Preface

Sexual offending is a profound international problem that wreaks havoc on the lives of far too many persons. The Association for the Treatment of Sexual Abusers (ATSA) in policy papers from May 2011 provided a perspective of sexual assault as a public health problem. Over 20 years ago, in 1995, the American Medical Association declared sexual abuse a "silent-violent epidemic;" clearly it remains one today. Close to 20 % of women and 6 % of males have reported the experience of coerced sex at some time in their lives, with a significant majority of those victims being sexually assaulted prior to age 18. Sexual offending of both adults and children is known to increase the risk of a wide range of medical and psychosocial issues for those who are its victims, including depression, substance abuse, posttraumatic stress disorder suicide attempts, maladaptive personality traits and disorders as well as physical injuries, sexually transmitted diseases, and risky sexual behavior. Secondary victims of sexual offending include family members and friends who are also often traumatized themselves when a loved one is victimized by sexual assault.

Significant scientific progress has been made in the past 20 years regarding the nature of sexual offending, particularly reoffending, and the bases for principles and practices of both evaluating and intervening to reduce the frequency and impact of sexual offending. Some regard the progress to date as a glass half-empty, while others as one half-full. The intent of this book on sexual offending is to offer a range of perspectives on multiple and important aspects of the predisposing conditions of this particular form of violent offending as well as to offer viewpoints and guidelines on a diversity of assessment practices and management issues, as well as on special populations of sexual offenders. In addition, relative to many books in the field of sexual offending, this book was informed by the decision to provide chapters authored both by well-known figures in the field of sexual offending and also by experienced, knowledgeable professionals who provide services regarding sexual offenders in their daily practice in the field but who committed to providing state-of-the-art reviews and discussions of relevant topics regarding sexual offending. We sought to include a unique breadth of chapter topics that would provide an updated, exceptional viewpoint on aspects of sexual offending, including some not addressed by other books in the field. In all of these ways, we sought to develop a volume that would be informative and useful to the great majority of the varied and increasing types of professionals—practitioners, advocates, and policymakers involved in addressing the pressing and persisting problem of sexual offending.

We hope that this book can play some role in the reduction or even prevention of sexual violence by informing and enhancing both practice and policy in the field of sexual offending.

Acknowledgments

I would like to acknowledge the large number of truly special professional friends and acquaintances who have been constant or intermittent sources of support, information, argument, and constructive feedback on my professional endeavors through the years. It is a blessing to be part of such a generous professional community that accepts and encourages critical thinking and striving to do one's best work. In particular, I thank my friends Jim and Michael for many things.

I would like to dedicate this book specifically to Dawn Koehler, as well as to my children, whose endless patience, support, and understanding during the 5+ years it took to bring this project to fruition is so greatly appreciated. Hopefully, one day each of you will have a genuine mental image of me that is something other than one of sitting at a desk reading research articles, reviewing records, or writing at the computer. It is already clear that each of you has already or will soon succeed in enacting distinctive lives of character, achievement, and amusement. All of you have enriched my life far beyond my expectations, and I thank each of you for your love, which means the world to me.

Harry M. Hoberman

I would like to express great appreciation to my husband, Doug Epperson, for his tireless support for my personal and professional endeavors.

Amy Phenix

Contents

Author Bios

Dale Arnold, Ph.D., is currently assigned to the Forensic Services Division of the California Department of State Hospitals. He also maintains a part-time private practice in Pismo Beach, California, and has 19 years experience in the evaluation and treatment of sexual offenders in a variety of settings. In addition, Dr. Arnold has provided education and training in the evaluation and treatment of sexual offenders to forensic examiners and attorneys alike. His area of interest is the application of empirical findings to contemporary sexual offender risk assessment methodology.

