Member attempts to address issues related to his criminogenic needs. The issues of high caseloads and limited services are nonexistent in the CoSA approach. This is the "support" element at work. But let us not forget about "accountability." This latter aspect requires that Core Members make genuine attempts to address lifestyle management deficits, to debrief their experiences during the process of community integration, and to engage in a dialogue about how to do things better. We submit that this is the essence of what Andrews and Bonta meant when they decreed that effective interventions must attend to criminogenic needs.

Proliferation of the Model

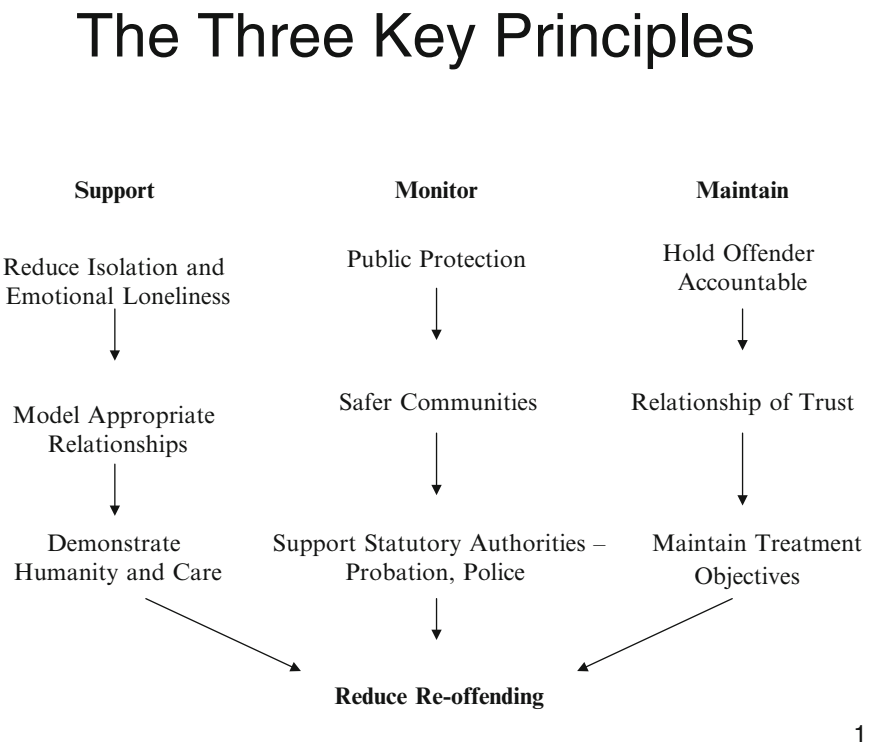
Circles of Support and Accountability started as a grassroots attempt to address a specific problem for a specific individual—Charlie was being released at sentence completion to a hostile community environment in which he would have little or no assistance in avoiding high-risk situations, developing new skills to compete with old ways of doing things, or finding a place for himself in the community. This at first seemingly simple gesture of kindness by Reverend Nigh and his congregation has subsequently grown into something of a movement in the restorative justice-friendly faith community. Unbeknownst to us, two probation officers from Minnesota took our handouts away from that first presentation in Arlington and just started doing it in their county. Many other CoSA projects have gotten their start in similar ways—by word of mouth or by acquiring literature describing the model, either at conferences, on the internet, or through informal sharing with like-minded organizations. Both authors receive email inquiries weekly from parties in international jurisdictions who are keen to explore CoSA project development.

CoSA has grown to become a viable community partner in assisting high-risk sexual offenders in their efforts at integrating with society. The CoSA model has now proliferated across Canada (from which the current sample was drawn) and into the international arena, with many countries investigating the model. Outside of Canada, the most ambitious application of the model is found in the Hampshire and Thames Valley (HTV) region of the United Kingdom. In 2000, five Canadian CoSA delegates were asked to travel to London to meet with restorative justice adherents from the Religious Society of Friends (Quakers), officials from the Home Office and Her Majesty's Prison Service, and related statutory agencies (see Peace and Witness, 2005). These discussions resulted in the formation of a demonstration project in the HTV region and another

endeavor sponsored by the Lucy Faithfull Foundation, a religious charity and social service provider. In June 2008, the British government established a national charity under the title "Circles UK."

The variant of CoSA available in the United Kingdom differs somewhat from its Canadian counterpart in that participating offenders remain under supervision while those in Canada are mostly in the community post-sentence and post-supervision. The systemic approach taken in Britain recognized the importance of two important key factors in offender management: firstly, the impact of sexual offender treatment programs and, secondly, the role of the Multi-Agency Public Protection Panel (MAPPA)—a process that mirrors, in many respects, the containment model used in the United States (English et al., 1998). The design of the MAPPA model is founded on three key principles (see below—Bates, Saunders, & Wilson, 2007; Saunders & Wilson, 2003; Wilson, McWhinnie, & Wilson, 2008), which are based on those significant issues relating to the recidivism of sexually aggressive behavior. The reduction of isolation and emotional loneliness is an imperative, while perceptions of intimacy and the significance of attachment deficits demonstrate the need for appropriate modeling—a central feature of a CoSA volunteer's role. Circles are only effective if a relationship of honesty and trust is developed within all the constituent parts. As with treatment, therapeutic alliances are important. By definition, the Circle has a therapeutic dynamic, and humanity and care become the context in which the Core Member is held accountable for his past abusive behavior.

A preliminary study published by British CoSA researchers (Bates et al., 2007) provided qualitative information regarding the development of Circles in their jurisdiction; however, numbers of participants were still too low to facilitate quantitative evaluation of recidivism outcomes. Nonetheless, Bates et al. reported that, over the first 4 years of the HTV project's existence, no Core Members had sexually reoffended. An updated, more comprehensive review of CoSA in the UK experience was recently published (Bates, Williams, Wilson, & Wilson, 2013), the results of which show low rates of sexual reoffending and other related misconduct roughly equivalent to the Canadian experience (i.e., a 75 % reduction in sexual or violent reoffending).



In addition to the development of CoSA projects in the United Kingdom, many jurisdictions in the United States are also looking at CoSA as a means to manage the risk posed by released offenders. As in Canada and the United Kingdom, the primary driving forces behind these projects has been the faith community, but, as statutory agencies find it increasingly difficult to shoulder the entire burden of community safety, these agencies are warming up to the idea of community-based partnerships that include members of the community. In Minnesota, where a CoSA project now flourishes with assistance from the Department of Corrections (MN-DOC), researcher Grant Duwe (2013) has shown that MN-CoSA recipients were 62 % less likely to be rearrested, 72 % less likely to be revoked for a technical violation, and 84 % less likely to be reincarcerated for any reason. Additionally, Duwe demonstrated a cost-benefit ratio of 1.82, meaning that for every dollar the MN-DOC spends on CoSA, they receive back $1.82 in community safety.

Community Development

The Circles of Support and Accountability model is an innovative community response to a problem with which statutory agencies and clinical personnel have continued to struggle—often at the expense of community safety. From our perspective, legislators have moved quickly to establish law and policy regarding risk management of released sexual offenders. However, sometimes bills have moved too quickly through their respective houses—seemingly without consideration of what might actually result (see Levenson and D'Amora, 2007). The community is understandably alarmed about the risk potentially posed to children and other vulnerable persons, but simply enacting legislation as a means to "get tough on crime," without knowing whether the law will actually decrease crime or increase safety is not the way to go. Research has shown that members of the community at large are able to comment intelligently on a given social issue when given enough information, particularly regarding sexual offenders (see Wilson, Picheca, et al., 2007a). One way to ensure greater information transfer to citizens is through the sort of town hall meetings promoted by Bob Shilling, an innovative detective with the Seattle Police Department.

Earlier in this chapter, we referred to the observation by Silverman and Wilson (2002) that solutions to risk in the community need to include participation by members of the community. Our experiences in CoSA over the past 16 years have done much to solidify that perspective. We are richer for those experiences, as are the Core Members, Circle Volunteers, affiliated professionals, and community activists who have also ridden the crest of this wave in sensible approaches to *community* risk management. Staunch CoSA advocate and participant Detective Wendy Leaver of the Special Victims Unit of the Toronto Police Service once said: "I put these guys in jail…I don't support them when they get out" (Correctional Service of Canada, 2002b). Thankfully, she did not leave it there. Over her 20 years of experience as a volunteer, advisory group member, and dedicated police officer, Det. Leaver has demonstrated the strength of the model. Slowly but surely, Circles projects have won over their critics.

Whenever a high-risk sexual offender is released from prison, the media publish negative stories about the foolhardiness of correctional policy and practice, laced liberally with such provocative questions as, "How could they release a monster like this?" Interestingly, this approach lasts about 3 or so days before the news gets old. Often, this results from the media's frustration with a reportedly bad person not engaging in the predicted bad behavior. This is frequently the time that CoSA gets its best press. Eager to keep the issue alive and to fuel the public's seemingly insatiable fascination with the lurid world of sexual deviance, the media starts looking for "good news stories," and they find us. We are happy for the attention, as it helps spread the news, inspires citizens to volunteer, and emboldens those who would attempt similar approaches in their own jurisdictions.

Maintaining a Nonproprietary Focus

Over the 20 years since Reverend Nigh and his congregation agreed to help Charlie, a loose-knit network of CoSA adherents has grown around the world. Websites abound, and sharing of information is an integral part of maintaining, pruning, and encouraging the growth of the model. Training manuals have been written, research studies have been published, training videos have been produced, and conferences have been held. Interestingly, virtually never is a cost associated with any of these. Being involved in CoSA has always been about being involved in your community—local, national, or international—and protecting the vulnerable. All anyone ever asks is that credit be given where credit is due.

Being involved in Circles of Support and Accountability is an irreversible, life-altering experience. All who have been drawn in have been changed by this innovative means of building community for those who have, by their behavior, been cast out. Why do "we" do this? In short, we do this because we care deeply about our community and about the risk for harm to its most vulnerable members. If that requires welcoming offenders back with open arms, so that we can be sure that they never harm another individual, then so be it. In closing, we leave you with another quote from Detective Leaver (Correctional Service of Canada, 2002b):

> These people [Circles participants] have no idea what [the core member] is going to do, what he's about, and I do…As months went into years, I saw the benefit of the Circle…I think what really caught my interest was, maybe this works [sigh], maybe it does.

Pharmacotherapy for Sexual Offenders

Mohan Nair

Over the last decades, there has been increasing interest and concern about individuals who sexually offend and what to do about them. Sex offenders are a heterogeneous group. As with the management of drug abuse and addiction in our society, the management of sex offenders has become a major function of the criminal justice system. Criminal justice system responses are focused on retribution, incapacitation, and deterrence. For reasons that are too complex to be pursued in this chapter, penological philosophy in the United States moved away from the rehabilitation models of the 1970s. Lawmakers seem to promote the belief that criminals, especially sexual offenders, cannot be rehabilitated. Sociopolitical and legislative policy have criminalized more behaviors and pushed for harsher punishments, such as longer mandatory prison sentences. Perceived high rates of recidivism among rapists and child molesters are a particular public concern. Following the *Kansas v. Hendricks* decision of 1997, a growing number of states in the United States have made provisions for the indefinite civil commitment of sex offenders.

Society is increasingly confronted with the fact that a significant proportion of offenders who find their way into the criminal justice system have a mental illness (Fazel & Danesh, 2002; James & Glaze, 2006; Steadman, Osher, Robbins, Case, & Samuels, 2009). The Los Angeles County's Twin Tower Jail, housing 1,400 mentally ill inmates, makes it the nation's largest mental institution (Montagne, 2008). For many sex offenders, their mental illness may be a complicating, contributory, or even a causal factor to their offending behavior and recidivism (Booth & Gulati, 2014; Langstrom, Sjostedt, & Grann, 2004).

Overview of Psychiatric Disorders in Sex Offenders

Sex offenders comprise a significant proportion of those who come into the criminal justice system. They constitute between 20 and 25 % of the approximately two million males incarcerated in the United States (Berlin, Saleh, & Malin, 2009). Mental illness may play a role in an individual's maladaptive sexual behavior that brings them in contact with the law just as it can with nonsexual offenses. A number of studies of sex offender populations have shown that in addition to having paraphilic disorders, some sex offenders have non-paraphilic (i.e., sexual disorder related) diagnoses including substance abuse, depression, anxiety, bipolar disorder, autistic spectrum disorders, attention deficit/hyperactivity disorder (Dunsieth et al., 2004; Fazel, Sjostedt, Langstrom, & Grann, 2007; Kafka & Hennen, 2002; McElroy et al., 1999; Silva, Leong, & Ferrari, 2004; Siponmaa, Kristiansson, Jonson, Nydén, & Gillberg, 2001), and personality vulnerabilities, such as antisocial, borderline, narcissistic, and schizoid avoidant spectrum disorder (Dunsieth et al., 2004).

Disorders that may make a person more likely to engage in sexual offending behavior include paraphilic disorders, non-paraphilic disorders, or both. A subgroup of sex offenders suffers from psychiatric disorders classified as paraphilias, a term somewhat synonymous with sexual deviance. Per the DSM-IV:

> The essential features of a paraphilia are recurrent, intense sexually arousing fantasies, sexual urges or behaviors generally involving: 1) nonhuman objects, 2) the suffering of oneself or one's partner, or 3) children or other non-consenting persons that occur over a period of at least 6 months. (APA, 2000, p. 566)

These fantasies, urges, and behaviors cause marked distress or interpersonal difficulty for the individual. Per the DSM-5 (APA, 2013), the term paraphilia "denotes any intense and persistent sexual interest other than sexual interest

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_32

in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners" (p. 685). A paraphilic disorder is a paraphilia that is currently causing distress or impairment to the individual or a paraphilia whose satisfaction has entailed personal harm, or risk of harm, to others. As DSM-5 points out, it is not unusual for an individual to manifest two or more paraphilias; comorbid diagnoses of separate paraphilic disorders may be appropriate or warranted if more than one paraphilia is causing suffering to the individual or harm to others (e.g., p. 687).

In addition to identifying paraphilic disorders, other psychiatric disorders that are comorbid to paraphilic disorders in sex offenders need to be identified and treated to further decrease an offender's risk for sexual and nonsexual criminal behavior. For example, a pedophile previously able to control his deviant sexual impulses, may, in the context of a manic episode, engage in pedophilic acts. Acute psychiatric illness and active symptoms can be a significant dynamic risk factor that may increase the risk of sexual offending. Once diagnosed with an underlying psychiatric disorder, standard of care dictates that appropriate medications be given to control the mood dysregulation (i.e., manic or hypomanic symptoms). Therefore, there are clinical and risk management reasons why one needs to identify and treat both the sexual disorder and the comorbid psychiatric conditions in such offenders.

Sexual offending behavior is heterogeneous and multifactorial and, therefore, calls for a variety of approaches to treatment. Cognitive behavioral therapy, the mainstay of both institutional and outpatient treatment for sexual offenders, has shown modest reduction in recidivism rates, but significant and long-term benefits have been less robust (Losel & Schumcker, 2005; Seto et al., 2008). To date, with few exceptions, treatment, when provided at all, has predominantly consisted of individual and group therapy and behavior modification. Although the literature supports the use of pharmacotherapy in selected sexual offenders (Bradford, 2000; Saleh & Guidry, 2003), medications have not been used—as the next section of this chapter will explore—to the extent that they could.

Turf Issues and Lack of Familiarity with the Medical Model

Lack of familiarity with the medical model and pharmacology lessens the likelihood for the use of medications among those who treat psychiatrically ill sexual offenders. Sexual offenders are often seen within criminal justice settings that have an inherent bias against the mentally ill, frequently misinterpreting psychiatric symptoms as bad behavior or malingering (Felner, 2006). Most mental health professionals who deal with sexual offenders do not have medical backgrounds. Nonpsychiatric mental health professionals may have varying levels of exposure and experience to serious mental disorders and may not identify the complex interplay of Axis I and Axis II disorders in their clients. They may not be aware that medications can help manage paraphilic disorders or the comorbid psychiatric conditions that may trigger or worsen such behavior (Noroian, Myers, & Saleh, 2009).

Notwithstanding their notable contributions toward the understanding of sexual psychopathology, psychiatrists have, as a group, not been on the forefront of the evaluation and treatment of sexual offenders in recent times. Most residency training programs do not provide significant didactic and clinical time in the area of sexual psychopathology and its treatment. In many ways, the field of sexual offending research is reminiscent of drug and alcohol treatment 30 years ago. Dual diagnosis, the coexistence of psychiatric illness with substance abuse, and the need to address both simultaneously have only been recently accepted. Drug and alcohol counselors trained exclusively in nonmedical models of addiction actively opposed the use of medications. Physicians, including psychiatrists, had little interest in dealing with alcoholics and drug addicts, even though alcoholics and drug addicts formed a significant number of both medical and psychiatric patients. The American Board of Psychiatry and Neurology did not introduce the subspecialty certification in Addiction Medicine until 1995. Medications now play an important role in treating substance abuse disorders.

Interventions based on the medical model are notable by their absence in leading journals that address sexual offending. There are just seven articles on the use of medications in the treatment of sexual offenders in the *Sexual Abuse: A Journal of Research and Treatment* from 1988 to 2014. Few psychiatrists join organizations dealing with sexual offenders and are poorly represented on the editorial boards of journals that deal with sexual behavior.

Psychiatrists' Reluctance in Treating Sexual Offenders

In the last two decades, there has been an explosion of medication use in psychiatry with a parallel reduction in the use of psychotherapy in community settings. These are driven by complex factors including disillusionment with the psychoanalytic model that dominated academic psychiatry into the 1970s, managed care, a better understanding of brain-based behavior, and, most importantly, the availability of more effective medications with more tolerable side effect profiles. Medications are routinely used in controlling agitation and violence and are seen as an efficient way of dealing with the mental health problems of a large population that has

limited mental health care access. For example, annual expenditures for medications in the Iowa prison system increased 28-fold, from $291 per 100 inmates in 1990 to $8,138 in 2000 (Lund, Flaum, Adam, & Perry, 2002). However, such a trend is not seen in the area of treating paraphilic sexual offenders. Psychiatrists may be overly cautious of the side effects of antiandrogen medications and are unfamiliar with the literature. While the risk of antiandrogen use cannot be minimized, many other commonly prescribed psychiatric medications can have serious and potentially life-threatening complications as well. With proper patient selection, protocols, and monitoring, androgen deprivation treatment may not carry more risks than the use of other psychotropic medications (Berlin, 2009; Reilly, Delva, & Hudson, 2000; Saleh, Berlin, Malin, & Thomas, 2007). Practitioners who use a particular medication or group of medications become more observant in identifying adverse effects early on in treatment, thereby increasing safety of such treatment modality.

The pharmaceutical industry is not committed to invest in the lengthy and expensive process of getting FDA approval for drugs that may be beneficial for treating paraphilias. Research-based evidence from large or even moderate randomized controlled double-blind trials and prospective open-label studies are lacking. Guidance for using medications is based on case reports or series, marked by methodological biases (Bradford, Fedoroff, & Gulati, 2013; Thibaut, De La Barra, Gordon, Cosyns, & Bradford, 2010). Treatment based entirely on off-label use has limited appeal with physicians. Generally speaking, endocrinologists are unlikely to treat sex offenders, and psychiatrists are wary of drugs with endocrine/metabolic complications.

Resistance on the Part of Patients

Sexual offenders may be resistant to considering medications for a variety of reasons. They may be in denial of their problem (e.g., denying culpability, difficulty controlling their behavior, or having sexual deviance). They may fear stigmatization as a psychiatric patient. For example, only one-third of sexual offenders in prison who were eligible to participate in California's Sex Offender Treatment and Evaluation Project (SOTEP) at Atascadero State Hospital chose to do so (Marques, Wiederanders, Day, Nelson, & Van Ommeren, 2005). Patients with prior exposure to medications may be concerned about the adverse effects (e.g., lethargy, dystonia, tardive dyskinesia) of psychotropic medications and distrustful of mental health professionals. Historically, many psychiatrists have overplayed the benefits and failed to adequately disclose potential harmful effects of biological interventions (i.e., lobotomy, electroconvulsive therapy (ECT), antidepressants, and antipsychotic medications). Psychiatrists are suspect of coming up with simple solutions for complex conditions (i.e., violence, fear, unhappiness) for which no "magic bullet" exists (Valenstein, 1986). For the psychiatrist and other medical providers, developing the trust of the patient remains an important part of the treatment dynamic. Adequate informed consent, which includes providing material information on medication side effects and realistic information on the benefits of proposed treatments, is a key element in developing a therapeutic alliance between patient and physician. The treatment provider needs to be open regarding the limits of confidentiality and about issues of dual agency. No less than in other areas of medicine, the establishment of the doctor-patient relationship becomes critical in the safe and effective use of available treatments. Ethical considerations regarding the use of pharmacotherapy for sexual offenders and specifically issues regarding informed consent will be addressed in the Informed Consent and Legal sections to follow.

Rationale for Treatment

Sexual offending imposes a terrible burden on individuals and society (Hankivsky & Draker, 2003; Shanahan & Donato, 2001). Sexual crimes such as rape and child molestation come at great cost, both human and financial. Rape and child sexual abuse often involve violence and may require medical attention. Other costs include victims' lost wages, psychological treatment, legal system fees, and imprisonment of the offender. The total national cost of sexual violence in 1996 was estimated at $261.25 billion (Post, Mezey, Maxwell, & Wibert, 2002). Hanson et al. (2002) conducted a meta-analysis of 43 studies of groups of sexual offenders (combined $n = 9{,}454$) who received psychotherapy; they were followed for an average of 4–5 years. Hanson et al. reported a 7 % decrease in sexual offense recidivism as a treatment effect, although those positive results were derived largely from studies with significant methodological issues. Consequently, any viable intervention to decrease further sexual victimization is relevant.

The following list, though not exhaustive, is an outline of the goals of treatment:

- Assist the offender to prevent sexual offense and recidivism.
- Control deviant urges in paraphilic offenders.
- Control aggressive behaviors in paraphilic and non-paraphilic offenders.
- Control impulsive behavior.
- Reduce distress produced by active symptoms of the paraphilic disorder.

- Treat coexisting Axis I and Axis II psychiatric symptoms/conditions that may contribute to offending risk, i.e., negative emotionality (irritability, anger, impulsivity), cognitive impairment, bipolar disorder, depression, traumatic brain injury.

Pharmacologic Agents

Androgen-Lowering Medications

Androgen-lowering medications should be considered for sexual offenders presenting with intense symptoms of a paraphilic disorder, such as intrusive thoughts, fantasies, or urges toward violent or "hands-on" behaviors. Convicted sexual sadist and serial killer Michael Ross wrote:

> The drug (Depo-Lupron) clears my head of the vile and noxious thoughts of rape and murder that plagued my mind for so long; the drug eliminates the previously uncontrollable urges that drove me to commit the crimes that put me here on death row. That monster still lives in my head, but the medication has chained him and has banished him to the back of my mind. And while he is still able to mock me, he can no longer control me - I control him; I am human once again. (Ross, 1996, p. #)

Surgical castration has been historically recognized to markedly reduce or eliminate sexual drive in animals and humans. Most studies since the mid-1960s show that orchiectomy reduces sexual offender recidivism with rates of re-offending between 0 and 10 % (Weinberger, Sreenivasan, Garrick, & Osran, 2005).

Individuals whose sexual offending is primarily driven by antisocial behavior or psychoses are unlikely to benefit from androgen-lowering medications. For individuals whose offending behaviors are related to psychotic disorders, treatment of the underlying psychotic disorder is the preferred treatment intervention. For those with antisocial personality disorder, antiandrogen medication would not be medically indicated where there is no evidence of a paraphilic disorder or any other condition responsive to this class of medications. Antiandrogens decrease but do not necessarily eliminate the risk of re-offending. However, given the overall data on efficacy, it would be counter-therapeutic *not* to offer these medications to symptomatic paraphilic sexual offenders, especially those with violent urges or those who are expressing a fear of losing control. The courts have upheld the duty of physicians to provide effective, available treatments. The case of *Osheroff v. Chestnut Lodge* (1984) Civil Action No 66024, Circuit Court for Montgomery County, Maryland, emphasizes that a failure to use all available and appropriate treatments could be grounds for malpractice. Dr. Osheroff, a nephrologist with a 2-year history of anxiety and depressive symptoms, was treated for 7 months with psychotherapy alone without improvement at Chestnut Lodge, a prestigious psychoanalytically oriented psychiatric hospital in Rockville, Maryland. Dr. Osheroff was then transferred to another facility where he was treated with psychotropic medications and rapidly improved. He then sued Chestnut Lodge and received a settlement (Klerman, 1990).

This concern would be especially true if it involves voluntary outpatient settings where there are no overt issues of coercion. Not educating a prospective and symptomatic patient about antiandrogen medications could be similar to failing to provide antidepressants or antipsychotic medications to a depressed or psychotic patient, respectively. There may be legal pressures not to withhold medications to those that are civilly committed since the failure to provide reasonable treatment would undermine part of the premise of their commitment. In short, medications should be considered both for the benefit of the individual and society that ultimately bears the consequences of sexual offending behavior. The successful use of resources in the community would also afford substantial cost savings. Community-based treatments operate at a fraction of the cost of inpatient treatment in hospitals or in correctional facilities.

The androgen-lowering medications such as cyproterone acetate (CPA), medroxyprogesterone acetate (MPA), and luteinizing hormone-releasing hormone agonists (LHRH) have been found to be effective in reducing sexual fantasies, desire, and urges in carefully selected and properly diagnosed patients (Bradford, 2001; Briken, Hill, & Berner, 2003). For example, leuprolide acetate, goserelin, and triptorelin are gonadotropin-releasing hormone (GnRH) analogues that have been used to treat paraphilic sexual offenders. Cyproterone acetate (CPA) is not available in the United States.

CPA is an androgen-lowering agent with antiandrogenic and antigonadotropic properties (Gilman, Rall, Nies, & Taylor, 1990; Goldenberg, Bruchovsky, Gleave, & Sullivan, 1996) that exerts its anti-libidinal effects by competitively blocking testosterone and dihydrotestosterone binding to peripheral and central androgen receptors. CPA has been used since the mid-1960s to treat paraphilic patients (Berlin, 1983; Berlin & Meinecke, 1981; Bradford & Pawlak, 1993; Gagne, 1981; Hucker, Langevin, & Bain, 1988; Meyer, Cole, & Emory, 1992). Dose range is oral (100 mg per day) or intramuscular (300 mg every other week). Possible side effects of this class of drugs include nausea, constipation, fatigue, lethargy, depression, headaches, hot flashes, night sweats, breast tenderness, galactorrhea, gynecomastia, decreased libido, thrombophlebitis, anemia, pulmonary embolism, weight gain, hyperglycemia, diabetes mellitus, hypogonadism, and hypospermia (low semen volume). Elevation of liver enzymes and hepatitis are also a concern. Bone demineralization, a potential side effect, has to be monitored and treated. Low-dose testosterone, calcium, vitamin D,

and bisphosphonate agents, such as alendronate, have been helpful in antiandrogen-related osteoporosis (Blake, Sawyerr, Dooley, Scheuer, & McIntyre, 1990; Goldenberg & Bruchovsky, 1991; Jurzyk, Spielvogel, & Rose, 1992; Levesque et al., 1989). Suffice to say, caution is required when prescribing testosterone to offenders receiving androgen-lowering medications.

Medroxyprogesterone acetate (MPA), a synthetic progestational agent, commonly used as a contraceptive in women, has been used in the treatment of paraphilic sexual offenders since the late 1960s. Injections have more predictable absorption than the oral route. Oral MPA is given in doses of 100–500 mg per day. The injectable form is given in doses of 100–1,000 mg per week although individual dosing may be increased or decreased, depending on the response (Guay, 2009). MPA exerts its anti-libidinal properties by lowering levels of circulating testosterone (Berlin & Schaerf, 1985; Gordon, 2008a, 2008b; Maletzky, Tolan, & McFarland, 2006). Adverse effects of MPA are similar to those of CPA and include weight gain, headache, nausea, gynecomastia, lethargy, elevated blood pressure, hot flashes, and thromboembolic events. Loss of bone density is also a serious potential adverse effect and must be carefully monitored in those receiving this treatment.

Leuprolide acetate (leuprolide), a synthetic analogue of endogenous gonadotropin-releasing hormone (GnRH analogue), with androgen-lowering properties and synthetic LHRH agonists such as leuprolide, triptorelin, and goserelin, is more potent than the LHRH secreted by the hypothalamus. Leuprolide has been found helpful in the treatment of paraphilias (Krueger & Kaplan, 2001; Saleh, Niel, & Fishman, 2004; Schober et al., 2005; Thibaut, Cordier, & Kuhn, 1993). Neuroimaging studies suggest leuprolide may decrease the brain activation responses to visual sexual stimuli in some pedophiles (Moulier et al., 2012).

Extensive experience and knowledge has been gained by the use of leuprolide in treating prostate cancer (Smith, 1986; Williams et al., 1983). GnRH analogues have also been used to treat paraphilic sexual offenders. Doses range from 3.75 to 7.5 mg per month. LHRH agonists like leuprolide cause an initial transient elevation in testosterone that may result in an increase in sexual drive. This risk can be lessened with the concurrent use of a testosterone-lowering agent. A transient increase in testosterone levels with increased sexual drive and fantasy has been reported during the first 2 months after leuprolide treatment cessation has been reported (Koo et al., 2013).

Adverse effects of leuprolide include bone mineral loss, nausea, weight gain, hot flashes, local reactions at the site of injection, blood pressure changes, depressive symptoms, and gynecomastia.

Selective Serotonin Reuptake Inhibitors (SSRIs)

Tricyclic and specific serotonin reuptake inhibitor drugs have been used in the general management of sexual offending (e.g., both paraphilic and paraphilic-like behavior) as well as "hypersexuality" (Greenberg & Bradford, 1997). While it appears to be beneficial to some individuals, the response to serotonin-enhancing drugs has not been comparable to hormonal treatments in controlling sexual offending behavior in those with paraphilic disorders.

Unlike antiandrogen drugs, the neurobiological rationale for the use of SSRIs in the treatment of paraphilic disorders remains somewhat speculative. Low brain serotonin states have been associated with both pathological impulsivity and obsessive-compulsive disorder. SSRI use in those treated for anxiety, depression, and obsessive-compulsive disorder has been associated in some cases with sexual side effects such as decreased libido, erectile difficulties, ejaculation failure, and delayed or absent orgasm. These side effects are estimated to occur in 2.7–75 % of users and are dose dependent (Baldwin, Thomas, & Birtwistle, 1997; Balon, 2006). If the primary mechanism of the "antiparaphilic" effect of these drugs is based on sexual side effects, it would be a problem since these side effects are not predictable and enduring. Of the four phases of the normal human sexual response cycle—desire, excitement, orgasm, and resolution—SSRIs predominantly affect ejaculatory function and orgasm but sexual desire is decreased unevenly or not at all (Ashton, Hamer, & Rosen, 1997; Keltner, McAfee, & Taylor, 2002; Rothschild, 2000; Seidman, 2006; Williams et al., 2006). Tolerance to SSRI-induced sexual side effects is common (Zajecka, 2001). Placebo-controlled studies and clinical trials assessing the efficacy of SSRIs in paraphilic sexual offenders have not been published (Baldwin et al., 1997; Montejo-Gonzales, Llorca, & Izquierdo, 1999; Stark & Hardison, 1985; Zajecka, Mitchell, & Fawcett, 1997).

Nonsexual side effects include gastrointestinal distress, hyperactivity/behavioral activation, "manic switch," akathisia, apathy, affective blunting, forgetfulness, and, in rare cases, the potentially life-threatening serotonin syndrome.

Selected Studies Pertaining to SSRIs and the Paraphilic Disorders

Stein et al. (1992) retrospectively studied five males ranging in age from 23 to 40 years old with sexual sadomasochism, pedophilia, fetishism, and cross-dressing in an open-label trial. Medications included clomipramine (an anti-obsessional medication) 200–400 mg for 3–6 months, fluoxetine 60 mg for 2–7 months, and fluvoxamine (an

antidepressant) 200–300 mg for 8 weeks. There were no changes in fantasies or sexual symptoms in any male except one who had decreased masturbation from impotence. Significant improvement was noted in OCD (obsessive-compulsive disorder) symptoms.

Kafka and Prentky (1992) treated 20 patients over a 3-month period. Subjects were diagnosed with either paraphilia or "non-paraphilic sexual addictions," with fluoxetine, mean dose of 39 mg per day. Paraphilic symptoms decreased after 4 weeks, but normal sexual behavior was maintained.

Kafka (1994) treated 24 men with paraphilia (exhibitionism, fetishism, transvestic fetishism, telephone scatologia, and voyeurism) or paraphilic-related disorders. Patients were treated with sertraline, 25–250 mg per day from 4 to 64 weeks. Nine sertraline nonresponders were switched to fluoxetine from 10 to 80 mg per day. Seventy-one percent improved with either sertraline or fluoxetine.

Bradford, Greenberg, Gojer, Martindale, and Goldberg (1995) treated 18 pedophiles with sertraline, mean daily dose of 131 mg. Deviant sexual arousal was self-reported and penile plethysmograph was reduced. Normal arousal was preserved and was increased in two patients.

Strohm and Bernerbtreated 16 male outpatients; age range was from 30 to 70 years with hands-on and hands-off (noncontact) paraphilias. Significant comorbidity was noted in the group. Duration of treatment was 23 months (ranging from 2 to 78 months). All patients also received psychotherapy. Marked reduction in paraphilic fantasies and masturbation was noted (Hill, Briken, Kraus, Strohm, & Berner, 2003).

SSRI efficacy has been assessed in open-label and retrospective studies with significant sampling bias. Sampling bias, the absence of placebo-controlled double-blind studies, halo effects, and uneven response raise concern about its use in paraphilic offenders (Saleh, 2009).

Other Drugs Used for Treating Paraphilic Disorders and Sexual Offending Behavior

A number of psychotropic drugs have been tried with this population. The published data is mostly anecdotal, with small sample size or single case reports with inadequate control of selection criteria and comorbidities of non-paraphilic disorders. It is not clear, for example, if the symptomatic relief in paraphilic symptoms is the result of treating comorbid conditions that help general self-regulation (e.g., by decreasing depression, irritability) or if there may be other underlying processes that directly affect the paraphilic disorder.

Lithium, a mood stabilizer, has been used for treating autoerotic asphyxia and other paraphilic behaviors (Cesnik & Coleman, 1989; Zourkova, 2000). Anticonvulsant drugs such as carbamazepine and topiramate for pedophilia and fetishism, especially in brain-damaged individuals (Goldberg & Buongiomo, 1983; Shiah, Chao, Mao, & Chuang, 2006; Varela & Black, 2002); neuroleptics such as haloperidol, thioridazine, and clozapine have been used to control sexually deviant behavior (Bartholomew, 1968); buspirone, an antianxiety medication, for transvestic fetishism (Fedoroff, 1992).

The Role of Medications in Treating Comorbid Axis I and Axis II Conditions

The assessment of sexual offenders requires that underlying mental disorders that may be a factor in the offending be carefully considered and appropriate treatment provided.

Both Axis I and Axis II mental disorders may be relevant in criminal and sexual offending. Sexual deviancy (i.e., the presence of active symptoms and severity of a paraphilic disorder) and criminality are the two basic independent variables that determine risk of offending. Other than paraphilic disorders, Axis I disorders include psychotic, mood, anxiety, impulse control, cognitive, and sleep disorders. Serious mental illness such as schizophrenia and bipolar disorder may increase the risk for violence especially when coupled with substance abuse disorders (Elbogen & Johnson, 2009; Fazel, Grann, Carlström, Lichtenstein, & Långström, 2009). Tourette's disorder has been associated, albeit rarely, with sexual offending behavior, including, but not limited to, indecent exposure and public masturbation (Jankovic, Kwak, & Frankoff, 2006).

Axis II disorders are enduring conditions such as personality disorders and mental retardation. Hanson and Morton-Bourgon (2005) identified individuals with Cluster B personality disorders (i.e., antisocial, narcissistic, and borderline) to be at higher risk of sexual re-offense. Individuals who feel hostile, victimized, and resentful and those who are vulnerable to "emotional collapse" when stressed are at higher risk of sexual re-offense. In addition to antisocial personality disorder, narcissistic, sadistic, borderline, and schizoid spectrum personality disorders also tend to be associated with paraphilic individuals. Paraphiliacs with comorbid autistic spectrum disorders may have impaired emotional appreciation and volitional problems. Self-absorbed and "odd" individuals are overrepresented among sexual offenders and the sexually deviant (Ahlmeyer, Kleinsasser, Stoner, & Retzlaff, 2003; Bogaerts, Daalder, Vanheule, Desmet, & Leeuw, 2008; Herkov, Gynther, Thomas, & Myers, 1996; Silva et al., 2004; Worling, 2001).

Medications such as SSRIs, anticonvulsants, and atypical antipsychotics have shown to be helpful in treating personality disorders, especially borderline personality disorders (Simeon & Hollander, 2009). Anticonvulsants and atypical

antipsychotics may be helpful in treating impulsive behavior in the intellectually disabled. Some studies suggest antiandrogens help in the management of intellectually disabled sexual offenders (Sajith, Morgan, & Clarke, 2008).

In an individual with multiple Axis I and II disorders, a sexual offense may involve varying levels of contribution from some or all of the coexisting conditions; for example, a pedophile or sexual sadist with antisocial personality disorder whose offenses occur only when they are off their mood stabilizer or when actively using cocaine or methamphetamine. Only a careful examination by a clinician knowledgeable in psychiatric differential diagnosis and phenomenology may recognize the possible contributions of hypomania or delusional psychoses in a sexual offense.

Axis III medical disorders such as traumatic brain injury, temporal lobe epilepsy, frontotemporal dementia, strokes, and brain tumors have been associated with sexual offending behavior.

Antipsychotic medications, anticonvulsants, mood stabilizers, and psychostimulants have been reported as being helpful in case reports (Guay, 2009).

Choice of Treatments

As noted above, the ultimate choice of which medications are used to treat a specific offender depends on the unique history of the offender. Treatment must be individualized to address the offender's underlying diagnosis, history of offending, risk of recidivism, and current medical condition. For paraphilic offenders with low risk of sexual violence, treatments might start with psychotherapy, SSRI medications, and oral antiandrogens. For those paraphilic offenders with more serious, violent offenses, treatments would more likely include psychotherapy, combination therapy of SSRI, and antiandrogen medications, with consideration given to injected antiandrogen medication where treatment adherence may be at issue. For increasingly severe risk profiles and paraphilic symptoms, treatments might include long-acting GnRH agonist medication, in combination with psychotherapy. An algorithm for the treatment of paraphilic disorders that designate different levels of treatment, based on severity of symptoms and behaviors, with the use of more aggressive and invasive therapies for those patients with the most severe paraphilic symptoms who are at highest risk for violence.

Psychotherapy is recommended for all offenders; typically, cognitive behavioral therapy has been recommended or utilized as the therapy of choice. Combination psychotherapy and medication therapy for paraphilic offenders have produced better outcomes than medication therapy alone (Hall & Hall, 2007). Per systematic reviews, cognitive behavioral therapy has been correlated with reducing rates of recidivism in some populations of offenders (Alexander, 1999; Gallagher, Wilson, Hirschfield, Coggeshall, & MacKenzie, 1999), although random controlled studies have failed to show differential effects between such treatment and control groups (e.g., Hanson et al., 2002). Current psychotherapies utilize both individual and group modalities, with an emphasis on relapse prevention. Treatment should also include therapies to address substance use disorders.

Psychiatric and Psychological Evaluation for Pharmacotherapy

As indicated earlier, individuals may engage in sexual offending behavior for a variety of reasons. A detailed psychiatric history, including family history, history of psychiatric treatment and hospitalizations, substance abuse history, criminal history, sexual developmental history, and sexual behaviors and relationships, should be obtained. The presence of comorbid Axis I, Axis II personality disorders, intellectual disability, and medical/neurological conditions should be thoroughly investigated and documented by both through an examination of the patient and thorough review of collateral data, particularly available records. Such collateral data should be as comprehensive as possible since the self-reports of sexual offenders cannot be relied upon exclusively. Where available, additional data should include victim statements, police/probation/parole reports, prior mental health and medical records, juvenile and adult criminal records including violent and sexually violent behavior while in custody, and forensic reports.

Formal assessment tools may include the Multiphasic Sexual Inventory (Nichols & Molinder, 1984), the Multiphasic Sexual Inventory II (Nichols & Molinder, 2000), Greenberg Sexual Preference Visual Analogue Scale (Greenberg, 1991), Sexual Interest and the Sexual Activity Rating Scale (Bancroft, Tennent, Loucas, & Cass, 1974), the Wilson Sex Fantasy Questionnaire (Baumgartner, Scalora, & Huss, 2002; Wilson, 1988), penile plethysmography (Blanchard, Klassen, Dickey, Kuban, & Blak, 2001; Freund, 1991), and the sexual history polygraph. A detailed substance abuse history should be obtained, including using formal screening tools, such as the Michigan Alcohol Screening Test (Seltzer, Vinokur, & Van Rooijan, 1975). It is critical to be mindful about the limitations of any assessment tool, particularly their transparency in the face of impression management and denial/minimization on the part of the sexual offender.

Failure to recognize and treat comorbid psychiatric disorders, particularly personality disorders, ADHD and cognitive limitations, may result in poor self-control or even sexual offending behavior. Psychological testing, and in some instances neuropsychological testing, may be warranted to identify the presence and severity of such conditions.

Medical Workup

A complete medical psychiatric workup is essential, both to rule out any medical conditions that might impact the use of medications and to rule in or rule out comorbid medical conditions.

The laboratory workup should include a complete blood count, serum electrolytes, lipid profile, liver function tests, blood urea nitrogen (BUN), creatinine and thyroid levels, urinalysis, and urine drug screen. A lipid profile should be obtained since several of the drugs used with hormonal and nonhormonal treatments may cause weight gain and elevated lipids. All medications that the patient is taking should be assessed for potential drug-drug interactions. Hormone levels obtained may include thyroid stimulating hormone (TSH), parathyroid hormone (PTH), free and total serum testosterone, progesterone, estradiol, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin. Osteoporosis is a serious concern with androgen-lowering medications; therefore, baseline bone densitometry should be obtained. Electrocardiogram and vital signs should be recorded for all patients receiving psychiatric medications with cardiovascular side effect profiles. Tests should be repeated as often as clinically indicated. Electroencephalogram (EEG) and neuroimaging studies may be warranted in some instances.

Informed Consent

All psychiatric medications can have serious and potentially life-threatening side effects. Many medications considered for sexual offenders treatment may involve "off-label" use (i.e., use of a medication in a manner that is not specifically approved by the Food and Drug Administration) so risk-benefit advisement with the patient should be thorough and well documented (Giltay & Gooren 2009). The process of informed consent requires that patients be competent, that they give consent voluntarily and that they not be coerced, and that they be informed of both the benefits and risks involved. Consent obtained from substituted decision makers brings another level of complexity. A properly conducted and thorough informed consent should be obtained prior to treatment, outlining the full scope of the risks and benefits of the proposed treatment. The risks and benefits of alternative treatments and of no treatment should also be thoroughly reviewed. The second and third elements of the informed consent doctrine may be somewhat problematic in some settings. In order for consent to be considered valid, it has to be given "voluntarily" without undue influence or coercion. Important as that is, the majority of patients that require or are likely to benefit from it are typically under some form of judicial control and/or in the criminal justice system, raising concerns about the true voluntariness of their consent. Ethics guidelines have been provided by organizations such as the American Psychiatric Association and the American Academy of Psychiatry and the Law (AAPL; Zonana & Buchanan, 2009).

Legal and Ethical Issues in the Treatment of Sexual Offenders

Prescribing medications to help manage paraphilic disorders and other problematic sexual behavior among those who are not under judicial control and deemed to be competent should present no ethical or standard of care issues as long as a well-conducted informed consent process is followed. Prescribing medications, especially androgen-lowering medications, to individuals who are civilly committed or subject to outpatient commitment, incarcerated, or on probation/parole raises complex legal and ethical concerns (Ward et al., Mellela, Travin, & Cullen, 1989; Miller, 1998).

In the United States, at this writing, nine states authorize some form of mandated treatment (commonly referred to as "castration") as an adjunct to parole or probation supervision for certain sexual offenders for whom release to the community, from incarceration, is being contemplated. Texas (Tex. Gov't Code Ann., 2003) provides for voluntary surgical castration as the only treatment option. Four states allow for some provision of either chemical castration or voluntary surgical castration—California (Cal. Penal Code, 2003), Florida (Fla. Stat. Ann., 2002), Iowa (Iowa Code, 2003), and Louisiana (La. Rev. Stat. Ann., 2003). Four additional states permit the use of pharmacotherapy (chemical castration) only—Georgia (Ga. Code Ann, 2002), Montana (Mont. Code Ann., 2002), Oregon (Ore. Rev. Stat., 2001), and Wisconsin (Wis. Stat. Ann., 2002). In addition, numerous other states have either considered such laws or have judicial decisions addressing the process without legislative authority (see *State v. Brown* 1985 and *People v. Gauntlett* 1984). The practice of some form of physical or pharmacological castration has also been sanctioned in a number of European countries, including at various times, Denmark, Germany, Norway, Sweden, and Switzerland (Druhm, 1997).

The United States has a long history of the use of sanctioned castration to forward what were perceived as legitimate societal goals. The forced eugenics movement, ostensibly to prevent a new generation of incompetent children who would become a burden on the state, reached its zenith with approval of the process by the US Supreme Court

in *Buck v. Bell*. Although the Court subsequently found that imposed vasectomies on persons convicted of certain crimes violated the Fourteenth Amendment (*Skinner v. Oklahoma*, 1942), it never expressly overruled *Buck v. Bell* (Druhm, 1997). Challenges to the current "castration" statutes have not yet reached the US Supreme Court.

Although full consideration of the legal and ethical issues involved in this topic is far beyond the scope of this chapter, an overview of the issues is provided below. In the various state actions, and in numerous commentaries (see Scott & Holmberg, 2003; Miller, 1998; Rice & Harris, 2011; Winslade, Stone, Smith-Bell, & Webb, 1998), such challenges are usually organized on a variety of grounds. Arguments based on Eighth Amendment grounds (that the forced treatment is cruel and unusual punishment) are usually counterbalanced by the argument that such treatment has distinct therapeutic value. Arguments on Fourteenth Amendment grounds (that the process is not sufficiently spelled out to satisfy due process concerns) can in some states (such as California) pose a valid concern, while in others, the process to be followed seems to be sufficiently established to address a compelling state interest in public safety without violating fundamental liberty such as a right to refuse treatment or a right to procreate. In addition, since all of the statutes appear to apply equally to women as well as men, an equal protection argument has been raised claiming that the evidence that the medications discussed may not have a demonstrated efficacy at reducing offending behavior by women may lead to disparate treatment of offenders based solely on gender. The issue is further complicated by the fact that the medications have demonstrated efficacy only for offenders whose behavior is based on sexual drive and not for offenders whose behavior is based in anger, hostility, or other dispositional bases. These issues remain to be resolved. Challenges have also been raised on First Amendment grounds—that a person has the right to his/her own thoughts and to refuse treatment. This argument is usually countered by pointing out that, at least with respect to child victims, the US Supreme Court has already held (*New York v. Ferber*, 1982) that where children are victims, a clear and present danger is created and child pornography is therefore not protected by freedom of expression. An adequate informed consent process as outlined herein should help address the right to refuse issue.

Finally, the statutes mentioned do not all provide for discrimination among offenders to ensure that only those who would actually benefit from treatment are actually receiving the treatment. This is a flaw that will have to be resolved by the courts if mandated pharmacological treatment is to proceed within the dictates of Constitutional law as it currently is understood.

Conversely, the clinician has to consider withholding a medication that may (1) help decrease a person's subjective distress or out of control feelings or impulses, (2) lessen the intensity of paraphilic fantasies and urges to facilitate fuller participation in a psychotherapy program, and (3) help the patient better manage behavior that could possibly keep him in longer confinement or return him to prison or a forensic hospital.

Within the California Department of Mental Health sexual offender commitment facilities, there are a number of individuals who have obtained surgical castration on their own initiative. The US Supreme Court in *Kansas v. Hendricks* (1997) ruled that the state can civilly confine (sexual offenders) in secure mental health facilities for custody and treatment. Withholding medications that could be particularly helpful for some sexual offenders might be construed as promoting confinement without adequate treatment.

Conclusion

Evidence suggests that medications can help some sexual offenders. Androgen deprivation and other drug treatment for sex offenders have side effects, but they are comparable to other extensively used psychotropic drugs (Berlin, 2009). The human and financial cost of sexual crimes in society calls for the use of every effective strategy in dealing with it. Sexual offending behaviors motivated by an underlying paraphilic disorders, paraphilias, or paraphilic-related disorders are best understood in a biopsychosocial context. Thus, it is known that the remediation of depression can be helped by exercise, cognitive behavioral therapy, and medications alone or in combination. In a similar manner, medications should have an increasing and cost-effective role in the overall management of sexual offenders (Garcia, Delavenne, Assumpção, & Thibaut, 2013; Rosler & Witztum, 2000).

Surgical Castration and Sexual Recidivism Risk

Shoba Sreenivasan and Linda E. Weinberger

Introduction

The efficacy of using castration to lower criminal sexual recidivism among sex offenders, especially those considered to be high risk, and in an uncontrolled release environment remains a controversial issue. The existing literature regarding castrated sex offenders reveals a very low incidence of sexual recidivism. However, the low sexual recidivism rates may not be generalizable to modern sexual violent predator assessments given the various methodological limitations inherent in these studies. Animal studies demonstrate that castration results in a loss of sex drive and an abolishment of mating behavior and that such a drive could be restored by testosterone replacement. While hormonal therapy is more widely accepted as a method of reducing testosterone among sex offenders, surgical castration (i.e., bilateral orchiectomy) is also presently used, albeit to a very limited extent.

Ethical issues raised by surgical castration as the treatment of choice for a sex offender: assessing whether the choice to submit to orchiectomy is done freely or is due to coercive elements inherent to the individual's situation (i.e., the individual opts for a drastic procedure in order to facilitate obtaining freedom from custody). The evaluator considering risk in surgically castrated offenders should be familiar with the impact of bilateral orchiectomy upon sexual function, the translation of such data to risk assessment when considering offenders who may be released under non-supervised conditions, and the potential for adverse outcomes if offenders access testosterone replacement. Orchiectomy may have a role in risk assessments; however, other variables should be considered, particularly as the effects can be reversed by replacement testosterone (Weinberger, Sreenivasan, & Garrick, 2005).

S. Sreenivasan, Ph.D. (✉) • L.E. Weinberger, Ph.D.
Keck School of Medicine, University of Southern California, Los Angeles, CA 90033, USA
e-mail: shoba.sreenivasan@va.gov; leweinbe@usc.edu

The purpose of this chapter is to (1) review existing studies involving surgical castration of sex offenders, (2) review ethical issues raised by bilateral orchiectomy of involuntarily committed sex offenders, and (3) provide a framework for the impact of bilateral orchiectomy in assessing risk reduction (Weinberger, Sreenivasan, Garrick, & Osran, 2005).