Kelly M. Babchishin, Ph.D., received her doctorate in Experimental Psychology from Carleton University (Ottawa, Canada) in 2013. She is currently completing a Banting postdoctoral fellowship (Canadian Institutes of Mental Health Research) with the University of Ottawa Institute of Mental Health Research and the Department of Epidemiology and Biostatistics, the Karolinska Institute Department of Medical Epidemiology and Biostatistics in Sweden. Her current research involves identifying causal candidates for the onset of sexual offending behaviours. Other research interests include change in sexual offending behaviours across the lifespan, pedophilia, and online sexual offenders. She has authored 31 articles in peer-reviewed journals. In 2015, she was appointed as an Editorial board member of *Sexual Abuse: A Journal of Research and Treatment*.

Judith V. Becker, Ph.D., is a professor of psychology at the University of Arizona. She has held her position at the University of Arizona since 1990 and previous to that she was a professor at the University of Tennessee Medical School and Columbia University, College of Physicians and Surgeons. She is a past president of the Association of Treatment for Sexual Abusers and the International Academy of Sex Research. She has published over 100 articles in peer-reviewed journals in addition to numerous book chapters. She is also a coauthor of two books *Treating Sex Offenders: An Evidence-Based Manual* (2012) and *Sex Offending: Causal Theories to Inform Research, Prevention, and Treatment* (2008). She has given numerous talks both nationally and internationally. Her current research interests include juvenile and adult sex offending prevention, assessment, treatment, and diagnosis as well as issues related to forensic psychology and sex offending in general. She is an instructor of courses including Abnormal Psychology, Child Abuse and Neglect, Forensic Psychology, and Forensic Assessment. She has also been working as a clinician in the field of forensic psychology since 1975 where she has engaged in the treatment and assessment of forensic populations in addition to serving as an expert witness. Over the course of her career, she has been the recipient of research funding to assess and treat both perpetrators of sexual violence and victims of sexual abuse/violence/assault.

Anthony Beech, D.Phil., F.B.Ps.S., C.Psychol., is the Head of the Centre for Forensic and Criminological Psychology at the University of Birmingham, UK. He has authored over 160 peer-reviewed articles, 50 book chapters, and authored/edited seven books in the area of forensic science/criminal justice. His particular areas of research interests are improving risk assess-

ment, exploring the neurobiological bases of offending, reducing online exploitation of children, and increasing psychotherapeutic effectiveness of the treatment given to offenders. In 2009, he received the Significant Achievement Award from the Association for the Treatment of Sexual Abusers in Dallas, Texas, and the Senior Award from the Division of Forensic Psychology, British Psychological Society, for recognition of his work in this area.

Gerry D. Blasingame, Psy.D., is a licensed marriage and family therapist specializing in the family violence field. He has worked with persons with various developmental disabilities for over 20 years. He has written several articles, chapters, and books involving assessment and treatment of persons with intellectual and other developmental disabilities who have sexual problems or offending behaviors.

Brooke E. Burbank, J.D., graduated from Colorado College with a B.A. in Studio Art. She received a J.D. from Northeastern University School of Law in Boston, Massachusetts, in 1996. She began work at the King County Prosecuting Attorney's Office, in Seattle, WA, immediately after graduation and was a Senior Deputy Prosecuting Attorney until February 2008, prosecuting offenders in several felony units, including the Domestic Violence Unit and the Special Assault Unit. From 2001 to 2008, she worked in the SVP unit, civilly committing dangerous sexual offenders. She joined the Office of the Attorney General in February of 2008, where she managed the 21-member unit responsible for civilly committing sexual predators in the State of Washington from 2008 to 2013. She is currently handling appellate matters for the Office of the Attorney General.

Franca Cortoni a clinical and forensic psychologist, is Associate Professor at the School of Criminology of the Université de Montréal and Research Fellow at the International Centre of Comparative Criminology. Since 1989, she has worked with and conducted research on male and female sexual offenders. Dr. Cortoni has published extensively and made numerous presentations at national and international conferences on both male and female sexual offender issues. Among others, she has coedited a book on female sexual offenders and a book on criminal violence (in French). Dr. Cortoni is Associate Editor for *Sexual Abuse: A Journal of Research and Treatment* and a member of the editorial board of the *Journal of Sexual Aggression*.

Marianne Davis, Ph.D., is a forensic psychologist employed by the California Department of State Hospitals as a Sexually Violent Predator Evaluator. Prior to becoming a State employee, she was in private practice and on the evaluator panel for the California Department of Mental Health's Sex Offender Commitment Program, performing sexually violent predator evaluations. The majority of her current forensic work focuses on the assessment of sex offenders. She has also worked in a correctional setting, assessing risk for violence in inmates serving indeterminate sentences, and at the Center for Forensic Psychiatry in Ann Arbor, Michigan, performing pretrial evaluations of criminal defendants. She obtained her doctoral degree from the University of Missouri, Columbia, in 1996.

Grant Duwe is Director of Research for the Minnesota Department of Corrections, where he conducts program evaluations, forecasts the state's prison population, and develops risk assessment instruments. His recent work has been published in Journal of Offender Rehabilitation, Journal of Sexual Aggression, Journal of Criminal Justice, and Criminal Justice Policy Review.

Kim English, M.S., is the Director of the Office of Research and Statistics in the Division of Criminal Justice, Colorado Department of Public Safety. Her responsibilities include forecasting adult prison and juvenile commitment populations, developing actuarial scales for use by the parole board and the identification of sexually violent predators, analyzing parole board decision-making, and conducting program evaluations and policy analyses as directed by the

General Assembly and the governor's office. Ms. English has been the principal investigator on a number of studies funded by the National Institute of Justice, including two studies of probation and parole management practices pertaining to adult sexual offenders. She coauthored "Managing Adult Sex Offenders in Community Settings: A Containment Approach," published by the American Probation and Parole Association. She has consulted for the National Institute of Justice, the National Governor's Association, the National Institute of Corrections, the Center for Sex Offender Management, and the Office of Juvenile Justice and Delinquency Prevention. She is currently a member of the National Academies of Sciences' panel to modernize the nation's crime statistics.

Douglas L. Epperson, Ph.D., is Professor of Psychology and Dean of the College of Liberal Arts at California Polytechnic State University in San Luis Obispo, California. He received his Ph.D. degree in psychology from The Ohio State University, and he is a licensed psychologist and a Fellow of the American Psychological Association's Society of Counseling Psychology. Dr. Epperson was the lead developer and author of two empirically developed and validated sexual offender risk assessment tools: the *Minnesota Sex Offender Screening Tool—Revised (MnSOST-R)*, and the *Juvenile Sexual Offense Recidivism Risk Assessment Tool—II (JSORRAT-II).* He has served as a consultant or trainer on risk assessment for many state departments of corrections and divisions of juvenile justice.

Stephanie Fisher, Ph.D., received her doctorate in clinical psychology from the Victoria University in Wellington, New Zealand. Her dissertation addressed how views of offenders impact on punishment and rehabilitation decisions. After graduation, she is a clinical psychologist in New Zealand**.**

Pamela Freske, Ph.D., A.B.P.P., L.P., is a licensed psychologist employed by the Minnesota Department of Corrections (MN DOC) since 2004. Dr. Freske earned her Ph.D. in Clinical Psychology at Washington State University and has worked in the Minnesota Correctional Facility—Lino Lakes Sex Offender Treatment Program, the MN DOC Risk Assessment/ Community Notification Unit, and the MN DOC Behavioral Health Services. She is Board Certified in Clinical Psychology and is currently Associate Director of Behavioral Health. Dr. Freske has served as cochair of the Minnesota Association for the Treatment of Sexual Abusers (MnATSA) conference committee for the past 2 years and is a member of the MnATSA Board of Directors. She also serves on the Minnesota Psychological Association's (MPA) ethics committee.

Robert Friedman an attorney, is the agency head of Capital Collateral Regional Counsel—North in Tallahassee, Florida. His office represents death-sentenced inmates in their state and federal capital post-conviction proceedings.

Theresa A. Gannon, D.Phil., C.Psychol. (Forensic), is Professor of Forensic Psychology and Director of the Centre for Research and Education in Forensic Psychology (CORE-FP) at the University of Kent, UK. Theresa also works as a Practitioner Consultant Forensic Psychologist specializing in sexual offenders and firesetters for Kent Forensic Psychiatry Services, UK.