Brief Overview of Antiandrogen Treatment and Sex Offenders

The production of testosterone in males occurs primarily through the secretions of the Leydig cells of the testes. Testosterone and dihydrotestosterone are the hormones responsible for maintenance of sexual behavior. The Leydig cells are stimulated by the release of luteinizing hormones from the anterior pituitary gland and are related to the release of gonadotropin-releasing hormones from the hypothalamus. Androgen receptors are found in several regions, including the midbrain limbic structures (as well as the hypothalamus), the spinal cord, and the penis. Antiandrogenic hormones were used to treat paraphilics and sex offenders before cognitive-behavioral therapy interventions were developed for sex offenders (Reilly, Delva, & Hudson, 2000). The first time these agents were used was in 1966 at Johns Hopkins University (medroxyprogesterone acetate) and at the Institute for Sex Research in West Germany (cyproterone acetate). Money (1986) conducted a number of studies and found that medroxyprogesterone acetate "suppresses or lessens the frequency of erection and ejaculation and also lessens the feeling of sexual drive and the mental imagery of sexual arousal" (p. 219). Current medical interventions in sex offender treatments include hormonal treatments that reduce testosterone levels, such as injectable Lupron (leuprolide acetate depot), Lupron implant, goserelin, Depo-Provera (medroxyprogesterone acetate), and cyproterone acetate (Bradford, 2001).

Research Literature on the Use of Surgical Castration Among Sex Offenders

The practice of surgical castration on human beings is not a recent phenomenon. In Europe, the use of castration as a form of treatment for sex offenders has been in existence since the early twentieth century. The Danish pioneered the first laws legalizing this type of medical intervention for sex offenders in 1929; soon thereafter, Germany (1933), Norway (1934), Finland (1935), Estonia (1937), Iceland (1938), Latvia (1938), and Sweden (1944) enacted similar laws. Bilateral orchiectomy (i.e., the surgical resection of the testes) results in a dramatic reduction of the production of testosterone.

The theoretical underpinning of the European castration laws was the elimination of sexual urges believed to be the dominant etiological factor in sexual criminal behavior. The first empirical studies examining the impact of surgical castration on sex offender recidivism were conducted in Europe (predominantly in Germany and Denmark) and date from the pre-World War II to postwar period. The original literature is difficult to assess because research methodology in these older studies was not well specified or performed to current standards. Freund (1980) previously provided a review of pharmacological sex drive reduction, including use of surgical castration.

A complete listing of the data for these European and Californian studies can be found under the article on this topic by Weinberger et al. (2005). A summary of the findings of data from studies published in English and reviewed by Freund and others, as well as a summary of other European articles that were translated and subsequently reviewed by Heim and Hursch (1979) and Heim (1981), is presented below. In addition, data from one United States study of castrated sex offenders conducted in California is reviewed (Smith, Brown, & Beck, 1952). The theory underpinning these studies was that the elimination of testosterone via orchiectomy would lead to a complete reduction of sexual deviancy, thereby assuring safe release of sex offenders into the community. However, these studies did not address directly whether there was an established linear relationship between low- or near-absent levels of testosterone and sexual interest, drive, and erectile capacity following orchiectomy.

Europe

As cited in our prior article on this topic (Weinberger et al., 2005), between 1934 and 1944, at least 2,800 sex offenders were compulsorily castrated in Germany, and between 1955 and 1977, 800 sex offenders were castrated in West Germany. The German data for the period arose from the "Nazi German Act" of November 24, 1933, which resulted in the involuntary castration of sex offenders. Germany enacted laws governing voluntary castration for sex offenders that remained effective after 1945.

Denmark

Danish laws governing castration began in 1929 and stemmed from the government's intent to protect society from recidivistic rapists (Sand, Dickmeiss, & Schwalbe-Hansen, 1964). These laws also allowed for persons to be castrated if they believed that their sexual drive placed them in danger of committing a crime and were amended to include castration for persons whose sexual drive produced considerable psychological suffering or social devaluation. From the years between 1929 and 1973, Heim and Hursch (1979) estimated that there were approximately 1,100 cases of orchiectomy in Denmark. The Treatment Institution at Herstedvester in Denmark, a penal institution, recorded 285 surgical castrations performed on the Institution's inmates between 1935 and 1970. Less than 10 % of these 285 castrates were serious sex offenders.

Stürup (1968, 1972) reported findings from the early Danish studies in a 1968 monograph for 900 patients who were castrated throughout Denmark between 1929 and 1959 and followed for at least 6 years, with 39 % followed for more than 10 years. According to Stürup, 44 % were "mentally defective" and 25 % were identified as "psychopaths"; only 13 % were described as sexually abnormal with another 10 % being labeled as "borderline cases" regarding sexual deviancy.

Norway

Bremer (1959) published data on 216 male Norwegian castrates. However, only 7 % (or 16 subjects) were described as "sexual deviates." Most were suffering from some form of schizophrenia, thus raising serious questions about the generalizability of these findings to sex offenders with a paraphilic process as their primary disorder. Bremer noted that the majority were identified as oligophrenics (51 %, $N=109$), followed by schizophrenics (25 %, $N=53$). Thirty-two percent (68) asked for castration and 68 % (146) were castrated at the request of another person. Of the 216 total samples, the results of recidivism for only 102 of the individuals were noted. Of these subjects, 58 % (59) re-offended prior to the castration, with 34 % having more than one previous re-offense. The follow-up period ranged from 1 to more than 10 years; however, most were followed for less than 5 years. Within this group of 102 subjects, there was a 2.9 % (3) rate of sexual re-offenses following castration. A subsample of

41 cases was observed for 5–10 years; this group had a 7 % recidivism rate. Of this group of 102 castrates, 41 % (37) were satisfied with the operation, 26 % (23) were dissatisfied or bitter, and 33 % (29) were indifferent. Several methodological limitations are apparent in this study. First, there was no comparison group of non-castrates, and, second, the castrated sample suffered primarily from severe psychiatric pathology other than sexual deviancy disorders. As with the Danish reports, the generalizability of these data to those whose sex crimes are driven predominantly by sexual psychopathology is potentially restricted.

Germany and Switzerland

Heim and Hursch (1979) reviewed many of the significant European castration articles, including those by Langelüddeke in 1963 and Cornu in 1973. Langelüddeke's data consisted of an archival review of criminal records of 1,036 German castrated sex offenders released into the community (the criminal records dated back to 1953). The castrated group consisted of 638 males who were castrated between 1934 and 1938, 259 males castrated between 1939 and 1941, and 139 males castrated between 1942 and 1944. These sex offenders were released soon after their involuntary castration. The comparison group consisted of 685 released, non-castrated sex offenders. With respect to sexual recidivism, 84 % (870) of the 1,036 castrated sex offenders had at least two convictions (numbers ranged from two to more than eight) for sexual crimes before castration. The sexual recidivism rate for the castrates dropped to 2.3 % (24 of the 1,036 castrates re-offended at least once after surgery). This rate rose to 2.6 % when corrected for those individuals who died; that is, a 10 % assessment was taken of the total sample, thus reducing the sample to 932 with 24 castrated recidivists. The nature of the sexual crimes (i.e., contact, noncontact, child molestation, rape) was not specified. Ten of the recidivists were castrated between the ages of 20 and 30, and these offenders showed a higher recidivism rate than offenders castrated at an older age. The time interval for recidivism after castration and release ranged from 6 weeks to 20 years. Castrated inmates who were sent to prison once or twice had a lower rate of recidivism than those castrates with three or more convictions. Nine of the 24 castrates who re-offended sexually did so 5 years after release; 20 committed nonsexual offenses in addition to sexual crimes. The non-castrated sex offenders had a sexual recidivism rate of 39.1 % (268). A follow-up study of 89 interviewed castrates from this 1963 sample revealed that 65 % (58) reported that their libido and potency were immediately or soon after extinguished following castration, 17 % (15) reported significant fading followed by extinction of sex drive, and 18 % (16) stated that they were still able to have sexual intercourse more than 20 years post-castration. Of the 15 castrates over the age of 50 (51–70), 80 % (12) described extinction of potency soon after castration, 7 % (1) described potency as obviously weaker, and 13 % (2) described potency as still present or weakened slightly. For those in the 31–40-year-old age group (28), 64 % (18) experienced extinction of potency soon after castration, 21 % (6) described obvious weakening of potency, and 14 % (4) stated that potency was still in effect or slightly weakened. A small percentage of the sample developed somatic sequelae. Nine percent (8) developed subcutaneous fat tissue similar to that of females, 11 % (9) had "strong" gynecomasty, and 25 % (22) developed "weak" gynecomasty. Fifty-one percent (45) of the individuals had soft or more compliant skin, beard growth in 17 % (15) of the castrates was weaker, and 69 % (59) had reduced body hair. Only one of the individuals developed osteoporosis. Twenty percent (18) stated that the operation positively influenced their life, with reports of feeling calmer and more balanced; however, 31 % (27) complained that since the operation, they were more depressed and felt inadequate, isolated, and passive. Fifty-two percent (46) said they were content with the outcome of the operation, while 26 %(23) were ambivalent; the remaining 22 % (20) expressed feeling markedly discontent.

Cornu in 1973 in Switzerland (and as reviewed by Heim & Hursch, 1979) examined 127 castrates who were sex offenders released postsurgery to the community and who were evaluated at least 5 years following discharge. The comparison group consisted of 50 non-castrated sex offenders who refused to undergo the procedure. The follow-up period ranged from 5 to 35 years. Of the 121 castrated subjects assessed during follow-up, 7.44 % (9) sexually re-offended; in contrast, 52 % (26) of the comparison group sexually recidivated. The comparison group of non-castrates committed sexual crimes within 10 years after castration was recommended to them. There were no significant differences between the two groups in regard to psychiatric diagnosis, sexual deviation, life history, or marital status.

Sixty-eight of the castrates in the Cornu sample were later interviewed. Sixty-three percent (43) described that their libido and potency extinguished quickly after castration, while 26 % (18) said that there was a gradual decline of sex drive. Ten percent (7) of those castrated stated that they were able to achieve sexual intercourse 8–20 years post-castration. Significant somatic sequelae included 51 % (21) who were extremely overweight and 82 % (49) who developed osteoporosis. Of those dissatisfied with having been castrated, 13 % (9) felt effeminate and mutilated, and 32 % (22) reported feeling miserable after the operation with complaints of depression, irritability, and isolation. Forty percent (27) of the castrates described feeling calmer, happier, and more active after the operation. Seventy-one percent (48) of the subjects interviewed were acceptant of and content with

their decision to be castrated. These individuals cited the positive benefits of castration as having decreased their abnormal sex drive, prevented their confinement, or improved the possibility of marriage.

Both the Langelüddeke (1963) and Cornu (1973) studies could be criticized on several methodological grounds. In the Langelüddeke sample, the castrated subjects had a sexual recidivism rate of 84 % prior to their surgery, while the non-castrated subjects had a sexual recidivism rate of 39.1 %. These rates suggested that the two groups differed beyond their surgical status. That is, the non-castrated group appeared to be at lower recidivism risk by base rate and may not have represented an adequate comparison group. It is possible that those subjects who were in the comparison group as non-castrates were not selected for castration because of a perceived low recidivism risk. Other than castration, it was unclear whether the individuals in both Langelüddeke's and Cornu's studies were treated differently (e.g., whether there was a higher level of social control during community supervision for the castrates). Also unknown was whether the castrates and comparison groups came from the same time cohorts and were followed for an equal length of time. Cornu's matched group consisted of those who refused castration and had to endure long periods of confinement. In addition, these non-castrates in Cornu's sample appeared to have a higher rate of alcoholism, were described as exhibiting diminished mental soundness, and came from more disruptive family backgrounds than the castrated sample. Further, the nature of the sex crimes (e.g., pedophilic, rape) were not specified for either the Langelüddeke or Cornu samples.

Another study from Germany was conducted by Heim (1981). He examined the sexual behavior of 39 West German sex offenders released from prison after voluntary surgical castration with no follow-up as to sexual recidivism. The offenders consisted of 12 (31 %) rapists, 12 (31 %) heterosexual pedophiles, 4 (10 %) homosexual pedophiles, 4 (10 %) bisexual pedophiles, 1 (3 %) sexual murderer, and 6 (15 %) homosexuals. Thirty-three (85 %) offenders committed two or more sex crimes prior to castration. Their mean age was 49.3 years, ranging between 32 and 69. The mean age at castration was 42.5 years, ranging in age from 25 to 50. The median time the offenders were in the community was 4.3 years, ranging between 4 months and 13 years. This study assessed the subjects' sexual functioning pre- and post-orchiectomy through questionnaires. Overall, the subjects reported a statistically significant decrement in the frequency of sexual intercourse, masturbation, and sexual thoughts after castration. However, 11 of 35 subjects reported the ability to have sexual intercourse after castration even though the procedure occurred several years (mean time was 4.8 years, range 1.3–9.5 years) previously. This study found that castration had the strongest effect on sexual behavior in those who were castrated between the ages of 46 and 59. The study is hampered by the lack of objective assessment of sexual functioning and interest (e.g., plethysmograph), relying instead on self-report data. In addition, the recidivism rates for these castrated individuals were not reported.

Wille and Beir (1989) reported recidivism rates for both castrated and non-castrated applicants to the general medical counsel in Germany for the period between 1970 and 1980. Initially, there were 104 castrated and 53 non-castrated applicants. The 53 non-castrated subjects consisted of those who were not castrated because their application was rejected by the authoritative commission (17), they canceled their application before the commission could render a decision (30), and they canceled their application after the commission granted their request (6). Among the castrated, 22 % (23) were described as "aggressive" offenders and 73 % (76) as pedophilic offenders. Of those who were not castrated, 28 % (15) were described as "aggressive" offenders and 49 % (26) as pedophilic offenders. These descriptions were based on offenses prior to application for castration. The average number of sex offenses was fairly similar for the two groups, with the castrated offenders having an average of 3.27 offenses and the non-castrated offenders having 2.87 sex offenses. Wille and Beir offered conflicting numbers as to the offense history of the non-castrates citing either 6 or 8 as having committed no sex offense.

For purposes of assessing recidivism, certain individuals from both the castrated and non-castrated groups were excluded from the analysis. They included those who had no sexual offenses prior to the application for castration (4), those for whom castration was not permissible under German Law (2), those who were castrated due to psychosis (2), those who were not traceable (7), and those for whom there was no valid follow-up (8). These exclusions reduced the number to 99 castrated and 35 non-castrated applicants. Among the castrated group, three sexually re-offended, yielding a recidivism rate of 3 %. Of the non-castrated applicants, 16 sexually re-offended for a 46 % recidivism rate.

While all castrates in the Wille and Beir sample experienced a reduction in sexual interest and activity, erotic fantasies, and capability of spontaneous or stimulated erection postoperatively, an examination of their sexuality 5-years after surgery revealed varying degrees of libido and sexually activity as related to age. Of a total of 81 subjects where data were available, the effects of castration on postsurgical sexual functioning at 5 years were reported. Among the castrates in the 30–44-year age group, 33 % (16/48) could function sexually, 20.8 % (10/48) required intensive stimulation, and 12.5 % (6/48) reported only reduced sexual activity and libido. Among those aged 45–49, 10 % (2/20) reported sexual activity with intensive stimulation, and only 5 % (1/20) reported non-drastic reduction of activity and libido following castration. Among castrates aged 60 and over, only 7.7 %

(1/13) experienced sexual capacity. These data underscored that castration was most effective in the reduction of libido and sexual activity among those who were aged 45 and older.

Seventy-seven of the castrated applicants were evaluated regarding their satisfaction with their current situation and the surgical procedure. Seventy-one percent (55) said they were pleased, 20 % (15) said they were undecided, and the remaining 9 % (7) said that they were dissatisfied. Methodologically, this study offered descriptors of the offense types as well as a comparison group of non-castrates with a similar average number of sexual offenses prior to intervention as the castrated group. The very low re-offense rate in castrates (3 %) compared to the much higher rate in non-castrates (46 %) could be argued more credibly as related to surgical intervention. However, a noteworthy limitation of the study is the small sample size.

Denmark

In 1997, Hansen's and Lykke Olsen's (1997) review of the treatment of sex offenders in Denmark summarized the history of the Treatment Institution at Herstedvester, a Danish prison facility that provides psychiatric care to inmates. Hansen (1991) followed 43 inmates who were sentenced to Herstedvester for extended detention for committing crimes of violent rape or another violent crime (e.g., murder, attempted murder, or severe bodily injury in connection with a sexual offense). Twenty-one of these inmates opted for surgical castration and early release on probation (i.e., 6–18 months after the operation). Originally, 24 inmates refused surgical intervention and remained incarcerated for an extended period of time; however, two later underwent castration after they were released and sexually re-offended. Two of the 21 castrates committed another sexual crime more than 15 years after their orchiectomy. These new sex crimes occurred after their physicians gave both individuals testosterone substitution therapy. Of those 24 inmates who were not castrated initially, 10 sexually re-offended (including the two subjects who had an orchiectomy after re-offending). Their new crimes occurred despite a lengthy incarceration for their original sexual crimes (non-castrates spent an average of 8 years in detention versus 2 years for the castrates). Therefore, the comparative rates for sexual recidivism were 10 % (provided replacement testosterone at 15 years) for the castrated group and 42 % for the non-castrates (unknown follow-up period).

United States

One report from the 1952 California legislative subcommittee on sexual crimes (Smith et al., 1952) stated that 60 individuals underwent orchiectomy in San Diego County since 1937, and further details as to demographics can be found under Weinberger et al. (2005). For those castrated, records revealed a 0 % rate of sexual recidivism: "he records reflect that not one of these individuals has committed a further sex offense" (p. 47). However, nonsex crimes were committed in some cases. The document provided limited information on 44 convicted sex offenders who underwent surgical castration between 1937 and 1948 and were released from custody. The document was unclear as to the period of time that each individual was followed after orchiectomy or when they were released to the community. It noted that a preliminary report was filed on March 8, 1950, and as best as can be determined, this date may represent the end of the follow-up period. However, the report was so limited in explanation that an assumption about the individuals' date of release into the community could not be made.

Despite the sparseness of data reported in this legislative document, it contained some case information with details as to provide a picture of the types of offenders who did not re-offend sexually after orchiectomy. Of the 44 cited cases, the instant offenses for 40 individuals met the criteria for clear "hands-on" offenses such as rape and/or child sexual molestation. With respect to the demographic breakdown of these 40 cases, the legislative document described 39 as White and 1 as Mexican; 39 were employed largely in lower middle to middle-class occupations, with the unemployed individual described as having subnormal intelligence. Regarding marital status, 15 were married, 12 were single, 7 were divorced, 4 were separated, and 2 were widowed. The age range of the castrated offenders was between 24 and 72. The level of education ranged from persons with a second grade level of education (1) to those with a medical degree (2).

The limited description of the 40 offenders and their offenses restricts an assessment of their risk level prior to surgical castration. Examination of the subjects' criminal history prior to the instant sex offense revealed that 60 % (24) of the sample had no prior crimes, 22.5 % (9) had a prior sexual offense, and 17.5 % (7) had a history of nonsexual offenses.

This legislative report is a highly relevant document that describes and follows a number of convicted sex offenders who were surgically castrated in the United States. However, it is not readily available within the public domain. Therefore, specific information *from the report is presented as a table for those who* may want to view data on the individual cases and can be found in the article by Weinberger et al. (2005).

Summary

The overall rate of sexual recidivism following castration is very low, ranging between 0 and 10 %. However, the 10 %

rate occurred in a small sample ($N=21$) where both of the re-offending castrates were given testosterone injections. The low sexual recidivism findings remained robust across the studies even though they varied in terms of methodology and had a variety of limitations. Many of the studies were hampered by the following: no presurgery base rate risk for sexual recidivism, lack of a true comparison group, no baseline data regarding pre-intervention offending and offense types, and small sample sizes. Further, there was a lack of corroboration postsurgery of deviant sexual interest via penile plethysmography, a method useful for assessing sexual deviancy among those seeking community release.

Orchiectomy and Sexual Behavior

The theory underpinning these studies was that the elimination of testosterone via orchiectomy would lead to a significant reduction of sexual deviancy, thereby assuring safe release of sex offenders into the community. However, these studies did not directly address whether there was an established linear relationship between low- or near-absent levels of testosterone and sexual interest, drive, and erectile capacity following orchiectomy. Testicular and prostate cancer studies that examine sexual functioning among "normal" males postsurgery offer one body of empirical data by which to examine the relationship between serum testosterone levels and behavior. These studies, in contrast to surgical castration of sex offenders, have the advantage of controlled designs that offer demonstrated markers of sex hormone level, drive, and function. Generally, the studies found that the sexual desire of testicular cancer patients who underwent bilateral orchiectomy was uniformly reduced or eliminated; however, their capacity to have an erection to sexually stimulating material was not eliminated. Of specific relevance to risk assessments of bilaterally castrated sex offenders is Van Basten et al.'s finding of laboratory confirmation of erectile capacity in those who self-reported such difficulty. These results highlight the need for laboratory corroboration of self-reports of diminished or absent sexual desire and capacity among sex offenders who have been surgically castrated.

Ethical Ramifications of Surgical Castration as a Treatment Choice

Ethical arguments have been made against and in favor of the use of surgical castration as a treatment option for high-risk sex offenders. Indeed, some professional organizations have taken a position against surgical castration as an intervention for sex offenders based on the availability of antiandrogen medications that can achieve similar results (ATSA, 2003). Still, others question the very capacity of a person under involuntary civil commitment, for example, to be able to choose surgical castration. In their review of 9 states where chemical and/or surgical castration statutes have been enacted, Scott and Holmberg (2003) raised ethical concerns as to the capacity of convicted sex offenders to make informed decisions regarding surgical or chemical castration.

Whether this type of treatment is medically appropriate is another ethical consideration. As Berlin (2003) noted, such intervention may be medically appropriate under narrow circumstances (i.e., where there is evidence that the sex offender's actions are mediated by intense, obsessional, and recurrent paraphilic urges and fantasies). In some of the states with castration statutes, there is no requirement for a psychiatric evaluation of the offender; therefore, the medical appropriateness of such treatment cannot be determined. However, it could be argued that under certain circumstances the most invasive treatment might be the only effective alternative for a high-risk sex offender. Winslade et al. (1998) outlined circumstances under which surgical castration of pedophiles may be legally and morally defensible.

Normative versus consequential ethics offers a template for viewing the ethical issues raised by bilateral orchiectomy of sex offenders. The normative approach assumes that there is a universal norm of right and wrong. Therefore, rules of conduct are black and white. The normative view may state that the procedure of surgical castration, given the invasive and in essence irreversible nature of the procedure, is not medically justifiable under any conditions. Consequential ethics offers another philosophical concept: that the circumstance dictates the ethics. In that view, there may be situational factors that in an applied context justify an action. Consequential ethicists would argue that surgical castration might provide a much better quality of life for the sex offender facing indefinite commitment in a prison or hospital setting in that the procedure would offer the potential of release. It would also potentially address the public's concern for safety in that the sex offender has taken severe means to greatly reduce or eliminate deviant libido.

Orchiectomy and Risk Reduction Among Sex Offenders: A Model

The orchiectomy studies highlight the complex nature of sexual functioning in human males who have undergone bilateral removal of the testes.

While orchiectomy can decrease the intensity of sexual motivation, it does not always eliminate sexual capacity. Men with low or no testosterone levels were still able to perform sexually and achieve functional erections as demonstrated in the cancer studies measuring penile tumescence to erotic visual stimulation (Rhoden, Teleoken, Sogari, et al., 2002). The studies of nonsex offender males who

underwent bilateral orchiectomy demonstrated that while testosterone might mediate physical sexual arousal, it was not uniformly essential to male sexual functions. Moreover, castrated individuals can achieve erections after surgery. The data from normal males suggest that erectile capacity occurred in response to stimuli they found to be erotic. It could be argued that erectile capacity in castrated sex offenders does not mean they will sexually recidivate, only that they are capable of sexual intercourse. However, when the arousing stimuli for the castrated sex offender remain deviant, then the prudent evaluator would need to consider erectile capacity as a variable in sexual recidivism risk.

The next portion of the chapter will provide a framework for addressing risk reduction among surgically castrated high-risk offenders that could be applied to a clinical risk assessment.

Framework for Assessing the Impact of Bilateral Orchiectomy in Assessing Risk Reduction

A framework for surgical castration of sex offenders as moderating their risk for sexual recidivism is considered below and as previously discussed by Weinberger et al. (2005). Since the original Tarasoff (1976) ruling, mental health professionals have incurred increased responsibility in the recognition and assessment of violence risk potential in psychiatric patients. Subsequent case law and legislation has charged mental health professionals with the responsibility of identifying potentially violent patients and protecting the public from them and as well in the realm of sexual offenders with the onset of the civil commitment statutes. A risk appraisal approach based upon a sole variable, such as bilateral orchiectomy, raises several questions: that of public safety, peer accepted standards of practice, liability issues, and concordance with evidence-based medicine practice (Sreenivasan, Kirkish, Garrick, Weinberger, & Phenix, 2000). Leading researchers and theoreticians have identified and advocated a heteromethod for understanding the relevant prediction factors for any future event. Such factors would include mitigating and aggravating risk factors (Heilbrun, 1996). This approach is widely used in medicine where the relevance of the person's unique individual strengths and weaknesses is considered when determining treatment options and likely outcome. Evidence-based medicine, in particular, is based upon the notion that individual patients typically differ from study samples in various ways and that clinical judgment must be utilized to determine how these differences impact the prognosis.

As the above discussion of the surgical castration review indicates, the bilateral orchiectomy studies are compelling due to the very low rates of sexual recidivism demonstrated among released sex offenders. However, as this review has also underscored, the studies are methodologically suboptimal, and the generalizability of findings to a present-day high-risk sex offender remains problematic. As noted, the sexual recidivism percentages were calculated from groups of highly variable castrated sex offenders whose conditions of release were not well specified. As we articulated in a prior article (Weinberger, Sreenivasan, & Garrick, 2005), the clinician should be even more circumspect when applying such data to an SVP/SDP sample that represents a small subgroup of extremely dangerous sex offenders.

Of primary concern in terms of public safety is that there is little empirical data regarding the recidivism rate of high-risk sex offenders who are surgically castrated, released, and free of community supervision. For those individuals who harbor entrenched pedophilic or sadistic sexual preoccupation, the removal of the testes without accompanying psychotherapy may leave the potent psychological risk factors in place. Those who are found to meet the sexually violent predator (SVP)/sexually dangerous person (SDP) civil commitment criteria (Weinberger et al., 2005) and who face indefinite hospitalization, by their very characteristics, are apt to represent the highest risk subsample of sex offenders. A recurrent pattern of sex offending suggests the ingrained nature of deviant sexual interests. Orchiectomy alone, without attendant psychological change, may be insufficient to mitigate sexual recidivism when high-risk offenders are in the community and subject to temptations. Community supervision allows for a safe way of monitoring "in vivo" how the high-risk sex offender copes with stress and how he handles risky situations (e.g., going to the grocery store and seeing young boys). As Hansen and Lykke Olsen (1997) noted, surgical castration is a treatment of symptoms and not a cure. The latter must be emphasized as orchiectomy of high-risk sex offenders may create an artificial sense of safety.

We do not mean to imply that the existing orchiectomy data are of little or no value in current sex offender risk assessment; rather, the risk analysis should reflect a prudent application of the orchiectomy data to the assessment of the *individual* sex offender. Each assessment should address some, if not all, of these four points:

1. Is the data set to be utilized detailed sufficiently so that the clinician can have a high degree of confidence that the sex offender being evaluated is similar to those examined within the study sample?
2. Are there non-testosterone-dependent neurobiological factors present that could drive sexual recidivism?
3. Are there psychological risk factors present that could increase sexual recidivism?
4. What is the risk that this individual will secure exogenous testosterone and/or other libido potentiating drugs if released?

Evidence-based medicine is based upon the notion that individual patients typically differ from study samples in various ways and that clinical judgment must be utilized to determine how these differences impact the prognosis (Braitman & Davidkoff, 1996). The low probabilistic sexual recidivism rates found in the sex offender orchiectomy studies should not be ignored. However, that data should be interpreted within a context. Therefore, we offer the following suggested conditions for use of the existing surgical castration recidivism rates in applied sex offender risk assessments: for those individuals where a persuasive argument can be made in support of their similarity to a sex offender orchiectomy data set, where there is no evidence of continued preoccupation with children or aggressive material as arousing sexual pleasure, where there is a pattern of involvement in interventions that demonstrates awareness of psychological and other risk factors and where the individual appears to have made substantial internal and behavioral changes, and where, as a result of these or other factors, the likelihood of access to exogenous testosterone and other drugs that enhance sex drive is low. Under such circumstances, it could be concluded that the confluence of variables, with orchiectomy as one, suggests that the individual would not present a "likely risk" and could be released into the community even with little to no supervised control. As remarked on by us previously (Sreenivasan et al., 2000), assessment for any purpose is a complex enterprise requiring understanding of research-based assessment tools and a solid theoretical framework that guides acquisition of relevant individual (clinical) information. Neither clinical judgment unguided by the research literature nor the use of a sole variable or model would meet judicially determined or professional standards of practice. Integrating these data is the acceptable standard of practice, and we would argue the same conceptual process applies when considering the impact of surgical castration in sexual recidivism risk assessments.

The current review underscores the difficult decisions to be made regarding the ethical use of surgical castration for select populations. The overall rate of sexual recidivism following castration is very low, ranging between 0 and 10 %. Parenthetically, the 10 % rate occurred in a small sample ($N=21$) after both of the re-offending castrates were given testosterone injections. The low sexual recidivism findings remained consistent across the studies even though they varied in terms of methodology and had a variety of limitations. Many of the studies were hampered by the following: no presurgery base rate risk for sexual recidivism, lack of a true comparison group, no baseline data regarding pre-intervention offending and offense types, or small sample sizes. Further, there was a lack of corroboration postsurgery of deviant sexual interest via penile plethysmography, a method useful for assessing sexual deviant interest among those seeking release into the community.

Moreover, surgical castration in and of itself is not a complete treatment for sex offenders. Consequently, the deliberate evaluator should consider carefully the impact of bilateral orchiectomy on the reduction of risk in sex offender populations, particularly those under civil commitment as a sexually violent predator or sexually dangerous person (Sreenivasan et al., 2000), and not weigh this variable with an inflated degree of importance.

Civil Commitment of Select Recidivistic Sexual Offenders Deemed Likely to Sexually Reoffend

Harry M. Hoberman and Rebecca L. Jackson

Introduction

In the United States, the civil commitment of recidivist sexual offenders concerns the indeterminate detention for the purpose of public safety (to reduce or prevent future sexual offending) of a select subset of sexual offenders (those deemed at particularly higher risk by virtue of certain psychological and/or psychiatric ("mental" or "personality") characteristics). Almost all such sexual offenders are persons who have completed an incarceration in the criminal justice system, typically with their most recent crime being a sexual offense. Such action necessarily involves the balancing of liberty interests or freedom of those select recidivist sexual offenders with public safety concerns about their potential persisting dangerousness, specifically the likelihood of their future sexual offending. Managing sexual offenders who have committed multiple and/or extreme sexual offenses as the result of some psychological or psychiatric conditions has long been a concern for Western society. Over the past 100 years, in the United States, public policy has shifted among different approaches to dealing with recidivistic sexual offenders perceived as still at elevated risk for sexual offending, sometimes emphasizing enhanced criminal sanctions, sometimes opting to offer a hypothesized therapeutic approach, and sometimes utilizing both increased criminal and civil commitments. The purpose of this chapter is to consider the current civil commitment of recidivistic sexual offenders, typically referred to as sexually violent offenders or "predators" (CCSVP) and to provide an overview of the key elements of so-called sexually violent predator (SVP) statutes, the characteristics of and evaluation of the sexual offenders considered for and currently committed under these statutes and aspects of the civil commitment programs for such individuals.[1]

History of Civil Commitment of Sexual Offenders in the United States

The civil commitment of recidivistic or "higher-risk" sexual offenders is certainly not new. As early as 1931, the state of Michigan had adopted such a statute. Such laws were initially enacted to allow for the prolonged commitment of a subgroup of identified sexual offenders. During the 1930s, a consensus developed that some individuals' sexual offending was a function of some form of "mental illness" and that these offenders might benefit from treatment as opposed to just punishment. Thus, early "sexual psychopath" laws were enacted to help society deal with sexual offenders who were viewed as "too sick to deserve punishment" (Janus, 2000). Under these statutes, treatment of the more dangerous sexual offenders generally *replaced* punishment or incarceration; thus, these statutes originally represented an attempt to place a small group of identified sexual offenders in secure hospital settings for treatment and not in prison. In some states, once attempts at treatment had taken place, individuals could also be required to serve a portion of a criminal sentence too, while in other states if treatment was deemed successful, persons were released back to society often years before the typical criminal sentence might have allowed. By 1971, as many as 31 states had implemented what were originally termed "sexual psychopath" statutes.

In 1939, the US Supreme Court upheld the constitutionality of Minnesota's "psychopathic personality" statute, one of these sexual psychopath statutes. That is, civil commitment

[1]For purposes of clarity, the term civil commitment of sexually violent predators, abbreviated as CCSVP shall be used to describe this domain.

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_34

of a select group of sexual offenders was found to be constitutional in the United States some 70 years ago. However, over time, this approach fell out of favor. It appears by the latter part of the century, political opinion began to change about both the effectiveness and the necessity of providing mental health treatment for sexual offenders instead of just punishment by incarceration. Most specifically, the movement to repeal sexual psychopath statutes was driven primarily by "disenchantment with the efficacy of treatment for sex offenders" (APA, 2000); thus, the impetus to shift repeat sexual offenders back into the criminal system was rooted in the belief that they were untreatable, at least from the then traditional psychiatric perspective. Similarly, per some writers, the sexual psychopath statutes fell into disfavor after sexual offenders reoffended after being released from civil commitment and the completion of sex offender treatment (e.g., Frances, Sreenivasan, & Weinberger, 2008). Formal opposition to civil commitment of "sexual psychopaths" was registered by significant professional organizations such as the American Bar Association and the Group for the Advancement of Psychiatry. Subsequently, by 1994, only 13 states continued to maintain their previous sexual psychopath statutes, and in many of those jurisdictions, such statutes were rarely utilized.

However, in the late 1980s and early 1990s, the tide again began to shift among states toward adopting a new generation of statutes designed to identify, detain, and treat persons designated most commonly as so-called sexually violent predators (SVPs). Concomitant with the decreased support for the previous sexual psychopath commitments, many states had switched from indeterminate to determinate sentences for sexual offenses as well as other types of crime. As a consequence, criminal offenders, including sexual offenders, were released at the end of a sentence without any determination of the degree of dangerousness for future sexual offending that might characterize them or with identified mechanisms for managing possible risk factors for dangerousness. However, shortly after eliminating their sexual psychopath statute, the state of Washington experienced a number of egregious sexual offenses by recidivistic sexual offenders who had been recently released from incarceration and had been viewed as still "dangerous" and committed sexual offenses. In Washington, without a sexual psychopath statute, no mechanism existed for evaluating, let alone detaining, identified sexual offenders deemed at elevated risk to sexually reoffend once their prison sentence had been served. Subsequently, the Washington Task Force on Community Protection issued a number of recommendations that were adopted as part of a "Community Protection Act" in 1990; among these was a new statute providing for the involuntary civil commitment of select sexual offenders, identified as sexually violent predators (SVP), following the expiration of their prison terms. Ironically, given that a perception that sexual offender treatment was not an effective mechanism of management leads to the rejection of the first generation of sexual predator statutes, the Washington legislature indicated that the basis for the second generation of civil commitment of sexual offenders was based on a poor prognosis for rehabilitating such individuals in a prison setting and the long-term treatment needs of such persons.

Subsequently, following the enactment of Washington's SVP statue in 1990, 20 other jurisdictions either have established similar laws or refined existing statutes regarding sexual offenders viewed as at elevated risk for sexual offending yet again [AZ, CA, FL, IA, IL, KS, MA, MN, MO, NE, NH, NJ, NY, ND, PA (targeting only juveniles aging out of juvenile correctional system), SC, TX (only outpatient civil commitment), VA, and WI and the US Federal Government.] In most states, such individuals are identified as a "sexually violent predator" (SVP); in other jurisdictions, they are referred to as sexually dangerous persons or similar terms. Thus, currently, 40 % of the United States have one or more laws permitting the civil commitment of recidivistic or higher-risk sexual offenders. The stated primary purpose of these SVP statutes was to provide one means of protection for society from a relatively small group of sexual offenders who were deemed to be characterized by psychological and/or psychiatric ("mental" or "personality") characteristics viewed as related to a higher risk of sexual offense recidivism. The great majority of the newer versions of these more recent "second-generation" statutes involve making a determination that a person meets criteria as a "sexually violent predator" and involuntarily and indeterminately committing them to a secure hospital setting. As noted, in the great majority of instances in the application of contemporary SVP statutes, identified sexual offenders are held indefinitely *after* they have served a criminal sentence, typically for a sexual reoffense. Thus, this "second generation" of commitment laws was enacted primarily as a public safety measure in extending the incapacitation of offenders who had already served their criminal sentences. In this newer model, sexual offender treatment typically followed incarceration or punishment for one or more sexual offenses.

The Constitutionality of Civil Commitment of Sexual Offenders in the United States

The first US constitutional review of civil commitment of sexual offenders occurred over 70 years ago. In 1939, the Minnesota legislature had defined a "psychopathic personality" (PP) as "the existence in any persons of such conditions of emotional instability **or** impulsiveness of behavior **or** lack of customary standards of good judgment **or** failure to appreciate

the consequences of personal acts **or** a combination of any such conditions, as to render such persons irresponsible for personal conduct with respect to sexual matters and thereby dangerous to other persons" (emphasis added). That statute was challenged for "vagueness" by a sex offender (Pearson), who had been committed as a PP. In response to that challenge, the Minnesota Supreme Court had narrowed the interpretation of the PP statute indicating that it should apply only to "Persons who, by a [1] habitual course of misconduct in sexual matters, have evidenced an [2] utter lack of power to control their sexual impulses and who, as a result, are [3] likely to attack or otherwise inflict injury, loss, pain or other evil on the object of their uncontrolled and uncontrollable desire." In 1940, *Pearson vs. the Probate Court of Ramsey (County)* was heard by the US Supreme Court. That Court upheld the constitutionality of Minnesota's statute, referring to the statute and the decision by the Minnesota Supreme Court. The Court wrote:

> "These underlying conditions, calling for evidence of past conduct pointing to probable consequences, are as susceptible of proof as many of the criteria constantly applied in prosecutions for crime…The question, however, is whether the legislature could constitutionally make a class of the group it did select. That is, whether there is any rational basis for such a selection. We see no reason for doubt upon this point. Whether the legislature could have gone farther is not…the question. The class it did select is identified by the state court in terms which clearly show that the persons within that class constitute a dangerous element in the community which the legislature in its discretion could put under appropriate control." (p. 309)

The US Supreme Court adopted the Minnesota Supreme Court's construction of the statute when it stated: "[The statute] intended to include those persons who, by a habitual course of misconduct in sexual matters, have evidenced an *utter lack of power to control their sexual impulses* and who, as a result, are likely to attack or otherwise inflict injury, loss, pain or other evil on the objects of their uncontrolled and uncontrollable desire" (309, emphasis added). Thus, the early sexual psychopath statutes were determined to be constitutional.[1]

Washington's SVP statute has served as a template for most other state's more recent adoption of statues for the civil commitment of recidivistic or higher-risk sexual offenders. However, the constitutionality of such contemporary statutes did not come before the US Supreme Court until *Kansas v. Hendricks* (1997) decision. In *Hendricks*, the Court upheld the state's police power rights and legitimized the constitutionality of SVP commitment laws. The Kansas statute allowed for the commitment of "any person who has been convicted of or charged with a sexually violent offense and who suffers from a mental abnormality which predisposes the person to commit sexually violent offenses in a degree constituting such person a menace to the health and safety of others" (Kan. Stat. Ann. 59-29[a], 1994). Following his commitment under the Kansas statute, Hendricks appealed the constitutionality of this law, based on double jeopardy and ex post facto arguments. His appeal was eventually denied by the US Supreme Court on both of these grounds. In *Hendricks*, the Court ruled that:

> " …the Kansas court's determination that *the Act's 'overriding concern' for the 'segregation of sexually violent offenders'* is consistent with our conclusion that the Act establishes civil proceedings…especially when that concern is *coupled with the stated goal of providing treatment to those offenders, if such is possible*. While we have upheld civil commitment statutes that aim both to incapacitate and to treat…we have never held that the Constitution prevents the state from civilly detaining those for whom no treatment is available, but who nevertheless pose a danger to others." (p. 366; emphasis added)

The *Hendricks* decision all but put to rest constitutional challenges based on double jeopardy and ex post facto claims.

Another avenue for direct statutory attacks on state civil commitment laws was closed by the US Supreme Court in *Seling v. Young* (2001). In this case, Young argued that, despite the constitutionality of sexual offender civil commitment laws in general (as determined by *Hendricks*), Washington's law as applied to him specifically was unconstitutional (a so-called as applied challenge). The US Supreme Court rejected Young's claim. Although Vlahakis (2010, pp. 2–5) characterized the *Seling* decision as the end to statutory challenges against sexual offender civil commitment, he notes that it "open[ed] the door to indirect attacks" based on civil rights violations, such as conditions of confinement, use of seclusions and restraints, and adequacy of treatment.

Constitutional issues of sexual offender civil commitment were again addressed by the US Supreme Court in *Kansas v. Crane* (2002). Crane, after his commitment as a SVP under the Kansas statute, argued that *Hendricks* required a complete lack of control of sexual impulses and behavior. He argued that, since he retained some control, he was ineligible for civil commitment. However, the US Supreme Court disagreed and denied his appeal. Rather, they concluded that "serious"—but not complete—volitional impairment was required for commitment. Most recently, in 2010, the US Supreme Court affirmed the constitutionality of civil commitment in *US v. Comstock*. They found that it was constitutional for the US Department of Justice to commit "a mentally ill, sexually dangerous federal prisoner beyond the date the prisoner would otherwise be released" (p. 1).

[1] In 1994, the psychopathic personality statute was modified by the Minnesota legislature and is currently known as the sexual psychopathic personality statute.

Indeterminate Commitment of Sexual Offenders in Canada, the United Kingdom, and Other Countries: Dangerous Offender and Similar Statutes

The United States is not the only country that has attempted to indeterminately detain individuals, particularly sexual offenders, deemed to be particularly dangerous to the public. In Canada, within the criminal justice system, a convicted person who is designated as "dangerous offender" may be subjected to an indeterminate prison sentence, whether or not the crime carries a life sentence. The purpose of the legislation is to detain offenders who are deemed too dangerous to be released into society because of their violent tendencies, but whose sentences would not necessarily keep them incarcerated under other legislation. The prosecution is required to prove that the individual qualifies as a dangerous offender. Once an individual has been deemed a dangerous offender, the National Parole Board is required to review the case of an offender with a dangerous offender label after seven years, and parole may be granted as circumstances warrant, but the offender would remain under supervision indefinitely. After the initial review at 7 years, the Parole Board must conduct subsequent reviews every 2 years. As in the United States, in Canada the dangerous offender provisions have been found constitutional: "The individual, on a finding of guilty, is being sentenced for the 'serious personal injury offence' for which he was convicted, albeit in a different way than would ordinarily be done. He is not being punished for what he might do. The punishment flows from the actual commission of a specific offence" (R. v. Lyons, 1987). In 2006, the Canadian government introduced legislation that made it easier for Crown prosecutors to obtain dangerous offender designations. The proposed amendments provided, among other things, that an offender found guilty of a third conviction of a designated violent or sexual offense acquires the burden of proving that he or she does not qualify as a dangerous offender; that is, they would have to prove that despite the three convictions, they do not qualify as dangerous offenders. In the United Kingdom, modification of criminal law now permits the indefinite detention of persons who are thought likely to represent a serious threat. Such persons mush have a severe personality disorder diagnosis that makes them "more likely than not to commit an offense that might be expected to lead to serious physical or psychological harm from which a victim would find it difficult to recover." In Holland, under "TBS" legislation, offenders convicted of a serious sexual or violent offense and determined to present a higher risk of reoffending can be sentenced by the criminal court to a TBS order. They serve a prison sentence relative to their criminal offense and are later transferred to a TBS facility for treatment at the end of that sentence. They remain within the TBS system indefinitely (subject to regular review by a tribunal), initially in a secure institution and later as conditionally discharged, supervised patients in the community. Similarly, both the United Kingdom and Denmark have dangerous offender statutes as part of their criminal commitment process. Thus, a number of Euro-American countries have enacted particular legislation creating varied systems to address the problem of recidivistic, higher-risk sexual offenders by providing for some means of detaining those individuals for the purpose of public safety.

Prototypical Definition of a Sexually Violent Predator

The definition of a SVP is a legislative one, shaped by subsequent judicial decisions; it is not a term created by or that emerged from the behavioral or medical sciences. Although state-to-state variation exists in the exact language of SVP statutes, generally these statutes share four common elements: (1) at least one or more past act(s) of sexual offending, typically adjudicated; (2) at least one current mental condition(s) or dysfunction, typically referred to as a "mental abnormality" and/or a personality disorder; (3) some particular relationship between the mental condition/dysfunction, deficits in emotional or volitional capacity and/or control, and the likelihood of future sexual offending; and (4) an opinion that the risk of future sexual offending exceeds some threshold, which varies across jurisdictions. Table 1 summarizes the language used in each of the statutes allowing for easy comparison across statutes.

Qualifying Sexual Offending History

All statutes regarding CCSVP require some evidence of a past act or acts of sexual offending. For many states, however, the requirement for this element is met simply by a history of a formal charge and/or conviction for one or more acts of statutorily defined sexual offenses that are deemed as sexual violent ones. However, some states such as Washington and Iowa apparently depart from the statutory criteria and apparently exercise discretion (e.g., typically referred to as "filing standards") and only consider cases for CCSVP where an individual has at least two adjudicated acts of sexual offenses in their history. In some states (e.g., Washington), the sexual offenses of interest are further qualified as "predatory" (e.g., committed against strangers or persons with whom the person had a casual relationship or cultivated the relationship for purposes of sexual gratification) or as constituting acts of "sexual violence," typically identified as an attempted or completed "contact" sexual offense. In other

Table 1 Civil commitment of sexual offenders: statute details by state

State	Year enacted	Eligibility	Standard of dangerousness	Qualifying disorders
Arizona	1997	Convicted, found guilty but insane, or incompetent to stand trial for a sexually violent offense	Likely	Mental disorder: a paraphilia, personality disorder, or conduct disorder or any combination of paraphilia, personality disorder, and conduct disorder
California	1995	Convicted of a sexually violent offense against two or more victims	Likely	Mental disorder: congenital or acquired condition affecting the emotional or volitional capacity that predisposes the person to the commission of criminal sexual acts in a degree constituting the person a menace to the health and safety of others
Florida	1999	Convicted, adjudicated delinquent, or found not guilty by reason of insanity for a sexually violent offense	Likely	Mental abnormality: a mental condition affecting a person's emotional or volitional capacity
Illinois	1998	Convicted, adjudicated delinquent, or found not guilty by reason of insanity for a sexually violent offense	Substantial probability	Mental disorder: congenital or acquired condition affecting the emotional or volitional capacity that predisposes a person to engage in acts of sexual violence
Iowa	1998	Convicted, found not guilty by reason of insanity or found incompetent to stand trial for a sexually violent offense	More likely than not	Mental abnormality: a congenital or acquired condition affecting the emotional or volitional capacity predisposing that person to commit sexually violent offenses
Kansas	1994	Convicted, found incompetent to stand trial, or found not guilty by reason of insanity for a sexually violent offense	Likely	Mental condition, whether congenital or acquired, which affects the person's emotional or volitional capacity predisposing that person to commit sexually violent offenses
Massachusetts	1999	Convicted, adjudicated delinquent, or found incompetent to stand trial for a sexual offense	Likely	Mental abnormality: a congenital or acquired condition that affects the emotional or volitional capacity of the person that predisposes that person to commit sexually violent offenses
Minnesota	1994	Engaged in a course of harmful sexual conduct that creates a substantial likelihood of serious physical or emotional harm to victims	Likely	Sexual, personality, or other mental disorder or dysfunction

(continued)

Table 1 (continued)

State	Year enacted	Eligibility	Standard of dangerousness	Qualifying disorders
Missouri	1999	Pled guilty, found guilty, or found not guilty by reason of mental disease of a sexually violent offense or has been committed as a sexual psychopath	More likely than not	Mental abnormality: congenital or acquired condition affecting the emotional or volitional capacity which predisposes the person to commit sexually violent offenses
Nebraska	2006	Convicted of one or more sex offenses	Likely	Mental illness or personality disorder which makes the person likely to commit future acts of sexual violence and unable to control his or her conduct
New Hampshire	2007	Has committed a sexually violent offense	Likely (serious likelihood)	Mental abnormality: a mental condition affecting a person's emotional or volitional capacity which predisposes the person to commit sexually violent offenses
New Jersey	1998	Convicted, adjudicated delinquent, or found not guilty by reason of insanity for commission of a sexually violent offense or found incompetent to stand trial for commission of a sexually violent offense	Likely	Mental abnormality: a mental condition that affects a person's emotional, cognitive, or volitional capacity in a manner that predisposes that person to commit acts of sexual violence
New York	2007	Convicted of a sexually violent offense	Likely	Mental abnormality or personality disorder that makes him or her likely to engage in predatory sexually violent offenses
North Dakota	1997	Shown to have engaged in sexually predatory conduct	Likely	A congenital or acquired condition that is manifested by a sexual disorder, personality disorder, or other mental disorder or dysfunction
Pennsylvania	2004	Sexually violent delinquent child: found delinquent for an act of sexual violence and remaining in the institution or facility upon attaining 20 years of age ("aging out" juveniles)	Likely	Mental abnormality or personality disorder: congenital or acquire condition of a person affecting the person's emotional or volitional capacity
South Carolina	1998	Convicted of, found incompetent to stand trial, found not guilty by reason of insanity, or guilty but mentally ill of sexually violent offense	Likely	Mental abnormality: mental condition affecting a person's emotional or volitional capacity
Texas (outpatient commitment only)	1999	Repeat sexually violent offender	Likely	Behavioral abnormality: a congenital or acquired condition that affects a person's emotional or volitional capacity

US Federal Government	2007	A person who is in the custody of the Bureau of Prisons, or who has been committed to the custody of the Attorney General , or against whom all criminal charges have been dismissed solely for reasons relating to the mental condition of the person	Serious difficulty in refraining from commitment of a sexually violent act or child molestation	Serious mental illness, abnormality, or disorder
Virginia	2003	Convicted of a sexually violent offense or unrestorably incompetent to stand trial	Likely (Static 99 = 5+)	Mental abnormality or personality disorder: emotional or volitional capacity that renders the person so likely to commit sexually violent offenses that he constitutes a menace to the health and safety of others
Washington	1990	Convicted of or charged with a crime of sexual violence	More probably than not	Mental abnormality and/or personality disorder: a congenital or acquired condition affecting the emotional or volitional capacity which predisposes the person to commit criminal sexual acts
Wisconsin	1994	Convicted of, or adjudicated delinquent for, a sexually violent offense, not guilty of, or not responsible for a sexually violent offense by reason of insanity or mental disease, defect, or illness	Much more likely than not	Mental disorder: a congenital or acquired condition affecting the emotional or volitional capacity that predisposes a person to engage in acts of sexual violence

Note: Adapted from Doren (2010a, 2010b); Jackson & Richards (2007)

states, for example, Minnesota, a "course of harmful sexual conduct" or a "habitual course of sexual misconduct" (e.g., two or three sexual offenses, respectively) must be determined as part of the commitment analysis and case. However, the statute and subsequent case law do not require that the person has a history of formal adjudication for all such sexual offenses but rather that there is sufficient evidence of sexual offending in their history and that such unadjudicated sexual offending is proved at trial or by stipulation by a respondent. In such instances, the burden is on the state to demonstrate that the individual has either offered credible admissions (self-report) of such sexual offending or to prove via witness or other testimony that an individual is characterized by some history of reported but unadjudicated sexual offending. In addition, in Minnesota, under the SDP statute, harmfulness of the sexual offending is at issue; there is a rebuttable presumption that the sexual offending has been physically and/or emotionally harmful for victim(s).

Mental Conditions or Dysfunctions that Constitute a Mental Abnormality and/or a Personality Disorder

All SVP statutes require some finding that the respondent be characterized by some psychological and/or psychiatric characteristics that are related to their sexual offending; these characteristics or "mental conditions" are most commonly referred to as a "mental abnormality" or a "personality disorder." Such a "mental condition" must be one that creates an increased likelihood of sexual offending in the future, typically if the person were to be released unconditionally into the community. As noted previously, the terms "mental abnormality" and even "personality disorder" are defined in a general manner by statute and are not derived from or necessarily synonymous with terms or conditions from the behavioral or medical sciences. This is quite similar to most areas where forensic mental health practitioners are asked to offer opinions: "insanity" and "competency to stand trial" in criminal law, "best interests of a child" in child custody matters, or "mental illness" in civil commitment. Thus, forensic mental health practitioners are applying psychological and/or psychiatric practice, principles, methods, and available knowledge to constructs created in the legal system.

Currently, approximately 70 % of the states that have SVP statutes utilize relatively similar language to define a "mental abnormality," namely, "a congenital or acquired condition affecting the emotional or volitional capacity that predisposes the person to the commission of future sex offenses" or conditions "which makes the person likely to engage in… acts of sexual violence." Some states such as Washington and Kansas also explicitly include a personality disorder as one type of condition that justifies civil commitment as a SVP. In other jurisdictions (such as Minnesota), the mental abnormality is identified as "a sexual, personality, or other mental disorder or dysfunction." It is useful to remember that in the Pearson case from 1939, the US Supreme Court upheld the constitutionality of a Minnesota statute that required that "the existence in any person of such conditions of emotional instability, or impulsiveness of behavior, or lack of customary standards of good judgment, or failure to appreciate the consequences of his acts, or a combination of any such conditions, as to render such person irresponsible for his conduct with respect to sexual matters and thereby dangerous to other persons." Per Pearson (cited in *Hendricks*), the presence of one or more personality dimensions or traits alone can provide an adequate basis for CCSVP, similar to the requisite mental disorder/abnormality or personality disorder referenced in more contemporary SVP statutes. Thus, effectively, the constitutionality of civil commitment of sexual offenders in the United States has been upheld if a sexual offender is characterized by just one or several particular personality dimensions (per Pearson, largely those associated with antisocial personality disorder) that are linked to his potential dangerousness for sexual offending.

In the first contemporary ruling on the constitutionality of civil commitment of sexually violent predators, the US Supreme Court in *Kansas v. Hendricks* found that the Kansas SVP statute was constitutional because of its attempt to narrow its focus so that commitment required some factor beyond simply past sexual offenses as the basis for the commitment. The Court noted that it had historically sustained civil commitment statutes when they had coupled proof of dangerousness (e.g., potential future offenses) with proof of some additional factor involving particular types of mental conditions or characteristics. The US Supreme Court stated:

> the Kansas act is plainly of the kind with other civil commitment statutes: It requires a finding of future dangerousness, and then links that finding to the existence of a 'mental abnormality' or 'personality disorder' that makes it difficult, if not impossible, for the person to control his dangerous behavior. The precommitment requirement of a 'mental abnormality' or 'personality disorder' is consistent with the requirements of these other statutes that we upheld in that it narrows the class of persons eligible for confinement for those who are unable to control their dangerousness. (p. 358)

Further, regarding the nature and definition of the mental condition (e.g., the mental abnormality or personality disorder) to be considered as the basis for commitment, the Court opined that no particular "mental illness" was a necessary prerequisite for civil commitment. Rather, that decision stated "… the term 'mental illness' is devoid of any talismanic significance. Not only do 'psychiatrists disagree widely and frequently on what constitutes mental illness,' *Ake v. Oklahoma*, 470 U.S. 68 (1985), the court itself has used a variety of expressions to describe the mental condition of those properly subject to civil confinement" (p. 359).

The Court further stated: "Those persons committed under the Act are, by definition, suffering from a 'mental abnormality' or a 'personality disorder' that prevents them from exercising adequate control over their behavior." The Court also noted that legal definitions (e.g., insanity and competency) varied substantially from their mental health counterparts and that "the States have, over the years, developed numerous specialized terms to define mental health concepts. Often, those definitions do not fit precisely with the definitions employed by the medical community" (p. 359). It noted that legal definition that take into account "'such issues as individual responsibility … and competency,' need not mirror those advanced by the medical profession." Further, in various statements as part of its decision in *Hendricks*, the Court noted that prior criminal sexual behavior was accorded a particularly significant and prominent role in the identification of a mental abnormality. The Court stated that prior criminal sexual behavior was to be used "for evidentiary purposes, either to demonstrate that a 'mental abnormality' exists…" (p. 362). It also emphasized that a prior conviction for or charged sexual offense as evidence of prior criminal conduct was significant "to determine whether a person suffers from a 'mental abnormality' or 'personality disorder' (their 'mental condition')" [as well as "to predict future behavior" that "poses a threat to the public" (pp. 362)]. Such language clearly directs for as careful an analysis as possible of the available data regarding the actual criminal sexual conduct so as to provide the strongest basis for determining if and/or which elements of a mental abnormality might be implicated in the enactment of sexual offenses. Further, given the prior decision in and continuing recognition of *Pearson*, the Court acknowledged that one or more elements of a mental disorder linked to sexual offending could serve as a sufficient basis for civil commitment relative to problematic, recidivistic criminal sexual behavior.

[It is also notable that the US Supreme Court explicitly recognized that the persons who were sexual offenders CCSVP might not be treatable:

> "Accepting the Kansas court's apparent determination that treatment is not possible for this category of individuals does not obligate us to adopt its legal conclusions. We have already observed that, under the appropriate circumstances and when accompanied by proper procedures, incapacitation may be a legitimate end of the civil law…*we have never held that the Constitution prevents a State from civilly detaining those for whom no treatment is available, but who nevertheless pose a danger to others.*" (p. 365, emphasis added)

Further, the US Supreme Court noted that in Kansas' statute, "the confinement's duration is instead linked to the stated purposes of the commitment, namely, to hold the person until his mental abnormality no longer causes him to be a threat to others."]

Thus, the decision in the Hendricks case indicated that a so-called mental abnormality and/or a "personality disorder" are each conditions that can serve as an element for CCSVP. Moreover, the Court appeared to emphasize that various constructions of a "mental illness" or mental abnormality could serve as the basis for such commitments; the commitment condition that is permissible to serve as a condition for SVP commitment is thus potentially defined quite broadly and by varied perspectives. More specifically, despite the opportunity to privilege a particular diagnostic nomenclature [e.g., the DSM-IV (1994) of that time], the Court indicated that CCSVP does *not* require a specific diagnosis from any formal diagnostic manual such as the more current DSM-IV-Twin Rivers or "5" (APA, 2000, 2013), as examples. Consequently, the opinion of the Court would appear to permit a very broad set of mental conditions to serve as a basis for CCSVP (e.g., including one or more of the four personality dimensions specified in Minnesota's Sexual Psychopathic Personality Statute). Similarly, most state statutes typically contain no language ruling out any specific diagnosis that might qualify as a mental abnormality or personality disorder. In *Brock v. Seling* (2004), US Court of Appeals (Ninth Circuit) identified that *Kansas v. Crane* "does not require specific findings on the nature of the condition responsible for a sexually violent predator's lack of control" and that "some combination of a mental abnormality and personality disorder" associated with sexual offending was sufficient to meet the "Crane standard."

Conventionally, in practice, evaluators in SVP cases have typically (but not exclusively) relied on the DSM-IV (APA, 1994), the DSM-IV-TR (APA, 2000), and now the DSM-5 (APA, 2013) as the primary source of guidelines for identifying "mental abnormalities" and "personality disorders." However, it seems clear that given the general nature of the legal construct of mental abnormality and personality disorder, particularly in the context of the available US Supreme Court cases is not required; the available diagnostic systems provide a convenient "at a particular" time view of how mental health conditions may be best viewed and categorized and were not developed to provide either etiological or treatment guidance. Thus, the DSM-IV-TR and particularly the more recent DSM-5 are clear that, at best, they represent a current, even temporary, "consensus about the classification and diagnosis of mental disorders at the time of its initial publication" (APA, 2000, xxxiii; APA, 2013) [a point validated by the US Supreme Court decision in *Hendricks*]. The APA noted: "In DSM-IV, each of the mental disorders is conceptualized as a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress (e.g., a painful symptom) or disability (i.e., impairment in one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of

freedom." The DSM-IV-TR utilized a categorical system for dividing mental disorders into "types" but explicitly recognizes that within these "types" there will be considerable heterogeneity and "boundary cases." In addition, the DSM-IV-TR itself notes that "specific diagnostic criteria included in the DSM-IV were meant to serve as guidelines to be informed by clinical judgment and not meant to be used in a cookbook fashion…the exercise of clinical judgment may justify given a certain diagnosis other an individual even though the clinical presentation falls just short of meeting the full criteria for the diagnosis as long as the symptoms that are present are persistent and severe" (APA, 2000, p. XXXII). Similarly, DSM-5 states: "Diagnostic criteria are offered as guidelines for making diagnoses, and their use should be informed by clinical judgment…On the basis of the clinical interview, text descriptions, criteria and clinician judgment, a final diagnosis is made" (p. 21). A particular emphasis of the DSM-5 is the increasing evidence that scientific evidence of various types directs "…that DSM, like other medical disease classifications, *should accommodate ways to introduce dimensional approaches to mental disorders, including dimensions that cut across current categories*. Such an approach should permit a more accurate description of patient presentations and increase the validity of the diagnosis" (p. 5, emphasis added). The DSM-5 has gone so far as to provide both a categorical and dimensional sets of criteria for personality disorders for describing the nature of combinations of maladaptive personality characteristics that create impairment for individuals.

Several things need to be drawn from these statements from the most recent DSMs. First, they are guidelines determined by contemporary consensus and not absolutes relative to categorizing the nature and types of mental disorders that actually may exist in persons. Second, there is clear and increasing recognition that a categorical approach to assigning person's mental disorders is most likely a less accurate manner of describing the nature and degree of signs (observable phenomena) and symptoms (subjective report) or actual constellations of demonstrable personality traits that characterize actual persons experiencing mental disorders. Consequently, it makes increasing sense to describe the nature, severity, context, and impairments associated with psychological and/or psychiatric characteristics or features that relate to the actual set of disordered mental signs, symptoms, and/or maladaptive personality traits.

Relative to forensic purposes, the DSM-IV-TR and the DSM-5 both emphasize that the included "diagnoses and diagnostic information may assist legal decision makers in their determinations" (p. 25) but may be insufficient to establish the existence of a legal term or standard. The DSM-5 emphasizes that an individual's elements or dimensions of mental disorders and their effect on particular abilities of an individual, including thoughts, feelings, and/or behaviors (and their related functional impairments) may vary widely within diagnostic categories. Consequently, in forensic contexts, beyond simply signs and symptoms identified as characterizing a disorder, there must be some specification of the relative effect of mental disorders on a person's capacities or ability or inability to perform some act. This relates to the various legal constructs that are central to most areas of the practice of forensic psychology. Just as "mental abnormality" is a legal concept so are such constructs as "insanity," "competence to stand trial," "Best interests of the children," and "personal injury." Greenberg, Shuman, and Meyer (2004) noted the general problems with the reliance on formal psychiatric diagnosis in forensic matters. They point out that "Psychiatric diagnosis provides a 'Good Housekeeping Seal of Approval,' which appears to validate the relevance and reliability of expert testimony in a language that seems familiar, yet professional" (p. 7). However, they note that the language of formal diagnostic systems is problematic for judicial decision-making by "obfuscating" professional opinions and testimony. In particular, they call attention to the fact that a substantial number of required diagnostic criteria reference internal events and thus involve the veracity and/or ability of an individual in providing such self-report. In particular, they emphasize that litigants are likely to be motivated to report symptoms in line with the "incentives" or their goals for a particular legal case. Greenberg et al. argued that in many forensic matters, the key issue is not diagnosis per se but functional capacity and consequently an evaluation should be focused on the actual behavior of a litigant as related to particular psychological factors or dimensions. Again, regarding SVP cases, such a point is validated by the language of the Court in Hendricks with its emphasis on utilizing the "criminal sexual behavior" to infer the presence of a mental disorder, as well as providing the basis or nexus for the particular dimensions or elements of the mental disorder or personality disorder that relate to past sexual offending and the probability of similar future behavior.

Relative to identifying a mental abnormality and/or personality disorder as the basis for issues in control and risk for future sexual offending, certain types of conventional mental conditions have been viewed as particularly relevant to SVP cases (although no disorders are typically explicitly excluded from consideration). In particular, per most state statutes, potentially relevant conditions are those that predispose an individual to committing future sexual or sexually violent offenses. An obvious qualifying set of disorders for CCSVP are the paraphilic disorders. As noted in the *Hendricks* decision, a paraphilia (pedophilia, now identified as pedophilic disorder) was noted to be a condition that the mental health field "itself classifies as a serious mental disorder… which qualifies as a 'mental abnormality' under the Act, thus plainly suffices for due process purposes." Per DSM-IV,

diagnoses of paraphilias were based on "recurrent, intense sexually arousing fantasies, sexual urges, or behaviors," involving particular activities or objects/persons which have occurred over a period of at least 6 months and which the individual has acted on or which have caused the individual distress or interpersonal difficulty. Historically, common paraphilias identified among SVP candidates per the DSM-IV-TR have been pedophilia (now pedophilic disorder per DSM-5) and variants of paraphilia not otherwise specified [(NOS) (now other specified paraphilic disorder per DSM-5)], either subtyped or specified as non-consent (or coercion or rape) or hebephilia [(NOS) (now other specified paraphilic disorder per DSM-5), specified as hebephilia or hebephilic disorder]. Pedophilic disorder involves deviant sexual interest in children, generally under age 14. Hebephilic disorder involves deviant sexual interest in peri- and postpubescent minors (see Stephens & Seto, 2015). Paraphilia NOS (non-consent/coercion) or other specified paraphilic disorder (non-consent/coercion) is applied to persons who have attempted or committed multiple sexual assaults against non-consenting victims and/or in a coercive manner. Per the DSM-5, these conditions would be classified as pedophilic disorder, other specified paraphilic disorder (hebephilia), and other specified paraphilic disorder (non-consent) or sexual sadism disorder.

For a variety of reasons, a particular rape paraphilia was not designated in DSM-IV; consequently, in civil commitment settings. Consequently, "A commonly used solution is to diagnose such individuals as paraphilia NOS, nonconsent" (Witt & Conroy, 2009). Although often attributed as a product of or "creation" of civil commitment proceedings, this nomenclature or designation had been utilized to describe recidivistic rapists case in criminal/judicial and correctional evaluation settings as well. Doren (2002) identified that the term paraphilia NOS (non-consent) was appropriate and accurate in describing a subset of recidivistic rapists and provided some suggested criteria in distinguishing such a designation. Most recently, the proposed paraphilic disorder criteria for DSM-5 originally included a specific diagnosis of coercive paraphilic disorder but prior to publication of the DSM-5 such a diagnostic category was again not identified as a specific paraphilic disorder per se, in part due to the available research indicating the difficulty distinguishing between the source of arousal between persons with so-called sexual sadism and those characterized by what were viewed as a coercive paraphilic disorder. However, subsequent research by Knight, Sims-Knight, and Guay (2012) has indicated that there is evidence that coercive paraphilia may exist as a dimension along an "agonistic continuum." They noted, "The IRT analyses do suggest a potential solution for measuring the Agonistic Continuum. They suggest a single dimension in which coercive fantasies and behavior are at the lower end, moving into arousal to psychological suffering of humiliation and fear, and finally ending at more severe forms of sadism at the higher end. Individuals can be ordered on this continuum according to the level of the scale they manifest" (p. 8). Thus, persons characterized by sexual fantasies, urges, and behavior involving "mere" coercion appear to fall on the lower end of the agonistic continuum, with sexual sadism representing a more extreme form of sexual fantasies, urges, and behavior on the upper end of the continuum. It is notable that a recent survey of case law regarding paraphilia not otherwise specified (non-consent) reported that, to date, all courts that have considered the issue of admissibility of the diagnosis between 2008 and 2011 admitted the conditions, and most courts found it sufficient to support a finding of a mental abnormality or similar condition in SVP proceedings (e.g., King, Wylie, Brank, & Heilbrun, 2014).

DSM-5 appears to have dealt with the dilemma of how to diagnose rape-related paraphilias by largely incorporating them into an expanded concept of sadism. Criterion A can be read as incorporating arousal to rape. In addition, it appears that the text and criteria provide that a diagnosis of Sexual Sadism Disorder can be made on the basis of recurrent 'sexual behavior involving the infliction of pain or suffering on a non-consenting individual' even where this behavior pattern is NOT accompanied by any admission of related sexual fantasies or urges. Further, it is clarified that this recurrence of sexual behavior involving the infliction of pain or suffering on a 'non-consenting individual' is sufficient to meet criterion A and B. Consequently, recurrent behavior involving sexual coercion should be taken as sufficient grounds for inferring that the person experiences sexual arousal from inflicting this kind of psychological suffering. As a result, the practice of diagnosing a paraphilic disorder based on multiple aggressive, forced, and/or violent stranger rapes appears to have been officially legitimated within DSM-5 by being incorporated into one of the specified paraphilic diagnoses (Sexual Sadism Disorder). From this perspective, the construct of Sexual Sadism Disorder has clearly been expanded and clarified to a more subtle and different concept of Sexual Sadism as described in the DSM-IV, one that clarifies and incorporates much of what has been previously viewed as rape-related paraphilic disorders such as the proposed Coercive Paraphilic Disorder. Given the degree to which other Paraphilic Disorders were maintained with no or little change in their substantive criteria, the changes in the language of Sexual Sadism Disorder appears particularly significant. Further, it appears convergent with the aforementioned research findings of Knight et al. (2012).

In addition to paraphilic disorders, personality disorders, particularly antisocial and narcissistic personality disorders, are common conditions of concern for evaluators in CCSVP. Studies have identified that many individuals present with maladaptive personality traits from several different specific personality disorder categories and show more of a mixed

versus a "single category" presentation (e.g., Verheul & Widiger, 2004). Research has demonstrated that across the recent DSMs, "Personality Disorder Not Otherwise Specified (e.g., PDNOS) or what had previously been termed a 'Mixed' Personality Disorder, are typically one of the most common 'PDs' identified by clinicians in practice and a meta-analysis across both structured and unstructured assessments" (e.g., Widiger & Trull, 2007). Thus, PDNOS is used to designate SVP candidates with a mixed presentation of maladaptive personality traits and/or who meet criteria for more than one specific personality disorder. [It is noted that in the case of *US vs. Murdoch* (1996), the US Ninth Circuit Court referenced DSM-IV and concluded that personality disorder NOS "comports with the general connotation of a 'disease or defect' in that it is neither a temporary condition nor a chosen way of responding but rather a systemic, impairing psychiatric abnormality" (p. 480).]

Finally, psychopathy is a well-recognized mental disorder, condition, or dysfunction that is not specifically identified in the DSM-IV or DSM-5 although it is referenced within the diagnostic criteria for antisocial personality disorder (ASPD). However, psychopathy (either measured as a category or dimensionally/linearly) has been identified as having a unique association with higher rates of criminal, violent, and sexual offending behavior (e.g., Hanson & Morton-Bourgon, 2004; Hare, 2003a, 2003b, 2003c; Hemphill, Hare, & Wong, 1998; Hemphill, Templeman, Wong, & Hare, 1998). Per a more recent meta-analysis, a higher degree of psychopathic traits is associated with a greater degree of sexual offending; persons with higher degrees of psychopathy appear to constitute a subgroup of sexual offenders who are more predisposed to future sexual offending (e.g., Hawes, Boccaccini, & Murrie, 2012). It is notable that some states' statutes pertaining to SVPs require consideration of psychopathy as part of the evaluators determination of mental disorder. Other states have recognized psychopathy as a distinct mental abnormality and/or personality disorder.

Each of the DSM-IV or DSM-5 diagnostic categories most commonly identified as mental abnormalities and/or personality disorders characteristic of SVPs has been the subject of criticism or attack. The prior use of a paraphilia NOS (non-consent/coercion/rape) diagnosis was attacked for evaluators following the current DSM-IV-TR criteria for relying on "just" a pattern of coercive or forced sexual behaviors to assign a diagnosis of a rape paraphilia (although the same criticism could be leveled against pedophilia or now pedophilic disorder). However, as noted by King et al. (2014), in the period between 2008 and 2011, to date all courts that reached the issue of the admissibility of this diagnosis both admitted it as a potentially viable mental abnormality and most found it sufficient to support classifying an individual as a SVP. Hebephilic disorder [or other specified paraphilic disorder (hebephilia)] has been argued to represent a normative phenomenon such that many males may show arousal to adolescents, particularly female adolescents; nonetheless, the ICD-10 includes early pubertal age in its definition of pedophilia, and studies of pubertal development indicate that aspects of pubertal development may not occur until age 15 among some youth. Some have contended that antisocial personality disorder is not an appropriate diagnosis to support civil commitment as a sexually violent predator. Such a personality disorder has been argued to be insufficient as a diagnosis because a large number of persons with this condition have no apparent history of sexual offending and/or engage in a broad range of antisocial behavior, inclusive of sexual offending. However, in *Kansas v. Crane*, a CCSVP was upheld for a sexual offender with a diagnosis of antisocial personality disorder (in addition to exhibitionism), following the respondent's plea to aggravated sexual battery. [It is notable that after being released from sexual offender treatment after his commitment was overturned by the Kansas Supreme Court, Mr. Crane was subsequently arrested for attacking a woman and charged with five counts of sexually motivated crimes.] Significantly, from an epidemiological perspective, only about 50 % of persons in the United States who meet diagnostic criteria for ASPD have an official record of some criminal offending (Robins & Regier 1991). That is, while a number of persons meet criteria for ASPD, many have not engaged in violent behavior but rather have enacted other rule-breaking and criminal behavior, demonstrated irresponsibility, or disregard for others. This suggests that half of the individuals who meet criteria for ASPD who are detected by the criminal justice system are somewhat distinct as persons with ASPD. In addition, while most persons with antisocial personality disorder may be more likely to commit nonsexual criminal offenses, the question for CCSVP purposes is one of whether a particular sexual offender diagnosed with antisocial personality disorder and under consideration as a potential SVP, with a history of one or more sexual offenses, satisfies the statutory risk threshold for as a SVP. That is, while an individual with ASPD may be at risk to commit other crimes as well as sexual offenses, SVP statutes only require that his risk to commit sexual offenses as a function of his particular set of maladaptive antisocial personality traits affects his emotional and volitional control to a serious degree relative to their sexual offending history. As Elwood (2009) explained, while behaviors such as cigarette smoking may be associated with various health conditions, that does not minimize or change the finding that such risk factors are, in fact, associated with specific conditions. Similarly, while ASPD is associated with various problematic conditions or behaviors, that does not minimize or change the empirical findings that this condition is particularly strongly associated with sexual offense recidivism. Case law exists for most states with SVP statutes validating that ASPD has been found to be sufficient as a mental abnormality and/or a personality disorder as the

basis for commitment; effectively, the US Supreme Court in *Kansas v. Crane* affirmed that position as well.

More generally, across states with SVP statutes, district court and appellate court decisions have upheld the commitment of sexual offenders with diagnoses of pedophilia, paraphilia NOS (non-consent/coercion), hebephilia, antisocial personality disorder, and personality disorder NOS. To date, both the state and federal judicial system has affirmed such disorders as a legitimate basis for CCSVP despite the varied criticisms of such diagnoses. In addition, in certain states and federal court, various other conditions apart from paraphilias have also been found to constitute mental abnormalities relative to repetitive sexual offending, including alcohol or substance abuse/dependence, borderline personality disorder, bipolar affective disorder, sexual disorder not otherwise specified, intellectual and developmental disabilities, and schizophrenia. Further, a qualifying "mental abnormality" has also been determined by courts to be a product or interaction among aspects of several mental and/or personality disorders or a combination of mental/personality characteristics. Again a case to this point is that of Mr. Crane who was determined to be a SVP based on the combined presence of ASPD and exhibitionism but not either condition on its own.

Looking to the future, as with other areas of forensic mental health, it seems likely that there is an increasing convergence of expert professional forensic opinion and the evolution of comprehensive, dimensionally based diagnostic systems. Relative to the former, Greenberg et al. (2004) have identified that "…the circumstantial use of diagnosis in the forensic setting is potentially more misleading than helpful to the trier of fact…We therefore urge that, as a general rule, forensic mental health professionals not testify in terms that include psychiatric diagnoses, unless they are required to do to address the applicable legal standard" (p. 13). Rather, Greenberg and Shuman encouraged the utilization of more specific psychological elements, characteristics, processes, and so on to provide a functional analysis of the relevant capacities, other psychological issues, and/or impairments that are encompassed by governing legal constructs. As Greenberg and Shuman identify with the application of psychological and psychiatric elements to forensic cases more narrowly, it seems evident from the process and product that was manifest in the development and in the actual presentation of the DSM-5, professionals are increasingly of the belief that in broader clinical application, nosological systems have recognized and have already begun to implement a dimensional approach to psychiatric classification (e.g., for personality disorders) as well as demonstrated increasing recognition of the artificial "overlap" of diagnostic "groups" of disorder. Per the preface of the DSM-5:

> …we recognize that mental disorders do not always fit completely with the boundaries of a single disorder. (p. 5)

In noting that the DSM must evolve relative to research advances, it was noted:

> "One important aspect of this transition derives from the broad recognition that a too rigid categorical system does not capture clinical experience or important scientific observations…These findings mean that DSM, like other medical disease classifications, should accommodate ways to introduce dimensional approaches to mental disorders, including dimensions that cut across current categories. Such an approach should permit a more accurate description of patient presentations and increase the validity of a diagnosis…" (p. 5, emphasis added)

Along these lines, it seems particularly notable that in clinical practice (per the recent DSM-IV), the most common diagnoses assigned in clinical settings were "NOS" or "not otherwise specified diagnoses" (e.g., Verheul & Widiger, 2004; Verheul, Bartak, & Widiger, 2007); thus, in actual mental health practice, most client's presentations of signs and symptoms were those of a "mixed" nature (e.g., across disorders, such as anxiety and depression or antisocial and borderline personality disorders) or did not fully satisfy the formal criteria for the listed specific diagnostic categories. Finally, a review of empirically oriented mental health journals demonstrates that an expanding body of research provides a scientific basis for dimensional models of psychopathology and it's increased and marked utility in providing more coherent and fine-grained applications of such understanding of what would be regarded as maladaptive and dysfunctional experiences and behaviors of individuals (e.g., Krueger et al., 2002, Krueger, Markon, Patrick, Benning, & Kramer, 2007; Krueger, Skodol, Livesley, Shrout, & Huang, 2007; Markon & Krueger, 2005; Markon, Krueger, & Watson, 2005).

The Nexus Between Mental Disorder and Elevated Risk for Sexual Offending: Emotional and Volitional Impairment and Predisposition

As with other aspects of the statutory and/or judicial language defining SVP, additional legally created terms that have some relationship to the behavioral, psychological, or psychiatric fields are also important factors in the determination as to whether a particular sexual offender meets criteria as a SVP. The most common statutory language, as noted previously, indicates that a diagnosis or some other described mental/personality sign, symptom, disorder, or dysfunction (problematic or abnormal characteristics) per se is often considered insufficient on its own to meet the criteria of a "mental abnormality." Rather, those statutes either direct or suggest that the so-called mental abnormality for a particular individual must have some particular characteristics or qualities relating to the "mechanism" of and probability for

committing future sexual offenses. First, as indicated previously, the most common definitions of "mental abnormality" indicate that as a mental disorder, it must affect or change a sexual offender's "emotional or volitional capacity." Second, most commonly the condition(s), disorder(s), or dysfunctions, through this effect, must *predispose* or influence a person to commit additional sexual offenses. Impairment is typically understood as or defined as involving "damage" or "diminishment to some functioning"; thus, a "mental abnormality" must be one or more signs or symptoms such that it "damages" or "alters" positive or negative emotional capacity and/or "volitional" capacity to a degree that effective functioning is decreased. Regarding emotional capacity, a disorder might affect an individual in several ways. First, emotional capacity might involve the threshold (e.g., lower) or intensity of the potentiation, elicitation, or intensification of a *positive* emotional state (e.g., the pleasure of sexual arousal; the hedonic anticipation of some set(s) of sexual behavior; generalized arousal; persistence of general, hedonic, or sexual arousal; and/or broad-spectrum thrill-seeking) and/or a negative emotional state (e.g., anger, distress, or, in some cases, sexual urge or desire). In these instances, the nature of the affective experience (low threshold to stimulation, heightened sensitivity, frequency of stimulation, pronounced reactivity—intensity—and delayed refractory capacity) could singly or in combination predispose someone to sexual offending. Second, emotional capacity might be affected by assorted conditions that limit or negate certain affective experiences that might inhibit sexual offending such as guilt or empathy. Thus, individuals with a variety of characteristics (evidence of callousness, a generalized lack of emotionality, lack of guilt or empathy, or particular attitudes about the perceived lack of effects of sexual offending on others or the perceived self-reward associated with obtaining general or specific sexual gratification) might be predisposed to sexual offending because they are deficient in emotional and/or cognitive capacities that might limit or inhibit the enactment of an incident of sexual assault or violence.

Regarding volitional capacity, a disorder would need to affect the persons' ability to recognize or manage/regulate an impulse or urge for inappropriate sexual behavior, either by "permitting" or aggravating/amplifying a "press" toward a particular behavior (e.g., sexual arousal and desire, thrill-seeking, entitlement, self-gratification) by undermining proximal self-control and/or by compromised executive functioning. One can easily understand how various deficits in the multiple aspects of cognition [e.g., both in terms of cognitive processing and content (beliefs or schemas)] or insensitivity to social norms or values could each or in differing combinations be of sufficient intensity or frequency that it would affect an individual's self-regulation relative to predispositions toward sexual harm toward others. Further, issues in emotional capacity likely interact with cognitive capacity and do so to varied degrees across persons (e.g., less to more). Certain affective states (either positive ones such as sexual arousal or negative ones such as anger or frustration)—"hot" experiences or situations—might additionally or further compromise different dimensions of cognitive self-regulation or executive functioning, that is, even generalized arousal can become transformed into sexual arousal by virtue of context or situational cues.

A sexual offense, as a sexual behavior, is motivated behavior; a person seeks out a particular sexual activity or experience as an end or goal that is desired. Sexual desire or arousal regarding an object, part-object, activity, and/or person is viewed as a motivational state, influenced by both internal and external factors. That desire could be long-standing and/or episodic, or it could be more fleeting and momentary for an individual. For persons with paraphilias and paraphilic disorders, it is likely that there is regular or recurrent sexual fantasy that leads to heightened sexual arousal; that sexual arousal could be generalized toward a particular category of victims or particular acts and/or it could be directed at a specific person or types of sexual activities. Sexual arousal, in and of itself, is almost always a hedonic state, and, depending on a person's degree or intensity of generalized sexual preoccupation and their responsivity to the experience of arousal, it may lead to sexual urges and a desire for release or gratification and at various levels of intensity. For sexual offenders not characterized by one or more paraphilias, their sexual urges are more likely a function of one or more additional factors—e.g., of emotional arousal determined by both generalized arousal (e.g., anger, distress, loneliness) and/or more immediate sexual arousal. In particular contexts or situations that contain perceived high generalized sexual stimulation or perceived sexual provocation and/or perceived opportunity, particular individuals are likely to act on the "totality" of their arousal and seek more heightened sexual stimulation and gratification to obtain some release from their generally aroused state(s). Alternately, for persons who seek sexual contact for predominantly (or even exclusively) nonsexual motivation, various personality traits [(motivators per Hoberman (2015)] and dimensions of disinhibition are associated with sexual reoffending. Both paraphilic and non-paraphilic sexual offenders can be subject to particular personality traits or states where they are characterized by various non-sexual motivators as well as a lack of internal affective controls (e.g., empathy, guilt), deficits in select internal cognitive controls (e.g., a lack of "moral" values, the ability to weigh alternative courses of action, attitudes supportive of general or more specific sexual offending or of persons as sexual objects) and/or an indifference to external controls (e.g., the

belief that they will not be caught and/or will not receive significant consequences for sexual acting out). While some sexual offending by some sexual offenders will be characterized by extensive fantasy, rehearsal, and planning, other sexual offending by some sexual offenders will be of a more impulsive, "non-reflective," or reactive nature. Both paraphilic and non-paraphilic offenders may be characterized by sexual offending that is either more or less anticipated or impulsive at particular times.

Additionally, sexual offending, like other behavior is a function of situational or contextual factors, such as real or perceived opportunity. Thus, Mischel (2004) pointed out that individual differences are expressed less in consistent cross-situational behavior and more in distinctive (but relatively stable) patterns of "if, then situation behavior relations" that form what he describes as contextualized, psychologically meaningful *personality signatures* (e.g., "he does A when X, but B when Y"). Such "if, then" patterns or "personality signatures" (or behavioral scripts) are likely to be activated in relation to the perception of specific situations; those scripts would be similar across perceived similarities in particular situations but might vary when such contexts were perceived as or were/are different. Further, various acute variables such as situational emotional states, cognitive beliefs elicited in particular situations, and, in particular, the disinhibiting or stimulating influence of alcohol and drugs can further increase the probability of acting upon either long-standing or more immediate sexual and/or nonsexual urges at particular times. Consequently, while sexual fantasies and urges may remain persistent, albeit fluctuating experiences over time (e.g., it is likely that no person has such occurrences *all* the time), the enactment of sexual offending will be function of a relatively "person-specific" sexual elements such as the availability of an "appropriate" victim (characterized by relatively preferred sexual stimuli) and perceived relatively permissive circumstances or context. The significance of context is reflected in the observation that effectively no sexual offenses against children or older (e.g., adolescent or adult) females occur while, sexual offenders are institutionalized.

As noted, SVP laws often require that combination of one or more "mental abnormalities" or personality disorders and their associated "impairment(s)" *predispose* an individual to commit sexual offenses. Most generally, a predisposition is simply a tendency to act in a particular or expected way or susceptibility toward particular behavior or actions. As Elwood (2009) has written, the most useful definition of "predispose" in this context is that "the effect of the mental disorder [is] to increase the incidence of sexual recidivism," such that "predisposition is equivalent to a risk factor and can be established by a statistical association, without having to invoke a casual mechanism (e.g., how it leads to such an increase)" (p. 401).

Serious Difficulty in Control in Relation to Emotional and Volitional Impairment

CCSVP is similar, relative to other types of civil commitment, in the requirement that an individual's dangerousness or severe impairment (in this case, likely difficulty controlling their sexual offending) be associated with or linked to some mental condition(s), a "mental abnormality" or personality disorder. As noted above, the most common type of SVP statute defines the mental abnormality as a condition affecting emotional and/or volitional capacity. Thus, a mental abnormality is not just a mental disorder per a DSM-5 diagnosis or some similar diagnosis. According to DSM-5: "Even when diminished control over one's behavior is a feature of the disorder, having the diagnosis in itself does not demonstrate that a particular individual is (or was) unable to control his or her behavior at a particular time" (p. 25). The issue of volitional capacity and/or impairment or "self-control" has historically played a central role in the CCSVP. As noted, in the first "SVP" case heard before the US Supreme Court in 1939, that Court upheld a Minnesota Supreme Court decision which narrowed the interpretation of an older form of an "SVP" statute to persons with a "habitual course" of sexual offending who "have evidenced an…utter lack of power to control their sexual impulses." Again, in *Kansas v. Hendricks* (1997), the discussion of mental abnormality was linked to an individual's difficulty in regulating and/or "controlling" sexual offending and that volitional impairment limited those individuals appropriate for CCSVP. In such cases, the Supreme Court's judicial language indicated that to be determined to be a SVP, it would have to be determined that it was "seriously" difficult—problematic or "hard"—for the person to manage their potentially dangerous behavior as result of one or more psychological/psychiatric elements or "disorders."

In *Kansas v. Hendricks* (1997), the US Supreme Court explicitly rejected the notion that in order to be determined a SVP, an individual must manifest a total or complete lack of control over their sexual offending behavior. Rather, that decision indicated that a SVP statute would fall within constitutional limits if a mental abnormality and/or personality disorder "indicated that civil commitment of sexual offenders could be applied to 'those who suffer from a volitional impairment rendering them dangerous beyond their control'" (p. 358) and thus concluded that some degree of "volitional impairment" narrowed the group of sexual offenders subject to civil commitment sufficiently so that such civil commitment of sexual offenders was deemed constitutional. It was noted that a finding of volitional impairment served to limit such civil commitment "in that it narrows the class of persons eligible for confinement to those who are unable to control their dangerousness." Subsequently, in *Kansas v. Crane*

(2002), a committed sexual offender challenged his commitment by arguing that the degree of "volitional impairment" must be a total or absolute. However, in that case, the US Supreme Court determined that the volitional impairment identified in the *Hendricks* case was not required to be absolute, only "serious." They noted that sexual offenders eligible for commitment would generally find it "particularly difficult to control their behavior." The decision stated, "in recognizing that fact, *we did not give to the phrase lack of control a particularly narrow or technical meaning*. And we recognize that in cases where lack of control is at issue, *inability to control behavior will not become demonstrable with mathematical precision. It is enough to say that there must be proof of serious difficulty in controlling behavior*" (emphasis added; p. 413). As was clear by the majority opinion in *Crane*, that decision did not provide any specific standard for determining serious difficulty in controlling behavior rather noting, "safeguards of human liberty in the area of mental illness and the law are not always best enforced through precise bright-line rules" (p. 407). Further, the Supreme Court in the *Crane* matter also noted that there might be "considerable overlap" between emotional and volitional abnormality or capacity. Per Kirwin (2010), "the Court appeared to indicate that commitment would be permissible in cases of 'emotional' abnormalities, as well as 'volitional' ones." The Court stated,

> "*Hendricks* must be read in context. The Court did not draw a clear distinction between the purely 'emotional' sexually related mental abnormality and the 'volitional.' Here, as in other areas of psychiatry, there may be 'considerable overlap between a… defective understanding or appreciation and....[an] ability to control…behavior. Nor, when considering civil commitment, have we ordinarily distinguished for constitutional purposes among volitional, emotional, and cognitive impairments." (p. 811)

By this discussion, the Court was apparently recognizing that "serious difficulty in controlling behavior" could arise not only where the person's disorder renders him unable to avoid sexual assault, despite his desire to avoid it, but also in situations where the disorder causes the person to want to engage in sexual assault (emotional incapacity) or causes the person to not understand or appreciate the nature of what he is doing (cognitive incapacity).

Consequently, "serious difficulty in control" (SDC) is an issue that is typically addressed in civil commitment cases either as an independent element of criteria specified for determination as a SVP in some states (e.g., Missouri) or, in other jurisdictions (e.g., Washington, Arizona), as part of the determination of the presence of and effects of a mental abnormality and/or personality disorder. For example, Washington Courts addressed the issue of volitionality in the case of In re the detention of Thorell (2003). Here, the Washington Supreme Court rejected the claim that *Hendricks* or *Crane* required a separate finding of impaired volitionality. Instead, *Thorell* clarified that "a *lack of control determination may be included in the finding of mental abnormality*" *(p 375). Thorell* further stated, "What is critical to both *Hendricks* and *Crane* is the existence of 'some proof that the diagnosed mental abnormality has an impact on offenders' ability to control their behavior" (p. 376). [It should be noted that two US Court of Appeals decisions in the Seventh and Ninth Circuit concluded that CCSVP does not require a separate factual finding regarding SDC because such a finding is implicit in the finding of the presence of a mental abnormality linked to a particular level of risk for sexual offender recidivism [e.g., *Laxton v. Bartow* (2005) and *Rose v. Mayberg* (2006)].

Starting with a straightforward semantic examination of these terms provides assistance in understanding the potential meaning and implication of these terms. Per Webster's New Collegiate Dictionary, "serious" is defined as "important" or "requiring much thought or work" or having "important or dangerous consequences"; "difficulty" refers to the state of something being hard to do or hard to carry out or "hard to deal with, manage or overcome"; and "control" is defined as "to exercise restraint" or "directing influence" or "to have power over" and/or "regulation." Consequently, one can suggest that "serious difficulty in control" involves conditions or characteristics that are important (in part because of their significant consequences) and involves a lack of or diminished restraint or self-management, self-control, or self-regulation (that precedes and is related to sexual offending) or where self-control or behavioral restraint is "hard" or "effortful." Similarly, the notion of "volitional impairment" can be better understood by examining how the term is used in other domains. For example, a "cognitive impairment" has been identified as a condition where a person has "more difficulty with a mental task or tasks than the 'average' person" or where a person has some problems with ability to think and learn. Thus, volitional impairment, as applied to a sexual offender, would suggest that an offender has more difficulty with controlling his sexual offending behavior relative to the average or typical offender.

From the perspective of forensic mental health and general criminal behavior, several writers have proposed domains for consideration regarding the presence of some degree of such self-regulatory impairment. Gottfredson and Hirschi (1990) suggested that the primary cause of criminal behavior is deficient self-control, with persons more motivated to pursue immediate desires for the satisfaction of pleasure and other rewards. They suggested that criminal behavior involved a number of elements relevant to compromised self-control including that criminal behavior was stimulating and thrilling; often required little planning or skill; provided immediate, easy, and simple satisfaction of desires; and had few or insufficient long-term benefits. In addition, Gottfredson and Hirschi (1990) emphasized that higher rates

of socially deviant and criminal behavior involve relatively immediate gratification of desires in conjunction with perceived or actual opportunity. Whiteside and Lynam (2001) used factor analysis of well-identified personality factors and found four distinct personality facets associated with impulsive-like behavior including sensation-seeking, urgency, (lack of) premeditation, and (lack of) perseverance (persistence). Thus, impulsivity reflects both motivational elements (urgency, sensation-seeking) and limitations in executive, self-regulatory functions including compromised foresight and persistence in resisting motivators. Somewhat similarly, Doren (2002) suggested that the issue of emotional and volitional impairment could be understood along two dimensions. First, he suggested that problems in control could be a function of a sexual offender's compromised ability to learn from experience. Second, he suggested that in some cases the sexual offender's desire for atypical or illegal sexual behavior "is sufficiently strong that it overwhelms the individual's ability to consider various options and consequences…It is not the desire per se that is the problem, but the strength of the desire relative to other actively considered options" (p. 17). Alternatively, Rogers and Shuman (2005) offered another very basic set of considerations. They suggested that that four areas should be explicitly addressed as a minimum standard in evaluations: (1) lack of choicefulness, claiming that evidence of planning or rational decision would support the capacity to choose; (2) disregard for personal consequences evidenced by attempts to reduce negative consequences of sexual offending (e.g., arrest); (3) incapacity for delay (of sexual gratification); and (4) chronicity, with the behavior representing an enduring characteristic or stable trait.

However, an increasing body of statute, appellate law in specific states, and recent Federal Appellate decisions provide direction as to the breadth of the requisite degree of volitional impairment necessary as a factor related to civil commitment of SVPs. On the state level, in Minnesota there have been an extensive number of state appellate decisions regarding the meaning of the legal construct of "utter lack of power to control" under the sexual psychopathic personality statute and related judicial decisions regarding the "control" or "volitional impairment" (VI) issue under Minnesota's more contemporary sexually dangerous persons (SDP) statute. The Minnesota Supreme Court in *In re Linehan* (VI) found that the SDP statute required that the sexual offender's mental "disorder or dysfunction does not allow [him] to *adequately control* his sexual impulses" or "does not allow the person to *adequately control* his sexual behavior" (emphasis added).

Several authors have examined the relatively extensive set of Minnesota appellate decisions regarding the "control" or "volitional impairment" issue, including Kirwin (2008, 2010, 2014) from a legal perspective and Mercado, Schopp, and Bornstein (2005) from a forensic mental health perspective. It can be argued that "an utter lack of power to control" (ULPC) is a more stringent construct than that of "serious difficulty in control" or "volitional impairment." The available reviews noted above identify several major points regarding the multiple perspectives that the Minnesota appellate courts have brought to bear on the ULPC (and not reversed by the Minnesota Supreme Court or any higher court to date). Mercado, Bornstein, and Schopp (2006) suggested that their review (largely based on Minnesota appellate cases to that date) suggested four factors seemed primary related to volitional impairment: (1) verbalized lack of control, (2) history of sexual crimes, (3) lack of offense planning, and (4) substance use. While noting such elements as well, Kirwin (2008, 2010, 2014) consistently identified the following domains as identified by the increasing Minnesota appellate case law regarding serious difficulties in self-control and/or volitional impairment.

1. *The respondent need not be out of control all the time.*
   In Minnesota, the two SVP statutes each have unique elements concerning the issue of relative control regarding sexual offending; the sexual psychopathic personality (SPP) statute requires evidence of utter lack of power to control (ULPC), while the sexually dangerous person statute requires evidence that a disorder or dysfunction does not allow a person to "adequately control" his sexual behavior. Per *In re Pirkl* and *In re Irwin*, Courts of Appeals held that a person could meet the ULPC standard without being out of control all the time. Similarly, a Court of Appeals in *In re Mattson* found that the respondent showed an utter lack of control when he acted out sexually, although he did not do so 24 hours a day. The court explained: "Lack of control is situational and will occur when the impulses arise or manifest themselves." In *In re Krueger*, the appellate court also found that contextual factors were central as to determining control and sexual reoffending, noting that "given an available victim, available means, and available circumstances," the individual was unable to control his sexual behaviors. In *In re Hommes*, the Court of Appeals noted that, "once the opportunity for sexual behavior presented itself, Hommes did not have the ability to control his impulses." Thus, several Minnesota judicial decisions emphasized that a lack of control was relative to context or situational factors; such a person who committed a sexual offense demonstrated ULPC when an "appropriate" victim was encountered and the appropriate means and a permissive situation were present. Similarly, appellate courts ruled that a failure to act out sexually while in custody (e.g., *In re Rubin*) or while on conditional release (e.g., *In re Preston*) or even while in the community for a limited period of time without being detected for a new sexual

offense did not contradict a finding of an "utter lack of power to control" (e.g., *In re Eberhart*). Finally, in two cases Minnesota appellate courts held that failure to reoffend or act out sexually while in prison did not demonstrate that the person has the ability to control his sexual behavior (e.g., *In re Rubin* and *In re Carner*). Similarly, the Court held that a 12-year period of no apparent sexual offending did not preclude a finding of ULPC, writing that because the person had been incarcerated or in residential treatment the majority of time, "his opportunity to reoffend has been minimal."

Regarding the lack of adequate control, the appellate courts have applied almost identical criteria as constituting evidence for "adequate control" of sexual behavior as those for ULPC, including an extended time since the person's last detected sexual offense, including a 10-year gap in offending history, relapse in alcohol or drug use leading to sexual misconduct, a long history of impulsive and noncompliant behavior (e.g., back to adolescence and/or childhood), failing to accept that the individual has a problem with sexual offending, or refusing sexual offender treatment (cited in Kirwin, 2014). As with the ULPC criteria, for Minnesota appellate courts, a lack of adequate control of sexual behavior clearly does not require that a person lack adequate control over their sexual offending either all or much of the time.

2. *Planning/grooming does not preclude an inability to control.*
Contrary to the proposition by Rogers and Shuman, numerous Minnesota Courts of Appeals have concluded that planning, premeditating, or facilitating the circumstances prior to attempting a sexual offense are not contradictory to a finding of ULPC. Rather, they appear to recognize that intermittent or repetitive planning (as exemplified by grooming of child victims) itself represents a lack of control, particularly when grooming has historically led to a sexual offense given opportunity.

Per *In re Bieganowski*, it was noted: "Although the 'grooming' process requires time, thus eliminating any 'suddenness' regarding the sexual activity, the habitual nature of appellant's predatory sexual conduct indicates an inability to stop the 'grooming behavior.'" In *In re Preston*, the court said: "Though grooming and planning behavior can show the ability to control the sexual impulse, where the grooming behavior itself is uncontrollable, the impulse is likewise not controllable." In *In re Adolphson*, a Court of Appeals held that a pedophile's "grooming" behavior does not preclude a finding of utter lack of power to control, "where there is an inability to stop such behavior." The court explained:

> "The fact that appellant engaged in 'grooming' behavior does not preclude a finding of utter lack of power to control, where there is an inability to stop such behavior and other indications of lack of control. *Appellant's behavior, which has elements of both control and impulse, appears to be a paradox, but closer examination reveals this is not the case. The planning and sex acts are a single unit of compulsive behavior, triggered by the presence of [appropriate victims], and played out in a predictable sequence of events.*" (emphasis added)

Similarly, the court of appeals in *In re Hart* held that a pedophile who used "isolation, bribes, threats, force, and alcohol' to approach, groom, and molest children met the utter-lack-of-power-to-control standard." More generally, In *In re Pirkl*, a commitment was upheld even though the respondent's actions involved a "fair amount of planning and deliberateness." In *In re Mayfield*, a Court of Appeals found an "utter lack of power to control" even though the sexual offender had stalked his victims and his actions were "deliberate to some degree." Further and more generally, *In re Mattson*, the court of appeals wrote: "Lack of control is situational and will occur when the impulses arise or manifest themselves." Thus, in Mattson, the Court effectively endorsed the model of "personality" or "behavioral" signatures defined by Mischel (2004) and signified that lack of control or volitional impairment may most often be an "if, then" phenomena demonstrated when appropriate victims and perceived permissive circumstances co-occur and an offender acts out sexually.