Theresa has published over 100 chapters, articles, books, and other scholarly works in the areas of male- and female-perpetrated sexual offending. She is particularly interested in research relating to both the treatment needs and overall supervision of sexual offenders. This includes offense-related cognition and emotion, rehabilitation models (i.e., the Good Lives Model), offense-process models of offending behavior, polygraph-assisted supervision and truth facilitation, and attitudes toward offenders. Theresa is lead editor of several books including *Aggressive Offenders' Cognition: Theory, Research, and Treatment* (John Wiley) along with Professor Tony Ward, Professor Anthony Beech, and Dr. Dawn Fisher and *Female Sexual Offenders: Theory, Assessment and Treatment* (Wiley-Blackwell) along with Dr. Franca Cortoni. Theresa is also coeditor of several books that discuss or integrate sexual offending

with other forensic topics and psychological factors including *Public Opinion and Criminal Justice* (Willan) along with Dr. Jane Wood, *Crime and Crime Reduction: The Importance of Group Processes* (Routledge) along with Dr. Wood, and *What Works in Offender Rehabilitation: An Evidence-Based Approach to Assessment and Treatment* (Wiley-Blackwell) along with Professor Leam Craig and Dr. Louise Dixon.

Theresa serves on the editorial boards of several journals including *Aggression and Violent Behavior*, *British Journal of Forensic Practice, International Journal of Offender Therapy and Comparative Criminology,* and *Sexual Abuse: A Journal of Research and Treatment.* Theresa is also Editor of *Psychology Crime and Law.*

Leslie J. Garrison, J.D., is a 1988 graduate from the University of Oregon School of Law. She holds a B.A. in Sociology with a focus on Criminology. Ms. Garrison began her legal career at The Defender Association in Seattle, Washington, where she practiced in the areas of misdemeanors, felonies, and traditional mental health commitment. She initially began representing men detained pursuant to Washington's sexually violent predator law in 1992. In 1998, her work focused solely on sexually violent predator cases. She supervised the Sex Offender Commitment division at The Defender Association from 2001 to 2011. In 2011, Ms. Garrison and three former public defenders formed Odyssey Law Group, PLLC, which handles exclusively sexually violent predator cases.

Ms. Garrison has expanded her practice and now handles collaborative and traditional family law matters in addition to her work with Odyssey Law Group, PLLC. Ms. Garrison has served on the Washington Pattern Instruction Committee—subcommittee for sexually violent predator jury instruction, the training committee for Washington's sexually violent predator Joint Forensic Unit, the Judicial Screening Committee of the King County Bar, and the Juvenile Court Steering Committee—and served as an Adjunct Disciplinary Counsel for the Washington State Bar Association. She has presented at numerous Continuing Legal Education programs for attorneys and judges pertaining to civil commitment of sex offenders.

R. Karl Hanson, Ph.D., C.Psych., is one of the leading researchers in the field of sexual offender risk assessment and treatment. Originally trained as a clinical psychologist, he spent several years providing direct service to offenders before starting a research position with the Canadian Federal Government (Public Safety Canada). His mandate has been to advance policy-relevant knowledge concerning the assessment and treatment of offenders. Most of his research has focused on sexual offenders, with a secondary interest in men who have been physically abusive to their intimate partners. He has published more than 150 articles, including several highly influential reviews, and has developed the most widely used risk assessment tools for sexual offenders (Static-99R, Static-2002R, and STABLE-2007). He is a Fellow of the Canadian Psychological Association and the 2002 recipient of Significant Achievement Award from the Association for the Treatment of Sexual Offenders.

Andrew J. Harris, Ph.D., is Associate Dean for Research and Graduate Programs in the College of Fine Arts, Humanities, and Social Sciences and Associate Professor of Criminology and Justice Studies at the University of Massachusetts Lowell. He received his doctorate in public administration from New York University's Robert F. Wagner School of Public Service and holds a Master of Public Policy and Administration from Columbia University. Before his academic career, Dr. Harris spent more than 16 years developing and managing criminal justice and human service policies and programs in New York City and Massachusetts. He has served as a consultant to state policy boards, public behavioral health agencies, community-based service providers, and state and municipal correctional systems on issues related to mental health populations and the criminal justice system. He has written and conducted policy research in the areas of substance abuse, behavioral health, prisoner reentry, correctional health care, and sex offender management.

Grant T. Harris was adjunct associate professor of psychology at Queen's University in Kingston, Ontario, and adjunct professor of psychiatry at the University of Toronto. He was a Fellow of the Canadian Psychological Association and received the Career Contribution Award from its Criminal Justice Section. Dr. Harris published over 170 scholarly works on the topics of violence risk assessment, psychopathy, sexual aggression, and the assessment and treatment of offenders and psychiatric clients. Sadly, Dr. Harris died of a massive stroke in October 2014.

Margaret Peggy Heil is a licensed clinical social worker. She is currently employed at the Colorado Division of Criminal Justice, Office of Research and Statistics. She has over 25 years' experience administering behavioral health programs in corrections and has provided training and consultation in sex offender treatment and management. Her prior experience also includes participating as a therapist representative on the Colorado Sex Offender Management Board and an executive board member for the Association for the Treatment of Sexual Abusers' and the Colorado Coalition Against Sexual Assault. She has been involved in a number of sex offender studies and has authored professional articles and book chapters related to sex offenders.

L. Maaike Helmus received her doctorate in forensic psychology in 2015 from Carleton University in Ottawa, Ontario, Canada. While completing her graduate studies, she served as a researcher with Correctional Services Canada. Her research interests focus on the assessment and treatment of sexual offenders. She has been deeply involved in the recent advances in structured risk assessment tools, such as STABLE-2007/ACUTE-2007, Static-99R, and Static-2002R. As a graduate student, she received numerous grants and academic awards that include the Joseph-Armand Bombardier Canada Graduate Scholarship and the Association for the Treatment of Sexual Abusers (ATSA) predoctoral research grant.

Harry M. Hoberman, Ph.D., L.P., is a forensic and clinical psychologist licensed in several states. While on the faculty of the University of Minnesota in the Departments of Psychiatry, Psychology, Pediatrics, and Child Development, he was the principal investigator on several funded research projects related to psychosocial risk factors and mental health service utilization as well as developing and implementing integrative psychosocial treatment protocols for various conditions. He is a past recipient of the U.S. Government Executive Branch's Distinguished Service Award. Currently, he practices exclusively as a forensic psychologist through Forensic Psychology Evaluations and Professional Consultations. He specializes in risk assessment of violent behavior and has contracts with various states and the Federal government to conduct evaluations regarding mental abnormalities, volitional/emotional impairment, and the probability of recidivism. In addition, Dr. Hoberman conducts forensic evaluations and provides expert witness testimony related to a broader set of psycholegal constructs and issues. Dr. Hoberman was twice elected to the Executive Board of the Association for the Treatment of Sexual Abusers (ATSA), authored a public policy statement on risk assessment for ATSA, and served on the public policy committee of that organization for over 10 years.

Rebecca L. Jackson, Ph.D., is the Clinical Director of the Florida Civil Commitment Center, Florida's only sex offender civil commitment facility. Previously, she was a Chief Psychologist with the South Carolina Sex Offender Civil Commitment Program and an Associate Professor and the Director of the Forensic and Correctional Mental Health Counseling program at Palo Alto University. Her primary professional interests are in the areas of psychopathy, risk assessment, and sexual offending. In addition to her published work, she has presented and delivered training regionally and nationally on these topics. In 2008, she received the Theodore Blau Award for Early Career Contributions to Clinical Psychology.