3. *Lack of insight showing inability to control*.
A number of Minnesota appellate court decisions have held that an inability to control sexual impulses can be determined by an offender's lack of insight into his sexual offending as a problem generally and/or the specific circumstances and factors related to sexual offending. In *In re Irwin*, the court of appeals credited testimony from an expert that "an important factor in determining whether one has power to control sexual impulses is *whether the person feels he has a problem*; if so, he at least has some control since he knows he is flawed, and *may be more vigilant in seeking assistance* …Without this basic insight, appellant has the utter lack of control" (emphasis added). Similarly, the Court of Appeals in *In re Adolphson* concluded that an individual's lack of insight and remorse was an indicator that the offender had an "utter lack of power to control." The court stated that Adolphson was aware that his conduct was against the law, yet had an "entrenched belief" that sexual activity with young boys was acceptable and was convinced that "he has provided a service to young men, and that the law is wrong. This complete lack of will shows he continues to have an utter lack of control." In *In re Beiganowski*, an appellate panel noted that the failure of an individual to remove himself from opportunities to offend and his failure to avoid precursors (e.g., substance use) that had historically triggered his impulsive behavior were indicative of an "ULPC."

4. *Sexual offending despite prior negative consequences shows a lack of control.*
   A number of courts have found that a person's failure to recognize or respond to consequences of his sexual misconduct (e.g., the harm it produces for victims) relates to reflect an utter lack of control of one's sexual impulses. In *In re Kunshier*, the court of appeals emphasized the finding that an offender who had committed sexual assaults without regard to consequences to victims was demonstrative of an ULPC. In the same case, the court also concluded that an utter lack of power to control sexual impulses was evidenced by and offender who had committed sexual assaults *without regard to consequences* to himself as well, including the commission of sexual offenses while on probation and after completing sexual offender treatment. More generally, in *In re Mattson*, the Court of Appeals cited an expert testimony that "when a person engages in behavior despite repeated consequences, it evidences a lack of control."
5. *Specific psychosexual facts about the respondent.*
   In *In re Reb*, the Court of Appeals indicated that ULPC was demonstrated by a respondent's continuing deviant sexual fantasies, his history of impulsivity and sexually acting out, his large number of victims, and the relative length of his period of sexual offending. In *In re Mattson*, the Court of Appeals cited an expert testimony that "the utter lack of control was demonstrated by the fact that, even when appellant was in a structured setting, he had difficulty refraining from the use of pornography." Again, specific situational or circumstantial factors related to a particular offender's sexual or criminal offense cycle have also been identified by Minnesota appellate courts as potentially demonstrating an ULPC including the following: failure to remove oneself from high-risk situations, failure to remove himself from situations that provide the opportunity for similar offenses, failure to avoid precursors that trigger impulsive behavior (e.g., the consumption of large quantities of alcohol), evidence of failure to engage in rule-abiding and/or appropriate programming while on conditional release has also been highlighted as related to an ULPC such as committing new sexual offenses while on conditional release, acting out sexually when discovery was likely or within a short time after release from confinement, and refusing sexual offender treatment.

From a statutory perspective, the Adam Walsh Act (the federal statute related to CCSVP) also offers instruction as to the determination of "serious difficulty in refraining from sexually violent conduct or child molestation if released." The statute states:

> "In determining whether a person will have 'serious difficulty in refraining from sexually violent conduct or child molestation if released,' Bureau [of Prison] mental health professionals may consider, but are not limited to, evidence: (a) Of the person's repeated contact, or attempted contact, with one or more victims of sexually violent conduct or child molestation; (b) Of the person's denial of or inability to appreciate the wrongfulness, harmfulness, or likely consequences of engaging or attempting to engage in sexually violent conduct or child molestation; (c) Established through interviewing and testing of the person or through other risk assessment tools that are relied upon by mental health professionals; (d) Established by forensic indicators of inability to control conduct, such as: (1) Offending while under supervision; (2) Engaging in offense(s) when likely to get caught; (3) Statement(s) of intent to re-offend; or (4) Admission of inability to control behavior; or (e) Indicating successful completion of, or failure to successfully complete, a sex offender treatment program."

[As suggested above, it should be noted that across several jurisdictions, there have been judicial findings that in situations where individuals have committed no additional sexual offenses while incarcerated [most likely because they had not had any meaningful opportunity (permissive circumstances) to reoffend against appropriate victims, such as children or adult females], while limited by terms of conditional release (bail, parole, or probation) or despite 5–12 years in the community without a known or detected sexual offense or lack of possession of particular erotic materials, did not mitigate against a finding of serious difficulty in control. Thus, while committing additional acts of sexual violence or possessing materials indicative of potential sources of deviant sexual arousal while confined or under conditional release can serve as indicia of SDC/VI/ULPC, the absence of such findings has not been regarded as dispositive but rather the expected behavior of confined or detained individuals.]

The broader construct of SDC (as opposed to the semantically narrower ULPC) would appear to encompass situations where an individual's self-regulation or self-control over personal, dispositional, or situational factors relating to perpetrating sexual offending is impaired. It can be impaired or difficult because they lost control in the face of appropriate victims or permissive circumstances or because they planned or facilitated the opportunity to act and failed to resist the push or pull (urge) to act. Thus, SDC includes the person who impulsively responds to a situation that involves attempted or actual sexual offending as well as other individuals who premeditate, plan, and then more carefully enact a situation that involves harm to another. Regardless of premeditation, it appears to be the repetitive enacting (or attempting to enact) of a sexual offense, particularly after sanctions or treatment, or when other potential options exist. It is notable that in Kansas *v. Crane*, a paraphilia, in that case specifically pedophilia, was seen as "…a mental abnormality that critically involves what a lay person might describe as a lack of control" (p. 7). Thus, one can surmise that the Supreme Court found that a person characterized by recurrent sexual fantasies, urges, or behaviors involving potential

victims was a sufficient basis for determining a serious difficulty in control.

Relative to "volitional incapacity" or "impairment," *Linehan v. Milczark* (2003) is a Minnesota case that was *filed* with the US Court of Appeals for the Eighth Circuit after the *Hendricks* decision was decided but *before* the *Crane* decision was announced. In this case, the Eighth Circuit Court considered a challenge to the Minnesota SDP statute regarding the construct of the constitutionality of civil commitment where the "volitional impairment" issue was framed as a "lack of adequate control." In this case, a respondent had been civilly committed as an SDP based on his criminal sexual history, a diagnosis of antisocial personality disorder, and a finding of being "highly likely" to sexually reoffend and that the respondent was characterized by "a lack of adequate control." In its original decision that Mr. Linehan met the criteria as a SDP, the trial court had concluded that since the respondent had been incarcerated for a long period, it needed to "look for more subtle signs than rape and killing when evaluating his condition and making its findings." The Minnesota Supreme Court concluded that Mr. Linehan lacked "adequate control" based on Mr. Linehan's diagnosis of antisocial personality disorder, his commission of an offense after one incarceration (during an escape) when he had the opportunity, his inability to delay masturbation in response to apparent stimulation by the presence of his young stepdaughter during family visits, and his continuing aggressive tendencies toward prison and hospital staff (Linehan IV, 594 N.W.2d 867, Minn. 1999).

Relying on the Hendricks decision, Linehan contested these findings by the Minnesota Appellate and Supreme Court, claiming that a lack of adequate control was insufficient to serve as the basis for civil commitment. The US Court of Appeals noted that Hendricks did not require proof of a complete lack of control, but rather required impairment of the ability to control one's behavior, specifically the Minnesota statutory requirement. In *Linehan v. Milczark* (2003), Eighth Circuit Court of Appeals concluded that the record showed that Mr. Linehan demonstrated a disorder that made it difficult, if not impossible, for him to control his dangerousness. That Court wrote:

> "We conclude that the Minnesota Supreme Court reasonably applied the clearly established Federal law when it considered the constitutionality of the stand for civil commitment under the SDP Act. The standard enunciated in Linehan IV requires a finding of lack of adequate control in relation to a properly diagnosed disorder or dysfunction, as well as findings of past sexual violence and resultant likelihood of future sexually dangerous behavior. This combination of required findings will adequately distinguish an offender subject to civil commitment, who has difficulty controlling his behavior because of a disorder or dysfunction, from the more typical offender with behavioral problems, who is best dealt with in the criminal system. Since the Court's application of Hendricks to the SDP Act meets constitutional requirements, it cannot be considered an unreasonable application of Supreme Court precedent." (p. 12)

In many ways, this decision was similar to that in *In re Thorell*. Similarly, also from the Ninth Circuit Court of Appeals in Brock v. Seling (2004), it was clarified that the Crane speaks to outer limits rather than specific elements. Crane does not require total or complete lack of control, but only some showing an abnormality that makes it difficult, if not impossible, for the dangerous persons to control their dangerous behavior and that finding a serious difficulty of controlling behavior by a trier of fact without specifying that it was emotional or volitional in nature was sufficient for commitment.

Two other US Court of Appeals decisions in the Seventh and Ninth Circuit [e.g., *Adams v. Bartow* (2003) and *Rose v. Mayberg* (2006), respectively] have subsequently cited with approval the Eighth Circuit decision in *Linehan v. Milczark*. Thus, in the former case, it was found that an individual with ASPD "…was eligible for civil commitment, not just because he suffered from APD but also because the specific nature of his disorder made him 'dangerous beyond [his] control'" (p. 963). In *Laxton v. Bartow* (2005), the US Court of Appeals Seventh Circuit concluded that it was reasonable for a trier of fact to conclude that the requisite serious difficulty in control was established when the nexus between a person's mental disorder and dangerousness (risk) was established. Regarding the meaning of "adequate control" relative to risk of future sexual offending, in *In re Ramey*, the Minnesota Court of Appeals wrote that the meaning of that phrase was simple and clear; an offender's history of harmful sexual conduct and the finding of an elevated probability of future dangerousness, coupled with an evidence of "mental illness" or dysfunction, demonstrated that an offender will find it difficult to control the behavior. That is, if a trier of fact concluded that a mental disorder was identified as characterizing an individual such that it was associated with the identified degree of likelihood or probability that an individual would engage in future acts of sexual offending (e.g., that the mental condition was predisposing to sexual offending), then that represented a conclusion that the person was also characterized by serious difficulty to control.

In short, the available state, appellate, and USSC decisions appear to make it clear that SDC is a relatively broad concept, as opposed to an absolute or narrow one. Various behaviors related to a mental abnormality or personality disorder, both distal and/or proximal, both related to general dysregulation or rule-breaking and specific to past history of sexual offending and opportunities to avoid sexual offending, are all potential factors to be considered as manifestations of mental conditions that increase the probability of future sexual offending by indicating limitations on self-control of either an emotional or volitional nature.

Assessing the Elements for Commitment as a SVP

The assessment of a sexual offender being considered for CCSVP must be a careful and comprehensive one. SVP evaluations have been conceptualized as a series of interrelated questions (Rogers & Jackson, 2005). Each question roughly corresponds to one of the four prongs of the laws: (1) one or more past acts of sexual offending, (2) the presence of a current mental disorder and/or abnormality (and/or personality disorder), (3) a finding of risk of future sexual offending, and (4) some relationship between the mental abnormality and the likelihood of sexual violence. As noted in previous sections, in the forensic mental health community, it is understood that legal constructs defined by legislatures and the judiciary are often different from psychological and psychiatric terms and constructs; such a disjuncture exists in many or most areas of psycholegal interest (e.g., insanity, best interests of the children in custody case, the issue of "psychological damages" related to a tort). Consequently, in considering individual, specific case, forensic mental health professionals rely on their relative expertise in psychological theory, methods, and science and attempt to apply that knowledge within the parameters of statute and case law in the SVP realm of a particular jurisdiction as the basis for their opinions.

An evaluation must attempt to provide an opinion as to the presence or absence of each of the statutory elements: (1) past history of sexual offenses, (2) a current mental abnormality and/or personality disorder, (3) a finding of risk of future harmful sexual behavior, and (4) some relationship between the mental abnormality and/or personality disorder, "serious difficulty in control," and the likelihood of future sexual offending, including sexual violence.

History of Sexual Offending

The determination of detected sexual offenses, particularly in states that require a charge or conviction for a sexually violent offense (as the predicate offense) is largely a function of reviewing an individual's official criminal history. [Available records also frequently contain previous admissions or self-reports of undetected sexual offenses that should be reviewed and considered as part of an evaluation.] As suggested by the US Supreme Court in *Hendricks*, the specific details of past sexual offenses provide the essential basis for identifying relevant aspects of potential mental abnormalities and personality disorders as well as that of determining the elements to be considered as more or less significant regarding the risk of future sexual offending.

The Determination of Mental Abnormality, Personality Disorder, and Serious Difficulty in Control

Principles of general forensic mental health assessments and evaluations have long emphasized the importance of multimethod, multi-measure data collection. Among others, Heilbrun (2003) has identified that primary principles of forensic assessment of significant or necessary connections between "clinical conditions" and the presence or absence(s) of functional abilities should include at least three components: (1) the review and application of nomothetic evidence (e.g., group data from testing and scientific study), (2) scientific knowledge and reasoning, and (3) idiographic evidence (e.g., case-specific data). An important possibility regarding forensic assessments is that such processes do not occur in a vacuum but rather in an adversarial context, often with high-stakes outcomes. Similar to Heisenberg's Uncertainty Principle finding that the act of observing something "changes it," being the subject of a forensic assessment is likely to change what is potentially reported and/or observed by the evaluator. This is likely to be particularly true for forensic assessments where the process is perceived by a litigant as a potentially adverse one. Consequently, standardized procedures of assessment should take on paramount importance in the evaluation of SVP candidates as they do in other areas of forensic assessment; psychological and/or physiological assessment should occur under customary circumstances. For such reasons, attorneys are never in attendance in forensic assessments of litigants in the set of personal injury or discrimination matters or child custody evaluations; they are also not in attendance at those forensic assessments that occur in the criminal realm such as matters of competency to stand trial and insanity questions. However, in many jurisdictions, attorneys are permitted by statute or judicial decisions to be in attendance at assessments involving psychological testing, interviews, and even the interview portion of psychophysiological testing. Notably, they are only present for what might be deemed as adverse assessment procedures and not for the assessments conducted by evaluators they retain. As a violation or at least a distortion of recommended administration protocols for such assessments, it raises questions about the integrity of the results (the validity and the content) of those assessment procedures.

Both the paraphilic and personality disorders are most likely to be diagnosed largely from past behavior, either described in formal or self-reported personal, diagnostic, and criminal histories. Various authors regarding the evaluation of sexual offenders have recommended a comprehensive evaluation of the presence of multiple paraphilias/paraphilic disorders and/or personality disorders (e.g., Hoberman,

1999; Jackson, 2008a). The emphasis of the diagnostic criteria for recent DSMs has been on behavioral "symptoms" or "traits, as well as signs or self-report," to provide the primary basis for diagnosis; consequently, archival records as vast repositories of behavioral history typically provide the primary source of information for making such diagnoses. Records regarding an individual's criminal history, prior evaluations, and/or treatment records are all particularly important sources of information. As numerous writers have articulated, the records as collateral sources of information almost always serve as the key basis for forensic evaluations (e.g., Hoberman, 1999; Hoberman & Jackson, 2015; Meloy, 1989). Typically, in the assessment and evaluation of candidates for SVP status, there may be a limited amount of information relative to "signs," the self-report of maladaptive features, particularly at the time of the assessment and as they relate to legally and socially "disapproved" categories of behavior such as deviant sexual fantasies and urges and even problematic personality characteristics. Regarding the latter, almost by definition, persons who have grown up manifesting maladaptive personality features may experience them as "ego-syntonic," or acceptable, consistent parts of who they are as persons and not as impairments or dysfunctional. For example, while regarded by others as deceitful, they may regard deceit as an acceptable aspect of what is necessary to live "effectively" in society. Given the noted problems with sexual offenders self-report, primarily defensiveness, denial, and minimization (e.g., Beckett, 1994; Clipson, 2003; Earls, 1992; Gudjonsson, 1990; Langevin, 1988; Marshall & Barbaree, 1989; McGrath, 1990), the centrality of records as collateral sources of information about an individual's behavior and persisting/recurring personality characteristics becomes even more significant. To date, no structured diagnostic interviews with demonstrated reliability or validity have been developed for the range of paraphilias or paraphilic disorders, let alone validated. More generally, for persons with a history of sexual offenses, while sexual fantasies and urges would be expected to be persistent for a significant number of sexual offenders by definition (e.g., those with identified or suspected paraphilic disorders that are typically viewed as chronic and enduring) [albeit fluctuating experiences over time (e.g., it is likely that no person experiences sexual fantasies and urges *all* the time)], the enactment of sexual offending will be function of a relatively "person-specific" sexual elements such as the availability of an "appropriate" victim (characterized by relatively preferred sexual stimuli) and perceived relatively permissive circumstances or context. The significance of context is reflected in the observation that effectively no sexual offenses against children or older (e.g., adolescent or adult) females occur while sexual offenders are institutionalized. It is highly unlikely that there will be overt behavioral evidence of sexual offending for offenders who have resided in institutions for extended periods of time since their last sexual offense. Limited study and anecdotal evidence exist of the frequency of potential proxy or analogue behaviors of indicia of "current" deviant sexual behavior. By nature, sexual fantasies are almost always private mental phenomena and not typically available for most means of observation. All of these factors increase the relative value of available records, particularly past sexual offending behaviors and offender self-report, as providing the significant basis for identifying the key indicia of deviant sexual interest, fantasies, and/or urges.

Given the high frequency of "crossover" of varied deviant sexual interests in detected sexual offenders, respondents should be assessed regarding their *range* of potential deviant sexual interests, including their experience of deviant sexual urges, fantasies, and behaviors. Systematic inquiry about the numerous possible paraphilic conditions is important as research suggests that in the use of unstructured interviews, evaluators will often cease their diagnostic inquiry after one particular condition may be identified (Rogers, 2001). In fact, the typical sexual offenders considered for commitment have been shown to have more than one paraphilia (e.g., Jackson & Richards, 2007). The Multiphasic Sex Inventories [Multiphasic Sex Inventory I and initial interview (Nichols & Molinder, 1984, 2000), both self-report measures, have been identified by several recent studies as providing potentially good indicators of the presence of deviant sexual interests (Craig & Beech, 2009; Stinson & Becker, 2008; Tong, 2007) in both clinical and research settings. For example, Stinson and Becker (2008) examined a combination of instruments (including the PPG, a VTM, and the MSI II), and they found that the combined measures, plus a self-report test of sexual fantasies involving children, identified 98 % of their child molester sample. Similarly, Tong (2007) found convergent validity for three sex deviance measures [PPG, VTM, and MSI II].

Interviews with candidates for CCSVP should be attempted; however, they may not always yield particularly useful or substantive information, particularly about key elements relevant to opinions regarding CCSVP. As Greenberg et al. (2004) pointed out, the self-report of litigants in general should be considered with significant caution given the potential interests at stake for those litigants. More specifically, as numerous writers have pointed out, the self-report of most sexual offenders should be considered suspect, for both personality and context factors, particularly if an evaluation takes place in a forensic context. This is particularly true if the individual is characterized by some elevated degree of psychopathy. Research suggests that, in general, sexual offenders are unreliable in their self-reports (Langevin, 1988; Rogers & Dickey, 1991; Sewell & Salekin, 1997). Most notably, sexual offenders are characterized by denial, minimization, or externalization of blame (Kennedy & Grubin, 1992; Langevin, 1988). Offenders who externalize responsibility tend to acknowledge the offense, but attribute the cause of their behavior to an external force out of their immediate

control (see also Sewell & Salekin, 1997). On its face, within a high-stakes adversarial context, it seems unlikely that an individual will self-report or otherwise admit current sexual fantasies and urges of a paraphilic nature. Evidence exists that many attorneys believe it appropriate and ethical to "coach" their clients in forensic evaluations (e.g., Wetter & Corrigan, 1995). It would not be surprising if respondents in SVP proceedings have been coached by counsel or their own peers relative to each of the elements of SVP statutes; in particular, the version of their sexual offense history provided while awaiting trial for CCSVP may come to vary significantly from all or most previous evaluations and reports.

Experienced forensic evaluators disagree regarding the importance of a clinical interview in the context of a civil commitment evaluation. Jackson and Hess (2007) found that a majority (71 %) of evaluators *recommended* the use of an interview, but only 17 % considered the interview *essential.* However, while interviews may not be a key component of an evaluation, an interview does provide the opportunity for a respondent to participate in the evaluation process and for the evaluator to have a direct set of interactions with the individual. The respondent is provided the opportunity to provide a contemporary version of their personal and offending history, to confirm or refute information in the file, to provide risk-protective information, and/or to supply the evaluator with his representation of information not available in the case file material. In addition, this exchange of information takes place under the observation of and with interactions with the evaluator, and various aspects of interpersonal functioning may be observed. As a result, further benefits of a direct evaluation include the opportunity (1) to conduct structured or semi-structured interviews, such as those associated with Psychopath Checklist-Revised (PCL-R; Hare, 2003a, 2003b, 2003c; Gacono, 2000) or those for personality disorders; (2) to attempt to gather information regarding the offender's current thoughts, feelings, fantasies, and behavior relevant to the diagnosis of paraphilias which are viewed as persisting and chronic; and (3) to assess participation in possible sexual offender treatment and their assessment of their own risk and release considerations.

In select cases, individuals being considered for CCSVP have provided self-report of additional, previously undetected victims as part of earlier evaluations or pre-polygraph interviews; in addition, they may previously have participated in penile plethysmography (PPG) as well. When possible, it is useful to obtain a sexual history polygraph and a penile plethysmograph (PPG) as part of the evaluation of an individual being considered as a possible SVP; in addition, a specific issue polygraph following the PPG assessment regarding possible attempts to suppress or manipulate sexual response is also particularly useful. The Association for the Treatment of Sexual Abusers (ATSA, 2014) most recent practice standards indicated that members "recognize that psychophysiological methods such as phallometry (PPG) may have "particular utility" both to obtain objective data about the client not established through other means and to explore the reliability of the client's self-report. However, per the ATSA, Guidelines, PPG, polygraph, and other psychopysiological assesment findings should not be used as the single source of data for any assessment but rather in conjunction with other sources of case-related assessment data. Further, psychophysiological results are likely to vary as a function of context and the anticipated "use" of obtained results. It is notable that Abel and Osborn (1992) reported that, in a scientific study where paraphilic subjects recruited from various community sources were provided a Federal Certificate (or guarantee) of confidentiality, 62 % of "paraphilics" confronted with their physiologic measurements admitted to *additional* paraphilic interests or behaviors that they had previously denied or not revealed. However, As with other psychophysiological measures, there have been issues raised regarding reliability and validity of the polygraph; in particular, the potential exists for some individuals to use "countermeasures" to regulate and dissimulate their physiological responses. Regarding PPGs, Hall, Proctor, and Nelson (1988) found that fully 80 % of inpatient adult sexual offenders asked to inhibit all sexual arousal were "successful" in doing just that; Looman et al. (1998) reported similar results without instructing offenders. Marshall and Fernandez (2000a, b) concluded, "…numerous studies have shown that rapists and child molesters are able to both inhibit arousal to preferred stimuli and degenerate arousal to nonpreferred stimuli." (p. 293). At contrast, as Jackson and Richards (2007) have noted (among many others), particularly in an adversarial context, the presence of positive indication of deviant sexual interest from the results of psychophysiological assessment likely provides useful information, whereas negative findings from such procedures do not typically provide useful information given the well-recognized ability of both offenders and non-offenders to dissimulate on the PPG. As is well established more generally, the PPG is a particularly sensitive measure (e.g., positive results indicative of deviant sexual arousal identify persons with paraphilic interests); however, such tests lack specificity—results that do not show a positive response to standardized deviant sexual stimuli do not rule out the presence of actual deviant sexual arousal. In addition, in the attempt to standardize PPGs, it may be the case that key features of sexual behavior, target/potential victim characteristics, and/or context related to a particular individual's sexual fantasies or urges are not well-represented in the conventional visual or audio stimuli. Consequently, individual sexual offenders may show no or little arousal to standardized stimuli utilized in PPGs. While PPGs may provide useful information in a more clinical context, there is no substantive body of data that would indicate that sexual offenders demonstrate expected levels or degree of sexual arousal in the context of all forensic contexts. In addition, on its face, within a high-stakes adversarial context,

it seems reasonable or likely that an individual will engage in behaviors to limit demonstrated arousal to current sexual fantasies and urges of a paraphilic nature.

Personality disorders, including antisocial personality disorder, narcissistic personality disorder, and other potentially relevant personality disorders (e.g., borderline, avoidant, schizoid, and/or dependent personality disorders) are best evaluated through Structured Psychological Assessment (SPA; Hoberman & Riedel, 2015). Otto (2002) demonstrated that traditional psychological testing was widely utilized by forensic evaluators for addressing a range of forensic issues; Archer, Stredny, and Wheeler (2013) reported that such tests have become widely accepted for use in forensic evaluation. Personality tests such as the MMPI-2 and the MCMI-III, and in adversarial settings, provide the most established methods across various forensic contexts for collecting information about the presence or absence of maladaptive personality traits and/or personality disorders and other mental disorders (e.g., Jackson, 2008b; Weiner, 2003). In particular, the MMPI-2 is the most commonly utilized psychological test in the forensic evaluation of sexual offenders (e.g., Lally, 2003). As Heilbrun (2003) and others have emphasized the use of self-report SPA as a primary means of obtaining information about a litigant's response style in the forensic context, this would seem to be of particular value in the assessment of SVP candidates. In addition, computerized interpretive systems for such tests provide actuarial-based interpretations of the sexual offender's own *self-report* in response to test items and can provide valuable information about the presence and degree of personality traits relative to diagnoses of personality disorders (as well as those related to varied aspects of emotional and volitional impairment). Further, in many cases, previous administrations of such psychological tests can be found in an individual's file. Consequently, a current administration of such personality and related tests provides a mechanism for comparing possible areas of relative stability or changes in reporting in various personality domains. Similar to forensic sexual offender evaluations more generally, given the potential utility of psychophysiological measures directed at the areas that most sexual offenders are most likely to dissimulate about (e.g., deviant sexual experiences and behavior), measures of personality (e.g., self-perceived or represented affect, attitudes, impulsivity, general and interpersonal behavior) may be particularly valuable, and attempts to include such practices as a standard part of forensic (including SVP) evaluations are highly recommended by a number of authorities.

While this should be obvious and well known to professionals working in legal and/or forensic contexts, including attorneys representing alleged or adjudicated sexual offenders, testing is intended to be administered under standardized conditions. Per the American Psychological Association (APA, 2007): "Psychologists enhance the validity of evaluation results by adhering to standardized procedures (when the techniques they use outline standardized administration procedures) and by developing and sustaining rapport with the examinee. In most testing manuals, standardized procedures and recommended practices for developing and sustaining rapport specify that only the psychologist and the examinee are present in the assessment setting." (p. 1). The APA notes studies showing various compromised findings when testing is administered with third-parties present; such findings also have been demonstrated with interviews. As the APA (2007) has noted such effects have been identified with litigant-provided interview data in forensic evaluations. Having additional persons present or observing the testing or other standardized assessment procedures may be quite likely to have particularly significant effects in forensic contexts, particularly when the outcomes are viewed as "high stakes" by the litigant.

However, the utility of the results of SPA such as standardized self-report personality, structured and semi-structured interviews, and as well as psychophysiological measures, when obtained in a uniquely high-stakes, adversarial context cannot be relied on without careful scrutiny of the results, particularly in comparison to previous similar testing and the respondent's and other's prior self-report contained in available records. As we have noted elsewhere (e.g. Hoberman & Jackson, 2015), in forensic or "clinical"/forensic settings, one must be aware that there is evidence that a significant number of attorneys may attempt to "coach" or advise their clients in responding to standardized psychological assessment. For example, in one study, almost half of a sample of practicing attorneys and somewhat smaller percentage of law students surveyed believed that when clients were to participate in a direct evaluation involving psychological testing, the client should "always" or "usually" be given information about the nature of validity scales used in such testing, as well as coaching as to what types of answers to provide or to avoid (e.g., Wetter & Corrigan, 1995). As Heilbrun (2001) noted the more information a subject possesses about validity scales of psychological tests, the more effectively they can dissimulate substantive "findings" on those tests; in situations, where an evaluatee produces test results markedly discrepant from collateral sources, this possibility should be considered. Consequently, there is always reason to be concerned that some individuals who are provided with or obtain information about the nature of tests and rating scales may be able to affect their presentation style on a test or to manipulate detection of maladaptive symptoms and traits. Practically speaking, it is important to ask an examinee in what ways he has prepared for the evaluation. Specifically, he should be asked generally what he has read or been told in forensic or clinical/forensic settings, one must be aware that there is evidence that a significant number of attorneys may attempt to "coach" or advise their clients in responding to standardized psychological assessment. For example, in one study, almost half of

a sample of practicing attorneys and somewhat smaller percentage of law students surveyed believed that when clients were to participate in a direct evaluation involving psychological testing, the client should "always" or "usually" be given information about the nature of validity scales used in such testing, as well as coaching as to what types of answers to provide or to avoid (e.g., Wetter & Corrigan, 1995). Other authorities have written about the implications and consequences (and sometimes negative to the evaluatee) as a result of advisers, including attorneys, relative to their client's presentations (e.g. Cato et al., 2002; Gutheil, 2003; Lees-Haley, 1997; and Youngjohn, 1995).

In addition, various information about psychological tests and clinical ratings scales is now available on various publically accessible web sites and, anecdotally, in correctional and other institutional facilities across jurisdictions from both peers and other advisers.

Practically speaking, it may be important to ask an examinee in what ways he has prepared for the evaluation. Specifically, he might be asked generally what he has read or been told about the proposed nature, content, or approach for the evaluation, whether he has read or been told about any material regarding the specific tests and other assessment measures chosen for administration (e.g., books or other materials about specific tests, rating scales, interviews and/or psychophysiological procedures), whether he has received advice from *any person* as to recommended responding for the specific tests, ratings or other assessment procedures chosen for administration, or if he has sought or received information from the Internet or other sources about evaluations or specific assessment procedures and what he knows about how responses to the particular tests or ratings may be utilized. This may become a particularly important concern if an offender's most recent test results are markedly discrepant from the results of previous testing or if the offender seems unusually "prepared" for the direct evaluation with circumscribed, seemingly "pat" descriptions of his sexual offense history. This may particularly significant if current accounts of sexual offending history are markedly discrepant from multiple, previous and convergent ones and/or the individual now blames external systems or factors for prior sexual offense admissions and/or the evaluatee now represents that he misunderstood terms used in other evaluations or settings (e.g., when he previously admitted to sexual arousal to children he now claims that they meant persons of age less than 18 or claims that they didn't understand the meaning of "forced" relative to a sexual offense). The evaluator may also ask the offender whether he has read or received verbal or other information or advice regarding the subject of risk assessment and/or ask him to affirm that he has not done so (as part of informed consent, for example).

As Heilbrun (2001) noted the more information a subject possesses about validity scales of psychological tests, the more effectively they can dissimulate substantive "findings" on those tests; in situations where an evaluatee produces test results markedly discrepant from collateral sources, this possibility should be considered. Consequently, there is always reason to be concerned that some individuals who are provided with or obtain information about the nature of tests and rating scales may be able to affect their presentation style on a test or to manipulate detection of maladaptive symptoms, traits and demonstrated sexual arousal or veracity on psychophysiological assessment measures.

In addition, the face validity of a self-report test becomes paramount. As a result, those self-report tests that are particularly transparent (e.g., it is easy to detect items more or less indicative of antisocial attitudes and behaviors) may lead to "surprising" results; persons with long, definitive, and/or extreme antisocial histories may produce particularly low scores on such measures, particularly in an adversarial context. Anecdotally, for example, it is striking how many individuals considered for or found to be SVP show unusually low scores on the "Antisocial" (ANT) scale of the Personality Assessment Inventory (PAI; Morey, 2007). Often, a careful inspection of the specific item responses indicates that an offender has provided a more or less minimized perspective of elements of antisociality relative to those indicated by his personal and criminal history.

As noted previously, the use of structured and semi-structured interviews for personality disorders is also recommended by numerous authorities, perhaps especially in forensic contexts. Such procedures have an established reliability and validity (e.g., Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995). High levels of psychopathy are also frequently identified among civilly committed sexual offenders (Jackson & Richards, 2007; Vess, Murphy, & Arkowitz, 2004). Experts who conduct civil commitment evaluations routinely assess psychopathy; 76 % of evaluators indicated the assessment of psychopathy is essential in assessment for CCSVP (Jackson & Hess, 2007). As noted, several structured or semi-structured interviews have been developed to collect information in a structured or semi-structured manner that can be utilized in rating the individual on the Psychopathy Checklist-Revised (PCL-R) (Gacono, 2000; Hare, 2003a, 2003b, 2003c).

Currently, available scientific evidence demonstrates adequate reliability for the determination of mental abnormalities and personality disorders. Packard and Levinson (2006) reported on the inter-rater reliability of various diagnoses offered by evaluators in Florida SVP commitments. They noted that in an earlier paper by Levenson (2004), kappa values measuring the degree of agreement between raters were, in fact, statistically significant. In reanalyzing the original data of Levenson, Packard and Levenson further concluded that various measures of inter-rater agreement were statistically significant, including proportion of agreement, odds and risk ratios, and estimated conditional probabilities. Packard and Levenson summarized their results, stating:

"Agreement on the existence of the majority of the diagnosed disorders was rather high…indicating that, overall, civil commitment evaluations were a reliable process" (p. 1). Wilson, Pake, and Duffee (2011) reached similar conclusions in applying proposed diagnostic criteria for DSM-5 to civilly committed individuals.

Assessing Emotional and Volitional Impairment and Serious Difficulty in Control

Relative to the issue of volitional impairment, again there are various sources of information to inform an opinion regarding this issue. In effect, per the US Supreme Court in *Kansas v. Crane*, persons who commit sexual offenses as the result of a paraphilia would be likely to be described as demonstrating serious difficulty in controlling behavior; the Court identified pedophilia as "…a mental abnormality that critically involves what a lay person might describe as a lack of control" (p. 7). Per the various extant decisions by the Federal Circuit Courts, the identification of a mental abnormality or personality disorder or some combination of those conditions may, in and of themselves, be sufficient to arrive at an opinion that SDC is present (e.g. Pedophilia per Kansas v. Hendricks). While researchers (e.g., Jackson & Richards, 2008; Mercado et al., 2005) have noted the complexity inherent in assessing volitionality, particularly in its dimensional form, current evidence suggests that evaluators evaluate volitionality in line with the guidelines provided by the courts (e.g., *In re Thorell*, 2003). For example, Jackson and Hess (2007) reported that evaluators commonly considered the combined aspects of mental illness and past behavior when evaluating volitional impairment. The most commonly endorsed method or basis for evaluating the degree of volitional impairment was the combination of a personality disorder or paraphilic disorder and the available history of previous sexual offending.

Further, from *Linehan v. Milczark* and related appellate court decisions, the issue of volitional impairment includes both issues in self-control relative to sexual behavior and to behavior more generally; thus, an evaluator is looking broadly at the degree to which mental abnormalities and/or personality disorders lead to "serious difficulty in control." The presence of the various factors identified earlier as related to control and volitional impairment can be investigated via careful record review and per varied judicial decisions provide the best or most significant basis for determining evidence of SDC or VI. The archival records and/or collateral reports of the respondent's past (and sometimes current behavior) typically provide important information about the nature and degree to which respondent's have displayed "volitional impairment" in the past. In addition, as noted, the results of interpretations of current and past psychological tests such as the MMPI-2 and the MCMI-III have long been relied upon by evaluators and courts in Minnesota as a key means of identifying personality characteristics related to both "an utter lack of power to control" and "inability to adequately control" sexual behavior. Such tests as actuarial interpretations of respondents' self-report offer potentially powerful sources of information about personality characteristics relating to the likely nature and degree of a respondent's SDC or VI, including potential motivators or factors of disinhibition (Hoberman, 2015a, 2015b).

Risk Assessment

The final prong of SVP statutes concerns developing an opinion that the specific sexual offender under consideration is characterized in such a manner that his likelihood or probability of committing an additional act of sexually motivated criminal behavior, whether it is detected or not, exceeds some threshold for a particular jurisdiction. In many states, the risk assessment outcome is not simply another sexual offense or a "harmful" sexual offense but more particularly "predatory acts of sexual violence," which involve a subset of physical contact sexual offenses. Given the nature of SVP statutes as currently written and interpreted by various courts, the likelihood of reoffending or the degree of risk posed by a sexual offender does not necessarily involve simply whether an identified sexual offender is detected and/or legally processed for a new sexual offense (e.g., not simply a future arrest or conviction). Thus, the last element to be considered in the evaluation of whether a specific sexual offender meets the criteria for SVP is the likelihood of sexually *reoffending* per se (almost all of which is most likely to be undetected, as will be discussed). To be eligible for CCSVP, a particular sexual offender must have some set of characteristics that individually or collectively indicate that he meets or exceeds a statutorily defined level of risk (e.g., "likely," "more likely than not," "more probable than not," or "highly likely" to commit a future sexual offense). Thus, an evaluator strives to provide an informed, comprehensive opinion regarding the probability of that a particular recidivistic sexual offender will commit at least one additional sexually motivated offense. In turn, a trier of fact will then consider that opinion, in the context of all other information provided at trial, to reach an ultimate opinion as to whether the risk for future sexual offending meets or exceeds the particular statutory definition.

Jackson (2008) wrote: "Risk assessment is the *sine qua non* of civil commitment evaluations." Risk assessment is the process of identifying the *probability* or *likelihood* of future dangerousness or harm, such as a future sexual offense for a particular individual. It is practically and scientifically impossible to *predict* any future event with 100 % certainty, including the likelihood that a specific person will commit a

particular act, including a future sexual offense. If such methodology existed, there would be no or diminished need for evaluations by trained forensic mental health practitioners; triers of fact and/or law would possess a valid finding about this element of the SCCSVP proceedings. Consequently, a risk assessment will always involve some degree of uncertainty about identified probabilities of future sexual reoffending generally and, more specifically, for an individual. In reality, risk assessments are relatively common experiences of mental health practitioners generally and forensic mental health professionals more particularly. Conroy and Murrie (2007) pointed out that risk assessment had become increasingly common across a verity of criminal justice [e.g., defendants pursuing not guilty by reason of insanity findings (NGRI)] and mental health settings (e.g., various types of mental illness commitments). A significant subset of such risk assessments is conducted for persons considered as potentially NGRI or as mentally ill and dangerous (MID); outcomes of such proceedings typically lead to indeterminate and/or long-term detention, similar to CCSVP. However, it is quite interesting that procedures and practices utilized in risk assessments related to CCSVP have been subject to much more contentious scrutiny, while a relatively minimal scientific and professional literature has developed around the methods employed for risk assessment of NGRI and MID individuals.

The task of risk assessment within the CCSVP is to strike a scientific and ethical balance in utilizing the best available set of practices for determining the likelihood of recidivism for a sexual offender while optimizing public safety. Since the focus of risk assessment for CCSVP is the degree of risk posed by a specific sexual offender with a particular history and set of characteristics, that risk assessment necessarily involves a balance between nomothetic and idiographic approaches. In the former approach, methods from research utilizing aggregated data from group samples provide the basis to develop a particular perspective regarding risk of future sexual offending relative to the individual of concern; in the latter, particular characteristics of that person (or case-specific information) are considered relative to their risk, particularly when such characteristics are related to information not included or covered by available nomothetic methods. Consequently, risk assessment regarding sexual offenders typically starts with various types of group data. Risk for a particular sexual offender is initially considered based on the degree to which the individual under consideration possesses one or more characteristics (or typically some varied collection of characteristics) similar to those sexual offenders studied in available data sets and then applying those set of characteristics to obtain sexual offense recidivism risk probabilities for groups of sexual offenders with some specified number or density/degree of risk factors. In addition, specific information about the specific sexual offender under consideration (typically information not included or adequately addressed by available "group data" or unique to the individual) may be considered. Since various studies have demonstrated the weaknesses of unstructured clinical judgment regarding the relative or absolute risk for determinations of sexual offender recidivism (e.g., Hanson & Morton-Bourgon, 2004) from a scientific perspective, empirically demonstrated approaches to risk assessment, particularly actuarial measures, have taken a prominent position in risk assessments. However, in virtually all known jurisdictions, appellate courts have specifically adopted a balanced perspective, allowing testimony about the results of standardized or nomothetic approaches (e.g., so-called actuarial instruments and structured professional judgment) but only or largely in the context of allowing or requiring evaluators to present and consider the totality of information bearing on risk that an evaluator feels is "case relevant" regarding a specific sexual offender's risk for sexual offense recidivism. For example, a Minnesota Supreme Court Case (*In re Blodgett,* 1994) wrote:

> "In applying the *Pearson* test, the court considers the nature and frequency of the sexual assaults, the degree of violence involved, the relationship (or lack thereof) between the offender and the victims, the offender's attitude and mood, the offender's medical and family history, the results of psychological and psychiatric testing and evaluation, and such other factors that bear on the predatory sex impulse and the lack of power to control it."

Similarly, other Minnesota Supreme Court decision (typically referred to as Linehan I & III) wrote:

> "[T]he trial court, in predicting serious danger to the public, should consider the following factors if such evidence is presented: (a) the person's relevant demographic characteristics (*e.g.,* age, education, etc.); (b) the person's history of violent behavior (paying particular attention to recency, severity, and frequency of violent acts); (c) the base rate statistics for violent behavior among individuals of this person's background (*e.g.,* data showing the rate at which rapists recidivate, the correlation between age and criminal sexual activity, etc.); (d) the sources of stress in the environment (cognitive and affective factors which indicate that the person may be predisposed to cope with stress in a violent or nonviolent manner); (e) the similarity of the present or future context to those contexts in which the person has used violence in the past; and (f) the person's record with respect to sex therapy programs."

As noted, the US Supreme Court identified that a respondent's behavioral criminal history provided the basis for a determination of his risk of future sexual offending. To the extent that risk assessment has been addressed by appellate courts, it appears that they have emphasized that individual courts should not consider any one particular approach (e.g., so-called actuarial risk assessment) as dicta or controlling but rather that courts should consider the totality of the evidence and identify relevant factors of significance in a particular case. Thus, currently, while so-called actuarial risk assessment instruments most often are utilized as a central component of evaluator's perspective's on the like-

lihood of future sexual offending most generally, the legal system takes a broader approach in the application of that information to a particular sexual offender and most commonly privileges other specific information about an offender's history that bears on their probability of sexual offense recidivism.

Of note, forensic mental health professionals have also recommended a broad and inclusive approach to risk assessment of violent behavior, including sexual offending. Conroy and Murrie (2007) recommend a comprehensive model for risk assessment regarding risk for violence, including sexual offending. They write:

> "A broad model for risk assessment helps guide evaluators through the process of collecting and considering relevant data, but also contextualizing this data to form and communicate opinions. It is essential to rely on scientific research in almost every risk assessment and to use formal tests or instruments in some. However, neither consideration of research nor testing is sufficient to constitute a thorough risk assessment *process*."

Further, violence risk assessment in general and sexual offense recidivism risk assessment are areas of increasing study and rapid revision of existing methods and the development of new ones. Regarding sexual offense recidivism risk assessment, Harris and Hanson (2010) described an "explosion" in the development, refinement, and use of risk assessment tools regarding sexual reoffending. They wrote:

> "In our view, the development of risk assessment has been somewhat like rebuilding a ship at sea, continually replacing one plank at a time when we sprang a leak. We view this rebuilding as a strength, not a problem. The willingness to update and change releases us from the Darwinian extinction that has claimed so many other psychological instruments and assessment processes in the past." (p. 12)

Clearly, quantifying the likelihood of future sexual offending for persons being considered for possible civil commitment is problematic for several reasons as it is more generally for any sexual offender. First, currently available follow-up studies range from estimates of 5 years to 10 years, with only a few limited studies providing estimates for longer periods, not "lifetimes" (the period of time required for consideration for the present purpose). Second, current research measures future re-offenses predominantly via rearrest or reconviction; it is the consensus, if not the unanimous perspective, of scientific research regarding this area, that rates of arrests and convictions for sexual offenses "significantly" underestimate the true rate (detected + undetected) of sexual offenses. Third, similar to criminal offenders, a significant percentage of sexual offenders are rearrested, jailed, and/or re-incarcerated for nonsexual offenses or conditional release violations with a brief period of time after release from prison and are thus lack the opportunity to reoffend. In addition, particularly over the past 15–20 years, sexual offenders were subject to longer and sometimes indeterminate sentences in the criminal justice system and consequently were not released to the community, and they too lacked the opportunity to reoffend. Finally, most follow-up studies for sexual offense recidivism have relied on "point base rates" and not survival analysis. Survival analysis provides perhaps the best or optimal means to account for only "opportunity time," time when an offender is actually in the community and not jailed, imprisoned or otherwise detained. Relative to this point, Langan, Schmitt, and Durose (2003) found that 43 % of sexual offenders were rearrested for some crime (75 % of which were felonies) within 3 years of their release from prison. Even more recently, Durose, Cooper, and Snyder (2014) showed that 71 % of violent offenders (including sexual offenders) were rearrested for some criminal offense within 5 years of release from prison. Consequently, some sizeable portion of those sexual offenders who would likely be regarded as at higher risk for sexual offense recidivism have not been available for follow-up study for potentially significant amounts of time and thus did not have the opportunity to commit an additional sexual offense.

Available scientific attempts to determine the true rate of actual offenses committed by sexual offenders are obviously problematic for a variety of offender, victim, and agency practices. From an offender perspective, to be forthright and honest about the actual number of such offenses places an offender at risk of additional and more extensive incarceration and other negative consequences. An extensive body of research now exists which indicates that the self-report of sexual offenders as to their sexual offending behavior is unreliable and invalid (e.g., Abel et al., 1987, Abel & Rouleau, 1990; Ahlmeyer, Heil, McKee, & English, 2000; English, 2003; Kaplan, Abel, Rathner, & Mittleman, 1990; Marshall & Barbaree, 1989; Weinrott & Saylor, 1991). From a victim perspective, the data indicates that not more than 1/3 of adolescent and adult victims of sexual assaults and fewer than 20 % of child victims of sexual offending even report their victimization to authorities (e.g., Bonta & Hanson, 1994; Craig, Browne, & Beech, 2008; English, 2003). Thus, most sexual offenses are not even reported to some authority or agency. Further, as English pointed out, the detection by authorities or agencies of alleged acts of sexual offending against both children and adults is rare and even that reduced group of alleged sexual offenses reported to authorities rarely result in arrest. That is, even in those limited instances when sexual offenses are reported in some manner, such events do not necessarily enter into systems where they are likely to "register" or "be counted" (e.g., Falshaw, Bates, Patel, Corbett, & Friendship, 2003; Marques, Day, Nelson, & West, 1994; Marshall & Barbaree, 1989). In short, the available cumulative studies indicate that a substantial number of "reported" sex offenses do not "enter" the formal legal system and/or result in new criminal charges or arrest, let alone a conviction for a sexual offense. Even when reported sexual offenses do "enter" the formal legal system and/or result in

new criminal charges, the "sexual motivation" element of an offense incident or episode may be "lost." Research has demonstrated that a significant number or percentage of what are recorded as violent arrests or convictions are, in fact, very or highly likely to be sexually motivated (e.g., Rice et al., 2007) and their recommendation to utilize "sexually informed" rap sheet data in considering sexual offense recidivism rates. In short, most sexual offenses (particularly those against youth) go unreported and undetected; official records of rearrests and reconvictions represent significant underreporting of the frequency of reported sexual offending (e.g., they may represent only a 10–33 % of all such offenses). Consequently, it is almost certain that all formal measures of sexual offense recidivism substantially underestimate the "true" rate of sexual offenses actually enacted either first-time or recidivistic sexual offenders.

A number of approaches have been developed to provide estimates of the probability of sexual offense recidivism for groups of sexual offenders in general. Best practices for risk assessment for sexual offenders have been identified by ATSA (2005, 2014) and by Craig and Beech (2010). These approaches include base rates, individual risk factors, actuarial risk assessment instruments (ARAI), and structured clinical or professional judgment (SPJ). The first three areas can be considered nomothetic approaches, relying on the availability of various group data. In addition, there may be person- or subgroup-specific factors that are related to sexual offending which may or may not be found in the available research but may constitute a risk factor for either the individual or subgroup of sexual offenders; these case-specific or idiographic considerations are also considered key to risk assessment of violent behavior generally and future sexual offending. SPJ can provide a more idiographic dimension to risk assessment, as can consideration of so-called dynamic or psychologically meaningful risk factors (DRF) or criminogenic needs. Each or all of these approaches offer particular utility relative to providing estimates of the likelihood of sexual offense recidivism for a particular individual by considering and integrating both group and person-specific groups of detected sexual offenders.

Several significant caveats must be identified at this point. First, effectively no follow-up or outcome data exists on persons who were deemed eligible for CCSVP released into the community. Obviously, since no outcome data is available, no sexual offense recidivism is available for extended or indefinite follow-up periods. Consequently, evaluators are left to rely on the approaches described just above as applied to general sexual offenders', and not a more narrow group defined by the presence of a mental abnormality or personality disorder, serious difficulty in control of their sexual offending behavior and for extended periods of time. By necessity then, an evaluator's development of an opinion regarding the probability of a specific individual being considered for CCSVP must rely on risk assessment approaches developed for and applied to more typical sexual offenders and a consideration and integration of various types of group data along with relevant specific aspects of the particular individual under consideration. Just as in other areas of forensic mental health, an evaluator's opinion about the psycholegal issues in a particular case must be largely based on the specific person's personal history, structured psychological and/or psychophysiological assessments of an individual (within the constraints of a high-stakes forensic context), and case-specific issues and factors, all considered within the measures of the best available related nomothetic data (e.g., available normative groups) from the general scientific literature regarding sexual offenders.

The base rate refers to the percentage of individuals in a group with a certain characteristic. Regarding sexual offender recidivism, base rate refers to the percentage of particular types of or subsets of sexual offenders who reoffend over some particular period of time; the base rate may vary as a function of the nature or composition of study sample (which sexual offenders are "available" to be studied), the length of the follow-up, the conditions applied to offenders during the follow-up period (e.g., supervision, re-incarceration), the measure of recidivism, and other factors. Base rates can be used to provide a benchmark for the likelihood of sexual offender recidivism for general or select groups of sexual offenders. Harris and Rice (2007), in reviewing the accumulated studies of sexual offender recidivism for general, non-selected sexual offenders, found that studies converged in identifying approximately 30 % of those "general" sexual offenders as being detected for subsequent sexual offenses at follow-up. In a later publication, they noted that the very high correlation (.81) between length of follow-up and recidivism, indicating that rates of sexual offense recidivism should/will rise as offenders, is followed for longer periods of time. Harris and Hanson (2004) in a meta-analysis of predominantly low-to-medium risk sexual offenders determined that 24 % of the samples were detected for another sexual offense over a 15-year follow-up period but noted that the rates were "double" for those sexual offenders with a previous sexual offense conviction. Doren (1998) pointed out that sexual offenders identified as candidates for potential CCSVP are a unique subset of more general detected sexual offenders, noting that most state systems only consider 1–10 % of the larger group of incarcerated sexual offenders for CCVP. This seems borne out by research such as that of Milloy (2007). She followed 135 sexual offenders who had been screened and recommended for civil commitment in the state of Washington but where no petition was filed, and they were released to the community and followed for a uniform period of just 6 years. Of the 135 offenders, 23 % committed some type of new felony sexual offense that resulted in a criminal *conviction* (84 % of this group were arrested for a felony sexual offense involving physical contact). In total, approximately 29 % of these sexual offenders committed an

additional sexual offense within just 6 years after being released from detention. Milloy concluded: "…the distinctiveness of the select population of sexual offenders in the current study is clearly illustrated by a comparison of this group's recidivism rates to those of an overall population of released Washington State sex offenders" (p. 8).

In addition, research has identified largely static or historical risk factors that can be used to identify those sexual offenders at a higher risk to reoffend. Sufficient studies of sexual offender recidivism have accumulated that researchers have been able to conduct "meta-analyses" or studies of the findings across multiple studies (e.g., studies of existing individual studies). Such studies identify the broad dimensions of risk factors while potentially missing select idiographic or less frequently studied variables. Hanson and Bussiere (1996, 1998) conducted a meta-analysis of general sexual offense recidivism studies to identify factors associated with such recidivism as defined by subsequent arrest or conviction. In summarizing their findings, Hanson and Bussiere identified that sexual offense recidivism was best predicted by *sexual deviancy variables* (deviant sexual interests and victim choices such as boys or strangers, prior sexual offenses), *general criminological factors* (younger age, total prior offenses), and *failure to complete treatment* (treatment failure). *Personality disorders* were also related to sexual recidivism, particularly *antisocial personality disorder*. More recently, Hanson and Morton-Bourgon (2004, 2005) selectively updated the earlier meta-analysis. This most recent meta-analysis of risk factors for general sexual offense recidivism found that the following domains were associated with a greater risk of sexual reoffending: deviant sexual arousal/interests, antisocial orientation, personality disorder(s), indices of rule violations (e.g., parole/probation violations, conduct violations), and issues (e.g., absence of or conflicts) in intimate relationships. Most recently, Mann et al. (2010) provided a meta-analytic summary of the empirical evidence as to whether specific risk factors were empirically supported, promising, "unsupported but with interesting exceptions," or "worth exploring." In addition, Mann et al. wrote: "We do not believe that the factors mentioned so far are an exhaustive list of possibly relevant risk factors. Further research is likely to identify new risk factors and refine the definitions of the factors already shown to empirically predict recidivism." Per the study by Jackson and Hess (2007), over 90 % of the evaluators reported that a consideration of static risk factors was essential to their evaluations.

Relative to the consideration of risk factors in some aggregated or nomothetic form, there has been an ongoing controversy, regarding how to combine information about risk factors for sexual offender recidivism. Generally, this position is one described as professional judgment versus an actuarial approach. Different investigators working with different sets of information available to those investigators about particular sexual offender samples have combined individual risk factors into risk assessment instruments have resulted in various risk assessment instruments. Some of these instruments are identified as actuarial risk assessment instruments (ARAI), while others are identified as structured professional judgment (SPJ). Actuarial methods are most commonly utilized by insurance companies involved in the computation of the probability of the occurrence of such events as illness, accidents, and death, using information that has been demonstrated to be related to the outcome of concern. The likelihood of the event of interest as determined by statistical combinations of identified risk factors is utilized to determine the costs associated with obtaining insurance relative to a particular individual's risk. Regarding ARAI, the recent meta-analyses of the sexual offender recidivism literature and other studies have identified select largely "static" or historical factors that are empirically related to recidivism. From this body of research and other studies, ARAI can be considered as attempts to develop adjusted base rates for groups of sexual offenders with particular numbers and types of easily measured risk factors. These so-called actuarial methods are ones that rely on objectively identified factors associated with an outcome of interest; an actuarial scale specifies *which empirically identified factors* are selected for examination and the relative *weight* that factor has as part of the particular instrument's assessment of some outcome.

Relative to sexual offending, actuarial scales represent statistical means of selecting and combining easily obtained information and examining the degree to which those particular variables are associated with some future outcome (e.g., predictive accuracy). Starting in the mid-1990s, several actuarial scales were developed that have been repeatedly demonstrated to show moderate predictive accuracy of sexual offender recidivism for adult male sexual offenders. More specifically, these actuarial instruments provide estimates of the degree of risk (probability) of a future sexual offense for sexual offenders with particular numbers of and/or degree of risk factors (Doren, 2002; Hanson, 1998; Quinsey, Harris, Rice, & Cormier, 1998; 2006; Harris, Rice, Quinsey, & Cormier, 2015). Different instruments rely on different "outcomes" to measure sexual offender recidivism, ranging from "rap sheet" convictions or arrests that have been demonstrated to "miss" or "mislabel" a significant number of sexually motivated violent criminal behavior; further, other instruments rely on broader outcomes [e.g., "informed" rap sheet-based sexual offenses or violent offenses which show a stronger association to specific sexual offending recidivism (e.g., Rice & Harris, 2015) to attempt to rectify the substantial underreporting of sexual offending. In short, actuarial measures have been developed which utilize statistical combinations of a limited number of risk factors and their association with the likelihood of rearrests or reconvictions for different behaviors providing varied but empirically demonstrated measures of future sexual offenses.

ARAIs include the Static-99 (Hanson & Thornton, 2000), the Static-99R (Hanson, Thornton, Helmus, & Babchishin, 2015; Helmus, Hanson, & Thornton, 2009; Helmus, Hanson, Thornton, Babchishin, & Harris, 2012a; Helmus, Thornton, Hanson, & Babchishin, 2012b; Helmus, Thornton, Hanson, & Babchishin, 2015), the Static-2002R (Hanson & Thornton, 2003; Helmus, Hanson, et al., 2012; Hanson et al., 2015), the Minnesota Sex Offender Screening Tool-Revised (MnSOST-R: Epperson, Kaul, & Hesselton, 1998; Epperson, Kaul, Huot, Goldman, & Alexander, 2003), and the Sex Offender Risk Appraisal Guide (SORAG; Harris, Rice, Quinsey & Lang, 2015; Quinsey et al., 1998, 2006; Rice & Harris, 1997). At present, actuarial assessment of risk for sexual offenders is regarded as a core assessment methodology. There are now sufficient empirical studies in the scientific literature that provide independent cross validation of key aspects of these *actuarial* instruments. Revised versions of the instruments are undergoing validation continuously. The modifications to the instruments have generally been relatively minor, and research to date suggests that the validity of the revised instruments will mirror their original versions. According to their meta-analysis (Hanson & Morton-Bourgon, 2004; 2007; 2009), in predicting sexual recidivism among sexual offenders, the *average* predictive accuracy of all the individual risk scales was in the moderate to large range: Static-99 (*d.* = .74), Static-02 (*d.* = .71), MnSOST-R (*d.* = 80), and SORAG (*d.* = .60). Hanson et al. showed that the confidence intervals for each of these risk scales overlap; this means that their respective predictive accuracies are not significantly different from each other. More recent studies have found that the revised versions of the Static-99R (AUC = .68–.72) and Static-2002R (AUC = .67–.69) have similar predictive accuracies to the four aforementioned instruments (e.g., Helmus, Thornton, et al., 2012). Therefore, studies published to date indicate that there are a number of actuarial instruments that provide reasonable predictions of sexual recidivism, with no apparent advantage to any specific measure.

However, there are a number of specific limitations to the ARAI, and the interpretation of the results and implications of ARAIs for sexual offender recidivism relative to *lifetime* risk of such recidivism must be qualified. First, most available measures were generally developed as "screening tools" for institutional settings and rely on information about empirically identified risk factors which can be more easily found for scoring purposes by persons with access to a basic correctional or similar file about a sexual offender. Second, as a consequence of emphasizing utility, ARAIs typically do not necessarily include variables that may be important but are difficult to measure (e.g., deviant sexual preference, personality disorder, psychopathy), variables that were not selected or measured by multiple studies, or variables that are idiosyncratically associated with sexual offending. Third, ARAIs may also rely on some idiosyncratic definitions about certain risk factors; thus, a factor such as "prior sex offenses" does not simply refer to the number of previous sexual offenses (e.g., reported to authorities and self-reported or the number of incidents of sexual offending). Instead, scorers/evaluators must adhere strictly to the definitions provided in the scoring manuals to maintain the integrity of the instrument. Fourth, ARAI are derived from multivariate statistical techniques; they necessarily "collapse" or "combine" variables and reduce the number of total variables available for consideration to a smaller number of such variables [e.g., the meta-analysis identified approximately 20 statistically significant risk factors but the Static-99 (which resulted from that research) includes only 10]. Correlated empirical risk factors, where they may have different relationships in sexual offense recidivism for specific individuals but "overlap" when those individuals area "merged" and viewed as a group, are lost as potential factors in identifying risk of sexual offense recidivism for those individuals for who they do apply. Overall, it is clear that ARAI do not provide comprehensive coverage of risk factors for sexual offending. Fifth, most RAIs are based upon rearrests and reconvictions, most commonly for rap sheet sex offenses (e.g., capturing just 10–33 % of relevant sexual offense based on the findings on underreporting of sexual offense). Sixth, only those sexual offenders released and available for follow-up are reported, to the degree that particular sexual offenders may not be released from incarceration for follow-up constitutes "sample censorship," and offenders serving long or indeterminate sentences (e.g., possibly higher-risk offenders) may not have been available for follow-up. Seventh, given that available ARAIs only provide risk estimates for sexual offenders followed for 6–15 years, these figures do not represent the actual *lifetime* risk of sexual recidivism for most offenders given normative life expectancy. Although researchers have provided methods to estimate the "true" rate of sexual offender recidivism (e.g., Doren, 2010a, 2010b; Hanson & Thornton, 2003; Thornton, 2009), none of the results of the ARAI per se provide a measure of *lifetime* risk of actual sexual recidivism (e.g., detected + undetected). Thus, it is widely agreed that the estimates of absolute recidivism rates provided by ARAIs represent significant underrepresentations of actual sexual reoffending, which may or may not be detected during a follow-up.

The use of multiple actuarial measures has been endorsed by multiple individuals (e.g., Barbaree et al., 2006; Barbaree in Langton et al., 2008; Hanson, 2008) based on several considerations and must be considered the standard of practice. One early study with a small sample, Seto (2005) found that combining ARAIs did not provide a significant advantage of the single best ARAI. However, the subsequent scientific literature provides several bases for the utility of examining the results of multiple ARAIs and other RAI; some of these

results are summarized in Doren (2010a, 2010b). Scientifically, there is no "best" instrument; each of the ARAIs possesses equivalent degrees of predictive accuracy from a measurement perspective (e.g., Hanson & Morton-Bourgon, 2009). As Doren noted, the sexual offense recidivism variance accounted for by the collection of known static risk factors appears to account for a very substantial portion of that domain's complete set of static factors. In addition, since the different actuarial instruments contain unique as well as overlapping variables, they each measure recidivism using different sets of risk factors. Consequently, the relative ranking of risk by the specific actuarial instruments may be different for an individual. Issues in scoring of the different measures will make less of a difference when multiple measures are utilized; multiple actuarial instruments lead to increased reliability in identifying the relative risk of a particular offender. Finally, to the degree that a "set" of (multiple) actuarial measures converge in identifying that an offender is at higher risk, then there can be increased confidence in concluding that that sexual offender is at higher risk for sexual reoffending.

In addition, as noted, there are non-actuarial-based RAI or structured professional judgment that can contribute to a comprehensive risk assessment in the CCSVP. The PCL-R is the most researched clinical rating scale in the general area of violent prediction Salekin, Roger, and Sewell (1996), Hemphill, Hare, et al. (1998), and Hemphill, Templeman, et al. (1998) have reviewed the literature on the PCL-R via meta-analysis of individual studies and concluded that the PCL-R represents a good predictor of violence recidivism generally, inclusive of sexual recidivism. Several studies have found an increased risk of future sexual offending across relatively brief follow-up periods for persons with elevated PCL-R scores (e.g., Quinsey, Lalumiere, Rice, & Harris, 1995; Rice & Harris, 1997). A meta-analysis of risk factors by Hanson and Morton-Bourgon (2004) found that higher PCL-R scores were associated with an increased risk of sexual offense recidivism specifically; a more recent meta-analysis found an even stronger relationship between PCL-R scores and sexual reoffending, particularly when those scores were computed by well-trained raters (Hawes et al., 2012). An RAI specifically developed for providing a structured professional risk assessment for sexual offender recidivism is the Sexual Violence Risk-20 (SVR-20; Boer, Wilson, Gauthier, & Hart, 1997). This instrument provides a list of twenty variables believed to be associated with a higher risk of sexual offense recidivism, including psychopathy. The evaluator rates the relative presence of these factors for a particular offender and offers a judgment based on the total number, intensity of particular risk factors and/or an identified combination of particular factors believed to be associated with that individual's risk for sexual reoffending. Recent research has demonstrated that the SVR-20 has significant predictive accuracy. Overall, SPJ instruments show somewhat lower levels of predictive accuracy than ARAIs (de Vogel, de Ruiter, Van Beek, & Mead, 2004; Hanson & Morton-Bourgon, 2008; 2009); however, in certain instances, they have demonstrated particularly high levels of predictive accuracy (Hanson & Morton-Bourgon, 2009; Logan, 2015).

"Static" risk factors, by definition, do not change; they are "facts" of an individual's personal history. Recently, there has been increased recognition of and attention to findings that a number of risk-relevant variables may not be fully accounted for by at least some ARAI. Originally, there was the notion that so-called dynamic risk factors might exist that were hypothesized to represent characteristics of sexual offenders which might be subject to modification and thus might vary over time for particular sexual offenders. For example, the Sex Offender Needs Assessment Rating (SONAR; Hanson & Harris, 2000) and later the STABLE-2000 (Hanson & Harris, 2001) were originally developed as attempts to study and quantify a set of what were viewed as "dynamic" risk factors for sexual reoffending. However, while the SONAR demonstrated some association with recidivism, the field test of the Dynamic Supervision Project (DSP) utilizing the STABLE-2000 essentially did not find a uniform association with its sample of sexual offenders on parole and probation. However, the DSP was used to test and validate the revised STABLE-2007 (Hanson, Harris, Scott, & Helmus, 2007) on the parole/probation sample. Eher, Matthes, Schilling, Hauber-MacLean, and Rettenberger (2012) applied the STABLE-2007 to sexual offenders released from incarceration. More recently, the notion of "dynamic" risk factors has been reconceptualized as "criminogenic needs" or social or psychological factors that "push" toward sexual reoffending. Per Thornton (2010), such needs represent either long-term vulnerabilities (e.g., a life history focus) or stable but potentially modifiable risk factors. New research has demonstrated that the inclusion of measures of criminogenic needs provides statistically and clinically significant information regarding a sexual offender's risk for future sexual offender recidivism. As Doren (2010b) noted, measures of dynamic risk characteristics have demonstrated roughly equal sexual offense recidivism predictive validity relative to ARAIs; this is evidenced in the research for each measure of dynamic needs or risk. In addition, they show significant small incremental predictive utility relative to measures of static risk factors such as ARAIs. The STABLE-2007 has been demonstrated to show incremental validity (e.g., added effects on absolute risk recidivism rates) to select ARAIs (Babchishin et al., 2012; Hanson et al., 2007) for a sample of sexual offenders on parole and probation. The Structured Risk Assessment (SRA; Thornton, 2002) framework has also been shown to produce similar effects on sexual offender recidivism rates for other samples,

including a preselected for treatment sample (Harkins et al., 2009) and a preselected for risk sample (Thornton & Knight, 2007; 2014). Other instruments that also attempt to assess dynamic risk or criminogenic needs have also shown substantial incremental predictive validity relative to select ARAIs (e.g., Allan, Grace, Rutherford, & Hudson, 2007; Olver, Wong, Nicholaichuk, & Gordon, 2007). Consequently, there is increasing evidence that integrating an empirically validated assessment of criminogenic needs with information from static ARAI provides additional important information about the degree of risk for sexual offender recidivism that may characterize a particular offender at the time of evaluation. Doren has suggested that a particularly useful means of considering risk would be a "risk profile" composed of relevant dimensions related to sexual offense recidivism.[2]

In addition to criminogenic needs, other considerations may also be relevant relative to risk assessment related to CCSVP. Assuming the application of the range of ARAIs and SPJ instruments, there are also several areas to be considered. First, the joint presence of deviant sexual arousal (DSA) and psychopathy has been identified as conferring a particular risk of sexual reoffending to sexual offenders by various individual studies (e.g., Harris et al., 2003; Hildebrand, de Ruiter, & de Vogel, 2004; Rice & Harris, 1997; Serin, Mailloux, & Malcolm, 2001). Most recently a meta-analysis of 20 studies found that offenders who scored high on the PCL-R and some measure of sexual deviance were more likely to reoffend sexually than other offenders (Hawes et al., 2012). Second, the relative age of a particular offender may have an effect on the rate of sexual offender recidivism. Several studies have indicated that particularly advanced age (e.g., 60+) may represent a period of significantly decreased risk for the general sexual offender. Hanson and Harris (2001) and Barbaree, Blanchard, and Langton (2003) reported that rapists, and less so child molesters, showed relative decreases in recidivism with increased age. However, a number of investigators have demonstrated that some sexual offenders continue to offend until relatively late in life (e.g., Abel, Rouleau, & Osborn, 1993; Hanson, Steffy, & Gauthier, 1993) or that subgroups of sexual offenders persist in offending or begin offending at relatively older ages. Others have found that more high-risk sexual offenders show less of a decline in sexual offender recidivism with age (e.g., Thornton, 2006). Alternatively, Harris and Rice (2014) found that age of *onset* of violent including sexual offending was associated with a greater likelihood of recidivism (as opposed to age at release).

[2]Per Doren, he hypothesized that the seven factors include general antisociality, desire for/enjoyment of sexual offending, sexual interest in children, sexualized hostility, immaturity, intimacy-detached hostility, and high-frequency sexual behavior.

Finally, prior sexual offender treatment should be considered as a potential dynamic factor with some association to the possibility of reducing certain risk factors related to sexual offense recidivism. Hanson et al. (2002) and Losel and Schmucker (2005) conducted meta-analyses of more recent treatment studies involving sexual offenders. In both studies, persons who completed sexual offender treatment showed lower rates of sexual offense recidivism than groups of persons who did not participate in treatment (of note, the latter meta-analysis reported on the results of both psychosocial and biological treatments). However, the rates of sexual offender recidivism for persons who participated in sexual offender treatment were not substantially different from the rates of sexual offender recidivism demonstrated by untreated sexual offenders considered in the two meta-analyses of risk factors (Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004). In addition, no effects of sexual offender treatment were demonstrated for the very limited number of studies that were random-controlled trials, considered the "gold standard" in psychotherapy outcome research. In addition, both meta-analyses by Hanson et al. (2002) and Losel and Schmucker (2005) showed that persons who were mandated for treatment or referred for treatment based on higher levels of "need" showed no treatment effect. Rice and Harris (2003; 2012) have offered critiques of the results of these meta-analyses. In addition, the most recent Cochrane Review of Dennis et al. (2012) have found no differences in sexual offense recidivism for the limited number of methodologically rigorous studies of sexual offenders to receive psychosocial treatments. It is noteworthy that the only random assignment-controlled scientific study of sexual offenders who volunteered for sexual offender treatment and who were then randomly assigned to treatment The Sexual Offender Treatment and Evaluation Project (SOTEP) found that cognitive-behavioral relapse prevention treatment (coupled with additional and extended community aftercare) showed no effect on the sexual offense recidivism rate of either child molesters or rapists (e.g., Marques, Wiederanders, Day, Nelson, & Ommeren, 2005). In their reviews of the sexual offender treatment literature, Dennis et al. (2012), Langstrom et al. (2013), and Rice and Harris (2003; 2012) concluded that there is no scientific basis for concluding that the effectiveness for psychosocial treatments for typical has yet been demonstrated. No random assignment-controlled studies have yet been conducted on high-risk, high-need sexual offenders such as those who are identified as appropriate for civil commitment. Thus, while sexual offender treatment may have a risk-reducing effect on select sexual offenders (most likely and predominantly, low-to-moderate risk sexual offenders), it is clearly not a uniform phenomenon, and there is no scientific basis or means that exists to identify which recidivistic and/or higher-risk sexual offenders are likely to

genuinely benefit from current sexual offender treatment models and practices. Consequently, the potential effects of sexual offender treatment cannot be assumed and must necessarily be considered carefully on an individual or case-specific basis.

Nature of Persons Civilly Committed

The purpose of sexual offender civil commitment laws are to identify and detained those individuals who are at high risk to commit future sexual offenses due to a mental abnormality and/or personality disorder. As such, populations of individuals held under such laws should share similar characteristics in terms of diagnosis and risk level. A growing body of data suggests such similarities do exist.

There are over 4,000 individuals either committed or detained under sexual offender civil commitment statutes. All but one program operates a total confinement inpatient facility to which residents are initially committed. Only Texas operates a strictly outpatient program. Pennsylvania also operates a slightly different program. Individuals committed under Pennsylvania's law are all juveniles who are aging out of the juvenile justice system, but are considered likely to reoffend due to a mental abnormality or personality disorder. As such, the mean age of residents[3] in the Pennsylvania program is likely to be quite a bit lower than the other programs. Programs also differ regarding whether individuals are detained in the total confinement facility while awaiting their commitment trial. While several states do detain precommitment individuals, other states house the detainees in county jails or other facilities prior to their commitment.

Several authors have provided published descriptions of civilly committed populations in Arizona (Becker, Stinson, Tromp, & Messer, 2003), Minnesota (Janus & Walbek, 2000), California (Vess et al., 2004), Wisconsin (Elwood, Doren, & Thornton, 2008), Washington (Jackson & Richards, 2007), and Illinois (Jumper, Babula, & Casbon, 2012). In addition, Florida (Levenson, 2004) and Texas (Boccaccini, Turner, & Murrie, 2008) have provided data regarding offenders who have been either referred or committed pursuant to a sexual offender civil commitment law. Furthermore, the Sex Offender Civil Commitment Programs Network (SOCCPN) conducts annual surveys of programs and gathers additional data relevant to resident characteristics as well as characteristics of the programs themselves (Jackson, Schneider, & Travia, 2009; Jackson, Travia, & Schneider, 2008). From these sources, it is possible to offer a composite description of individuals held under these laws.

The vast majority of individuals detained and committed under sexual offender civil commitment statutes are male. Only four states reported having female residents as of 2008 (Jackson et al., 2008). Jumper and colleagues (2012) reviewed the published data relevant to civil commitment and provided demographic and diagnostic summaries. The average age in the seven samples reporting age was 45.7 ($SD = 11.4$). Of the seven samples reporting ethnicity, 64 % of the national sample was Caucasian, 23.7 % African American, 7.1 % Hispanic, 3.9 % Native American, and 5.2 % were classified as Other. The ethnic proportions are similar to those reported by Deming (2007) in his survey of civil commitment programs. In Deming's sample, 15 states reported ethnic data. In aggregate, 68.3 % of individuals were Caucasian, 24 % African American, and 6 % Hispanic. Deming (2008) noted that African American individuals are overrepresented in sexual offender civil commitment programs as they make up only about 12.8 % of the US population and that Hispanic Americans are underrepresented as they comprise 14.1 % of the US population (US Census Bureau, 2005, as cited by Deming, 2007).

Jumper et al. (2012) reported that approximately half (49.0 %) of all residents in the national sample ($n = 1{,}684$ for diagnostic information) were diagnosed with pedophilia. Other common paraphilia diagnoses included paraphilia NOS-non-consent (27.5 %), paraphilia NOS-other (16.6 %), sexual sadism (6.4 %), voyeurism (8.6 %), exhibitionism (7.8 %), frotteurism (2.6 %), and fetishism (3.1 %). Apart from paraphilias, common formerly identified Axis I disorders included substance abuse disorders (50.4 %) and mood disorders (20.9 %).

Personality disorders are also very common in this population. Nearly three-quarters (72.7 %) of the residents in Jumper et al.'s (2012) national sample were diagnosed with at least one personality disorder. Antisocial personality disorder was the most common specific disorder (43.2 %), followed by personality disorder NOS. Typically, personality disorder NOS is qualified with "with antisocial features," although, "with borderline features" is also common. Personality disorders from Clusters A and C are uncommon in this population (7.3 %). In addition, where data was available, approximately 23 % and 9 % of persons civilly committed were characterized by borderline intellectual functioning or mildly mentally retarded (now intellectual disability) (Table 2).

Psychopathy Checklist-Revised (PCL-R; Hare, 2003a, 2003b, 2003c) data were reported for 1,481 residents included in the Jumper et al. (2012) analysis. Overall, the mean PCL-R score was 24.2, which is identical to the mean PCL-R scores reported by Hare (2003a, 2003b, 2003c) in a sample of sexual offenders who had been

[3]The majority of programs refer to detained and committed individuals as "residents" (Jackson et al., 2007). For ease of communication, we will also utilize that term throughout this chapter.

Table 2 Diagnostic and psychopathy profiles of civilly committed sexual offenders[a]

	Illinois ($n=377$)	Wisconsin ($n=331$)	Texas ($n=321$)	Florida ($n=229$)	Washington ($n=190$)	Arizona ($n=120$)	Minnesota ($n=116$)	National ($n=1,363$)
Paraphilias								
Pedophilia	59 %	47 %	42 %	39 %	56 %	63 %	35 %	**49 %**
Paraphilia NOS (non-consent)	31 %	21 %	21 %		43 %			**28 %**
Paraphilia NOS (other)	20 %	16 %					6 %	**17 %**
Total paraphilia NOS	51 %	38 %		51 %		56 %		**47 %**
Sexual sadism	7 %					13 %		**6 %**
Personality disorders								
ASPD	53 %	25 %	55 %	48 %	41 %	40 %	26 %	**43 %**
NPD	5 %				6 %	3 %		**5 %**
PDNOS	40 %	14 %		28 %	42 %	42 %	15 %	**36 %**
Other PD	8 %			4 %	5 %	13 %	8 %	**7 %**
Any PD	94 %	41 %		80 %	88 %	77 %	49 %	**72 %**
PCL-R (mean)	26 (7)	24 (7)	23 (8)	26 (7)	24 (7)			**24**
PCL-R >/= 30	38 %				27.5			**30 %**
Intellectual disability/borderline IQ	35 %	43 %			17 %			**32 %**

[a]Rounded percentages taken from Jumper et al. (2012); PCL-R = mean (standard deviation)

administered the PCL-R under standard procedures (i.e., interview plus file review). Not unexpectedly, the mean score for PCL-Rs given under "file review only" conditions was considerably lower in Hare's normative sample ($M=17.5$). The majority of PCL-R data reported in the Jumper et al. study were collected clinically (rather than primarily for research) and therefore are most likely to mirror the standard administration condition. Mean scores for individuals with adult victims only ($M=26.7$) and mixed offender (those with both child and adult victims; $M=26.1$) were substantially higher than those with child victims only ($M=21.8$), a trend consistent with Hare's normative data. Similar to percentages reported by Hare (2003a, 2003b, 2003c), approximately 30 % of the national sample met or exceeded the recommended cutoff score for psychopathy of 30. As expected, a substantial difference existed between those residents with only adult victims (44 % met or exceeded cutoff score) and those with child victims (17 %) or mixed offenders (26 %).

Six programs ($n=1,363$) included in the Jumper et al. (2012) analysis reported victim information for their residents. A large majority of residents (79.2 %) had offended against at least one child or teen. This percentage is similar to 2008 SOCCPN data in which nine programs responded that 75.1 % of their residents had offended against at least one child or teen (Jackson et al., 2008). The remaining residents offended exclusively against adults. Approximately 60 % of the national sample had offended against only female victims; the remaining had offended against male victims or victims of both genders.

Treatment Approaches

As cited previously, the US Supreme Court noted in the *Hendricks* decision that "we have never held that the Constitution prevents the state from civilly detaining those for whom no treatment is available". Nonetheless, despite limited evidence that current forms of sexual offender treatment can be effective, particularly for more high-risk sexual offenders, currently, all sexual offender civil commitment programs offer treatment to their residents. However, states have a great deal of discretion in developing and implementing such programs (*Kansas v. Hendricks,* 1997; *Youngberg v. Romeo*, 1982). Despite the latitude afforded treatment programs, several legal challenges have been heard in trial and District Courts that may govern certain aspects of treatment delivery in the relevant jurisdictions. Vlahakis (2010) provides an excellent overview of legal challenges to sexual offender civil commitment treatment delivery and program operations.

The Sex Offender Civil Commitment Programs Network (SOCCPN) has been gathering data regarding treatment approaches and delivery since 2007 (Jackson, Schneider, & Travia, 2007; Jackson et al., 2008; 2009). Participation in treatment ranged widely among programs. In 2008, 10

programs reported a range of treatment participation from 10 to 100 % of committed residents. The average was 78 % treatment participation. For the 8 responding programs that also detain individuals prior to their commitment, treatment participation among detainees ranged from 0 to 100 %, but the average was 35 %.

Fifteen programs responded to questions regarding treatment groups. All 15 offered group treatment aimed at sexual offender-specific issues. In addition, all also offered drug and alcohol treatment groups, 80 % offered vocational programming, and 80 % offered educational programming. In recognition of responsivity needs, 80 % of the programs offered a Special Needs Treatment Track and 60 % offered a Psychopathy Treatment Track.

In terms of sexual offender-specific treatment in 2008, the programs reported that residents spent from 3 to 20 hours per week in treatment. Group meetings accounted for between 1 and 10 hours. Group size ranged from 4 to 12 residents, with 10 participants being the modal number. Duration of each group ranged from 30 minutes to 3 hours. The majority of groups were facilitated by two therapists, although some programs reported a single-facilitator format. Data gathered from 2009 indicated few changes to treatment delivery. The number of sexual offender-specific treatment hours per week declined slightly to 1.5–12 hours. Groups meet between 1 and 12 times per week, for a range of 60–120 minutes. The average length of a group session was 90 minutes. Eighty-nine percent of programs also offered individual treatment to at least some of their residents. Of the programs who offered individual treatment, the range of residents receiving this treatment was 1.5–100 %.

The most common types of treatment offered were sex offense process groups (93.3 % of programs offered this group) and cognitive-behavioral treatment groups (86.7 %). Other common treatments included dynamic risk factors (80 %), relapse prevention (73.3 %), self-regulation (73.3 %), organized milieu (66.7 %), motivational interviewing (60 %), and approaches derived from the Good Lives Model (60 %). Less common treatments included sexual arousal management (46.7 %), unstructured process groups (33.3 %), and Circles of Support (6.7 %). Many programs offered several types of treatment, and the categories are not necessarily mutually exclusive. For example, cognitive-behavioral treatment groups may target dynamic risk factors or relapse prevention planning.

Discharge and Conditional Release

Several avenues exist for discharge from a civil commitment program both within and across jurisdictions. Ultimately, a judicial body may issue a release or conditional release order. Residents may petition the court directly for release or they may be recommended for release by the program. In jurisdictions that detain individuals before their commitment trials, individuals may be discharged from total confinement without ever having been committed.

All jurisdictions have provisions for discharge when an individual no longer meets criteria for civil commitment due to reduction in risk and/or changes in the mental abnormality that impact future risk. In addition, 16 jurisdictions also have provisions for conditional release (i.e., less restrictive alternatives [LRA]) for individuals who continue to meet criteria for commitment, but are judged to be capable of being managed in a less restrictive setting. A unique approach was chosen by Texas, which operates an outpatient only program. Essentially, all of their residents are on conditional release from the time they are committed. Arizona also operates somewhat differently in that the majority of their committed residents are transferred to LRA status within 120 days of their commitment. The LRA has several levels, most of which are housed on the grounds of the state hospital. Only the final level of LRA occurs in the larger community. A key issue for any type of release relates to the further demonstration of the effectiveness of sexual offender treatment for high-risk sexual offenders and the ability of treatment programs and the courts to make meaningful determinations about the degree to which residents' mental abnormalities, personality disorders, difficulties in control, and risk for sexual offense recidivism have changed while living within a highly structured environment.

In 2009, 16 jurisdictions reported discharge data for the SOCCPN survey (Jackson et al., 2009). Of those, six programs had released no residents from their total confinement facility. Eight additional programs reported a range of 1–39 discharges for a total of approximately 179 discharges directly from total confinement. Twelve programs provided further data regarding the avenue for discharge of these residents. Roughly 50 individuals were discharged following "completion" of treatment, meaning either the program recommended their release or the resident was judged to have obtained "maximum treatment gains." Others were discharged against the recommendation of the program; although two programs specifically reported that they made no recommendations to the Courts regarding release. Additionally, approximately 100 individuals have died during the course of their civil commitment.

Discharges from conditional release number approximately 155, with 110 of those from the Arizona LRA program (Jackson et al., 2009). Five programs reported they have had no discharges from conditional release. Sixteen individuals have died while on conditional release status.

Release, including conditional release, from civil commitment facilities varies across jurisdictions along several

dimensions. Programs with no conditional release provisions entail the most abrupt transition from total confinement to community living. Other programs, such as Washington State, operate secure transition facilities where conditionally released residents live directly following total confinement. Secure transition facilities allow residents more freedoms than those living in total confinement, but provide more support, structure, and external controls than living in the community. Lastly, certain programs, including Kansas and Arizona, have levels of conditional release where residents are gradually given more freedom over time, ultimately culminating in community living.

Despite the existence of conditional release programs, or their structure where present, releasing individuals from sexual offender civil commitment programs present formidable challenges. States who do not operate conditional release facilities or who lack provisions for conditional release must contend with state residency restrictions, community notification, and the potential for public outcry often faced by sexual offenders moving into a community. Jackson et al. (2007) reported common impediments to community living for released residents. Commonly cited barriers included legal residency restrictions (63.6 % of reporting programs endorsed this as a barrier), restrictions on where residents can live resulting from their specific release plans (54.6 %), negative publicity and public reactions (54.6 %), lack of housing or lack of affordable housing (36.4 %), and available/affordable housing in undesirable, risky areas (63.6 %). In addition to residency barriers, individuals released from civil commitment facilities often have difficulties finding adequate employment, particularly if the jurisdiction requires a 1:1 custodial escort (Jumper, 2010).

Residents who are conditionally released to the community or conditional release facility may be subject to a host of supervision requirements. Common management approaches include GPS monitoring, escorted supervision into the community, corrections supervision in the form of probation or case management, as well as periodic polygraphs and penile plethysmographs, antiandrogen treatment, and ongoing sexual offender treatment (Jumper, 2010). Violations of conditional release often take the form of technical violations (Jackson et al., 2007; 2008). The vast majority of violations were for rule infractions, rather than for new crimes; crimes constituted less than 20 % of all reported violations. Sexual recidivism was virtually nonexistent. One program reported a charge for child pornography that had actually occurred prior to the individual's index offense. Other sexually related violations consisted of failure to register as sexual offender in the community. Residents who commit technical violations are typically returned to the secure facility until such a time that they re-earn their conditional release. In Texas, where no total confinement facility exists, residents are returned to prison following any violation of conditional release.

Issues Regarding Sexually Violent Predator Statutes

Sexual offender civil commitment laws are not without controversy. Despite constitutional support, scholars have voiced scientific and ethical objections to the statutes (Campbell, 2003, 2004; Janus, 1998; 2000; Morse, 1998, 2003; Zander, 2005). Ethical questions center around the issue of preventive detention, the morality of depriving individuals of their liberties for offenses they *may* commit at some future date. Continuing to detain individuals after they have served their time for past criminal acts is unacceptable to some, although civil commitment is used in virtually all jurisdictions for persons with mental disorders that place them at risk to self or others. Balancing the rights of individuals to be free from unnecessary detention with the public's right to be protected is an ongoing consideration. Scientific objections, on the other hand, center primarily on the state of the science of risk assessment, specifically, claims that the current knowledge of risk assessment is insufficient to opine, with a requisite degree of confidence, who is likely to reoffend.

Economic objections to CCSVP have also been raised (Goodnough & Davey, 2007). By its nature, a hospital or intensive treatment placement is much more expensive to fund than a prison, particularly one that is highly secure (e.g., similar to a prison) in its environment and management personnel but also has an appropriate staffing of trained treatment personnel. Texas' outpatient approach to CCSVP appears to be the most cost-effective at a total cost of approximately $1.2 million per year (Gookin, 2007). California's SVP program costs approximately $147 million per year, roughly $166,000 per resident per year, making it the costliest program. As Goodnough and Davey (2007) point out, in many states, these figures far exceed what the state spends per inmate in corrections. On average, states spend approximately $94,000 per year per resident, and the average yearly budget of civil commitment programs is approximately $454 million (Gookin, 2007). Skepticism over the success of treatment (Goodnough & Davey, 2007) leaves some to question the value of civil commitment over longer criminal sentences. For example, media reports have characterized civil commitment of sexual offenders as "extremely expensive, marginally useful, and legally dubious" (Concord Monitor, June 10, 2009).

Future Directions

Since 1990, 21 jurisdictions have enacted civil commitment laws specially designed to detain high-risk sexual offenders. Approximately 75 % of these programs have been enacted since the Supreme Court ruled on the constitutionally of sexual offender civil commitment statutes in 1997 (*Kansas v. Hendricks*, 1997). Many jurisdictions have turned to civil commitment to address shortcomings in the criminal statutes regarding sentences of sexual offenders, such as plea-bargaining to lesser charges and perceived inadequacy of sentence lengths for sexual offending, and also address public concerns about sexual offending and recidivism.

Looking toward the future, it would seem that evolving criminal justice practices and economic pressures will each likely influence the disposition of at least some recidivistic sexual offenders of the type currently considered as candidates for civil commitment. It seems likely that public opinion regarding more severe dispositions for sexual offenders, particularly those who are repeat offenders, may continue to create pressure for significant sanctions of some type. To this end, over the past 20 years, most states have increased the length of criminal sentences for sexual offenders as well as increased the terms of conditional release when such offenders are released from incarceration (including lifetime parole, GPS, and intensive supervision). Changes in the nature of punishment for sexual offenders, including longer criminal sentences, may eventually substantially reduce or eradicate the need for civil commitment programs for sexual offenders. As such offenders spend more time incarcerated for their offenses, the rate at which recidivistic sexual offenders are released into the community from the criminal justice system should slow dramatically. The trend toward longer criminal convictions has led some scholars to speculate that sexual offender civil commitment may merely represent a "stop-gap" measure to detain those offenders who committed their offenses prior to criminal sentencing changes. Offenders who are sentenced according to newer sentencing guidelines may not be released for long periods of time, if at all, and therefore, not subject to civil commitment (D. Shuman, personal communication, December 12, 2002). The effects of revised sentencing guidelines are not yet known, but it seems very likely that they are and will continue to reduce the number of offenders considered for civil commitment to SVP programs.

In addition, economic issues will also likely play a role in the management of sexual offenders deemed to be at particularly high risk for sexual reoffending. As noted above, with an average price of $94,000 per resident, increasing rates of committed sexual offenders and very slow rates of release will lead to substantially increased costs for jurisdictions with CCSVP. In part, as a means of controlling costs and as a means of avoiding other issues related to civil commitment, some jurisdictions such as Minnesota have implemented the same long-term intensive sexual offender treatment programs provided to sexual offenders who have been civilly committed for sexual offenders deemed high risk while still incarcerated. In this way, it is hoped that some sexual offenders may receive a sufficient dose of sexual offender treatment while in prison to provide for a more rapid transition back to the community public safety may perhaps be protected without the necessity of civil commitment following their incarceration. Some states such as Colorado and eleven others have opted to provide for some degree of lifetime supervision of select sexual offenders by specially trained probation/parole officers. However, neither of these options has yet to receive empirical validation that they provide effective means for managing high-risk sexual offenders. Nonetheless, it seems likely or simply possible that over time resources may be shifted away from CCSVP to alternative means of managing such select groups of high-risk sexual offenders. In addition or alternately, an adoption of a model similar to Canada's Dangerous Offender statute might also be considered. By making the determination of the degree of dangerousness of the offender at entry into the criminal justice system, such an approach offers a means of addressing the ethical/legal issues raised by CCSVP and as a means of controlling costs related to detaining and offering evidence-based treatment to sexual offenders determined to be at higher risk of future sexual offending.

Sexually Violent Predator Cases: A Prosecutor's Perspective

Cameron C. Page and Brooke E. Burbank

For decades, society has endeavored to deal with the vexing problem of sexual offending and reoffending, both in the United States and internationally. Coupled with the emergence of psychiatric and psychological inquiry and explication of criminal behavior, especially in the area of sexually deviant criminal behavior, legislatures in approximately half the states in the United States had promulgated sexual psychopath laws in a variety of forms between 1939 and 1980. Most were premised on the idea that at least a portion of the sex-offending population was mentally disordered, rather than simply criminal. These statutes sought to provide treatment in broad-based fashion to sex offenders, occasionally in mitigation of, and oftentimes entirely in place of, penal consequences (Group for the Advancement of Psychiatry, 1977). These statutes did not target a narrow population, and some included misdemeanor conduct (see, e.g., *California Welfare & Institutions* Code § 6300, et seq., repealed 1981). These statutes met with mixed societal response (especially those that were implemented in place of penal sanction), and by 1990 only 13 states had sexual psychopath laws still on the books (APA, *Dangerous Sex Offenders*, 1997).

Clearly a more focused approach was needed. Beginning in the late 1980s, state legislatures began passing "sexually violent predator" and "sexually dangerous person" statutes, beginning in Washington (1990) and Minnesota (1995). Currently, there are 20 states that have similar civil commitment schemes for mentally disordered sexual offenders in effect. These statutes have followed a typical pattern in that they ostensibly target a more select population of repeat sexual offenders, namely, those characterized by a mental condition and an elevated risk of sexual reoffending. They have also taken into account some of the differing treatment needs of this subgroup of the mental health population (see, e.g., the findings of the Washington State Legislature in enacting their SVP statute) (RCW 71.09.010, 1990 c.3, Section 1001 …the prognosis for curing sexually violent offenders is poor, the treatment needs of this population are very long term, and the treatment modalities for this population are very different…).

These statutory commitment schemes have engendered substantial controversy in both the legal and the mental health communities. They have, however, withstood repeated constitutional challenge on both state and Federal levels [*Kansas v. Hendricks* (1997) 521 U.S. 346; *Selig v. Young* (2001) 121 S. Ct. 727; *Hubbart v. Superior Court* (1999) 19 Cal.4th 1138; United State v. Comstock 131 S.Ct. 1949 (2010)] and have every appearance of remaining on the books. Additionally, significant advances in the area of risk assessment and contemporary treatment focus have combined to support this process.

Given the mixed results historically of involuntary civil commitment schemes for sexual offenders, the important public safety issues involved, and the significant deprivation of liberty that is entailed, it is incumbent on both prosecutors and independent evaluators testifying in the State's case to be competent, prepared, and objective in their handling of these cases. The purpose of this chapter is to discuss the appropriate pretrial preparation of SVP/SDP cases as well as issues related to direct and cross-examination.

It is important to bear in mind the roles of the participants. Perhaps most readily apparent is that of the prosecutor, who bears responsibility for proving the essential elements necessary for civil commitment. This typically involves presentation of testimony by independent evaluators who have been selected by the state mental health authorities to conduct evaluations of potential SVP candidates, as well as other (lay and percipient) witnesses and relevant documentary evidence.

While each state differs slightly in its procedures, typically the independent evaluators conduct their assessment according to general forensic practices and within the framework of a state-established protocol if one exists and prepare written reports. Such reports are provided to the prosecutor for review and for consideration as to whether to file a petition for commitment.

Defense-retained experts fulfill a somewhat different role. They are hired to review the state's case (and, in particular, the independent evaluator's reports) and then to offer their own opinion as to whether the individual meets the requirements for commitment or to testify about one or more issues pertaining to the prosecutor's case. Often, the defense expert is selected with a particular area of expertise involved in the case (e.g., psychometric testing, criticisms of actuarial assessment tools, topics such as age, etc.). They often advise the defense attorney as to questions for cross-examination of the independent evaluator.

Roles of the Prosecutor and the Independent Evaluator

Integral to discussing the area of trial preparation and testimony is clarifying the respective roles of the prosecutor and the independent evaluator in a trial, where the finder of fact is either a jury or a judge.

Prosecutors are ethically bound to pursue both truth and justice; this duty is no less applicable to involuntary civil commitments than to criminal prosecutions. Conceptually, the "truth" may be a bit more intangible in civil commitment process than in criminal cases, but both categories of cases often share the goal of determining the defendant's (or respondent's) state of mind, ability for self-control, etc. From the independent evaluator's point of view, it is important to understand this basic ethical duty of prosecutors, namely, that there is a duty to share their full and honest assessment of the individual, not just those aspects that auger in favor of commitment.

Similarly, it is not the role of the independent evaluator to "win the case." The evaluator must thoroughly conduct their evaluation in the first instance, honestly and clearly report their opinion on the central issues, and remain open to potential changes in the factual basis for their opinions as well as developments in the evolving mental health field that may impact those opinions. An evaluator's opinion should be based on the existing case facts and the extant research, filtered through their expertise and training. When a defense attorney raises facts or other issues that are not supportive of an evaluator's opinion, a professional should not become defensive or argumentative. Rather, they should concede the points that are weak in the case and acknowledge they have considered such relative weaknesses but emphasize that the other aspects of the case were stronger. For an independent evaluator, strongly and persuasively conveying their opinions and conclusions is acceptable, expected, and desirable; advocating for one *side* in the litigation is not. For example, being unwilling to reconsider one's opinion when presented with information that clearly requires that one do so will make it appear that an evaluator is biased. It remains an issue of objectivity—whether the evaluator appears to consider the facts fairly and objectively, without bias or agenda. Both judges and jurors are usually fairly perceptive in drawing that line and knowing if you cross it. At trial, an independent evaluator is called to offer their opinion and defend it when it is challenged, but that is different from advocating for a particular outcome. A jury can typically differentiate between an impartial witness and one who is vested in the outcome. Consequently, an independent evaluator should be strong in their opinion—in a manner of speaking, an evaluator's testimony allows them to be an advocate *for their opinion*, and the jury or judge needs to see that you have a high degree of confidence in that opinion.

Likewise, jurors are typically very sensitive and canny when it comes to the attitude of the participants, including that of the independent evaluators. If evaluators appear arrogant, condescending, or superior, jurors often will not hesitate to discount or ignore that independent evaluator's opinion, no matter how well founded. On the other hand, when jurors perceive that the evaluator is there to offer knowledge and opinions in areas well beyond the "ken" (knowledge or experience) of the regular person, they typically appreciate and value the independence of an evaluator's perspective. In all likelihood, the jury (or judge) will be relying on your opinion to educate them about the history of a particular offender, mental disorders that characterize the offender, and the nature and results of the risk assessments. The areas of mental health expertise are not common knowledge, and an independent evaluator will need to spend some time making sure that they understand the case material and research so that they communicate this information clearly and carefully to the jury so that they can reach a verdict. Most of this information exchange with the jury or judge occurs on direct examination, but it does not stop during cross-examination. A key is for the evaluator to answer every question as if a member of the jury had asked it, avoiding being argumentative with the defense attorney. Even under cross-examination, an independent evaluator strives to remain as polite and clear as they were on direct. It is the prosecutor's job to ask the court to intervene if the prosecutor believes that the defense attorney is out of line in their questioning; it is the independent evaluator's roles to answer every question posed and with poise. The most successful attitude we have observed is that of *teacher*; evaluators who are effective as witnesses function from a perspective of seeking to help the jurors understand the subject they are addressing with a goal of equipping *them*—the jury or

judge—to make the decision *they* ultimately have to make. This brings up another related and important consideration. As any good teacher knows, one strives to teach to the level of students in the class or, in SVP/SDP cases, the jury. Unless the material is presented in a manner that they can understand, an evaluator's efforts are likely wasted. Recent studies have suggested that, in the digital age, the typical person's attention span is approximately 1–7 min (Becker-Arvin, 2003). This would strongly suggest presenting the information simply and concisely to maximize retention, something that may well require practice and rehearsal.

Independent evaluators should not use language that only a few can understand. Rather, an evaluator strives to appear knowledgeable but also understandable. "Translate" terms and concepts so that the jury understands everything that is presented. Scientific terms can be used, but then evaluators should succinctly explain what they mean. Evaluators will also need to ensure that their language is clear; for example, evaluators in SVP matters do not make predictions but instead provide assessments of the level or degree of risk an individual poses (and why). This issue can be a classic example of where a defense attorney would like to blur the lines between an SVP evaluation and what that attorney would like the jury to think. In short, it is the independent evaluator's task to make sure that their methodologies and procedures are clear to the jury, often despite a defense attorney's best efforts. Another helpful technique for evaluators is to use analogies from common experience to give them a frame of reference. A frequently used analogy is likening the assessment of risk for future sexual offending to that of the assessment of risk for heart disease. Almost everyone has had someone close to them, sometimes themselves, experience cardiac health issues. Common risk factors for heart disease (smoking, high cholesterol, high blood pressure, sedentary lifestyle, obesity, stress, family history of heart disease) are easily understood by most jurors. The transition to looking at empirically derived risk factors for sexual reoffending (history of sex offenses, single, male victims, stranger victims, prior sentencing dates, etc.) is quite natural. This type of comparison can assist the jury when the evaluator talks about "research-based factors" and "scientific data." Jurors can readily grasp the discussion about an individual who is characterized by "X" number of risk factors and the percentage of smokers developing heart disease and will understand a similar discussion of risk factors associated with a higher level of risk for sexual offenders in similar fashion.

Pretrial Preparation

Forensic mental health evaluators provide testimony in a variety of forensic settings and legal cases involving mental health conditions and the probability of future outcomes. General mental illness commitment hearings, insanity proceedings, mentally disordered offender, grave disability and conservatorship cases, probation suitability assessments, and developmental disability commitment schemes are but some that psychiatrists and psychologists address in a forensic setting. From a prosecutor's perspective, none of these types of cases consistently demands the high level of pretrial preparation that SVP/SDP cases do.

In large part based on the "preventive detention" nature of these cases and the indeterminate nature of commitment, SVP/SDP cases are typically zealously litigated by the defense. The particular information and methods upon which the evaluator bases his or her opinion and the scientific basis of the evidence presented may be intensely scrutinized. SVP/SDP cases are largely based on circumstantial evidence (e.g., indirect evidence). Consequently, it is important to understand the distinction between direct and circumstantial evidence. Direct evidence provides proof of a fact without the necessity of inference (e.g., a witness testifies that she knew it had rained on a given day because she had been outside and stood in the downpour). Circumstantial evidence is that which requires an inference to prove the fact (e.g., a person is sitting in a windowless cubicle in an office but sees that everyone who comes in from outside is shaking water off their umbrellas and coats as they enter. The individual didn't see it rain, but the most reasonable inference for them to draw is that it is raining outside). Consequently, both the nature of the inferences and the reasoned opinion of the independent evaluator are likely to be examined to determine if it supports another inference contrary to that drawn by the evaluator.

Whenever one seeks to establish the existence of a mental disorder or posit a risk of reoffense, a mental health professional is using observable or verifiable facts to support logical and reasonable inferences. For example, an individual frequently seeks out situations where he will come in contact with prepubescent children and he gives them gifts, takes them on outings, etc. These types of overt behaviors identified in existing records, combined with the person's known history of sexual offenses against children, provide a reasoned, even strong inference that the individual is abnormally interested in the children and is "grooming" them for future sexual activity. This reality makes it necessary for the evaluator to be as clear on these supporting facts as possible.