Jain Ashok, M.D., M.P.H., is Associate Professor in the Department of Emergency Medicine at the University of Southern California/Keck Medical School. Dr. Jain is Board Certified in

Internal Medicine, Emergency Medicine, Occupational/Environmental Medicine, and Medical Toxicology. Dr. Jain is Consultant Toxicologist, Los Angeles County Medical Examiner, Department of the Coroner. Prior positions include Director, Division of Toxicology and Occupational Environmental Medicine at USC, and Co-Medical Director, Los Angeles County Drug and Poison Information Center. Dr. Jain has been an expert witness for high-profile criminal and civil cases involving industrial, general toxicology, and emergency medicine occupational and environmental cases.

As a supervising physician and medical toxicologist at USC/Los Angeles County Medical Center, the busiest emergency department in the United States, Dr. Jain has experience in medico-legal evaluation of victims of drug-facilitated rape.

Meg S. Kaplan, Ph.D., a clinical psychologist, is currently the Director of the Sexual Behavior Clinic at the New York State Psychiatric Institute and an Associate Professor of Clinical Psychology in the Department of Psychiatry at Columbia University, College of Physicians and Surgeons. She received her Ph.D. in Human Sexuality from New York University in 1979 and has conducted clinical research in psychosexual disorders since then. Dr. Kaplan was on the Board of the Association for the Treatment of Sexual Abusers and is the current Director of the Special Classification Review Board at Avenel Correctional Facility in New Jersey. Early in her career, she worked as a parole officer for the State of New York for 10 years. She reviews for numerous publications and has over 50 publications in the sexual disorders field.

Drew A. Kingston, Ph.D., C.Psych., received his doctorate in clinical psychology at the University of Ottawa and completed his residency at the Royal Ottawa Health Care Group. He is a registered psychologist in the province of Ontario and is currently the senior psychologist and the Director of Groups and Program Evaluation at the St. Lawrence Valley Correctional and Treatment Centre, a secure treatment unit for incarcerated mentally disordered offenders. Dr. Kingston is on the editorial board of *Sexual Abuse: A Journal of Research and Treatment* and serves as an ad hoc reviewer for several journals. He has published a number of articles and book chapters in the areas of hypersexuality, exhibitionism, pedophilia, and sexual sadism, the impact of pornography on sexual aggression, and the sexual offense cycle.

Richard B. Krueger, M.D., is a psychiatrist and Medical Director of the Sexual Behavior Clinic at New York State Psychiatric Institute. He is President of the New York State Chapter of the Association for the Treatment of Sexual Abusers. He is an Associate Clinical Professor of Psychiatry in the Department of Psychiatry, Columbia University, College of Physicians and Surgeons. He received his M.D. degree from Harvard Medical School in 1977 and is board certified in internal medicine, psychiatry, forensic psychiatry, and addiction psychiatry. He consults on individuals who have committed sexual crimes for the New York State Office of Mental Health and his research interests and publications have focused on the psychopharmacological treatment of compulsive and aggressive sexual behavior. He was a member of the Paraphilias Subcommittee of the Sexual and Gender Identity Disorders Workgroup of the Diagnostic and Statistical Manual, Fifth Edition (DSM-5), which revised the criteria for paraphilias in DSM-5, and he is a member of the Sexual Health and Disorders Committee of the World Health Organization, which is making recommendations for the paraphilic disorders for the International Classification of Diseases, 11th Edition, (ICD-11).

Jill S. Levenson is currently an Associate Professor of Social Work at Barry University in Miami, FL. She is also a licensed clinical social worker with over 25 years of practice experience in interpersonal violence. She has treated victims, survivors, and family members of child maltreatment and sexual abuse. Since 1992, she has provided assessment and treatment services to sex offenders on probation in an outpatient setting, as well as to individuals with other types of problematic sexual behaviors. Dr. Levenson received her Ph.D. in Social Welfare from Florida

International University in 2003. She earned her Master's degree in Social Work from University of Maryland in 1987 and her BA in Sociology from the University of Pittsburgh in 1985.

Dr. Levenson's primary areas of research interest involve studying the impact and effectiveness of social policies and therapeutic interventions designed to reduce sexual violence. She has been a coinvestigator or consultant on five grants funded by the U.S. Department of Justice. Most recently, her research endeavors have focused on the prevalence and impact of adverse childhood experiences and their relationship to adult health, mental health, and criminal outcomes. She has published over 80 peer-reviewed articles and book chapters and has coauthored three books on the treatment of sex offenders and their families. She is well known as an international expert on sexual aggression and is frequently quoted in the media.