Given the nature of circumstantial evidence and the importance of careful, grounded inference, the professional interaction between the prosecutor and the independent evaluator is crucial. Whereas, in other commitment proceedings, an evaluator may be comfortable simply "touching base" with the prosecutor prior to being called to the witness stand, that is a likely recipe for disaster in SVP/SDP cases. The earlier the prosecutor and evaluator connect and discuss the case, the better the testimony will go in court. Such interactions allow

the opportunity for the prosecutor and independent evaluator to arrive at the same "wavelength" concerning the nature of the case information and the evaluator's report (including methodology and reasoning) as well as refining the approach to the testimony, discussing how to handle any potentially controversial or likely to be challenged areas in the evaluation analysis, discussing how the opposing attorney and judge usually deal with various issues, etc.). Many times these cases are handled by prosecutors with a diverse caseload, and the SVP/SDP case may well not be a priority for that prosecutor. That reality, in conjunction with the likelihood that a given prosecutor may not appreciate the increasing complexity of these cases, requires that the independent evaluator do whatever is necessary to connect meaningfully with the prosecutor well before the trial commences. If this means that the evaluator must take up "the laboring oar" in communicating with the prosecutor, then so be it. Not fair, but it will likely make the difference between a satisfying experience in court or a frustrating one.

Another reason to grow this relationship is that, from the evaluator's perspective, the prosecutor can be an invaluable source of information. Not only does the prosecutor have subpoena power to obtain documents that might otherwise be difficult or impossible for the evaluator to access, they can also provide additional information from their criminal files that may be of assistance to the evaluator. Specifically, in that the evaluator is likely to be subject of particularized questioning, the prosecutor may, upon availability and request, provide the evaluator with:

- Full access to information from both state and national criminal history indices
- Original police reports from crimes referenced in the criminal history, both sexually related crimes and non-sexually related crimes
- Court documents as to prior convictions
- Preliminary hearing transcripts
- Probation officer reports and presentence investigation reports
- Victim statements
- Psychological reports from prior cases
- Defendant's statements from prior cases (which often differ substantially from statements to the evaluator)
- Other miscellaneous errata from underlying criminal files
- Assistance in obtaining documentation from other prosecution and law enforcement agencies

In most court evaluations, such original source material may not be directly reviewed or available to the evaluator as he or she prepares for court. Experience teaches that in SVP/SDP cases, access to the original material is essential, as cross-examination is much more vigorous than in the typical mental health cases, and the evaluator's credibility to the trier of fact suffers in direct proportion to the lack of preparation done. This, in plain terms, requires that the evaluator be able to testify, often from memory as much as possible, as to the facts supporting his opinions and specifically the sources from where those facts are drawn. Defense counsel in SVP/SDP cases are oftentimes very aggressive in cross-examination, so the level of preparation must be commensurate. This typically requires the evaluator to devote extensive hours both to carefully authoring the report and in preparation for testimony.

Handling the Deposition

Evaluators are frequently deposed prior to trial. A deposition is testimony taken out of court, typically at the office of the attorney who scheduled the deposition, although it may be taken at any mutually agreed-upon location. A court stenographer is present to administer the oath, record the testimony, and transcribe it for use at the trial. The deposed evaluator has the opportunity to review and correct the transcript, although the opposing side can, at the trial, cross-examine and comment on any changes made.

Often accompanying the notice of deposition will be a deposition subpoena, detailing records that the evaluator is required to bring to the deposition. Usually required by the subpoena are all records the evaluator has reviewed in preparation of his or her report and frequently other materials (books, articles, studies, and the like) that the evaluator has specifically relied on in forming his or her opinion. Standard reference materials (e.g., DSM–V) can often be exempted from the subpoena, although it is good practice to ask the attorneys to clarify beforehand exactly what the evaluator is expected to bring to the deposition.

At the deposition, opposing counsel will be exploring the basis for the evaluator's opinions in great detail, encouraging the evaluator to discuss at length the factual basis for their opinions, as well as the theory on which they rely. The evaluator will be asked to lay out everything they are basing their opinion on, usually followed by the question "anything else?" Opposing counsel's intent is to lock the evaluator into specific theories and facts in order to minimize the potential for surprise at trial. It is good practice for an evaluator, at one or more points during the deposition, to make clear that the testimony provided at that time is based on the facts as currently known but that the evaluator recognizes that should additional facts become known, that may affect their opinion.

It is therefore crucial that the evaluator be as prepared for the deposition as for the actual trial. Familiarity with the facts on which the opinions are based, as well as ready knowledge as to the source of those facts, is essential. It is well and good to feel confident in a particular diagnosis, for

example, but if the evaluator cannot readily describe the diagnostic criteria and reference the facts on which it is based (including where those facts came from), the evaluator's testimony will be unpersuasive. The temptation will always be there to give preparation for the deposition short shrift, usually accompanied by mental mantras such as "I know my stuff," "I don't want to prepare this case twice!," "I'll just wing it and then really prepare for trial," etc. This is a formula for failure—your confidence will be shaken at the deposition and your performance at trial will suffer accordingly.

The upside is that, if the evaluator is organized and prepared for the deposition, this will essentially prepare him or her for trial and might well point up some soft spots or problem areas that can be resolved before one finds one's self in front of the jury.

Direct Examination

Essentially, direct examination is the initial portion of the testimony by a witness, independent evaluator, or otherwise. This stage of the testimony is usually a relatively straightforward and noncombative process, where you are examined by the attorney who has called you as a witness in the case. As discussed above, a successful direct examination (i.e., one that proceeds smoothly and communicates your opinions and conclusions clearly and persuasively) begins long before an evaluator actually takes the witness stand.

To convey one's opinions, and the facts that support them, evaluators will need to make note or keep a record as to where those facts are found in your source materials and have them readily available to you in court. Most trial courts allow expert witnesses to refer to written materials, as needed, in order to refresh their recollection. However, this may be a trap for the ill-prepared witness; referring to written materials too often in front of the jury undermines an evaluator's credibility and expertise—they may *accurately* conclude you are not all that familiar with the case and judge the evaluator and their opinion accordingly. Even though an evaluator will have the opportunity to refer to their source materials in court, typically that should be done as little as possible. Again, the necessity of being extremely familiar with source materials, the theory, methods, and substance of the available science makes preparation absolutely key! To obtain the necessary and desired level of preparation entails reading and rereading of the available reports, supporting documentation, and scientific literature to maintain the requisite level of familiarity with the material.

Evaluators will also be well served by preparing succinct answers to generic issues that will arise in virtually every SVP/SDP case. These include a brief definition of each of diagnoses of common sexual disorders and other frequent diagnoses in these cases; these would include definitions or descriptions of paraphilia, pedophilia, exhibitionism, voyeurism, and other paraphilias (e.g., those not specified such as hebephilia and paraphilic coercive disorder as well as personality disorders and substance abuse/dependence disorders). Other clinical terms should be explained such as psychopathy and deviant sexual arousal pattern. Finally, the evaluator should be intimately familiar with legal terms and their definitions specified in relevant SVP/SDP statutes such as predatory, predisposition, volition, volitional impairment, and the standard for "likely" in a particular jurisdiction. It may sound simplistic, but an evaluator will want to practice these sets of definitions until they come very easily. Such additional preparation, in the end, will save the evaluator and the court time as well as make a favorable impression on the jury.

Statutory Elements for SVP/SDP Cases

The current SVP/SDP laws typically have four components (variously described and broken down in the statutes): (1) a history of sexual violence or dangerous sexual behavior; (2) a requisite mental condition (e.g., mental disorder, mental abnormality, personality disorder); (3) the requisite mental condition must "cause" or "predispose" the individual to criminal sexual acts; and (4) likely to recidivate in a sexually dangerous or violent manner. A further constitutional requirement has been imposed by the US Supreme Court—that the individual have "serious difficulty controlling behavior" [Kansas v. Crane 534 U.S. 407, 413 (2002)]. There are individual differences in the statutory elements in across jurisdictions; however, the above components are core to virtually all these statutory schemes.

History of Sexual Violence

Many, but certainly not all, of the SVP/SDP statutes have what may be referred to as "predicate" or "qualifying" prior criminal history of sexual offending (arrests and/or convictions) or, in some cases, unadjudicated sexual offenses which must be proven at trial. Those that do not have such an explicit requirement nevertheless consider the facts from the person's sexual offending history in the areas of mental disorder and risk of reoffense.

Some jurisdictions allow that the testimony of the evaluator may serve as actual proof of the facts of the predicate offenses (see, e.g., *California Welfare & Institutions* Code § 6600(a)(3); *Va. Stats Anno*., § 37.2-906). Most jurisdictions, however, simply provide some sort of guidelines for the evaluation, usually referencing criminal history, institutional history, and risk assessment in general terms.

Sometimes the evaluator is asked to render an opinion as to whether a particular offense qualifies under the statute as a "predicate" offense. This question would be subject to objection as calling for a legal conclusion and beyond the scope of the evaluator's expertise. If there is no objection, and the evaluator is comfortable enough with knowledge of the legal criteria in that jurisdiction, it would seem nominally permissible to answer. An alternative approach would be to state that whether it qualifies is up to the jury but that you'd be glad to testify about the facts of the offense. In some jurisdictions, such as California, it depends upon which judge is handling the case as to whether he or she will allow you to testify to the ultimate fact (or some might say legal conclusion) that this criterion has been met. Some judges regard it as part of the stated protocol and a proper subject of testimony given the evaluator's experience. Others judicial officers may see it as invading the province of the jury and offering a legal conclusion that an evaluator is not qualified to make. Whether or not the evaluator is addressing a "predicate"/"qualifying" offense, or more generally discussing sexual offending history, however, the nature of the testimony is essentially the same. The evaluator must be able to recall and recount the facts of an individual's sexual offense history accurately and be able to locate the source material in his or her file to verify that account, as necessary. Experience suggests that in jury trials, the particulars of the individual's sexual offending history are of substantial significance. It follows that the more detailed and conversant the evaluator is in discussing these offenses, the more persuasive the testimony will be.

Mental Abnormality

The mental condition is variously defined among the jurisdictions. Statutory schemes refer to "mental abnormality," "mental disorder," "diagnosable mental disorder," "personality disorder," "paraphilia," "mental disorder or dysfunction," etc. Almost all of the statutes include language to the effect of "congenital or acquired condition that affects the emotional or volitional (and sometimes cognitive) capacity of the individual. The Federal Sexually Dangerous Person's Statute defines the mental condition collectively as a serious mental illness, abnormality, or disorder. Much has been written in the past decade about the applicability, propriety, validity, and reliability of the diagnostic process in SVP/SDP cases (Miller, Armenta, & Conroy, 2005; Prentky, Janus, & Barbaree, 2006).

It is easy to get caught up in the various diagnostic distinctions and controversies. From a legal perspective, it is important to bear in mind that the law and especially constitutional standards do not necessarily match or "mirror" any particular diagnostic criteria, manuals, or formulations.

The landmark cases in the area are *Kansas v. Hendricks* (1997) 521 U.S. 346 and *Kansas v. Crane* (2002) 534 U.S. 407. In *Hendricks*, the US Supreme Court specifically addressed the need for congruence between legal and clinical formulations:

> Contrary to Hendricks' assertion, the term 'mental illness' is devoid of any talismanic significance. Not only do 'psychiatrists disagree widely and frequently on what constitutes 'mental illness' *Ake v. Oklahoma*, 470 U.S. 68, 81, 105 S.Ct.1087, 1095, 84 L.Ed.2d 53(1985), but the Court itself used a variety of expressions to describe the mental condition of those properly subject to civil commitment. See, e.g. *Addington*, *supra*, at 425–426, 99S.Ct. at 1808–1810 (using the terms 'emotionally disturbed' and 'mentally ill'); *Jackson v. Indiana*, 406 U.S. 715, 732, 727,92 S.Ct. 1845, 1855, 1857–1858, 32 L.Ed.2d 435 (1972) (using the term 'incompetency' and 'insanity'); cf, *Foucha*, 501 U.S., at 88, 112 S.Ct., at 1789–1790 (O'CONNOR, J. concurring in part and concurring in judgment) (acknowledging State's authority to commit a person when there is 'some medical justification for doing so.')
>
> Indeed, we have never required state legislatures to adopt any particular nomenclature in drafting civil commitment statutes. Rather, we have traditionally left to the legislators the task of defining terms of a medical nature that have legal significance. (*citation omitted*) As a consequence, the States have, over the years, developed numerous specialized terms to define metal health concepts. Often, those definitions do not fit precisely with the definitions employed by the medical community. (*Id*., at 359)

Of particular note for our discussion of requisite mental disorders in these proceedings are the comments found in *Hendricks*, supra, Footnote 3, at page 360:

> We recognize, of course, that psychiatric professionals are not in complete harmony in casting pedophilia, or paraphilias in general, as 'mental illnesses.' Compare Brief for American Psychiatric Association as *Amicus Curiae* 22–25. These disagreements, however, do not tie the State's hands in setting the bounds of its civil commitment laws. In fact, It is precisely where such disagreement exists that legislature have been afforded the widest latitude in drafting such statutes. Cf. Jones *v. United States*, 463 U.S. 354, 365, n.13, 103S.Ct. 3043, 3050, n. 13, 77 L.Ed.2d 694 (1983). As we have explained regarding congressional enactments, when a legislature "undertakes to act in areas fraught with medical and scientific uncertainties, legislative options must be especially broad and courts should be cautious not to rewrite legislation. *Id*., at 370, 103 S.Ct., at 3053 (internal quotation marks and citation omitted.)

In *Kansas v. Crane* 534 U.S. 407, 122 S.Ct. 867, 151 L. Ed.2d 856 (2002), the US Supreme Court reversed a decision by the Kansas Supreme Court, which had interpreted *Hendricks*, supra, as "leading to the inescapable conclusion that commitment under the Act is unconstitutional absent a finding that the defendant cannot control his behavior" (in re *Crane*, 269 Kan. 578, 586, 75 P.2d 285, 290 (2000)). However, the US Supreme Court in *Crane* reached another conclusion holding that only "serious difficultly controlling the dangerous behavior" is required constitutionally.

The US Supreme Court pointedly did not revise the legislature's broad powers to define the mental "element" utilized

in the statute. The Court held, inter alia, that these types of statutes are constitutional when:

> …(1) the confinement takes place pursuant to proper procedures and evidentiary safeguards;
>
> (2) there is a finding of dangerousness, either to one's self or to others; and
>
> (3) proof of dangerousness is coupled with the proof of some additional factor, such as mental illness or mental abnormality. (*Id*., at 409–410)

Thus, such language represents the current constitutional threshold. Where does this leave the evaluator as he or she conducts the evaluation and prepares for court testimony?

Given the broad variety of mental components and definitions that are constitutionally permissible, and the inherent independence in clinical assessment, it seems that it remains a function of factually supported assessment of the individual using the specific definition provided by the state's commitment statute. Once again, preparation, ready knowledge, and easy reference to source material are critical.

It is an evaluator's decision as to whether it is or is not necessary to reach a DSM-based diagnosis (or diagnoses) as part of addressing the statutory standard. One can readily see from the above constitutional discussion that either approach, if articulated and factually supported, will pass muster legally. One might even say that the "legal" definition of the mental component is simply some predisposition to commit sexually violent acts and serious difficulty controlling that behavior. This "predisposition" may or may not coincide with any particular psychological or medical diagnosis (see *Hendricks*, supra, 521 U.S. at 359, stating that "legal definitions" of mental illness or mental abnormality "need not mirror those advanced by the medical profession"). Each evaluator must decide how they understand and implement the mental abnormality or disorder requirement for SVP/SDP statutes and the "coupling" (see, *Crane*, supra) of a particular mental disorder or condition with the issues of dangerousness as well as the issue of "volitional impairment."

Many of the SVP statutes reference "volitional impairment." Volition is popularly defined as "an act of making a choice or decision" or "the power of choosing or determining" [Webster's Collegiate Dictionary (Tenth Ed.)]. There is no legal definition of "volition," so it can be a complicated issue to address in an evaluator's opinion and testimony.

One persuasive and integrated approach is to discuss the issue of volitional impairment in terms of "serious difficulty controlling behavior." This has the advantage of relating this construct directly to the requirement imposed constitutionally in *Crane*. Thus, conceiving the issue of control as along a continuum, both in the moment and over the course of time, one can conclude that serious difficulty controlling behavior is the sine qua non of volitional impairment. That is to say, if an evaluator has concluded that, based on all the available data, a person has "serious difficulty controlling his behavior," it must necessarily be that there is significant "volitional impairment." This position also relates to the definition of volition as "the power of choosing or determining" one's action, especially over a span of time.

Oftentimes the issue is framed as follows: "If the individual chooses, each and every time, to commit a sexual assault, isn't he clearly acting volitionally?" The answer may well be that in the short term (i.e., individual decisions) that is a tenable notion, but that after repeated instances, often attended by increasingly severe societal sanctions (i.e., conviction, probation, jail, increasingly lengthy prison sentences) in the long term, the individual *cannot enforce or maintain* a decision not to engage in the offending behavior. As was stated in *People v. Burris* (2002) 102 Cal. App.4th 1096, 1107, discussing volitional impairment: "Certainly a person who does not want to rape, feels remorse after raping, yet continues to rape anyway, 'lacks control.' But a person who *does* want to rape, feels *no* remorse after raping and continues to rape despite having been criminally punished for prior rape, *also* 'lacks control.' This is so because neither offender is likely to be deterred by the risk of criminal punishment; this both should be dealt with civilly" (*emphasis* original).

Thus, rather than getting involved in an exchange about the vagaries of the concept of volition, framing the matter in terms of "serious difficulty controlling behavior" and describing the factual basis for *that* opinion is perhaps the most persuasive approach. Essentially, this is a position that, based on a person's overall life and offending history, the person's "power to choose or determine" is impaired, even though the person may be able to choose *at points* to not offend. Certain jurisdictions have held that "serious difficulty controlling behavior" is satisfied by proof of the statutory elements, including volitional impairment. (See *People v. Williams* (2003) 31 Cal.4th 757, 774.) This would seem to lend support to such an approach. Further, the US Code of Federal Regulations operationally defines "serious difficulty in refraining from sexually violent conduct or child molestation if released" as the following considerations, although the final determination is not limited to these factors:

(a) The person's repeated contact, or attempted contact, with one or more victims of sexually violent conduct or child molestation;
(b) The person's denial of or inability to appreciate the wrongfulness, harmfulness, or likely consequences of engaging or attempting to engage in sexually violent conduct or child molestation;
(c) Established through interviewing and testing of the person or through other risk assessment tools that are relied upon by mental health professionals;

(d) Established by forensic indicators of inability to control conduct, such as:
   1. Offending while under supervision;
   2. Engaging in offense(s) when likely to get caught;
   3. Statement(s) of intent to re-offend; or
   4. Admission of inability to control behavior; or
(e) Indicating successful completion of, or failure to successfully complete, a sex offender treatment program.

Likelihood to Reoffend

Even considering the level of controversy surrounding the diagnostic and volitional issues in the SVP/SDP cases, one has to conclude that the most contentious area has been, is, and will be the area of risk assessment. This is a rapidly developing area in both law and psychology and thus requires the practitioner to be absolutely up to the minute in terms of developments in the field. It seems apparent that the defense bar in SVP/SDP cases shares new developments or concepts, both legal and scientific, within hours and days, not weeks and months. An evaluator can fully expect to be examined on these latest developments at the very next court proceeding. As such, the relationship between the independent evaluator and prosecutor must be ongoing, in order to share and consider how any changes affect the case posture and prepare for new issues of direct and cross-examination.

The area that most concerns independent evaluators in these cases, that of *cross*-examination, is discussed later in this chapter. The discussion here relates to considerations in how to effectively communicate risk assessment opinions and their basis on *direct* examination. These observations assume the evaluator is knowledgeable and current on both law and research in the SVP/SDP arena.

It Is Critically Important to Consider Your Audience Through the jury selection process, most individuals who have any significant background in psychology or statistics will have been excused by one side or the other. Typically, one-third to one-half of the persons who end up sitting on a jury will have no higher than a high school education, if that. In discussing risk assessment, it becomes necessary, therefore, to break down what is fairly nuanced and arcane material into a form they can process. This can be done by the following certain techniques:

1. *Take the time to define your terms as you go*. This relates to the point made earlier about approaching your testimony from the attitude of a *teacher*. Any term that is not in very common usage should be explained in simplified fashion. For example, the term "cross-validated" will mean nothing to virtually any of the jurors. Taking the time to explain what this is, why it is important in research, and why it makes the research results in something they can find credible is very important. The same would be true with "peer review," for instance. One might assume that most people know what "recidivism" means. Not true—at best a few will have a vague idea. Evaluators will need to take the time to define such terms generally, and also how it is used in context. This will help the jurors understand the concepts, the scientific results, and the evaluator's opinion and, at the same time, both help one connect with the jurors and enhance credibility in the jury's eyes.
2. *Use examples from common experience to illustrate difficult concepts*. Earlier, we discussed the example of using the analogy of risk factors for heart disease to illustrate risk factors for sexual reoffense. Taking that analogy a bit further, one might point out that it includes both static and dynamic risk factors. Static ones would include such things as family history of heart disease and prior cardiac events in the patient, and dynamic factors would include such things as weight, diet, smoking habit, stress, etc. Most jurors can readily identify with this type of explanation from everyday experience; the extent that evaluators communicate their opinions in readily understood fashion is the extent to which it will serve to persuade the jury of the correctness of your position.
3. *Do not claim, by attitude or otherwise, to know more than you do*. An attitude on the part of the independent evaluator that he or she "knows everything" is sure death. If the jury decides that's your attitude, they will hold you to it, and any deficiency in your testimony will be used to discount it entirely. Juries are not at all shy about doing this. When appearing as an "expert," it is an easy trap to fall into to assume that you *should* know the answer to a question posed. Defense attorneys can, and do, use this tendency to position an evaluator out on a limb where they have no way to go but down. That is to say, if an evaluator presents as knowing something they really don't, opposing counsel can often sense the change in attitude (perhaps a "whiff" of uncertainty?), and the attorney is likely to drill down until the evaluator is forced to admit that he or she does not truly know what they claimed to know, resulting in a significant hit to the evaluator's credibility. The preventive measure an evaluator should employ is to always be aware of the limits of your knowledge base, both factual and theoretical, and absolutely stay within those bounds throughout testimony. This posture also dovetails appropriately with the previously discussed position that the court case itself is not an evaluator's to "win." The impression an evaluator makes on the jury is wholly different when their attitude is one of an advocate,

as opposed to an informed and prepared professional explaining and supporting their conclusions and the basis for those conclusions.

Now, we turn to issues regarding cross-examination in SVP/SDP cases.

Handling Cross-Examination

Cross-Examination of Experts in Sexually Violent Predator Cases

Preparation by the Independent Evaluator

Black's Law Dictionary defines cross-examination as:

> The examination of a witness upon a trial or hearing, or upon taking a deposition, by the party opposed to the one who produced him, upon his evidence given in chief, to test its truth, to further develop it, or for other purposes. The examination of a witness by a party other than the direct examiner upon a matter that is within the scope of the direct examination of the witness. Generally, the scope of the examination is limited to matters covered in direct examination and matters affecting the credibility of the witness though the court may in its discretion permit inquiry into additional matters as if on direct examination.

The independent evaluator should keep in mind two critical aspects when preparing for cross-examination: the purpose is to "test the truth" of the evaluator's testimony and "raise issues that affect the credibility" of the witness. In short, the opposing attorney's goal in cross-examination is to challenge the evaluator's opinion and its basis, but often by making the evaluator look like they are wrong, to exaggerate any mistakes they may have made and to emphasize what research and professional opinion that does not support the evaluator's opinion. The best way to prepare for cross-examination is for the evaluators to do the same thing they do to prepare for direct examination: ensure that they know the facts of the case, know where in the record to access the particulars, and know what the research says about each point that one has made previously in a report, deposition, or testimony. Preparing an outline with the pertinent facts for each point is usually a good method to have the facts and references handy during your testimony. Also preparing a chronological timeline will allow an evaluator to more easily track the historical facts of the case. Since these SVP/SDP cases often involve lengthy histories of criminal and sexual offending, a timeline can easily refresh one's memory without having to refer back to a report or the available records.

As discussed earlier, the evaluator will also need to know the statute and case law in the particular state where they conduct evaluations, as each of the states have different sexual assault statutes and different evidentiary standards. Including legal definitions in the evaluation provides a quick reference for use in court testimony. The evaluator will be asked by opposing counsel many questions designed to make the evaluator appear as if he or she is unaware of the various legal standards. They may be asked to define each aspect of the statute, notably mental abnormality, personality disorders, volitional control and/or impairment, and any particular legal definitions particular to the state where you are testifying. It is important that the evaluator understand the elements of the various sexual and nonsexual crimes for which the individual has been charged or convicted. For example, if the crime is against a child, one needs to know the legal requirements of the age of the child and the offender. Or, for a crime using physical force, one would need to know the specific definition of the degree of force used. It is the prosecuting attorney's responsibility to make sure that the evaluator is educated as to those aspects of the legal definitions that a case involves, so it is again important for the evaluator to communicate early and often with him or her. Additionally, the prosecuting attorney will usually have a good sense of the direction the opposing counsel will likely be taking with the evaluator and can assist in preparation for cross-examination. Common areas for cross-examination are the age of the individual, the empirical status of sex offender or chemical dependency treatment, low actuarial scores, or a lack of a paraphilia diagnosis.

Meet with the Prosecutor Early in Your Preparation

The prosecutor should be able to answer any legal or factual questions the evaluator might have. The evaluator should be sure to identify any areas of uncertainty in law or fact and discuss it with the prosecutor prior to deposition or testimony. This includes missing factual information, identifying sources of information relied upon, and the scoring of the actuarial instruments. An evaluator will also want to discuss the law with the prosecutor handling the case, to make sure that they understand the particular state law as it applies to the case. This should include the various definitions of sexually violent offenses, the specific definitions of sexual intercourse and penetration, and the ages of consent in the jurisdiction where you are testifying. In many states, the definition of "sexual intercourse" differs, as some require vaginal/penile penetration and others do not. An evaluator will also need to know how relevant the case law is or how the state courts have interpreted the sexually violent predator statute. Ask the prosecutor for copies of the decisions in those cases that will be relevant to the particular case and, as necessary, what their implications are. The US Supreme Court cases dealing with sexual predator statutes have broad application in each jurisdiction, but each state has its own set of nuanced statutory and case law.

In most jurisdictions, the parties will have pretrial motions, called motions in limine, before the presentation of testimony begins. The court will usually rule on the

admissibility of certain pieces of evidence, including the documents and factual issues the independent evaluator relied on as the basis of the opinion. In some instances, facts that the evaluator has relied on may be deemed prejudicial or unreliable and thus excluded from the trial. Consequently, prosecutors and evaluators should both clarify with one another those areas that have been excluded by the judge and/or any topic areas that have been limited or sanitized. For example, many jurisdictions will not allow testimony about the actual results of polygraphs but will admit statements made during polygraph examinations or sexual histories collected as part of that procedure. Some courts will limit evidence of prior criminal charges, particularly if they cannot be proven by a preponderance of the evidence. While on cross-examination, the defense attorney will likely steer clear of areas that are prejudicial to his or her client (e.g., unfavorable polygraphs), there are frequently times when an evaluator's best answer is a fact that has been excluded by the court. Discuss in advance with the prosecutor the best way to handle this situation. The prosecutor may want the evaluator to signal that they are unsure if they can answer a question with particular information so it can be brought to the court's attention before an answer is provided. If this occurs, it will be up to the prosecutor to argue that the door has been opened and that the evaluator should be permitted to testify about a fact previously ruled inadmissible.

The prosecutor can also advise the evaluator as to the most likely issues that will be covered during cross-examination. The prosecutor will be most familiar with the particular defense attorney and his or her cross-examination content and style. Many attorneys will have a different approach during cross-examination than they do during a deposition. If the defense attorney is reasonable and polite during your deposition, it may not be the same manner in which your cross-examination is handled. Depositions and cross-examination have different purposes, and an attorney may affect one demeanor in order to accomplish his or her goals for the deposition but present a completely different style in open court. The prosecutor will also know what the particular pretrial motions involve (see above) and can let the evaluator know what areas of the research the defense is likely to address. For example, if the offender is over 50, you can almost certainly expect to be questioned extensively on age and recidivism data. Alcohol and/or substance abuse issues are also likely to be raised on cross-examination as what issues contributed to the individual reoffending but might have been addressed in treatment while he or she was incarcerated. An evaluator should be prepared to testify about substance abuse treatment, or lack thereof, that the individual has undergone, as well as any related facts pertinent to the issue. In many cases, an offender will assert that he has successfully completed substance abuse treatment and therefore is no longer dangerous—despite previously being "treated" while in custody and relapsing as soon as drugs and alcohol are available.

Paraphilia not otherwise specified (NOS) is a diagnosis given to offenders with deviant sexual arousal to nonconsensual sex or with deviant sexual attraction to peri- or postpubertal children. Because it is not a specified diagnosis and because of perceived issues in the available research, these categories typically receive increased attention; challenges to these diagnoses are inevitable in cross-examination.

It is also fair to expect that the portion of the cross-examination that focuses on risk assessment will be in depth and will involve attempts to show that it is a "numbers game" or an impossible prediction. Given that data suggests that recidivism rates have fallen in the last decade, defense attorneys may try to emphasize that it is impossible to calculate any one individual's risk over the necessary threshold for civil commitment. In addition, many defense attorneys incorrectly label risk assessment as risk predictions and will try to persuade the jury that no one is able to predict the future. It is important to clarify that you are not attempting to make predictions, and explain the purpose of and limitations of risk assessment. Be sure to correct the attorney if they are using the term prediction in lieu of risk assessment.

The evaluator will need to emphasize those facts in the individual's history that indicate why they believe the individual falls into the higher-risk category. The same factors that indicate serious difficulty controlling behavior are often related and therefore valuable in this effort. Many of the points the defense attorney may try to make are areas that jurors will be interested in as well. For example, the defense will emphasize the length of time the individual has been incarcerated, thus attempting to show that he has either changed or it has been too long since he has been in the community to say how he would act if released. Around these issues, an evaluator may emphasize that the type of mental disorders which characterize a particular offender tend to be chronic and do not go away just because an individual has been in confinement. Nor is the way an individual performs in a secure facility a good indication of how they will behave with no restrictions, supervision, and an available victim pool.

Most of the qualities that make the evaluator effective on direct examination apply equally for cross-examination. An evaluator should appear confident in their opinion and the basis for that opinion. Knowing the facts "backward and forward" will assist in giving the appearance of confidence. Independent evaluators must be familiar with the range and depth of relevant scientific literature, including research that has been published after you completed your evaluation. Techniques used to access and remember facts of the case during direct examination will serve the same purpose in cross-examination such as creating an outline with the statutory elements and all the facts that support your opinion

regarding that element and making a timeline. If Bates' stamping is used in the jurisdiction, use the Bates number in your outline for easy reference to the factual basis for your opinion. Preparing for cross-examination requires many additional hours of preparation in advance, to rereview both general and case-specific issues, to prepare and review outlines and timelines that will aid you in the delivery of your testimony, and to be able to respond to particular case issues and likely points to be made in cross-examination.

It is important to make every effort to ensure that there are no mistakes in the evaluator's report, either factually, legally, or in the application of the research. If an evaluator somehow overlooked a mistake and a report has been produced, bring it to the attention of the prosecutor to ensure that the error can be addressed in direct examination; also they should be prepared to address it again in cross-examination. The defense attorney's objective is to make the evaluator look like they have made an error in their opinion, and any errors in the report will be used to support this theory. The evaluator should not be defensive about a mistake but rather take ownership of it and make the point that it would not affect your opinion.

The defense attorney will try to get the independent evaluator to agree with incorrect statements of law, fact, and science. The evaluator must think and carefully consider these suggestions or intimations from the defense and clarify and counter incorrect statements. The evaluator will need to correct any misstatements, as to what your understanding of your task is—"I am not predicting whether he will or will not offend, I am simply determining whether or not he is more likely than not." or "I am merely determining whether his risk level is higher than 50 %." It is also a common tactic to simply misstate some aspect of the science—for example, giving a false recidivism rate in a particular study or making false claims about the applicability of instruments like the PCL-R (e.g., Hare, 2003). The evaluator should listen carefully to such questions and make sure there are no false inferences in your answer. This can be difficult when testimony is lengthy and the expert may be fatigued. However, it is critical for the evaluator to listen carefully and to correct even the simplest of misstatements before you answer. There is a fine line between being argumentative and corrective, especially if the defense attorney becomes aggressive. But evaluators should remember that they are professionals, despite the adversarial environment, and that explaining the correct application and interpretation of the science is critical.

In cross-examination defense attorneys may refer to books, journal articles, depositions, prior court testimony, and clinical information. It is perfectly acceptable, indeed desirable, to ask for a copy of whatever documents the defense attorney is referring to. Whether it is a journal article or a document from the discovery, the evaluator should not agree with it until one has been shown a copy and had sufficient time to review the document relative to the question being asked. Defense attorneys will try to get the evaluator to agree with things they are holding in their hands, but an evaluator is entitled to review it before responding. Consequently, the evaluator should take their time to carefully review the material of concern before answering, particularly if it is a study with which they are not familiar. If a resource is outdated or pertains to a population that is not comparable to sexual predators, this is important information for the jury to hear. It is the evaluator's role on cross-examination to explain why they did not rely on a particular study or concept or why it does or does not have a bearing on your ultimate opinion. Sometimes the documents, particularly journal articles, are lengthy to review and the evaluator may be asked to review the material at lunch or overnight and offer their opinion at a later time. During trial, in addition to their own anticipated preparations, evaluators should expect to spend additional time out of court reviewing unexpected material.

Obviously, the evaluator's experience and expertise relative to the SVP/SDP cases and the relevant assessment, scientific, and psycholegal issues is the primary reason why they were selected to be assigned to the case. Deep and comprehensive familiarity and comfort with the relevant science is essential so that an evaluator can convey their opinion clearly, articulately, and accurately. Uncertainty about any of the topics may cast a shadow on your opinion and ultimately jeopardize the case. Such areas are ones a defense attorney will try to exploit. As discussed earlier, it is essential that the evaluator fully understand all of the legal constructs that bear on SVP/SDP cases in particular jurisdictions and the relevant and extensive and evolving science. When discussing risk assessment protocols, the evaluator should take the time to explain the difference between actuarial assessments, structured professional judgment, and empirically based clinical assessments. The evaluator should explain how the different methods of risk assessment overlap and interact and the basis for choosing the method(s) you employ. In addition, one should be able to explain the difference between static and dynamic risk factors and how that body of research applies to the particular case. Two of the favorite topics of defense attorneys in risk assessment are the effects on sex-offense recidivism of both treatment participation and the age of the offender. Obviously, the research on these two areas is mixed and ongoing, so it becomes important to clarify the evolving and conflicted nature of those areas for the jury.

Overall, the general sexual recidivism rates appear lower than previously measured. The use of actuarial assessments alone may not adequately address the risk posed by mentally disordered offenders who have difficulty controlling their behavior. It is imperative that the evaluator address the specific characteristics of this individual and clearly relate why he appears likely to reoffend. For example, an individual

may have only been caught and convicted one time but admits to a lifetime of sexual offending that is not captured by any of the actuarials. Or, an older offender who scores lower on the actuarial as a result of advancing age may readily admit that he is still sexually active and attracted exclusively to children. These factors specific to the individual are critical points to be made when the defense challenges your opinion that the individual is likely to reoffend.

In summary, during cross-examination, you should:

Stay within one's area of expertise and training. The evaluator should not offer professional or medical opinions if they are not qualified and they should not offer legal opinions. An evaluator is the psychological expert offering an opinion regarding diagnosis and risk assessment.

Refer to specific factual bases for your opinions. For every diagnosis and risk assessment opinion offered in either a report or testimony, the evaluator should have multiple factual bases to support it and be able to document those bases in their testimony.

Maintain a calm and confident demeanor. The evaluator doesn't need to argue with the defense attorney and should concede the points that are appropriate to concede. However, an evaluator should not agree with factual, legal, or scientific points that are incorrect.

Communicate clearly in language and terms the jury can understand. The evaluator must be able to translate "psychological speak" into plain language. In addition, he or she should avoid appearing arrogant and "above" the average juror. It is important for the evaluator to know the difference between being knowledgeable and being a know-it-all.

Know all the facts of the particular case. The evaluator must master the facts of a case, good and bad. This is the most essential factor in delivering solid testimony. Any errors in facts will likely be exploited by a defense attorney and held against you by the jury.

Conclusion

As this discussion makes abundantly clear, trial in SVP/SDP cases requires the best from the evaluator, in terms of education, training, preparation, poise, and presentation; civil commitment proceedings of sexual offenders are much more complex and challenging than the typical mental health court proceeding entails. Hopefully, some of the comments and observations shared here will help to motivate, equip, and guide the professionals undertaking this task through this oftentimes demanding and difficult process.

Given that both public safety and fundamental liberty interests are significantly impacted and this area remains a controversial one for involuntary civil commitment, it is incumbent on both prosecutors and the independent evaluators called as their witnesses to be very well prepared relative to the facts, the science, the theories, the general issues, and the case-specific issues. It takes a substantial amount of time, effort, and willingness to focus on the necessary breadth and detail of extensive material, issues, and science to adequately prepare quality reports and adequately prepare for depositions and testimony.

Sexually Violent Predator Law: A Defense Perspective

Leslie J. Garrison

Lost causes are the only ones worth fighting for.

Clarence Darrow

Sex offenders are the modern-day lepers. They are arguably the most despised and feared people in the country, beating out even murderers as the most hated group. But demonization of these criminals leads to even bigger problems: too much vitriol and venom often overwhelm our ability to accurately perceive the facts at hand.

Sex offenders not only scare us, but they baffle us. We wonder: How could the perpetrator do this again and again and still be human? Isn't the nature of being human marked by the ability to control one's sexual urges toward others, an ability lacking or simply disregarded in this population? And here is where the logic can leap into dangerous territory, because the next step is that one can be led to believe that an individual cannot commit a sex offense and still be human. And if we begin to believe that a perpetrator is not human, then what is he? Unfortunately, most of us come to the conclusion that sex offenders are monsters, unworthy of the allocation of any meaningful societal resources designed to recognize them as human beings.

Society has always reserved the right to punish those who refuse to follow the rules. However, we have legal rules in place to guard against the potential for abuse inherent in any criminal justice system. Our Constitution and ensuing criminal laws recognize that the deprivation of liberty requires heightened procedural protections. For example, someone charged with a crime is presumed innocent and has the right to remain silent, the right to confront witnesses who testify against him/her, and the exclusion of hearsay testimony at trial. In addition, the State's burden of proof in a criminal case is a high one: beyond a reasonable doubt.

On the other hand, most States also have civil commitment laws aimed at detaining the mentally ill or inebriate who is gravely disabled, a harm to themselves, or a harm to others. One of the most striking features of any of the current sexually violent predator laws is the degree to which the line between punishment and treatment has been blurred. No other specific category of crime warrants a stand-alone civil commitment law. And when a sex offender has completed his imposed punishment for the crime, his liberty interests are afforded few, if any, of the protections reserved for those accused of a crime.

The crux of every problem one encounters with civil commitment of sexual offenders as it currently exists is that almost all of the issues involving the current state of sexually violent predator civil commitment of sex offenders are clouded by the notion that sex offenders are less than human or that different standards should apply to them given the nature of their crime.

In the following chapter, the reader will be given a tour of the sex offender civil commitment process from the defense perspective—with an effort to encompass both the attorney and client viewpoint. We will discuss the initial evaluation to commitment and beyond, shedding light on how the demonization of the sex offender affects every step of the civil commitment process.

Client's Initial Evaluation

There are two ways a sex offender in Washington (and most other jurisdictions) can find himself in the maze of the sexually violent predator law. The first is directly from prison when his criminal sentence is about to expire. The other is after he has been released and alleged to have committed a "recent overt act." This discussion focuses primarily on civil detention directly out of prison. However, once the arrest has occurred, the process remains the same.

With special thanks to Gerald Gregory.

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_36

When the sex offender's prison release date is a few months off, often unbeknownst to the offender, the prison bureaucracy begins the process of reviewing his file for assessment as a sexually violent predator. As part of this initial review, the State looks at the offender's criminal history; prison behavior; treatment records; court documents, including police reports and victim statements; and his proposed release plan. Once prison personnel determine that the individual warrants further evaluation for possible civil commitment, the State employs its psychologist (or, in rare cases, its psychiatrist) to evaluate whether the person meets the statutory criteria as a sexually violent predator.

Similar to other states with such statutes, Washington State (the first State to enact this law in 1990) defines a "sexually violent predator" (SVP) as any person convicted *or charged* with a crime of sexual violence who suffers from a mental abnormality or personality disorder which makes the person likely to engage in predatory acts of sexual violence if not confined in a secure facility (RCW 71.09.020 (18)). "Predatory" acts are those directed toward strangers and individuals with whom a relationship has been established or promoted for the primary purpose of victimization or persons of casual acquaintance with whom no substantial personal relationship exists. RCW 71.09.020 (10). In Washington State, and those States with the "predatory" requirement, incest offenders do not qualify for civil commitment under this statute, no matter how prolific their offending, unless at least one of their crimes fits the "predatory" definition.[1]

Prior to the expert conducting an SVP evaluation, a correctional employee typically tells the inmate that the authorities have decided to review his case for possible civil commitment and ask him whether he'll agree to meet with the evaluator. The inmate usually has very little notice or an opportunity to consult with an attorney prior to making this crucial decision.

The initial forensic evaluation itself is like no other in our judicial system, and its impact on the inmate's life cannot be overstated: it may lead the individual to serve what is tantamount to a life sentence of detention. Washington law allows probable cause to be found based on the individual's record and a single professional's opinion that the person is more likely than not to commit a predatory crime of sexual violence sometime in the future if he's not locked up. In contrast, in California, it requires two to four evaluators to establish probable cause. This opinion is admissible even if the inmate declined to participate in the forensic interview; the evaluator simply renders an opinion based solely on a records review.

In Washington and some other jurisdictions, there is no requirement that the evaluator begin the review process with the presumption that the person does not meet the commitment criteria; given the weeding-out process of potential candidates for civil commitment, it appears likely that the opposite may be true. In an initial SVP evaluation, whether a forensic interview is conducted or not, the evaluator's focus is primarily on the individual's past conduct and static risk factors. Factors that should be considered include treatment, age, increased education, and community support. It is an open question whether such preliminary evaluations are truly unbiased.

The standard practice of forensic psychologists conducting civil commitment evaluations of prison inmates unrepresented by counsel is arguably in violation of the ethical standards of the profession. The Specialty Guidelines for Forensic Psychologists' states:

> Forensic psychologists do not provide professional forensic services to a defendant or to any party in, or in contemplation of, a legal proceeding prior to that individual's representation by counsel, except for persons judicially determined, where appropriate, to be handling their representation *pro se*…(Committee on Ethical Guidelines for Forensic Psychologists)

State evaluators may wish to consider whether they "run the risk of becoming inadvertently complicitous in a [civil commitment] system that promises far more than it delivers in the protection of individual rights and at its worst represents a return to warehousing a class of individuals" (Petrila, 2008, p. 361).

There is no right to court-appointed counsel during this preliminary evaluation and screening process. Few, if any, inmates have the resources to hire an attorney. If an inmate can consult an attorney knowledgeable in this field prior to the evaluation, he will have the opportunity to understand and discuss the law. He will learn what kind of information the evaluator may find useful, such as details about his prior treatment, including his dynamic risk factors and relapse prevention plan and his specific release plan. The individual can refer the evaluator to collateral resources who offer information that may make a difference when determining whether someone meets the criteria of the law upon release.

If the evaluator finds the person does *not* meet the criteria for civil commitment, the State will do one of the two things: allow for the release of the person through the prison system or retain another expert for a second opinion. (In California, the statute always requires a second opinion.) If the second evaluator agrees that the person does not meet the criteria, then the State will not file a petition for civil commitment. However, in some prison systems, Washington State included, the fact that the person was considered for civil commitment may delay the process of release from prison.

[1] In states without the predatory qualifier, incest offenders are subject to commitment; in most states with predatory language, incest offenders can and are committed because some of their crimes fall within the predatory definition. Also research indicates that a significant portion of intrafamilial offenders also has extrafamilial victims.

If the evaluator determines that the offender meets the civil commitment criteria, the State will file an ex parte petition (a petition filed without notice to the defense) for an order of an initial finding of probable cause that the person is a sexually violent predator and a warrant for his arrest from prison. The ex parte nature of the petition is analogous to the criminal system where the State can file charges without notice to an alleged offender and send law enforcement out to arrest the accused. Once the court signs the order, the inmate is taken into custody while still in prison, handcuffed, and transported to the county jail located in the jurisdiction of his most recent conviction for a sex offense. Upon booking such inmates into the local jail, the jail personnel are alerted that a "sexually violent predator hold" is on the inmate. This may impact jail placement and treatment by jail staff, meaning that the inmate may find himself in protective custody to prevent him from being hurt by other inmates. Within hours, the detainee meets his new lawyer(s), who come to introduce themselves and begin the lengthy process of representing his interests, a process which will likely go on for many years.

Within 72 h of arrest, exclusive of weekends and holidays, the statute provides that the person receive notice of their right to appear and contest the ex parte finding of probable cause. Within 24 h after filing, the prosecuting agency must provide a complete copy of the discovery to the defense. In contrast to the months the State had to prepare for this hearing, under the statute, the defense has a maximum of 3 days to review potentially thousands of pages of records and prepare to challenge the State's expert's opinion. The respondent can waive his right to a speedy hearing to prepare; however, that will prolong his stay in a local jail and is unlikely to change the outcome at the probable cause appearance; the respondent can contest the initial probable cause finding that was made just days earlier by the same judge [RCW 71.09.040 (2)]. Recently, in an effort to cut costs, the Washington statute was amended to prohibit the parties from conducting legal discovery prior to the hearing contesting probable cause.

Once the court affirms the prior finding of probable cause (an outcome that is all but certain, given the fact that the same judge has already made that finding—see above), the respondent has the right to a trial within 45 days. Jurisdictions may vary, and the average time between arrest and trial ranges from a matter of months to over a year. In some jurisdictions, the presumption is community-based treatment. In most jurisdictions, detention in a maximum security treatment facility is the norm.

Upon arrival at the treatment facility, the resident is processed through intake, given the option to enroll in treatment pending a commitment trial, and advised that "everything you say and do will be used against you." Many residents are greeted by others with whom they served time in prison and quickly learn that hopelessness is pervasive among the residents in the institution.

An Important Decision Pretrial: Treatment or No Treatment?

One of the most important decisions the detainee faces in the detention facility is whether or not to participate in treatment. Prior to treatment at the detention facility, he must sign paperwork which informs him in no uncertain terms that everything he says and does in that facility, including every facet of his treatment participation, can be used as evidence against him in his upcoming commitment trial. It is in this double-edged context that he is offered treatment for the very conditions that the State must prove exist at the commitment trial in order to commit him—most typically antisocial personality disorder (a disorder that has been diagnosed in approximately 80 % of a given prison population); substance abuse or dependence combined with some sort of a paraphilic disorder, usually otherwise specified paraphilic disorder (OSPD); and/or pedophilic disorder.

The resident is faced with what we view as a Hobson's choice (a choice in which only one option is offered): agree to enter into treatment and have his statements and assignments open to negative interpretation by the State's expert, his treatment providers, and the jury or decline to enter into treatment and have *that* decision used against him in trial. The treatment offered in Washington State is the same in both pretrial and posttrial. And similarly, what the State learns for treatment participation can be used against the detainee in a future commitment trial or release trial.

Treatment programs vary across the county. There is a broad range of experience among treatment providers, and presently there are no approved standards or a national model for running sex offender civil commitment detention treatment programs. Consequently, each State can revamp their program independent of the statutory criteria that was used to commit the person. When a new treatment protocol is introduced, often residents are required to restart the treatment program from the beginning. This leads to the almost ubiquitous perception that the treatment providers keep "moving the goal post" and thus prevent participants from advancing in ways they had at some point been led to expect. Staff turnover remains high, and the offender must start over with a new provider. Another reason is that very few treatment participants have been released. The International Association for the Treatment of Sexual Offenders (IATSO) sets forth Standards of Care for the Treatment of Adult Sex Offenders. The ninth Principle of the Standards of Care set forth by IATSO states, "Professionals who work with sexual offenders should be prepared to work with the criminal justice system in a professional and cooperative manner." [The International Association for the Treatment of Sexual Offenders (IATSO). Standards of Care for the Treatment of Adult Sex Offenders (emphasis added). http://www.iatso.org/care/ Standards%20of%20Care.pdf.] Indeed, this

principle seems basic and fundamental to a process in which all stakeholders share the same statutorily defined goal: the resident's safe release back into the community. The lack of cooperation with the legal process can be interpreted in such a way as to suggest the uncooperative party follows a different agenda. When professionals running a treatment facility give short shrift to the legal criteria governing whether a resident should be released to a less restrictive alternative (LRA) or released unconditionally, they adopt an approach that is counterproductive and violate internationally established principles of the treatment of sexual offenders. Trial courts vary on the admissibility of someone's participation in treatment during trial. If the prosecutor can argue that the respondent has "refused treatment" while awaiting trial, he/she may elicit from the State's expert that the individual's refusal to "take advantage" of treatment is a red flag, an indicator that the respondent has no insight into his various maladies or chooses not to address the very mental abnormality and/or personality disorder that the jury is impaneled to decide even exists.

Meanwhile, the man whose fate is hanging in the balance of all this is sitting there at the counsel table listening in disbelief. *This* is how the State is going to lock him up for life. It is exactly this kind of "damned if you do, damned if you don't" routine that leads many facing SVP commitment trials to think that the deck has been stacked against them. Combine the lack of confidentiality facing the respondent making the treatment choice, and it is easy to see why treatment is not a viable option prior to trial in the majority of the cases. Harry we need to change this paragraph or omit it. I say omit it.

Most jurisdiction's statutes require that the offender is *more likely than not* to reoffend. Treatment facilities are reluctant to release someone they find may be only 30 % likely to reoffend instead of the statutorily required 51 %. In addition, in Washington State, the issue before the court for release to an LRA is whether conditions can be imposed on the individual of concern that adequately protect the community and are in the best interests of the respondent. An LRA assumes the risk for re-offense is higher than 51 % without release conditions in place and requires the court to turn its attention to community management.

The two most significant events facing a respondent whose trial is imminent are the pretrial forensic evaluation, and, in Washington State, where there is no right to silence, being deposed by the prosecutor. Typically, the former occurs first, so the prosecutor has additional information to use in the deposition.

The Forensic Evaluation

How might a detainee perceive the evaluation? The major advantage a respondent has concerning the pretrial evaluation that he didn't have in the pre-probable cause evaluation that preceded his release from prison is the opportunity to confer with counsel. (Some might say that it is the major *disadvantage*.) Unlike the prison evaluation, when the prisoner had no one to advise him beforehand about what to expect, this time, an experienced attorney will be there to fill him in on details of the process and to educate him on what the expert will likely focus on during the interview.

The conundrum surrounding this entire process is this: in Washington State, the respondent is required by law to cooperate with the evaluation, and if he refuses, he faces being found in contempt of court and detained until such time as he complies with the court order (RCW 71.09.040: Washington Administrative Code 388-880-035—Refusal to participate in pretrial evaluation.) Other jurisdictions, like in California or Minnesota, allow the respondent to refuse to participate in the pretrial direct evaluation.

In typical civil cases, the litigant is compelled to participate in a professional evaluation once they have involved themselves in the legal system: for example, the employee who brings a harassment suit against an employer or a car accident victim suing the insurance company. In those cases, the adverse party is the *defendant*, not both the plaintiff and the government. Similarly, in a criminal case, the only time the court can compel an evaluation is if the *defendant* raises an affirmative defense such as insanity.

In an SVP proceeding, the forensic interview cannot always be considered voluntary. Moreover, one shouldn't overlook the impact on the respondent's attitude and emotional response to the prospect of submitting to a direct evaluation with the forensic psychologist who *has already made a prior determination that he meets commitment criteria.* Since even the most cognitively impaired and uneducated inmate intuitively understands that one cannot prove a negative, what should the detainee expect from such an encounter? A few questions come to mind. If the psychologist has interviewed the inmate in prison, why would a second interview change anything? And if the inmate declined to participate in the interview out of a healthy and well-founded Darwinian instinct for self-preservation, what foreboding of doom might accompany his thoughts during a coerced interview? Moreover, what of the standard practice of forensic psychologists, namely, to be wary of relying on an offender's self-report? From the defense perspective, it certainly appears that little good can come out of these pretrial evaluations, no matter what the client has to say or how he says it; the expert is unlikely to change his/her opinion and instead illicit factual details to bolster his/her existing opinion.

Court Ordered Penile Plethysmographs and Polygraphs Pretrial

The use of a penile plethysmograph (PPG) to measure an individual's arousal to various sexual stimuli has been used in the treatment of many sex offenders. A patient's arousal is

measured through different stages of treatment to determine how well the interventions learned in treatment are working to counter the patient's deviant arousal. Polygraphs are routinely employed by community corrections officers to determine whether an offender has falsely reported his adherence to release conditions and by treatment providers to find out whether PPG results are valid (i.e., whether arousal interventions were used by the patient when they shouldn't have been.) In select states, including Washington, respondents can be court mandated to participate in both PPG and polygraphs as part of the pretrial evaluations.

The Pretrial Deposition

In Washington State, in spite of the fact that SVP proceedings may result in a life sentence for the detainee, he does not have the right to remain silent as he would in any other proceeding where his liberty is at stake. There is not much more to say; in SVP cases, prosecutors relish the opportunity to question the respondent under oath about anything and everything except privileged communications with his lawyer. This is almost always the first time in his history the respondent has had to answer under oath directly to the prosecutor not just about his crimes, but about everything in his life.

The detainee's experience of this process is not insignificant and is worth mentioning. He is forced to answer questions under oath posed to him by the same prosecutor who is determined to do everything he or she can do to see to it that he is detained indefinitely for behavior he *might* engage in the future. The significance of the deposition for the forensic psychologist's opinion is often minimal, except, insofar as the deposition may reveal heretofore unknown details about the detainee's life, offense history, or the respondent provides different or conflicting information during his deposition than he did during the forensic evaluation.

Trial: The Crucible

The Washington SVP statute gives the respondent, the State, and the judge the right to demand a jury trial. If both parties and the judge agree, the respondent can have a bench trial—a trial in which the judge is the sole fact finder. Such trials are a rarity; the State likes juries because the average citizens that comprise juries are highly likely to want to commit a respondent the moment they hear about the terrible crimes he's committed. Defense lawyers often prefer taking a chance with juries rather than subject the client's future to a judge whose reelection chances would diminish dramatically if he were to release a sex offender in a predator case.

Selecting a panel of truly unbiased jurors in an SVP case is extremely difficult and requires a great deal of time in voir dire (the process by which prospective jurors are questioned about their backgrounds and potential biases before being selected to sit on a jury); the goal of voir dire is to identify prospective jurors whose biases may prevent them from remaining impartial. During voir dire, a potential juror will often express horror at the prospect of a repeat sex offender being released from custody. But that same juror, when questioned by the judge or prosecutor, will just as often assure the parties that he/she can comply with the court's directive to "apply the law to the facts that the juror finds to be true and accept the law as the court gives it, regardless of what the juror personally believes the law is or what they think it ought to be" (WPIC 365.01—Washington Pattern Jury Instructions: Civil, No. 365.01). Defense lawyers typically believe that courts do not provide sufficient time to identify biased jurors, particularly in cases involving pedophiles. In rare instances, courts grant the parties enough time to pick an impartial jury. Commitment is the norm following a jury trial. Research shows that the public perception about sex offenders is that the vast majority will reoffend. An interesting study would be one in which results in SVP cases were matched with time allotted by the respective courts for voir dire. It would not be surprising to discover a correlation between the very rare cases won by the defense and the amount of time granted by the court for voir dire in those cases.

The standard of proof for continued detention in the twenty States that have enacted civil commitment laws for sex offenders varies and includes "more likely than not"; "highly likely"; "clear, cogent, and convincing"; and "beyond a reasonable doubt." During the SVP trial, the State has the burden of proof and calls its witnesses first. It is during this phase that the victims, law enforcement, treatment providers, and evaluating experts testify. Unlike in a criminal case where the defendant also faces confinement, the respondent does not have the right to remain silent, and the State can call him as a witness during their case in chief or during rebuttal. The respondent's attorney can cross-examine all of the State's witnesses, including the victims. Typically, there is rarely an issue with respect to a victim's version of the sexual assault (and thus no necessity for the victim to testify), and defense lawyers almost never question victims.

The State's expert is permitted to testify about facts that they considered in forming his/her opinion, even if the underlying facts are not themselves admissible as evidence. One would expect, given that involuntary civil commitment entails a "massive curtailment of liberty," (*In re the Detention of LaBelle,* 107 Wash.2d 196, 201, 1986)) that experts would observe the highest professional and ethical standards in their deposition and trial testimony. Unfortunately, this is not

always the case. Part of the problem lies with the courts themselves. Judges in sexually violent predator proceedings can sometimes have a "let's just get this over with" attitude and as a result "often exercise comparatively lax supervision in managing the admissibility of evidence of future dangerousness, and may characterize such evidence as more scientifically based than it is" (Petrila, 2008). This approach by the court leaves the issue of scientific rigor and integrity up to the experts. "In the absence of aggressive judicial gate keeping, mental health professionals serving as experts must police themselves" (Petrila, 2008, p. 261).

It is in this venue that the state's expert can enhance his/her credibility by acknowledging the controversy that surrounds some aspects of the SVP law, such as the fact that some experts disagree that the diagnosis of "otherwise specified paraphilic disorder (OSPD)" is appropriate for an adult rapist. Psychology and psychiatry are not fields known for empirical testing as are chemistry or physics. State experts should acknowledge the inherent difficulty predicting *anyone's* future behavior, let alone the person in the courtroom. Rarely during direct testimony does the state expert point out that the actuarial tools used in their assessment don't predict any one individual's risk, but rather the risk of a group of individuals with similar characteristics as the person on trial.

In a typical SVP trial, the respondent may present his own witnesses, including family members, community support people, treatment providers, and prison personnel, in addition to their own retained expert. Family members often are able to testify to the changes the offender has made since he committed his last crime. Prison personnel can testify to the respondent's compliance with rules, gainful employment, and pro-social activities. Prison treatment providers can testify to treatment gains and, if the offender developed a comprehensive relapse, prevention plan and his ability to implement the plan. The respondent's defense team can help the individual find community resources on release, including acceptable housing, sex offender and substance abuse treatment providers, spiritual support, vocational resources, and employment. Unfortunately, what a respondent's release plan looked like prior to the State filing the SVP petition may have become obsolete due to the significant passage of time. Many offenders during their incarceration establish pro-social ties with the community through religious or recovery groups, and these community connections can be vital for the offender's success if released to the community.

At the close of all the testimony and following deliberations, the judge reads the jury instructions to the jury and sends them off to deliberate. The verdict form requires nothing more from the jury's foreman than that he or she checks a box indicating whether the State has met its burden of proving beyond a reasonable doubt that the respondent is a sexually violent predator. If the jury finds the State has not met its burden, the offender is released to the community to begin implementing his new release plan or, in the worst-case scenario, to pick up the pieces of whatever might be left from his original release plan. If the jury finds the State met its burden, the offender is committed. Orders of commitment in most jurisdictions result in indefinite commitment and can be analogous to a life sentence. Budget cuts in many jurisdictions have resulted in an increase in those unconditionally released and released to community-based treatment (statutorily required annual reviews notwithstanding). In contrast, traditional civil commitment laws detain a person for a finite period of time. In Washington State, in SVP proceedings, with one judicial signature, the person is committed to a secure State facility for control, care, and treatment until such time as "[t]he person's condition has so changed that the person no longer meets the definition of a SVP or conditional release to a less restrictive alternative (LRA) is in the best interest of the person and conditions can be imposed that would adequately protect the community" (source, p. #) (RCW 71.09.090.) If the jury fails to reach a verdict, the court declares a mistrial, and the respondent is sent back into custody to await a retrial.

Posttrial Commitment

Life at a commitment center after trial differs very little, if at all, from pretrial detention unless the offender decides to participate in treatment.

In many facilities, the treatment becomes secondary to detainment. This is particularly true when the institution chooses to disregard the legal criteria for release, prolonging treatment unnecessarily or detaining offenders when they are infirm, have completed all of the treatment offered, or have refused formal treatment offered by the institution but sought treatment on their own. This practice severely undermines the credibility of the treatment program and thus its effectiveness among the treatment participants and its viability for *prospective* treatment participants. Treatment participation may increase if the institutions fostered an attitude of treatment with the goal of release instead of indefinite incarceration that offers treatment. This would involve continuity in treatment providers, a treatment program with discernible goals and a discharge planner actively assisting the person in creating a safe living environment outside of the institution—as is done in traditional civil commitment proceedings.

An example of why the program is considered by many inmates to be a means to keep them detained indefinitely is useful to consider. A resident who participates in treatment has an expert who finds he no longer meets the commitment criteria. The prosecutor's expert even agrees. However, the treatment team at the institution disagrees with the proposed release for reasons which appear amorphous and elusive

(e.g., he needs to be more "transparent"; he needs to "internalize" the treatment principles). Release is stalled and word travels fast within the institution. As a result of the treatment team disregarding the legal criteria set forth for release, trust breaks down, not just with that individual, but throughout the institution.

Systemic obstructions notwithstanding, successful participation in treatment will lead to community transition. Offenders who are released on an LRA, as in Washington, remain under court supervision and are required to cooperate with intensive community management. Release typically requires community chaperones, GPS monitoring, restrictions placed on movement in the community, weekly treatment appointments, and meetings with a parole officer.

Many issues confront a sexual offender on conditional release to the community. Often, prior to release, the media take notice. When the offender has a spouse or other family members willing to take on public condemnation, the release may happen sooner than it would for someone lacking such resources. Due to public pressure, few landlords are willing to rent to high-profile sex offenders, and without available housing, there is no release from a State institution. Once in the community, under strict release conditions, the public scrutiny remains intense. The offender has a very low likelihood of finding a job unless they have connections in the workforce. The treatment provider or community corrections office must agree to reduce conditions of supervision such that the person can work.

Obtaining *unconditional* release through the treatment process is rare barring old age and infirmity or decades of treatment. The State's view, if a person is doing well on release conditions, is often "if it's not broken, why fix it," i.e., if the individual does fine on release conditions, why reduce them?

Conclusion

The sexually violent predator laws are here to stay. As States increase prison sentences for convicted sex offenders at the time of sentencing, the number of people detained by these laws may decrease. It may also come to pass that State budget cuts will mandate the amount of resources governments are willing to spend on preventive detention.

The expert plays a pivotal role in every sexually violent predator proceeding. The methodology and acceptance of risk assessment of sex offenders have grown tremendously in 20 years. As the field of sex offender risk assessment grows, so should the awareness that a person's liberty interest is at stake. The rules that we create for sex offenders can and will spill over to affect the lives and liberties of others in the penal system and ultimately, to the innocent and average people who live outside the prison walls, putting everyone's rights and freedoms at risk.

Twenty years ago, the first experts to evaluate men under Washington's new SVP law were acutely aware that they were covering new ground that rendering an opinion that a person should be detained for something they *might* do was significant, and they should proceed delicately with the utmost caution. Since then, in our opinion, a new generation of professionals has emerged whose familiarity with this law may cause them to inappropriately place undue confidence in their role as an evaluator. More statistical data and research that examine what impact, if any, the sexually violent predator laws have on community safety are needed. It is also an area of the law that requires the utmost integrity from the forensic professionals who hold the key to an individual's freedom.

Reconciling Sexual Offender Management Policy, Research, and Practice

Christopher Lobanov-Rostovsky and Andrew J. Harris

Why Do We Do What We Do?

The Disconnect Between Sex Offender Management Policy, Research, and Practice

The past two decades have witnessed a surge in legislative activity ostensibly intended to reduce the societal risk presented by known sexual offenders. Prompted in part by federal mandates, all 50 states have adopted systems calling for known sexual offenders to register with law enforcement and providing public access to much of this information. States and localities across the country have adopted stringent restrictions on where previously convicted sexual offenders may work or reside. Federal and state lawmakers have passed a range of sentencing reforms reducing judicial discretion, calling for lengthier sentences for those convicted of sexual offenses and expanding the use of lifetime electronic monitoring and supervision for an expanding group of individuals. These policies and others have been implemented in a manner that has called for an increasingly "widened net" that has often contravened existing evidence regarding the heterogeneity of the sex offender population in terms of behaviors, motivations, and risk.

Paradoxically, these policy developments have occurred amidst a robust expansion of the research enterprise related to risk assessment, treatment, and sex offender management. While significant knowledge gaps remain, researchers and practitioners in the field have developed a much better sense of how risk may be effectively assessed and mitigated among sexual offender populations. Emergent evidence-based strategies such as integrated models of supervision and treatment as well as circles of support and accountability—while under active use in some jurisdictions—have received nowhere near the level of resources and support that have been accorded to sex offender registration and notification (SORN), civil commitment, and related policy strategies, despite limited evidence attesting to the public safety efficacy of these latter approaches.

In this general context, the present chapter examines contemporary sex offender management policy and its historical, social, and political antecedents, with a particular focus on those factors that have contributed to the current state of affairs. In so doing, the chapter aims to inform more effective efforts by the research and practitioner communities to elevate the role of evidence in the design and implementation of effective public policies to reduce sexual violence in society.

The chapter includes five main sections—the first providing historical background describing the evolution of contemporary sex offender management policy, the second offering an overview of the data regarding the problem of sexual violence in American society, the third identifying and discussing the scope and key trends associated with current sex offender management policies, the fourth examining the major themes and patterns in current sex offender management policy and the challenges associated with bringing evidence into the sex offender management policy process, and the fifth providing a blueprint for action on the part of researchers and practitioners in the sex offender management field, with the goal of translating what is known about evidence-based *practice* into the realm of evidence-based *policy*.

Historical Context of Sex Offender Management Policy

> Images of the sex offender have changed dramatically and cyclically over time … In each era, the prevailing opinion was supported by what appeared at the time to be convincing objective research. One reality prevailed until it was succeeded by another (Jenkins, 1998).

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_37

As noted by social historian Jenkins (1998), social and legal responses to sexual offending prior to the late nineteenth century were based predominantly on Puritan era moral codes. The dawn of industrialization, however, brought with it a series of economic, social, political, scientific, and cultural developments that produced dramatic shifts in the way in which criminal sexual behavior is explained and addressed.

On the economic and political front, industrialization led to the rise of urban centers of commerce, coupled with significant demographic transformation. With immigrants flocking to American cities and African Americans migrating northward, the social and demographic landscape saw dramatic changes. A wave of progressive reform, prompted largely by this changing ethnic and social landscape, swept through the intellectual and political establishment. The rise of the Progressives, many of whom viewed growing urban immigrant communities as breeding grounds for vice and immorality, led to new views of criminal behavior as "social disease." As an extension of this view, sexual crime was typically attributed to the underclass, who were viewed as lacking in basic morality and intelligence.

Within the realm of science, several ideas emerged that would shape the manner in which sexual deviance and criminal behavior is viewed, including Darwin's theory of evolution, new paradigms for explaining disease transmission, and the birth of genetics and modern psychiatry. Drawing on the emerging scientific fields of genetics and psychiatry, the social engineering efforts of the time were based in presumed linkages between poverty, amorality, low intelligence, and criminal behavior—characteristics viewed as hereditary and potentially intractable in the lower classes.

Finally, the industrial era brought about a sea change in journalistic practices, setting in motion the birth of mass media. Paramount among these developments was the emergence of *yellow journalism*, a new brand of reporting that fed upon the public's appetite for scandal and vice and which publishers quickly recognized as a viable means of increasing circulation. Coupled with the advent of the telegraph, which facilitated the interregional transmission of information, the media was able to cover sensational stories of sex and violence from across the country and abroad.

By the turn of the twentieth century, amidst this changing social order, a shifting intellectual and scientific landscape, and the growing power of the media to galvanize public opinion and fuel public fears, lawmakers were faced with a pressing challenge to come up with explanations and solutions for the problem of sex offenders. The period produced two pieces of notable legislation, each asserting expanded government roles in managing individuals deemed as sexual threats. At the state level, the Briggs Act, passed by the Commonwealth of Massachusetts in 1911 and amended in 1921, provided for the preventive detention of "defective delinquent" offenders who were deemed as at risk to escalate their offenses if not incapacitated. The law was loosely constructed on the Commonwealth's recently enacted commitment laws for the insane, requiring the examination and concurrence of two psychiatrists. Unlike that process, however, the new system mixed criminal and civil elements, involving both prosecutors and criminal court judges. Although the law ostensibly encompassed a range of criminal subtypes, those with records of sexual-related activities were most likely to be covered. While the Briggs Act (1921) encountered a range of implementation problems due to its hybrid nature, it ultimately served as a model for the subsequent proliferation of sexual psychopath statutes across the United States in the mid-twentieth century—a series of laws that will be reviewed shortly.

The second key legislative milestone of the era, the Mann Act of 1910, represented the federal government's first foray into the realm of responding to sexually deviant behaviors. As extensively chronicled by Langum (1994), the Mann Act emerged from a confluence of political forces linked to the social transformations of the time, notably growing concerns among the entrenched white male establishment over the changing status of women and the societal effects of immigration and urbanization.

Propelled by media-fueled speculation that organized criminal rings were actively engaged in forcing girls into sexual servitude—a practice termed *white slavery*—the Mann Act was based on fears that prostitution was widespread, heavily organized, and the work of the underclass, particularly immigrants. Evoking the powers granted to Congress under the commerce clause of the Constitution, the Mann Act asserted federal authority to arrest and prosecute those who transported women over state lines for "immoral purposes." The act was signed into law in 1910 by President Taft, with the newly founded Federal Bureau of Investigation (FBI) charged with enforcement. Although the FBI was unable to uncover any significant evidence of the purported white slavery rings, a series of Supreme Court rulings in 1913 and 1917 (Athanasaw v. United States, 1913; Caminetti v. United States, 1917; Hoke v. United States, 1913) supported the application of the law to individuals deemed to be a threat to common morality. Langum's analysis delves further into the specific cases in which the Mann Act was applied throughout the twentieth century, including the prosecutions of African-American boxer Jack Johnson, actor and suspected communist sympathizer Charlie Chaplin, and rock musician Chuck Berry

While the political impetus behind the Mann Act of 1910 has been linked by some historians to xenophobia due to its initial targeting of immigrant and African-American populations, significant parallels may be seen between the Mann Act and current policy responses to sexual offending. The manner in which the problem was defined and framed in

public discourse, the passage of sweeping legislation based largely on media reports that alarm the public, the political hazards of resisting legislation that seeks to uphold prevailing moral codes, and the potential gap between the assumptions made by lawmakers and the actions of those charged with implementation all reflect themes that resonate with contemporary policies, as will be highlighted below.

The Sexual Psychopath Era

The 1920s witnessed a relative diminution of interest on the issue of sexual offending, amidst law enforcement focus on prohibition and organized crime and a societal shift in sexual mores. Yet with the beginning of the depression in the 1930s, the country entered a new era in its attitudes toward sexual crime. Events such as the kidnapping and murder of the Lindbergh baby by immigrant Bruno Hauptman in 1930, followed by a reported "wave" of child abductions, the Leopold and Loeb murder of Bobby Frank, and the 1934 arrest and highly publicized trial of the notorious Albert Fish for the murder, sexual mutilation, and cannibalism of a 12-year-old girl all contributed to a growing concern over *stranger danger*, the sense that predatory psychopaths were lurking in the shadows and that public officials were doing little to stop them.

Building on the systems such as those delineated in the Briggs Act (1921) from a quarter century earlier, states, beginning with Michigan, began passing a series of statutes that became known as *sexual psychopath laws*, allowing states to commit those deemed as sexually dangerous to psychiatric facilities for *day-to-life* (i.e., indefinite) sentences, in some cases without any direct evidence of prior sexual offenses. In his seminal study of the proliferation of sexual psychopath legislation, criminologist Sutherland (1950) cited a series of conditions related to the passage of these laws. Notably, Sutherland cited the responses of the media, citizenry, and the political establishment to high-profile sexual crimes and noted the convergence of these concerns with the "solution" offered by the field of psychiatry and its attendant therapeutic ideal. In 1939, the US Supreme Court upheld the constitutionality of Minnesota's sexual psychopath statute, clearing the way for states to freely apply the laws as a means of preventive detention.

Shifting Views

From the postwar period through the mid-1960s, sexual psychopath laws proliferated, with 15 states adopting such laws by 1950 and 29 by 1960 (Group for the Advancement of Psychiatry, 1977). The expanded use of these laws, which also corresponded to a general surge in psychiatric institutional populations in the United States, produced a growing population of individuals held on day-to-life sentences and the preventive incapacitation of thousands of individuals deemed to be at risk of committing sexual offenses.

By the early 1960s, however, attitudes were poised for another shift, this time in favor of a more compassionate (and arguably more tolerant) perspective toward sexual deviance. Setting the stage for this shift were a number of general contextual developments on the intellectual, political, and cultural landscape. These included a rise in liberal thought within intellectual circles, which significantly challenged prevailing approaches toward criminal behavior; a burgeoning civil rights movement which, coupled with mounting pressures on state budgets from the exploding census in psychiatric facilities, led toward a massive push for deinstitutionalization; and significant changes in sexual norms and attitudes, particularly among the young—changes that found their further expression in the rise of the feminist and gay liberation movements by the late 1960s.

It is also during this period that the concept of rape becomes redefined, due in part to the ascendance of the feminist and victims' rights movements. No longer conceived as a strictly sexual crime, rape was reframed as an issue of male dominance and exertion of power (Brownmiller, 1975), with rape victims accorded additional protections in legal proceedings and investigations. Meanwhile, the convergence of a shifting legal landscape (e.g., *Specht v. Patternson*, 1967) and the diminished faith of the psychiatric establishment (Group for the Advancement of Psychiatry, 1977) led most sexual psychopath laws to be repealed or fall into disuse. (For a review of the factors contributing to the rise and fall of sexual psychopath statutes, see Brakel & Cavanaugh, 2000.)

Crime Control Era and the Birth of Modern Sex Offender Policy

In the mid-1970s, an influential study by Martinson (1974) challenged the philosophy of crime and punishment that had flourished through the 1960s. Martinson's conclusion that "nothing works" to reduce criminality prompted a fundamental shift in correctional philosophy, setting the stage for massive sentencing reform in the United States (Lipton, Martinson, & Wilks, 1975; Martinson, 1974). By the early 1980s, the nation had entered the *crime control era* in which legislatures gradually assumed increased power over sentencing decisions, which decreased the power of judges (via policies such as "mandatory minimums" and three strikes laws) and parole boards (via determinate sentencing and "truth in sentencing" statutes).

The emergent dominance of determinate sentencing, which essentially reduced the capacity of correctional authorities and parole boards to calibrate release decisions to

community risk, created demand for new policies that would allow for tighter controls over sex offenders following their release from prison. In this general context, Washington State's Community Protection Act of 1990 ushered in the contemporary era of sex offender policies, both through its introduction of a new type of sex offender registration and notification (SORN) statute and its resurrection of civil commitment. Regarding the former, although other states had previously adopted sex offender registration systems for the use of law enforcement, Washington's law was the first to provide for the release of registration information to the general public. As for the latter, Washington's new "sexually violent predator" civil commitment law represented a retooled return to the general approach that had characterized the earlier generation of sexual psychopath laws, sparking similar legislation in 21 states and, ultimately, the passage of a federal civil commitment statute in 2006.

Amidst a subsequent surge in state-based legislation, the US Congress stepped into the fray with the passage of the 1994 Jacob Wetterling Crimes Against Children and Sexually Violent Offenders Registration Act (Wetterling Act), which established sex offender registration laws as a nationwide imperative. A string of subsequent amendments to the Wetterling Act, including the 1996 passage of the federal Megan's Law, which mandated community notification, incrementally expanded the scope and reach of the nation's SORN systems, firmly establishing the federal government as a driving force behind state-based sex offender management policies. This legislative sequence culminated with the 2006 passage of the Adam Walsh Child Protection and Safety Act (AWA), perhaps the most sweeping piece of sex offender legislation in US history. The AWA addressed an array of issues, including immigration law reform, expanded enforcement of internet crimes against children, enhanced sentencing provisions for certain crime types, and the establishment of a new federal sex offender civil commitment statute. While each of these provisions has attracted some measure of legal and policy attention, its most prominent feature was the 2006 Sex Offender Registration and Notification Act (SORNA), which repealed the Wetterling Act provisions and substantially expanded the federal government's scope of control over the nation's registration and notification systems with the ostensible aim of establishing greater consistency.

Placing the History into Context

The statement from Jenkins (1998) presented at the beginning of the chapter demonstrates how the progression of history raises a fundamental question for consideration: When policy responses to sexual offending are discussed, is there an "absolute truth," or is everything contingent on social, political, and cultural context? One answer—certainly one that policymakers would most *like* to believe—is tied to the notion of scientific and intellectual progress. Specifically, it might be concluded that policy responses to sexual offending have improved over time as more has been learned through empirical investigation—that is, we are more enlightened today than we were in the past, leading to more sensible and rational policies. Alternatively, a more cynical perspective might hold that our attitudes and beliefs toward sex offending are driven first and foremost by idiosyncratic views of factors such as family, gender roles, and social order and that our policies are no more informed today than they were 50 or 100 years ago. In the context of this general question, we turn now to a review of the evidence surrounding sexual violence in today's society and to a consideration of how extensively this evidence is reflected in chosen policy responses to sexual offending.

The Problem of Sexual Violence: The Evidence

As Sutherland (1950) observed over a half a century ago, much contemporary sex offender policy has unfolded amidst unprecedented citizen mobilization efforts, often generated in the wake of tragic events surrounding children. Victim names such as Adam Walsh, Polly Klaas, Jacob Wetterling, Megan Kanka, and Jimmy Ryce have routinely been attached to legislative efforts to stem the tide of sexual-related violence, adding to the emotional weight and perceived correctness of the policies.

These catalyst events, which generally involve abductions and murders of white, middle-class children, undoubtedly reflect significant tragedies calling for appropriate policy responses. However, within the broader context of sexual violence, these events are generally atypical in terms of the nature of these crimes, the perpetrators, and the victims. National data suggest that approximately 115 stereotypical stranger abductions of children occur each year (Sedlak, Finkelhor, Hammer, & Schultz, 2002). In contrast, national crime statistics suggest that an estimated 203,830 rapes and sexual assaults of individuals 12 and older occur each year (Rand, 2009), while police make approximately 22,584 arrests each year for forcible rape (Uniform Crime Report (UCR), 2009). Among reported sexual offenses, data from the National Crime Victimization Survey (NCVS) suggest that African Americans and those listing two or more races have a sexual victimization rate of 1.9 per 1,000, compared to the rate for those listed as white at .6 per 1,000 and other races at .9 per 1,000 (Rand, 2009). In terms of the age of victims, it appears that adolescents are more at risk to experience sexual victimization than adults, as the 2008 NCVS describes a rate of 3.8 per 1,000 for 12- to 19-year-olds, 2.8 per 1,000 for 20- to 34-year-olds, and 1.2 per 1,000 for those older than 35 (Rand, 2009).

Victimization survey data also suggest that the "stranger danger" scenarios that tend to drive much public policy surrounding sexual offending tend to be the exception rather than the rule. According to 2009 NCVS data, 79 % of the sexual assaults against males were by friends or acquaintances, while 21 % were by intimate partners, with no sexual assaults on males reported by strangers (Rand, 2009). For females, 63 % of sexual assaults were by non-strangers, including 42 % by friends or acquaintances, 18 % by intimate partners, and 3 % by relatives, while 32 % were by strangers (5 % relationship unknown) (Rand, 2009).

It is also noteworthy that rates of sexual assault appear to have decreased over the past 20 years. Uniform Crime Report (UCR, 2009) statistics indicate a 6.4 % decrease in forcible rape from 2004 to 2008, with the 2008 figure being the lowest in 20 years. NCVS data also indicates a downward trend in sexual assault over the period from 1999 through 2008, with an overall decrease of 53 % (Rand, 2009). Finally, the rate of substantiated child sexual assault cases also decreased by 53 % from 1992 to 2006 (Finkelhor & Jones, 2008).

In sum, sexual assault in the United States is a multifaceted problem, striking males and females as well as individuals of all ages and ethnicities in multiple different circumstances. There do, however, appear to be certain characteristics of individuals and situations subject to higher rates of sexual victimization. Moreover, as we will see shortly, this empirically grounded distribution of risk within the population does not always comport with those circumstances that tend to influence the public policy process.

Applying the Evidence in a Policy Framework

If there is one message that has emerged from recent research advances, it is that, in addressing the management of sex offenders, few approaches lend themselves to simple answers. Sex offenders are an extremely diverse population with a wide range of motivations, victim preferences, and behaviors. Victims of sexual assault, and the settings in which sexual victimization occurs, similarly reflect wide variability. The current policy approaches—even those that seem like "no-brainers"—all carry implicit risks and unintended consequences.

Yet in the arena of public opinion (and in turn in our political responses to fears of sexual offending), we tend to deal in moral and practical absolutes. The popular sentiment is quite simple: Individuals who commit sexually motivated crimes should be held responsible for their behaviors and the consequences of their actions. As a result, most Americans believe that the criminal justice system should employ whatever means necessary to isolate sexual offenders from society and diminish their opportunity to recommit their offenses. Americans expect law enforcement to do anything it can to identify the perpetrators of such crimes and bring them to justice; after all, there are few things more terrorizing to a community than an unsolved murder or disappearance of a child and the associated idea that a sex-crazed murderer is at large. Americans expect the justice system to include measures such as harsh prison sentences; full disclosure to the community of who sex offenders are and where they live; stringent restrictions on employment, residence, and daily activities; and, in certain cases, indefinite (perhaps lifelong) commitment to secure mental health facilities. Finally, citizens expect results in terms of preventing sexual victimization, leading the justice system to attempt to target any individuals who might be at any risk of committing such offenses, often regardless of the broader consequences.

Certainly, few would disagree on the merits of these goals: effective investigation of sex crimes, dependable justice strategies to punish and prevent re-offense, and viable means of prevention. Yet the manner in which we pursue these goals, with the attendant assumptions about the nature of sexual offenses, its perpetrators, and its victims, must in the end comport with the evidence around what works, despite the recognition that the public may continue to support popular policies regardless of their effectiveness. As result, policymakers must consider and be willing to address public sentiment for policies such as the ones listed below as part of policy development. In the following section, we discuss a series of policy strategies that have emerged as dominant elements to contemporary sex offender management practice, evaluating each in accordance with available evidence.

Sex Offender Registration and Notification

Over the past two decades, amidst public demand for expanded social control over those who have sexually offended, SORN policies have emerged as prominent and ubiquitous elements of the nation's public safety infrastructure. Laws requiring sexual criminals and others to register with law enforcement began with California in 1947. The registry at the time was maintained strictly as a law enforcement tool and was not publicly accessible. It is unclear what impact the law had on sex offender management, but a suspect in the kidnapping of a 9-year-old girl in 1940 was reportedly identified using the registry ("Kidnap," 1940). By 1990, 12 states had established sex offender registries, while contemporary SORN policies gained particular traction in the early 1990s as several more states passed legislation calling for expanded use of registration and asserting the public's access to certain registered sex offender information.

In 1994, the US Congress entered the picture with the passage of the Wetterling Act, requiring that all states develop systems of tracking convicted sexual offenders in

the community. The Wetterling Act was originally designed as a law enforcement tool to create a database of convicted sex offenders for use when conducting an ongoing sexual offense investigation, a goal that was uniformly supported by law enforcement agencies. Over the ensuing decade, the scope of this general mandate was broadened significantly through a sequence of amendments, including Megan's Law (1996), which required states to make certain registration data publicly available. In 2006, federal involvement in SORN-related issues reached a new level with the passage of the AWA, which repealed the Wetterling provisions and replaced them with a new, and significantly more prescriptive, set of requirements.

Partially in response to federal actions, SORN systems now operate in all 50 states, the District of Columbia, and US territories, with jurisdictions reporting over 700,000 individuals contained in their registries (National Center for Missing and Exploited Children (NCMEC), 2010). While laws calling for the relative emphasis of these varying strategies have varied from state to state, the practice of SORN has emerged as a universal element of state-based sex offender management policies. Under SORN, individuals convicted of—or in some cases adjudicated delinquent for—designated sexual crimes are required to register their whereabouts with law enforcement authorities and to regularly verify their information. Further, state laws provide that registration information be made available on publicly accessible Internet sites, allowing citizens an easily accessible mechanism to check for the presence of sexual offenders in their neighborhoods.

The initial federal guidelines related to the implementation of Wetterling's and Megan's Laws granted a fair degree of latitude to the states in implementing SORN laws. For instance, states could determine procedures for assessing risk, categorizing offenders, choosing which sex offenders would be subject to the release of information, and disseminating registry information to concerned citizens.

The resulting variation among states, along with expanded federal focus on developing a national public sex offender registry, led to the 2006 passage of the AWA. In repealing the Wetterling Act's SORN provisions and replacing them with a new set of requirements, Congress set forth a series of new mandated standards for states and other jurisdictions to follow. Among its provisions, the AWA set forth an offense-based categorization system; required all registered sexual offenders to be listed on state and national registry websites; expanded the scope of sexual offenders who must register, including mandated inclusion of certain juveniles adjudicated delinquent for specified sexual offenses; set forth specific requirements for duration of registration and frequency of reporting; and required the retroactive registration of certain classes of individuals. The United States Department of Justice has issued Supplemental Guidelines for AWA that make inclusion of juveniles optional for jurisdictions, but these Guidelines have not as yet been finalized.

In total, the AWA represented a significant assertion of federal authority over state-based SORN systems, prompting a good measure of concern among states, particularly those that had invested considerably in developing systems that contravened the new federal mandates. As of mid-2010, only a limited number of states and other covered jurisdictions had achieved compliance with the AWA mandates.

Prominent among states' concerns was the contention that the federally mandated systems of classification failed to adequately distinguish between registered offenders who presented significant threats to public safety and those who presented less of a risk (California Sex Offender Management Board, 2009). Indeed, research has supported the notion that transitioning to the AWA-mandated classification system places a significant majority of registrants into the highest category of offenders, while contravening evidence suggests that the highest risk of sexual re-offense is concentrated among a much smaller group of offenders (Harris, Lobanov-Rostovsky, & Levenson, 2010).

The Research

Research to date has been somewhat inconclusive in its assessment of the public safety benefits and reduced sexual recidivism associated with expanded SORN systems. A number of states, including Iowa, New Jersey, Washington, and Wisconsin have examined the impact of implementing SORN on sex offenders within their state. The results of several studies found no significant decrease in recidivism between registered and non-registered sex offenders (Adkins, Huff, & Stageberg, 2000; Schram & Milloy, 1995; Zevitz, 2006; Zgoba, Witt, Dalessandro, & Veysey, 2008), or a potential increase in the rate of sexual recidivism for those classified at the lowest level based on the AWA as compared to those classified at higher levels (Freeman & Sandler, 2009). Consistent with this, a series of studies examining rates of sexual assault both pre- and post-SORN showed no significant reduction in the rate of sex crimes post-SORN (Sandler, Freeman, & Socia, 2008; Walker, Maddan, Vasquez, VanHouten, & Ervin-McLarty, 2005). Further, there is no research to suggest that SORN is an effective intervention for juveniles—a population that has increasingly been subjected to state-based registration requirements (Letourneau & Armstrong, 2008).

Conversely, some studies have indicated a significant decrease in sexual recidivism for sex offenders subject to SORN, although the cause of the reduction could not be fixed on the SORN policy (Barnoski, 2005; Duwe & Donnay, 2008). Along these lines, there are some indications that registration may have certain selective effects: Registration has been found to be correlated with a reduction in the frequency of sex offenses against non-stranger victims, and notification

was found to deter sex crimes for first-time sex offenders but increased recidivism for registered sex offenders based upon disincentives for law-abiding behavior provided by notification (Prescott & Rockoff, 2008).

Finally, studies have questioned the effectiveness of the sex offender registry based upon concerns for inaccuracies in the information provided. For example, a state of New York audit found that one-fourth of the records did not match driver's license information (New York State Comptroller, 2006), and a state of Vermont audit found that about three-fourths of the records had critical or significant errors (Salmon, 2010). As a result, some policymakers have called for increased consistency, oversight, and enforcement of the sex offender registry (NCMEC, 2007), while others have suggested current sex offender management policies lead to the unintended consequence of sex offenders absconding from the registry (Iowa County Attorney's Association, 2006).

Residence Restrictions

Another prominent trend in sex offender management is to pass restrictions on where sex offenders can reside. Currently, approximately 60 % of states have laws restricting sex offenders from living near such places as schools, daycare centers, parks, and bus stops (Council of State Governments (CSG), 2007). This management strategy is based on the assumption that sex offenders will seek out stranger child victims in places children frequent near the sex offender's residence. These strategies have also been used by jurisdictions to ostensibly remove sex offenders from their jurisdiction, pushing them into outlying, more rural jurisdictions where less sex offender management services may be available.

The Research

When state and local jurisdictions began passing sex offender residence restrictions in the late 1990s, there was no research to suggest that such a sex offender management strategy would effectively reduce sexual recidivism and provide for enhanced community safety. Since then, a number of studies have failed to demonstrate reduction in sexual recidivism from a residence restriction policy (Colorado Department of Public Safety, 2004; Duwe, Donnay, & Tewksbury, 2008; Zandbergen, Levenson, & Hart, 2010). Such research has typically taken the approach of retrospectively reviewing those sex offenders who have sexually recidivated in terms of whether they live near a place a child might frequent, or to compare them to those who have not sexually recidivated in terms of residence location.

One study in particular, completed by the Minnesota Department of Corrections, consisted of a file review of 224 recidivist sex offenders and found that 85 % of the sex offenses took place in a residential setting (as compared to a public place where children congregate) (Duwe et al., 2008). The study further found that 113 of the recidivist sex offenders accessed the victim through an intermediary, who was typically an adult, and 79 % knew the victim prior to the sex offense. Finally, of the 35 % ($n=79$) of recidivist sex offenders who made direct contact with a victim, 16 made such contact with a child victim within 1 mile of their residence. However, per the researchers, none were near parks, schools, or other prohibited areas where children congregate, leading to the conclusion that none of the sexual offenses would have been deterred by residence restrictions (Duwe et al., 2008).

In addition to research on the lack of public safety benefit of residence restrictions, there has been some evidence to support the notion that residence restrictions may in fact undermine public safety by leading registered sex offenders to become homeless, go "underground," and fail to register. Both California and Iowa reported increased numbers of homeless and/or absconding registrants following implementation of a residence restriction law (Levenson & D'Amora, 2007; Thompson, 2007).

Therefore, residence restrictions have not been shown to effectively reduce sexual recidivism and enhance community safety. However, even jurisdictions that recognize the negative impact of such a policy often have difficulty in repealing such a law (e.g., Iowa County Attorney's Association, 2006).

GPS Tracking

Electronic monitoring, of which Global Positioning Systems (GPS) is one type, has been used with criminal offenders, including sexual offenders, since New Mexico began using such technology in 1984. By 1990, it was estimated that 60,000 criminal offenders in 36 states were supervised under electronic monitoring (Rondinelle, 1997). In its current incarnation, GPS information on the whereabouts of sex offenders is provided for supervision officers. Six states have passed mandatory lifetime GPS laws, including California's Jessica's Law in 2005 (Nieto & Jung, 2006), and approximately three-fourths of all states use GPS with some sex offenders (Turner & Jannetta, 2007).

The Research

Prior to the passage of mandatory GPS laws, the research was mixed in terms of their effectiveness in reducing sexual recidivism. It has been suggested that use of GPS in the absence of a rehabilitative component would not lead to any expected behavior change (e.g., reducing sexual recidivism) (Aos, Phipps, Barnoski, & Lieb, 2001; Gendreau, Goggin, Cullen, & Andrews, 2000). Since that time, much of the research generated on GPS has been completed by states that have implemented such a policy.

Multiple states, including California, Florida, New Jersey, and Tennessee, have completed studies of GPS effectiveness. The results of such studies have been mixed, in that New Jersey reported a low rate of sexual and nonsexual recidivism and parole violations for those on GPS but offered no comparison group data (New Jersey State Parole Board, 2007). Florida also reported reduced felony recidivism and technical violations for those on GPS compared to those who were not, although it was conceded that 70 % of those on GPS were lower-level property and drug offenders (Office of Program Policy Analysis & Government Accountability (OPPAGA), 2005). On the other hand, California and Tennessee found no significant reductions in recidivism or violations for sexual offenders on GPS compared to those who were not (Tennessee Board of Probation and Parole, 2007; Turner & Jannetta, 2007).

In addition, several of the studies noted significant implementation issues for use of GPS, including lack of staffing resources, the need to use the technology more discriminately, signal problems, and equipment malfunctions (Tennessee Board of Probation and Parole, 2007; Turner & Jannetta, 2007).

In summary, while GPS may ultimately be shown to effectively reduce and deter recidivism for certain sexual offenders, the current research support for this policy is mixed, and it has been observed that GPS, where utilized, should be one component of an overall management strategy that includes rehabilitative services.

Civil Commitment

In the early 1990s, a series of states, beginning with Washington, passed legislation providing for the involuntary and indefinite civil commitment of a limited group of individuals designated as sexually violent predators (SVP). Following Washington's lead, a succession of states moved to adopt similar laws, with 20 states establishing civil commitment policies as of 2010 and many others considering their passage (Fitch & Hammen, 2004). Other states with currently active SVP civil commitment laws are, Kansas, Minnesota, Wisconsin, Iowa, New Jersey, California, Texas (outpatient only), Arizona, Illinois, North Dakota, Missouri, Florida, Massachusetts, South Carolina, Pennsylvania ("aging out" juveniles only), Virginia, New York, New Hampshire, and Nebraska. While the majority of these states adopted civil commitment legislation during the 1990s, interest in the laws experienced a resurgence beginning in 2006, as reflected by California's expansion of civil commitment criteria pursuant to Proposition 83, the passage of new civil commitment laws in New York and New Hampshire, and the congressional passage of a federal civil commitment statute under provisions of the AWA.

Typically applied following completion of a criminal sentence, SVP civil commitment permits the state to retain custody of individuals found by a judge or jury to present a risk of future harmful sexual conduct by virtue of a mental abnormality or personality disorder. Following commitment, states remand individuals to the custody of mental health authorities, or in some cases correctional agencies, which ostensibly provide treatment for the condition that makes the individual likely to engage in acts of sexual violence. In most states, commitments are for an indeterminate period, with mental health authorities retaining custody until the individual is determined to no longer pose a threat to society. As of mid-2007, over 4,500 individuals had been committed under state SVP statutes (Gookin, 2007).

Since their inception, civil commitment policies have engendered significant controversy. Proponents of the laws have maintained that civil commitment represents a necessary "stopgap" measure to protect society from a small but dangerous group of individuals who continue to pose a threat to society following completion of their formal criminal sanctions. Criticism of the policies has emerged primarily within two sectors: the legal establishment, where debate has focused on constitutional concerns related both to civil commitment's fundamental premises and to its application, and the mental health community, where many have cited concern over the limitations of treatment and risk assessment technology. Mental health professionals and advocates have also expressed concerns regarding the "co-opting" of the psychiatric profession to fulfill a criminal justice function, misappropriation of public mental health resources, and the effects of the laws on compounding stigmatization of individuals with serious mental illness (Mental Health America, 2006). Further, some have questioned the policies' long-range sustainability considering their significant and mounting costs (Harris, 2006; LaFond, 1998). However, it has also been noted that the willingness of states to continue to devote resources for this sex offender management strategy, which in many cases was initiated during a period of economic growth, has continued even in times of economic uncertainty (Harris, 2006).

Three US Supreme Court rulings since 1997 have validated the use of civil commitment within the states (*Kansas v. Crane*, 2002; *Kansas v. Hendricks*, 1997; *Seling v. Young*, 2001), and a fourth ruling in 2010 supported the federal government's civil commitment authority (*U.S. v. Comstock*, 2010). Given this legal validation, it appears that civil commitment remains a stable element of the nation's sex offender management landscape.

The Research

As an incapacitative strategy ostensibly focused on the most high-risk offenders, civil commitment carries inherent public safety benefits. Assuming that the policies are appropriately

targeting those individuals who are likely to present the greatest risk of re-offense, these individuals' removal from society should intuitively lead to reduced rates of sexual victimization. As an empirical matter, however, it remains difficult to quantify and validate such claims. Any assumptions regarding the individual-level public safety effects of civil commitment (i.e., the extent to which the commitment of a particular individual prevented future sexual crime) are by nature speculative and conjectural, and—particularly given civil commitment's focus on a relatively miniscule proportion of offenders—it is highly problematic to attribute any aggregate shifts in sexual crime to the policies. To date, no experimental or quasi-experimental studies have been undertaken evaluating the relative public safety effectiveness of civil commitment against alternative means of managing high-risk offenders.

On another level, an arguably more relevant series of empirically testable premises relates to the relative effectiveness of civil commitment compared to alternative and less costly means of managing high-risk sexual offenders. In this regard, it is particularly notable that the Supreme Court's validation of civil commitment is predicated on the assumption that the purpose of commitment is therapeutic rather than punitive in nature—a finding that mandates the provision of a treatment-conducive environment. Paradoxically, those subjected to civil commitment tend to be those most highly resistant to treatment, resulting in very few releases from custody and, in turn, a costly and incrementally growing population.

Lifetime Supervision/Indeterminate Sentences/Mandatory Minimum Sentences

As an alternative to civil commitment, many states have instead passed laws that require longer criminal sanctions for sex offenders, including lifetime supervision (e.g., Colorado, Minnesota, and Washington) or mandatory minimum sentences (e.g., California and Florida), and these are frequently part of Jessica's Laws. As many as half of all states have passed mandatory minimum laws that may require 25-year minimum sentences for certain first-time felony sex offenses against children (Center for Sex Offender Management (CSOM), 2008). It should be noted that sex offenders receive longer sentences than any other violent criminal offender, and they serve more time in prison (Durose & Langan, 2007).

However, based on implementing such laws, the criminal justice system has seen adjustments taking place to avoid such sentences through plea arrangements. As an example, sex offenders who take their case to trial and who may be convicted of a mandatory minimum charge receive twice as long of sentences as those who accept a plea bargain to a lesser charge (Durose & Langan, 2007). Such sentences also may place increased pressure on victims to either not report in the first place or recant once reported. Finally, such policies have significant impact for incarceration costs (CSOM, 2008).

The Research

Thus far, there is limited research to suggest that longer prison sentences reduce recidivism, and research has noted that strictly punitive measures do not lead to behavior change (Gendreau et al., 2000). What is most likely true is that removing sex offenders from the community eliminates their likelihood of offending while so incarcerated, which clearly has a community safety benefit.

Although research support for treatment effectiveness has been somewhat mixed (see, e.g., Furby, Weinrott, & Blackshaw, 1989; Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005), research on offenders receiving treatment while incarcerated indicates that incarceration leads to reduced sexual recidivism and reduced outcomes (Lowden et al., 2003; McGrath, Cumming, Livingston, & Hoke, 2003). Further, research suggests that the longer a sexual offender is in prison-based treatment, and presumably incarcerated, the better the outcome (Lowden et al., 2003). Therefore, there does appear to be some research to suggest that incarceration, perhaps in conjunction with treatment, may lead to reduced sexual recidivism.

In summary, research is ongoing related to existing sex offender management policies in use today, and the results have been mixed. It appears essential that research on these policies continues and strategies that are proven effective in the reduction of sexual recidivism be emphasized.

Contemporary Policies: Major Patterns and Themes

The primary goals of sex offender management policy and legislation may be characterized as incapacitation of the offender, retribution/punishment of the offender, deterrence of future offending by the offender and non-identified offenders alike, and rehabilitation (CSOM, 2008). As noted by the preceding reviews, however, evidence surrounding currently dominant policy responses—responses such as SORN, residence restrictions, expanded GPS tracking, and civil commitment—has been quite mixed and inconclusive regarding the achievement of these goals. This, in turn, raises two primary questions: (1) why do we have the policies that we do? and (2) what are some promising alternatives? These two questions form the foundation for the remainder of this chapter.

How Does Sex Offender Management Policy Happen?

The development of sex offender management policy and legislation seems to have repeatedly followed a similar pattern throughout modern history. Observing the proliferation of sexual psychopath laws in the early 1950s, criminologist Sutherland identified the major factors associated with these policies: a high-profile case or cases possibly involving a kidnapping, sexual assault, and murder of a child, which pressures officials to act. This high-profile case or cases typically leads to a public backlash, media exposure, and desire for a policy response. Thereafter, this public reaction often leads to the formation of a committee to study the issue and make recommendations for legislative action (Sample & Kadleck, 2008; Sutherland, 1950). An example of the triggering mechanism for such a policy implementation process is the aforementioned Washington Community Protection Act of 1990, which occurred in response to several high-profile cases (Sample & Kadleck, 2008).

In addition, much of the public fear about sexual offenders may be based upon misperceptions about the problem of sexual violence. Many members of the public, as well as the media and policymakers, are not aware of the evidence regarding sexual violence and, therefore, call for action in ways based upon these misperceptions (e.g., most victims are sexually abused by known offenders, but much of the policy is geared toward stranger danger) (CSOM, 2008; Sutherland, 1950).

Why does this happen? Research has demonstrated that the public is more likely to respond to an individual victim than to cumulative victimization statistics (Small, Loewenstein, & Slovic, 2007). When presented with the case of an individual victim, the emotional response and desire to help tend to be high. However, when presented with summary statistical information about victims or even when statistical information is presented with the case of an individual victim, both the emotional response and desire to help diminish. Small et al. (2007) concluded that deliberative thought decreases the sympathetic response for identifiable victims.