Christopher Lobanov-Rostovsky has worked for the Division of Criminal Justice within the Colorado Department of Public Safety as the Program Manager for the Colorado Sex Offender Management Board since 2006, where he is responsible for overseeing the development of standards for the treatment and management of sexual offenders, approving treatment providers, and providing legislative and policy input. Mr. Lobanov-Rostovsky holds a Master Degree in Social Work from the University of Michigan and has been a Licensed Clinical Social Worker (LCSW) since 1990. Prior to his current position, Mr. Lobanov-Rostovsky worked as a clinician and evaluator adult sex offenders and juveniles who commit sexual offenses. Mr. Lobanov-Rostovsky also works as a private consultant for a variety of federal, state, tribal, and private agencies in developing and enhancing sex offender management services, including providing training and technical assistance, program assessment, literature reviews, peer review of grant solicitations and reports, and legislative and policy development. More specifically, Mr. Lobanov-Rostovsky has worked since 2009 with the National Criminal Justice Training Center at Fox Valley Technical College as a consultant on the implementation of the Sex Offender Registration and Notification Act (SORNA) for tribal jurisdictions and has overseen the Native American Sex Offender Management (NASOM) project to identify the research support for needed sex offender treatment, management, and reentry services. Mr. Lobanov-Rostovsky has also been co-project consultant lead for the National Criminal Justice Association (NCJA) on the Sex Offender Management Assessment and Planning Initiative (SOMAPI) to identify research-supported sex offender management and treatment practices. Further, Mr. Lobanov-Rostovsky has published a number of articles and chapters related to federal and state sex offender management public policy. Finally, Mr. Lobanov-Rostovsky served on the Board of Directors for the Association for the Treatment of Sexual Abusers (ATSA) from 2008 to 2015 and is cochair of ATSA's public policy committee.

Caroline Logan is the Lead Consultant Forensic Clinical Psychologist in the Specialist Services Network of Greater Manchester West Mental Health NHS Foundation Trust in the North of England. She is also Honorary Research Fellow in the Institute of Brain Behaviour and Mental Health at the University of Manchester. She has worked in forensic settings for almost 20 years, working directly with clients who are at risk to themselves and others and, in a consultancy role, with the multidisciplinary teams and local and national organizations that care for and manage them. She is a former Board Member of the Scottish Risk Management Authority, the Dangerous and Severe Personality Disorder Programme Expert Advisory Group, and the Project Board of Resettle, the Liverpool clinical risk and case management service for high-risk offenders. She is currently a member of the Advisory Panel for the Close Supervision Centres and Managing Challenging Behaviour Strategy in the Her Majesty's Prison Service Directorate of High Security. She is a coauthor of the *Risk for Sexual Violence Protocol*, a structured professional judgement approach to sexual violence risk assessment and management and a coauthor of the Department of Health guidelines *Best Practice in Managing Risk in Mental Health Services*. Dr. Logan has research interests in the areas of personality disorder, psychopathy, and risk and a special interest in gender issues in offending, on which she has published two books and many articles.

Wesley B. Maram, Ph.D., is currently clinical director of Orange Psychological Services, a sex offender treatment program for parolees, probationers, and individuals with intellectual disability, and an independent evaluator for California Department of State Hospitals Sex Offender Commitment Program. He was formerly Assistant Clinical Professor (volunteer) UCLA Forensic Psychiatric Fellowship Program and provided psychophysiological evaluations for Patton State Hospital sex offender program. He received his Ph.D. in psychology from United States International University, San Diego, and has served on the Executive Committee for California Coalition on Sexual Offending as Chair and Vice Chair. He is an award winner of the Faye Honey Knopp Award. He specializes in the evaluation and treatment of sexual abusers and is a recognized expert witness in criminal and civil court proceedings.