So what is the problem with this style of policy formation? Small et al. (2007) concluded that, while it may be more effective to develop a policy based upon connecting with the public's emotions, it may not lead to the most efficient use of resources to focus on one individual victim rather than developing policies and using resources for all victims. The development of sex offender management policy is often advanced based on an identifiable victim and the desire by the public to somehow respond to this specific tragedy, rather than the problem of sexual violence as a whole. Again, the conclusion of Small et al. (2007) is telling: "Insight, in this situation, seems to breed callousness" (p. 151).

It is also important to note that most legislators reported obtaining their information from the media even when that information was a summary of an agency report or research study. Therefore, and in summary, it has been observed that sex offender management policy development appears to be based on policymaker perception, public perception and concern, and the media (Sample & Kadleck, 2008).

Stranger Danger and Disproportionate Influence of High-Profile Events

Despite the fact that the vast majority of victims know the sexual offender prior to the sexual offense, the predominant driving force behind sex offender management policy appears to be the extreme, stranger sex crimes, which lead to public outcry, media sensationalism, and policymaker and legislator desire for action. Based on this decision-making framework, it makes sense that most of the implemented policies are designed to prevent stranger sexual assaults. SORN, residence restrictions, and special license plates and driver's licenses, among other policies, are all geared toward protecting the public from stranger sex offenders (CSG, 2010). The federal government's current sex offender management policy, emphasizing SORN systems, certainly seems to be directed toward this type of sexual offender, as have many state and local policies. What is less clear, however, is how best to address the issue of the non-stranger sex offender and provide for public safety from a sex offender who is already known to the victim but may as yet not have been identified as such by the criminal justice system. Public education campaigns, including those as part of community notification efforts, may help, but these push up against policies aimed at potential stranger sex offenders and also exacerbate public denial that such a problem can occur within their own family.

Expanded Role of State Legislatures

Over the past two decades, sex offender management public policy and legislation have experienced unprecedented growth. There has also been the re-fostering of historical policies including sex offender registration, which was originally enacted in California in 1947, and sexual psychopath laws under the guise of civil commitment laws (Sample & Kadleck, 2008). Sex offender management public policy continues to be popular, reaching number five on the priority list facing state legislators (NCSL, 2007). Similarly, public opinion polls also demonstrate that sex offender management should be a chief legislative priority (Levenson, Brannon, Fortney, & Baker, 2007; Mears, Mancini, Gertz, & Bratton, 2008).

During 2007–2008 state legislative sessions across the United States, 1,500 bills related to sex offenders were considered, with 275 being enacted into law. It should be noted that this number is even more significant given that six states had no legislative session during the studied period of time. The most typical type of legislation observed at the state level was related to the state implementation of the federal AWA, including adding juveniles to the sex offender registry. In addition, other state laws included a prohibition on plea bargains and good time, lifetime supervision, use of GPS, residence restrictions, civil commitment, prohibition of erectile dysfunction drugs, specialized license plates and driver's licenses, and the death penalty for certain sex offenders (CSG, 2010).

Expanded Federal Role

The current sex offender management policy development style that is in favor appears to be a top-down approach (Logan, 2008). There have been significant changes in the area of sex offender management public policy over the past 15 years, particularly related to the federal government becoming increasingly involved in the management of sexual offenders. Through such legislation as the Wetterling Act, Megan's Law, and the AWA, the federal government has directed states to monitor, via registration and notification, identified high-risk sex offenders and has pushed for increasing consistency of and control over state policy. The latter evolution was based on the belief that inconsistency across jurisdictions and a patchwork of weak laws allowed sex offenders to avoid accountability (Logan, 2008).

The federal government has also become increasingly involved in areas formerly left to states, including the mandate of the AWA to civilly commit sex offenders within the federal system and federal enforcement of failure-to-register criminal violations. In this way, the federal government is taking an increasingly active role in the development and implementation of sex offender management policy.

By contrast, other countries, such as Canada, have taken a different approach to sex offender management public policy, with much of the impetus for such policy coming from the provincial level, with the Canadian government taking a more deliberative and cautious approach (Petrunik, 2003). This approach has also been observed in other countries including the United Kingdom, which thus far has resisted efforts to implement a broad-based notification law.

One-Size-Fits-All Models

Another significant challenge currently facing sex offender management policy is the proliferation of one-size-fits-all models. Sex offender SORN policy has by intention and design become increasingly prescriptive in a desire to increase consistency and continuity. As a result, SORN policy has become a more one-size-fits-all model. In addition, many of the policies being implemented (e.g., residence restrictions, GPS, and mandatory minimums) are being applied on the basis of an offense or all sex offenses, and there is little distinction in the policies based upon the type of offender (adult vs. juvenile, high risk vs. low risk, etc.). Sex offender management policies are increasingly treating sex offenders as a homogenous group despite research that suggests otherwise. Frequently the argument for such a one-size-fits-all policy is based on the concern that risk assessment cannot adequately distinguish higher- from lower-risk sex offenders. Therefore, it is better to be more inclusive in a policy to ensure that those sex offenders who are truly high risk will be managed under the policy. The problem with a one-size-fits-all policy is that research suggests that lower offender risk can be exacerbated by applying higher-intensity interventions to lower-risk offenders (Andrews & Bonta, 2003; Aos et al., 2001).

In sum, a one-size-fits-all sex offender management policy is designed to ensure consistency and continuity across jurisdictions as well as to ensure that all higher-risk sex offenders are managed under the policy. However, the problem with such a strategy is that a one-size-fits-all strategy fails to account for the heterogeneity of sexual offenders and overmanages some sexual offenders unnecessarily. Overly inclusive policies consume public resources and unnecessarily disrupt the stability of lower-risk sex offenders and thereby actually increase their risk (Levenson & D'Amora, 2007). There are also significant implications for net widening in terms of the management of sexual offenders.

Sex Offender Management Cost Considerations

It should be noted that the federal government has embarked on a sex offender management policy of increasing expansion and rigor in the requirements for sex offenders. The Wetterling Act and Megan's Law were focused on a certain types of offenders, whereas the AWA generally has similar requirements of all sex offenders in terms of registration and notification. It should be noted that studies have demonstrated a net-widening effect of the AWA, where the vast majority of sex offenders are now classified in the highest risk category rather than a more evenly distributed bell curve or majority in the lower-risk category (Harris et al., 2010). This inversion effect has led to the enhanced management requirements for a larger number of registered sex offenders at a significant unfunded mandate to state and local jurisdictions.

In terms of cost considerations, it has been estimated that 10–20 % of all prisoners currently are incarcerated for a sex offense (Velazquez, 2008). In sum, the number of sex offenders in prison has grown from 19,900 in 1986 to 43,500 in 1991 and 60,700 in 1997, an increase of 39 % from 1991 to 1997 (Finkelhor & Jones, 2004). More recently, it has been estimated that there were 110,000 sex offenders in prison in 1999, 142,000 in 2002, and 150,000 in 2004 (Daly, 2008). At an estimated prison cost in 2001 of $22,650 per inmate (Velazquez, 2008), this means the cost of incarcerating sex offenders has grown from $451 million in 1986 (using the 2001 per inmate cost) to $3.4 billion in 2004 (Velazquez, 2008).

There is also a significant administrative cost associated with the management of more than 700,000 registered sex offenders. Much of this cost is borne by local communities and law enforcement in terms of registration and address verification functions. In addition, there is considerable cost to the criminal justice system of locating and prosecuting the estimated 100,000 noncompliant registrants (NCMEC, 2007). Finally, the cost of implementing the AWA has been estimated as being $1.5 billion over 5 years (Sandler et al., 2008).

In addition, many states have implemented Global Positioning Systems (GPS) for sex offenders at an estimated cost of $10–14 per day for each offender as well as the need for increased staffing to track down noncompliant offenders. In terms of cost parameters, prior to passage, California's Jessica's Law was estimated to be applicable to 9,650 sex offenders on parole at a cost of $88.4 million per year (Nieto & Jung, 2006), while Florida's cost from 2003 to 2004 was $2.4 million for 1,706 offenders (OPPAGA, 2005).

In terms of civil commitment, the cost is significantly higher than for incarcerating a sex offender in a correctional facility, averaging $97,000 per sex offender per year. Therefore, it has been estimated that civil commitment programs cost states approximately $454.7 million annually (Gookin, 2007).

Costs are also a consideration in expanding sentencing alternatives such as mandatory minimums and indeterminate sentences, as the costs of incarceration skyrocket in a period of significant government budget shortfalls. While the federal government can pass increasingly expansive policies regardless of bottom-line cost, given that the federal government can run a deficit and has more significant fiscal implications for state and local jurisdictions, states may be subject to balanced budget requirements each fiscal year. As a result, state legislators may be faced with opposing a sex offender management policy for budgetary considerations. However, oftentimes policymakers focus more on the cost to society of failing to effectively manage sexual offenders rather than the bottom-line costs of a given policy.

Promoting Evidence-Based Policy

There are significant challenges in adequately identifying the effectiveness of a sex offender management policy due to the low base rate for sexual recidivism (making statistically significant findings between those subject to the policy and those not subject to the policy extremely difficult), the significant underreporting of sex crimes leading to uncertainty about the comprehensiveness of the research (e.g., NCVS from Rand (2009) data suggests that only 41.4 % of sexual assaults are reported to the police), and the need for long-term follow-up to truly determine effectiveness in a climate where immediacy is the expectation (Levenson & D'Amora, 2007).

For example, sexual recidivism rates are reported to be relatively low for identified sex offenders (see, e.g., Hanson, Bourgon, Helmus, & Hodgson, 2009; Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2005; Harris & Hanson, 2004; Langan, Schmitt, & Durose, 2003). Does this mean that sex offender management policies are effective in reducing recidivism for known and identified sex offenders and for the rate of sex crimes in general? Or is it indicative of difficulties in detecting sexual offending behavior for identified sex offenders? The answer is uncertain given the difficulties with criminal justice policy research, since it is conducted in the real world, not a variable-controlled laboratory setting. It is exceedingly difficult to isolate variables and determine whether an individual variable, say a certain policy, has led to a statistically significant change in outcome. Therefore, it is difficult to state that a certain policy has significantly affected the rate of sex crimes or sexual recidivism to the exclusion of any other policy. So what do we know about promoting evidence-based policy?

Advances in Risk Assessment

The advances in risk assessment and the use of actuarial risk assessment methods such as the Static-99 have been proven effective in the discrimination of the levels of risk for sex offenders. Therefore, sex offender management policy using risk assessment to determine an individualized intervention would appear to be a promising evidence-based strategy for sex offender management. Many researchers, practitioners, and policymakers focus on the importance of risk assessment in the management of sex offenders. Despite the AWA moving away from risk assessment to an offense-based classification system, many states have implemented registration and notification schema based on risk (e.g., Minnesota and Washington). Thus, an effective sex offender management strategy, based on evidence, may be to classify sex offenders into discrete risk categories and design management strategies based upon the level of risk.

The challenge for sex offender risk assessment is that risk prediction is an inexact science. The public and policymakers have an expectation of accurate classification of sex offenders, and inevitably an offender classified as low risk will recidivate. This reality must also be addressed by practitioners and researchers via public and policymaker education to prevent backlash against risk assessment.

Evidence on Treatment Effectiveness

There is an increasing body of research to suggest specialized sex offender treatment is an evidence-based and promising practice. Historically, sex offender treatment has been subject to challenges by both practitioners and policymakers. Early studies questioned the effectiveness of sex offender treatment in reducing sex offender recidivism and enhancing community safety (Furby et al., 1989; Marques et al., 2005). More recently, there have been a number of research studies demonstrating the effectiveness of cognitive-behavioral treatment (Aos, Miller, & Drake, 2005; Losel & Schmucker, 2005) and treatment based on the risk, need, and responsivity principle (Andrews & Bonta, 2003) for sex offenders (Hanson et al., 2009). Further, treatment in conjunction with collaborative multidisciplinary supervision and polygraph monitoring has been shown to have utility in managing sex offenders (Aytes, Olsen, Zakrajsek, Murray, & Ireson, 2001; Lowden et al., 2003). At this point, it appears as if the evidence on treatment supports the use of treatment as one option in the effective management of sexual offenders.

Circles of Support and Accountability

Another promising practice for sex offender management and reintegration is the circles of support and accountability (COSA) model. Developed in Canada 15 years ago, this program combines accountability with community support by identifying volunteers who will provide assistance to a sexual offender during community reintegration. This COSA group around the sex offender provides resource assistance in terms of housing and jobs, while holding offenders accountable for their behavior. The COSA model is a promising practice, transforming community concern and the desire to do something into tangible assistance, support, and monitoring for the sex offender. This model has been replicated across Canada, in the United States, and in the United Kingdom.

Research suggests that the COSA model is an effective strategy for high-risk sexual offenders in that those who participated in an initial pilot program had a 70 % reduction in sexual recidivism as compared to a group of sexual offenders who did not participate in the COSA program (Wilson, Picheca, & Prinzo, 2005). Additionally, a follow-up independent Canadian sample had an 83 % reduction in sexual recidivism over a nearly 3-year period (Wilson, Cortoni, & McWhinnie, 2009).

Sex Offender Management Policy Boards

One possible mechanism to facilitate policy development is the use of state-level sex offender management policy boards to address policy and practice. The origin of such an approach was the development of the Texas Council on Sex Offender Treatment in 1982, and to date more than half of states have some type of sex offender management policy group (Lobanov-Rostovsky, 2007). The goal of such groups is to standardize sex offender management strategies and practices, make recommendations for key sex offender management policies, and oversee the delivery of sex offender management services. Such groups, typically made up of key stakeholders and experts in the field, may be a mechanism to develop evidence-based sex offender management policies and offset the traditional mechanisms of sex offender management policy development (extreme cases, public perception, media, and policymaker reaction).

One example of a sex offender management policy group affecting sex offender management strategies is the way in which the Kansas Sex Offender Policy Board and the Colorado Sex Offender Management Board both independently addressed the issue of residence restrictions by reviewing the evidence and doing research, respectively. Such an approach led to both states not passing residence restrictions at the state level.

While there is no current research to suggest the effectiveness of the management policy board in advancing evidence-based sex offender management policy, it does appear to be an effective mechanism to advance such policy and practice and avoid making hasty and politically expedient recommendations.

Recommendations for Promoting Evidence-Based Policy

The field of sex offender management continues to evolve. Over the past 30 years, there have been an increasing quantity and quality of studies that have identified the problem of sexual violence and methods to address the problem, and it is essential that policies be informed by this research (CSOM, 2008). Mechanisms to achieve this outcome include legislative briefings and forums, the development of sex offender management boards and policy groups, state use of research institutions like the Washington Institute for Public Policy, and collaborative teams advocating for evidence-based

policy and practice. The benefits of such efforts would be internal confidence in sex offender management policies, explanatory power to stakeholders, accountability for the policy, and appropriate use of resources (CSOM, 2008).

It has been further suggested that risk-based policies, such as longer sentences for those at higher risk with alternative sentences for those who are lower risk; use of intensive interventions such as intensive and lifetime supervision and GPS for high-risk sex offenders; a continuum of programs with different levels of intensity based on risk; and use of risk to determine the extent of registration and notification (CSOM, 2008) are an effective strategy for sex offender management policy that provides for the most intensive interventions for the most dangerous sex offenders (Levenson & D'Amora, 2007). It should be noted that the goals for sex offender management policy are now nearly a century old but continue to be dogged by questions about the effectiveness of treatment, cost parameters, questionable effectiveness of changing offender behavior, and the need for adequate risk prediction (Bowman, 1953). There does appear to be a strong argument about the need for research as an equal partner in sex offender management policy.

In summary, an ideal sex offender management policy development process would include such features as research based, informed risk-distinguishing policies, and collaboration between practice, research, and policy.

Moving Toward a New Paradigm of Sex Offender Management Public Policy

While the overarching goal is the development of evidence-based sex offender management policy, the inherent challenges may suggest that an interim step is necessary to achieve this outcome. Sex offender management policy appears to be suffering from a chicken and egg problem in that there is insufficient research on which to develop a policy and the expedited nature of policy development often fails to account for research to verify the policy's effectiveness. However, given the way in which sex offender management public policy has historically been developed, it may not be realistic to wait for the necessary research before implementing a policy.

As an alternative, it has been suggested that evidence-generating policies allow policymakers to treat policy changes as experimental and expected outcomes as hypotheses. The goal is to implement a policy to generate specific evidence about its effect, which appears to be a more honest approach by acknowledging the current lack of an unambiguous evidence base. In sex offender management public policy, as with much criminal justice, there appears to be a preference for innovation over studying, and this policy process would allow for study as innovation occurs. In order to compare a policy's effectiveness, the use of staggered implementation over time and place, sunset provisions, and gathering pre-implementation data for comparison purposes may allow for research on an expedited policy (Liberman, 2009).

In terms of the disadvantages of evidence-generating policy development, there may be a slight delay in implementation due to the need to identify and collect comparison, pre-implementation data, but the end result could be to have useful data on policy effectiveness. This is also a far more objective strategy, however, than hurriedly implementing a policy and then casting about for a comparison group (Liberman, 2009), perhaps using the one most advantageous to the policy development (a weak comparison for those in favor of the policy or a strong comparison group for those opposed).

If sex offender management public policy is going to move to an evidence-generating policy, the following considerations are needed. First, the key desired outcomes to be measured must be identified. Second, the potential unintended consequences must be identified. Third, feasible methodological approaches to overcoming unintended consequences must be identified. And finally, available data on the policy outcome must be identified. This work must be done in advance of the policy debate, not during, as by then it is too late. Evidence-generating policies can counter policies that are pushed too fast, are relatively uninformed, and are even faddish, in response to crises (Liberman, 2009).

Influencing Research, Policy, and Practice

To develop evidence-based sex offender management policy, it is essential to collect evidence about what works and provide this information to policymakers. Collaboration between researchers and practitioners can help bridge the gap between available information and informed policy. On the one hand, practitioners typically lack the skill necessary to do quality research, which is where research professionals can be of benefit. On the other hand, researchers need access to data and can benefit from collaborating with practitioners. If the two groups collaborate, sex offender management policies can be evaluated and adjusted accordingly.

In this regard, technology can play a role in helping researchers and practitioners to collect data. An advantage of top-down policies is the ability to provide uniform interventions and policies, and therefore, data will be analyzable across jurisdictions. One of the frequent complaints from practitioners is the lack of time to do research and the added business cost of doing so. If research-friendly data collection systems can be developed and shared, this will assist practitioners in collecting data for researchers to analyze. There needs to be expectations to do research as part of practice,

but there should be incentives and support from the policy system to do so.

Given the importance of research to analyze the effectiveness of sex offender management public policy, federal grant funding must include provisions for research. There should be an expectation for data collection, with all grant initiatives and specific federal grants geared toward research. All policies should be evidence-generating, and the federal government should stipulate as such in its grant funding strategies by supporting the innovative application of pilot projects.

Finally, it is important to provide policymakers, the public, and the media with an accurate picture of the problem of sexual violence (e.g., research suggests most victims know the offender prior to the offense), noting the significant underreporting of sex crimes and the issues related to evidence-generating policies. To this end, collaboration between research, policy, and practice is essential to the development of effective sex offender management policy and practice. This requires a shift from the current paradigm where those who challenge existing or proposed policies and call for evidence-based policies are viewed as anti-victim and pro-offender. Proactive advocacy for sex offender management strategies such as containment, which includes specialized treatment and supervision, circles of support and accountability, and risk assessment speak to the ability to have solutions rather than merely objecting to bad policy.

Summary

The field of sex offender management public policy, practice, and research needs to make some adjustments to effectively enhance community safety. Policies and practice need to be flexible and individualized, not a one-size-fits-all model. Implementation of evidence-based and evidence-generating policies requires a change in approach to policy development. The current principles of risk, need, and responsivity assist in conceptualizing this approach and need to be applied to policy development as well. It is possible for practitioners and researchers to make a positive contribution to sex offender management policy. Ultimately, the most effective strategy may be a series of sex offender management policies such as the ones identified earlier in this chapter (e.g., specialized sex offender treatment and supervision, actuarial risk assessment, circles of support and accountability, and the like), rather than one overarching strategy to address the myriad of sex offenders and a diverse and varied problem. As Patty Wetterling observed, "there is no silver bullet" to solve the problem of sexual violence (Human Rights Watch, 2007), and sex offender management policies need to take into account the heterogeneity of sexual offenders and develop a variety of evidence-based management strategies.

Acknowledgment The findings and opinions expressed in this chapter reflect solely the views of the authors and are in no way endorsed by the Colorado Division of Criminal Justice or the Colorado Sex Offender Management Board and do not represent government policy or views.

An Evidence-Based Perspective on Sexual Offender Registration and Residential Restrictions

Jill S. Levenson

Turning Knowledge into Practice: Future Directions in Sex Offender Management Policy

Protecting children from repeat sexual offenders has been a priority in US crime policy over the past two decades. In an effort to prevent known sexual abusers from reoffending, a variety of federal, state, and local laws have been passed in the USA. Registration and Residence Restrictions are two areas that have been directed at sex offenders as part of government attempts to manage sex offenders when residing in the community. First, anyone convicted of a sexual crime is required to register with law enforcement authorities so that their whereabouts are known. Some registration information is publicly available online, allowing citizens to easily identify registered sex offenders living nearby. Second, many jurisdictions also prohibit known sex offenders from living or working near places where children are present, such as schools, parks, day care centers, and playgrounds. These community protection policies have become some of the most popular and widespread crime prevention policies in contemporary America.

This chapter will first describe what is currently known about the registered sex offender (RSO) population in the USA. Then, common public perceptions about sexual offenders will be compared with research findings. Residence restriction policy will be examined to illustrate the gaps that can exist between evidence and practice. Looking into the future, the chapter will explore how contemporary sex offender management policy might better incorporate empirical research into sound prevention strategies.

What Do We Know About the Nation's RSO Population?

Community protection policies generally have been passed in response to highly publicized crimes against children, often involving abduction and sexually motivated homicide. In fact, such offenses are very rare; according to the Office of Juvenile Justice and Delinquency Prevention, in a given year there are only about 115 cases nationwide in which children are abducted by strangers (U.S. Department of Justice, 2002). Most child abusers are well known to their victims; according to the Department of Justice, in 93 % of sexual molestation cases, the child is abused by a relative or acquaintance. Though community notification laws are intended to increase awareness of sex offenders living close proximity so that citizens can protect themselves and their children, one study of repeat sex offenses in Minnesota revealed that only in 4 % of cases was the perpetrator a neighbor of the victim (Duwe, Donnay, & Tewksbury, 2008).

Some sexual offenders will reoffend, of course, though sexual recidivism occurs less often than commonly believed. According to the U.S. Department of Justice, 5.3 % of sex offenders released from prison were rearrested for a new sex crime within 3 years (Bureau of Justice Statistics, 2003), although most of those were under community supervision at the time. Over longer follow-up periods, the cumulative number of sexual recidivists increases (Hanson, Morton, & Harris, 2003). For instance, over 4–6 years, about 14 % of 29,000 sex offenders in an international sample were rearrested for a new sex crime (Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2005). A 24 % recidivism rate was observed over 15 years, although rates of sexual offending were double for sexual offenders with just one prior conviction. The greatest amount of detected recidivism occurs within the first few years sex offenders are at large in the community, and the probability that an individual offender will be arrested for a subsequent sex crime decreases substantially as they spend more time in the community

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_38

offense-free (Hanson et al., 2003; Harris, Phenix, Hanson, & Thornton, 2003).

However, arrest data underestimate true victimization rates and distort the nature of sexual offending. It appears that only about half of actual sex crimes are reported to police (Bureau of Justice Statistics, 2008). In addition, research has found that some rapists have committed undetected sex crimes against child victims (Ahlmeyer, Heil, McKee, & English, 2000), and some sex offenders have many more victims (and a variety of victim types) than those for which they have been arrested (Abel et al., 1987; Abel, Becker, Cunningham-Rathner, Mittleman, & Rouleou, 1988; Ahlmeyer et al., 2000; Heil, Ahlmeyer, & Simons, 2003). Some offenders, therefore, may pose risks not readily known by their documented arrest history. The available research suggests, however, that after two decades the majority of convicted sex offenders do not repeat their crimes.

It is often reported that "the average sex offender has over 100 victims." This statistic, which comes from a 1987 study in which immunity was granted to sex offenders to encourage them to honestly disclose their offense histories (Abel et al., 1987), may be misleading. The study found that the average (mean) number of reported victims for pedophiles who molest boys was 150; the average for pedophiles with girl victims was 20. However, the median (midpoint) number of victims was 4.4 and 1.3, respectively, and the "average" incestuous offender had fewer than two victims. The mean figures were skewed by a small number of offenders with exceedingly large numbers of victims, and the authors cautioned that the median figure is the more representative measure. In other words, it appears that a large proportion of victimizations are perpetrated by a limited number of predatory offenders.

Characteristics of the US Sex Offender Population

In December of 2010, there were a total of 728,435 registered sex offenders (RSOs) nationwide (National Center for Missing and Exploited Children, 2010). Studying the US sex offender population in an effort to paint a national portrait has proven challenging because registries are independently administered by states. Recently, however, using data downloaded directly from public registries (about two-thirds of the total RSO population), researchers were able to draw some inferences about American sex offenders (Ackerman, Harris, Levenson, & Zgoba, 2011). Registered sex offenders are overwhelmingly male (98 %) and predominantly white (66 %). It is perhaps unsurprising that few females are found on registries, as victims may be less likely to report abuse by females since it is easily disguised as caretaking or nurturing behavior (Sandler & Freeman, 2009; Vandiver & Kercher, 2004). Blacks are overrepresented on registries compared to estimates that they comprise less than 13 % of the US population (U.S. Census Bureau, 2009), which is not unexpected, since blacks and minorities are overrepresented in general criminal justice populations for a complex array of reasons (Miller, 1996). Individuals of all ages can be found on the nation's registries, but the average RSO is in his mid-40s.

Approximately 33 % of RSOs reported by NCMEC are not found on public registries (Ackerman et al., 2011). Thus, presumably, about one-third of the nation's sex offenders have been assessed by their state's sex offender management procedure to pose low risk for future offending. Among public registrants (higher risk offenders from some states and all offenders from other states), about 14 % nationally have been designated as high risk, predator, or sexually violent (Ackerman et al., 2011). At least 85 % are first-time sex offenders. Approximately 90 % of registered sex offenders have had a minor victim, and about 33 % have had victims under 10 years old. Most (87 %) of the victims (adult and minor) are female.

Notably, Ackerman et al. (2011) found that a considerable number of RSOs may not reside in the community. Approximately 12 % of RSOs listed on public Internet registries appear to be incarcerated or civilly committed, deceased, or deported. One particular anomaly is Florida, where nearly half of all registrants were listed as living out of state or institutionalized. Between 2 % and 4 % of the nation's sex offenders are transient, homeless, absconded, noncompliant, or their whereabouts are otherwise unknown (Ackerman et al., 2011). It is difficult to specifically confirm the actual number of fugitive sex offenders because states have differing methods for classifying absconders, registration violators, and others whose locations are uncertain. It has been widely reported that "at least 100,000 sex offenders are noncompliant and no one knows where they are" (National Center for Missing and Exploited Children, 2007). Yet the reality appears to be quite different. Using the data downloaded from public registries, Ackerman et al. (2011) found no evidence to support the notion that 100,000 of the nation's sex offenders are missing or unaccounted for.

Public and Professional Perception About Sex Offenders: Myths and Misinformation

Research suggests that most sex offenders assault victims known to them, that only a minority are repeat offenders preying on very young children, and that many sexual offenders pose low risk for future reoffense. Yet surveys of citizens confirm that the public continues to hold stereotypical and negative views of sexual abusers. In Washington State, 643 randomly selected phone numbers were called to solicit participation in a survey about sex crimes and notification (Lieb

& Nunlist, 2008). The majority of participants said they felt safer knowing where sex offenders lived, believed that sex offenders would behave better as a result of public disclosure, and favored community notification for both adult and juvenile offenders.

In Florida, a survey of nearly 200 citizens declared overwhelming support for notification policies (Brannon, Levenson, Fortney, & Baker, 2007; Levenson, Brannon, Fortney, & Baker, 2007). The majority (76 %) believed that all sex offenders should be publicly identified, regardless of risk. The Florida residents displayed exaggerated beliefs about recidivism rates and the threat of stranger danger and were quite skeptical about the potential of sex offenders to be rehabilitated (Fortney, Levenson, Brannon, & Baker, 2007; Levenson et al., 2007). In an online survey of 127 adults via an online message board, it was found that most believed that sex offenders will reoffend and that psychological treatment is not effective (Katz, Levenson, & Ackerman, 2008). Though most citizens favor public registries, notification can increase citizens' anxiety due to a lack of education and information about protecting oneself or one's children from sexual assault (Caputo, 2001; Zevitz & Farkas, 2000b).

Law enforcement officials have mixed reactions to public notification policies. Many favor more discretionary notification procedures whereby information is disclosed according to the risk of the offender (Finn, 1997). Yet police chiefs in Washington State believed that notification enhanced surveillance of sex offenders and, therefore, would likely deter future sex crimes (Matson & Lieb, 1996). Law enforcement agents also expressed concerns, however, in the early days of the Sex Offender Registration and Notification Act (SORNA), about the fiscal resources and manpower required to implement community notification (Zevitz & Farkas, 2000a). Redlich (2001) surveyed community members, law enforcement officials, and law students about support for notification laws as well as sentiments about sex offender's constitutional rights. Law enforcement officials showed the highest support for Sex Offender Registration and Notification (SORN) laws, and law students were least supportive. Interestingly, less knowledge about child sexual abuse was associated with greater support for notification (Redlich, 2001).

A survey of legislators from Illinois provided insight into politicians' motivation for sponsoring sex crime prevention bills (Sample & Kadleck, 2008). Sex offenders were commonly described by lawmakers as perverted, sick, compulsive, and untreatable, with 78 % believing that sex criminals will almost surely reoffend. Though many believed that community protection laws were not especially effective in preventing sex crimes, they noted that by endorsing these laws they were enacting what they perceived to be the wishes of their constituents.

The majority of mental health practitioners express cynicism about the potential deterrence effects of SORN laws and express concerns about registries creating false reassurance to the public (Malesky & Keim, 2001). Criminal justice practitioners were more likely to approve of these laws than mental health providers, but professionals working directly with offenders viewed SORN laws less favorably than those working with victims (Levenson, Fortney, & Baker, 2010). Professionals with conservative political beliefs seem to favor a broader and more inclusive approach to SORN than those identifying themselves as more liberal. There were few differences attributable to gender, parenting status, or victimization experiences. Those working primarily with victims expressed more fear and anger about sex offenders, less tolerance for their presence in communities, and more optimism about the effectiveness of notification and residence restriction laws (Levenson et al., 2010). Professionals who worked primarily with victims tended to endorse higher recidivism estimates and had less confidence in sex offender treatment than those who work primarily with offenders (Fortney, Baker, & Levenson, 2009).

Social psychology theories of prejudice and stereotyping can inform our understanding of public views about sex offenders. With other types of social prejudice, it is known that unfamiliarity and lack of knowledge about a specific group results in greater prejudice and stereotyping, whereas personal experience with a particular group reduces prejudice (Allport, 1954; Gaertner et al., 1991). Stereotypes can develop from uninformed perceptions and may serve to reduce fear and manage interactions (Sherif, Harvey, White, Hood, & Sherif, 1988). Sex offenders may seem—to those who know only what they see in the media—to be unpredictable, evil, and very dangerous. Less knowledge of sexual abuse is associated with more stereotypical attitudes about offenders (Sanghara & Wilson, 2006), while, interestingly, those with a reported history of sexual abuse viewed offenders *less* negatively than those who had never been victimized (Ferguson & Ireland, 2006).

Cognitive dissonance theory suggests that people attempt to bring their attitudes in line with their behavior when discrepancies make them uncomfortable or when realities are not congruent with their values or beliefs (Festinger & Carlsmith, 1959). Exposure to information alone, however, does not appear to diminish prejudice (Sherif et al., 1988). Interaction and personal relationships are more likely to contradict negative expectations and to facilitate more positive views, greater acceptance, and less intolerance (Wright, Aron, McLaughlin-Volpe, & Ropp, 1997). Current laws mandating public notification may inadvertently promote stereotyping and prejudice. Laws restricting where sex offenders can live and work further segregate sex offenders from mainstream society and therefore reinforce ostracism, exclusion, and fear (Levenson et al., 2010).

Residence Restrictions: An Example of Misguided Community Management Strategies

Residential restriction laws are fairly new, but provide an example by which to illustrate how public misperceptions about sexual violence can lead to the proliferation of policies that hold little promise of effectiveness. These laws restrict sex offenders from living near places where children are likely to be found. There are currently 30 state laws designating where sex offenders can live (Meloy, Miller, & Curtis, 2007). The first state law was passed in 1995 in Florida and applied only to sex offenders on probation who had sexually abused minor victims. This law created 1,000 foot buffer zones around schools, parks, playgrounds, day care centers, and other places where children congregate. By 2004, there were 15 state statutes, but within 2 years of the 2005 murder of a 9-year-old Jessica Lunsford by a convicted sex offender in Florida, the number of states with housing restrictions doubled. The most common proximity zones are 1,000–2,000 feet around a variety of protected venues such as schools, parks, playgrounds, and day care centers. Some laws also include other facilities such as arcades, amusement parks, movie theaters, youth sports facilities, school bus stops, and libraries (Meloy, Miller, & Curtis, 2008).

Too abundant to count are local housing ordinances passed by cities, towns, and counties. The first municipal sex offender ordinance in the USA was passed in Miami Beach in June 2005, modeled after regulations that prohibit adult establishments (e.g., strip clubs and adult bookstores) from operating within a certain distance from schools. Local ordinances can be found in most states, even those without statewide laws, and often exceed state laws by expanding restricted areas to 2,500 feet (almost a half mile) surrounding places frequented by children. When one city or county enacts such a law, a domino effect results, as surrounding towns and counties often pass similar ordinances in order to prevent exiled sex offenders from migrating to their communities.

Residence restrictions are based on the seemingly logical premise that by requiring child molesters to live far from places where children congregate, repeat sex crimes can be prevented. The limited extant research, however, finds no support for the hypothesis that sex offenders who live close to child-oriented settings are likely to reoffend. In fact, the empirical research indicates that where sex offenders reside is not a significant contributing factor to reoffending behavior.

Residential proximity to schools and day cares is not empirically associated with recidivism. Zandbergen, Levenson, and Hart (2010) compared the proximity of recidivists and non-recidivists to schools and day cares ($N = 330$) in Florida. Those who lived within 1,000, 1,500, or 2,500 feet of schools or day care centers did not reoffend more frequently than those who lived farther away. There was no significant correlation between sexual recidivism and the number of feet the offender lived from school. The two groups were matched on relevant risk factors (prior arrests, age, marital status, predator status), and proximity measures were still not significant predictors of recidivism (Zandbergen et al., 2010). Similarly, in Colorado, the addresses of sex offense recidivists and non-recidivists were found to be distributed randomly throughout the geographical area with no evidence that recidivists lived closer to schools and day care centers (Colorado Department of Public Safety, 2004).

In Jacksonville, Florida, researchers investigated the effects of a 2,500 foot residence restriction ordinance on sex crime rates and sex offense recidivism (Nobles, Levenson, & Youstin, 2012). Using a quasi-experimental design, pre- and post-policy measures of recidivism were compared, and no significant differences were found. As well, a trend analysis revealed no significant differences in sex crime arrest patterns over time. The results indicated that the city's residence restriction ordinance had no meaningful effect on sex crime rates or sex offender recidivism. The authors concluded that the residence restriction ordinance did not achieve its intended goal of reducing recidivism and that such laws do not appear to be an effective strategy for preventing repeat sexual violence.

The Iowa Department of Criminal and Juvenile Justice Planning studied the effect of Iowa's 2,000 foot residence restriction law, which went into effect in August of 2005 (Blood, Watson, & Stageberg, 2008). The researchers' goal was to determine the impact the law had on sex crime rates by examining the number of criminal charges for sexual assaults of minor victims in the 12 months preceding implementation of the law and within 24 months after the law went into effect. Researchers did not observe a downward trend in the number of charges over time following the passage of the law. In fact, sex crime arrests increased steadily each year, with 913 charges filed during the year prior to implementation, 928 filed the subsequent year, and 1,095 the following year. The authors concluded that Iowa's residence law "does not seem to have led to fewer charges or convictions, indicating that there probably have not been fewer child victims" (Blood et al., 2008, p. 10).

In Minnesota, a review of 13 recidivistic sex crimes found that only two cases occurred near parks and none occurred on school property. The reoffenders lived far from the parks and drove a vehicle to the crime scene, suggesting that their residential proximity to the parks did not facilitate the crimes (Minnesota Department of Corrections, 2003). A closer

analysis of 224 repeat sex offenses in Minnesota led the authors to conclude that residential restriction laws would not have prevented even one reoffense (Duwe et al., 2008). Most of the cases involving children were committed not by strangers, but by registered sex offenders who were well acquainted with their victims, such as parents, caretakers, paramours of the mother, babysitters, or friends of the family. The repeat offender was a neighbor of the victim in only about 4 % of the cases. Predatory assaults that occurred within a mile of the offender's residence typically involved adult victims, and although some of the offenders established relationships with minor victims within 2,500 feet of their homes, none of the crimes took place in or near a school, day care center, or park. Sex offenders do not appear to abuse children because they live near schools, but rather, they take advantage of opportunities to cultivate relationships with children and their families in order for sexual abuse to take place (Duwe et al., 2008).

Similarly, the majority (67 %) of New Jersey offenders met victims in private locations, while relatively few (4 %) met victims in the types of locations designated as off-limits by residential restriction laws (Colombino, Mercado, Levenson, & Jeglic, 2011). Noteworthy is that sex offenders rarely encountered their victims in public locations where children congregate, and, therefore, policies emphasizing residential proximity to schools and parks may ignore the empirical reality of sexual abuse patterns. However, Colombino et al. (2011) also demonstrated that offenders who met their index victim in a restricted or child-oriented venue were more likely to commit a repeat sex crime. In other words, those with index victims met at bus stops, parks, camps, carnivals, boardwalks, and hospitals were significantly more likely to sexually reoffend (although only eight offenders recidivated). These particular offenders appeared to engage in predatory patterns, seeking to meet children with whom they were not previously acquainted. Since residence restrictions regulate only where an offender sleeps at night, alternative policies such as child safety zones or loitering laws might be especially helpful for these offenders. Restricting their ability to visit places where vulnerable victims may be present would be a more useful strategy than restricting their residential proximity to such venues, which fails to address their ability to travel to an offense location (Colombino et al., 2011).

In summary, the research literature provides no support for the hypothesis that sexual reoffending can be prevented by prohibiting sex offenders from living within close proximity to places where children congregate. For the minority of sex offenders who demonstrate predatory patterns of seeking out minor victims in public settings, laws that forbid sex offenders to visit such locations might be more effective than laws designating where they can live.

Unintended Consequences of SORN Policies and Residence Restrictions

The reentry challenges encountered by all criminal offenders are even more pronounced for registered sex offenders. The unique stigma of SORN and the ways these laws can impede community reentry and adjustment are well documented; sex offenders report employment obstacles, housing disruption, relationship loss, threats and harassment, physical assault, and property damage (Levenson & Cotter, 2005a; Levenson, D'Amora, & Hern, 2007; Mercado, Alvarez, & Levenson, 2008; Sample & Streveler, 2003; Tewksbury, 2004, 2005; Tewksbury & Lees, 2006; Zevitz & Farkas, 2000c). Psychosocial stressors such as shame, embarrassment, depression, or hopelessness were also reported by sex offenders as common by-products of public disclosure of their status. A survey of 584 family members of registered sex offenders across the USA revealed that they, too, are profoundly impacted by these laws (Levenson & Tewksbury, 2009). Employment problems experienced by the RSO and resulting financial hardships emerged as the most pressing issue identified by family members. Family members living with an RSO also experienced threats and harassment by neighbors, and some children of RSOs suffered stigmatizing treatment by teachers and classmates.

Residential restrictions also create barriers to offender reintegration, and as the size and number of buffer zones increase, so do transience, homelessness, and reduced employment opportunities (Levenson, 2008). Many sex offenders reported that housing restriction laws forced them to relocate, that they were unable to return to their homes after incarceration, that they were not permitted to live with family members, or that they experienced a landlord refusing to rent to them or to renew a lease (Levenson, 2008; Levenson & Cotter, 2005b; Levenson & Hern, 2007; Mercado et al., 2008). Many indicated that affordable housing is less available due to limits on where they can live and that they are forced to live farther away from employment, public transportation, social services, and mental health treatment. Young adults seemed to be especially impacted by these laws; age was significantly inversely correlated with being unable to live with family and having difficulties securing affordable housing (Levenson, 2008; Levenson & Hern, 2007). Family members of RSOs also reported that residential restriction laws created housing disruption for them; larger buffer zones led to an increased chance of a housing crisis (Levenson & Tewksbury, 2009).

These self-report surveys of sex offenders have been corroborated by independent empirical research. A quickly growing body of evidence illustrates how residential restrictions profoundly diminish housing options for sex offenders. In Orlando, Florida, it was found that 99 % of all residential

dwellings are located within 2,500 feet of schools, parks, day care centers, or school bus stops (Zandbergen & Hart, 2006). The vast majority of residential territory in Nebraska and New Jersey is also located within 2,500 feet of a school (Bruell, Swatt, & Sample, 2008; Chajewski & Mercado, 2009; Zgoba, Levenson, & McKee, 2009). Affordable housing is especially impacted, since less affluent areas tend to be more densely populated, and, therefore, homes are in closer proximity to places frequented by children. Of nearly one million residential parcels studied in Miami-Dade County, Florida, only about 4 % of residential units were compliant with the overlapping state and local residence restrictions in effect, and only 1 % had a monthly housing cost of $1,250 or less (Zandbergen & Hart, 2009). In Nebraska, average home values were significantly lower within a buffer zone of 2,000 feet than outside the buffer zone (Bruell et al., 2008), and in Ohio, compliant addresses were also more likely to be located in less affordable census tracts (Red Bird, 2009).

When prisoners are released from incarceration, they commonly seek housing with relatives, but strict residence laws can eliminate such options for sex offenders. Unable to reside with family and without the financial resources to pay security deposits and rent payments, some sex offenders face homelessness. Ironically, housing instability is consistently associated with criminal recidivism and absconding. In Georgia, every time a parolee moved, the risk of re-arrest increased by 25 % (Meredith, Speir, & Johnson, 2007). Residential instability was a robust predictor of absconding in a study of California parolees (Williams, McShane, & Dolny, 2000), and in a national sample of 2,030 offenders, those who moved multiple times during probation were almost twice as likely as stable probationers to have some sort of disciplinary hearing (Schulenberg, 2007). In New Zealand, unstable housing, unemployment, and limited social support were found to predict sexual recidivism (Willis & Grace, 2008, 2009). Some prosecutors and victim advocates have publicly denounced residence restrictions, cautioning that the transience created by housing restrictions undermines the validity of sex offender registries and makes it more difficult to track and supervise sex offenders (Iowa County Attorneys Association, 2006; NAESV, 2006).

Where Do We Go from Here? Implications for Sex Offender Management

With the implementation deadline for the Adam Walsh Act having passed in July 2011, it is perhaps time to reflect on where we have been (see Lobanov-Rostovsky and Harris 2015) and where we are going. In 2006, the Adam Walsh Act was passed. Title 1 of the law is the Sex Offender Registration and Notification Act (SORNA). This act standardized registration and notification procedures across the states, created an offense-based tier classification system, and required all registered sex offenders to be listed on state and national registry websites. The new guidelines expanded the scope of sex offenders who must register and allowed juvenile sex offenders as young as 14 years old to be placed on public registries. The duration of registration was lengthened, with Tier 3 offenders having to register for life, Tier 2 registering for 25 years, and Tier 1 registering for 10 years. The act also increased penalties for sex offenders who failed to comply with registration obligations.

At the time of this writing, 16 states have passed legislation approved by the federal government to become compliant with SORNA. Many states are grappling with increased expenses associated with the unfunded mandate; expected costs include technology for updating existing registration systems, enforcement of stricter registration requirements, and prosecution of violators. Other states are contemplating whether to implement the federal requirement to publicly list all registered sex offenders, which means having to forego the more refined, risk-based classification and notification procedures developed by many states across the country. The decision to publicly register juvenile offenders is also a point of controversy, as it contradicts a century of criminal justice philosophy and practice in the USA, which has embraced the rehabilitation potential of youth and the belief that individuals should not be stigmatized into adulthood for juvenile transgressions.

It is estimated that there are currently approximately 730,000 registered sex offenders in the USA (National Center for Missing and Exploited Children, 2010). As those numbers continue to grow and more sex offenders are publicly identified within online registries, law enforcement resources are spread thin, and the ability to differentiate truly dangerous offenders is diluted. Increased resources are needed to enforce registration compliance and track violators, despite evidence suggesting that failure to register as a sex offender is not predictive of sexual reoffending (Duwe & Donnay, 2010; Levenson, Letourneau, Armstrong, & Zgoba, 2010). SORNA requires states to implement an offense-based classification system even though empirically derived risk assessment has demonstrated better utility than SORNA tiers in identifying offenders who are likely to reoffend (Freeman & Sandler, 2009). The use of empirically derived assessments based on factors known to correlate with recidivism should be used to identify those who pose the greatest threat to public safety. Public registries, if used, should be reserved for high-risk offenders. In this way, the public can be better informed, specifically about pedophilic, predatory, repetitive, or violent sex offenders likely to commit new sex crimes. At the same time, collateral consequences could be minimized for lower-risk offenders reintegrating into society and attempting to become productive, law-abiding citizens.

As more people are placed on registries for long durations (or life) with little attrition, the mean sex offender age will continue to grow older. This anticipated trend contradicts research indicating that risk declines with age for all criminals (including most sex offenders) and sex offense recidivism becomes more rare with advanced age (Hanson, 2002; Thornton, 2006). Over time, the sex offender population will include a growing proportion of aging or elderly individuals who probably pose lower risk for reoffense. Furthermore, registration durations of 25 years to life contradict empirical evidence that risk declines with increased time spent in the community offense-free (Harris et al., 2003). In fact, Harris et al. stated that "the expected offense recidivism rate should be reduced by about half if the offender has 5–10 years of offense-free behavior in the community" (p. 63). Thus, the emphasis on registration compliance over longer registration periods will likely create an inefficient distribution of resources without contributing meaningfully to community safety.

Sex offenders do not molest children because they live near schools. They abuse children when they are able to cultivate relationships with youngsters and their families and gain trust and familiarity that creates opportunities for sexual assault. Thus far, research provides no support for residential restriction policies, and, in fact, emerging evidence strongly demonstrates a negative impact on housing availability when residence restrictions are in effect. Housing instability exacerbates risk factors for recidivism, and therefore residence restrictions are likely to create more problems than they solve. Though seemingly sensible, they regulate only where sex offenders sleep at night and do nothing to prevent sex offenders from frequenting child-oriented venues during the day. For this reason, jurisdictions should consider "loitering zones" in lieu of residence restrictions, which would more effectively prevent sex offenders from hanging around in places where children congregate.

Especially in these economically sparse times, lawmakers should invest in evidence-based policies rather than those that, in fact, demonstrate negligible public safety benefit. Sexual assault is a prevalent social problem, and prevention strategies should reflect not only public opinion, but also empirical demonstrations of actual effectiveness. Resources spent on policies that fail to enhance community safety take funding away from more promising programs and services for victims. A paradigm shift toward evidence-based case management might prove more effective in achieving the important goal of preventing repeat sexual violence.

Sociologist Robert Merton (1936) shrewdly cautioned that social policies, even when well intentioned, can sometimes lead to paradoxical results, which he referred as the "law of unintended consequences." Merton observed that when a society overreacts to a perceived threat and seeks to curtail that threat by drastically altering the social order, unexpected outcomes can subsequently result. As they endeavor to achieve desired goals, advocates of social change may fail to anticipate the potential negative consequences of a law. Collective values also play a role in social movements, and popular concepts of good and evil are motivating forces that can obscure the more detrimental effects of change (Merton, 1936). For all of these reasons, the unintended consequences facilitated by sex offender policies are likely to be ignored by lawmakers and citizens hoping to deter sexual violence. Those who point out counterproductive effects, especially as they relate to the reintegration of sex offenders, are often dismissed as offender advocates who are unconcerned about the safety of children.

Some scholars have asserted that sex offender policies are designed to accomplish both instrumental and symbolic objectives (Sample, Evans, & Anderson, 2011). Understanding both is essential in the continuing dialogue about SORN laws and prevention of sexual violence, they argue. While most empirical investigations have not detected instrumental effects such as reduced reoffending (Letourneau, Levenson, Bandyopadhyay, Sinha, & Armstrong, 2010; Sandler, Freeman, & Socia, 2008; Vasquez, Maddan, & Walker, 2008; Zgoba, Witt, Dalessandro, & Veysey, 2009) or increased community protection behaviors (Anderson & Sample, 2008; Kernsmith, Comartin, Craun, & Kernsmith, 2009), SORN policies may achieve vital symbolic effects. Policy enactment can serve to inspire and reinforce social solidarity by uniting against a common "enemy" or social problem (Roots, 2004). They send a clear message that sexual victimization will not be tolerated and that politicians are willing to address public concerns (Sample et al., 2011; Sample & Kadleck, 2008). Moreover, symbolic policies can achieve instrumental effects over time, perhaps measured by a wider range of positive outcomes beyond recidivism. Sample et al. (2011) speculated that in the cost/benefit analysis, the symbolic expression of zero tolerance for sexual violence will always outweigh offender rights, fiscal considerations, and empirical testing.

But policy analysis also requires a continuous process of evaluation that measures movement toward realizing intended goals as well as minimizing or avoiding unanticipated results that might prove contrary to the best interests of the community. Levenson and D'Amora (2007) opined that ignoring such evidence is analogous to Hans Christian Andersen's story, "The Emperor's New Clothes," in which the king paraded through town nude, fooled by gypsies into wearing invisible clothes that purportedly could be seen only by an enlightened few. Similarly, in the absence of compelling evidence indicating that policies for sex offender registration and residence restrictions reduce sexual reoffending, attention should be paid to mounting evidence of cost and reintegration obstacles fostered by these laws. In fact, the unintended consequences of these laws might undermine their very purpose.

Social policies should be based on extant scientific data and are most likely to be successful in reaching their goals when they incorporate research findings into their development and implementation. A more reasoned approach to sex offender policies would utilize empirically derived risk assessment procedures to create classification systems that apply more aggressive monitoring and restrictions to those sex offenders who pose the greatest threat to public safety. In this way, laws could more appropriately identify and target high-risk offenders, resulting in a more cost-efficient allocation of resources. As well, the collateral consequences of community protection policies could be minimized, and sex offenders could be better enabled to assume a law-abiding and prosocial lifestyle. Most sex offenders will ultimately be returned to the community, and when they are, it behooves us to facilitate a reintegrative approach that relies on empirical research to inform community protection strategies.