Saprina Matheny, L.I.C.S.W., obtained her MSW from The College of St. Catherine/University of St. Thomas in St. Paul, Minnesota. She has provided outpatient adult sex offender treatment and inpatient and outpatient adolescent sex offender treatment and participated in the evaluations of adult and adolescent offenders. Currently, she works at the Human Development Center, a community mental health center, as the Director of Trauma Services providing services to adolescent and adults. Ms. Matheny also works for the Ambit Network, a National Child Traumatic Stress Network at the University of Minnesota. She coordinated the Dialectical Behavioral Therapy program and began a Trauma Assessment and Family Treatment Program. Ms. Matheny sits on the Multidisciplinary Team for Firstwitness, the local child advocacy center.

Robert J. McGrath, M.A., is Clinical Director of the Vermont Department of Corrections statewide network prison and community sex offender treatment programs. Among his publications, he is coauthor of the books *Supervision of the Sex Offender* and *Current Practices and Emerging Trends in Sexual Abuser Management*. He is also a codeveloper of three risk assessment instruments, the *Vermont Assessment of Sex Offender Risk-2* (*VASOR-2)*, the *Sex Offender Treatment Intervention and Progress Scale (SOTIPS),* and the *Risk of Sexual Abuse of Children Checklist (ROSAC).* He currently serves or has served on treatment advisory boards of several sex offender programs in the United States and the national sex offender treatment programs in Canada, England, and Hong Kong.

Andrew J. McWhinnie is the National Advisor to the Associate Director General, Chaplaincy Services, Correctional Service of Canada for Circles of Support and Accountability. Operating as Andrew McWhinnie Consulting, he is also a therapist specializing in male sexual dysfunction. Andrew earned his Master's Degree in Psychology (specializing in the Psychology of Criminal Conduct) at Carleton University in Ottawa. In the 15 years, Andrew has authored and coauthored well over 35 articles and book chapters on topics related to Restorative Justice, Recidivism, Civil Commitment, and Sex Offender Reintegration methodology. With respect to the reentry of high-risk sexual offenders to communities through Circles of Support and Accountability (CoSA), Mr. McWhinnie's corporate client list is global in scope and practice. He provides training and technical assistance to CoSA project grantees in the United States under a grant program with the U.S. Department of Justice, Office of Justice Programs, the Sex Offender Management, Apprehension, Registration and Tracking (SMART) office.

William D. Murphy, Ph.D., is a Professor in the Department of Psychiatry at the University of Tennessee Health Science Center in Memphis, Tennessee. He specializes in the evaluation and treatment of adult sex offenders and adolescents who have engaged in sexually abusive behavior. Dr. Murphy has provided consultation and training in these areas and also has published a number of articles and chapters in the field. He is the past president of the Association for the Treatment of Sexual Abusers and serves on the Editorial board of *Sexual Abuse: A Journal of Research and Treatment.* He works with Tennessee's Department of Children's Services focusing on effective management of sexually abusive youth and juvenile justice

youth through implementation of best practices including evidence-based assessment and interventions.

Mohan Nair, M.D., is a board-certified forensic psychiatrist and psychopharmacologist. Dr. Nair trained at the University of California and Harvard and has been on the clinical faculty at UCLA and the University of Hawaii. He has been actively involved in the evaluation and treatment of sex offenders for the last 25 years. He has testified extensively in civil and criminal proceedings on sex offending and sexual victimization. Dr. Nair's publications of relevance to this area include chapters on stalking in Principles and Practice of Forensic Psychiatry (Ed.) Richard Rosner, 2003; and psychopathy in International Handbook of Psychopathic Disorders (Ed.) A. Felthous A. & H. Sass, 2007.

Mark E. Olver, Ph.D., is Associate Professor, Registered Doctoral Psychologist (Saskatchewan, Canada), and Director of Clinical Psychology Training at the University of Saskatchewan, Canada, where he is involved in program administration, graduate and undergraduate teaching, research, and clinical training. Prior to his academic appointment, Dr. Olver worked as a clinical psychologist in various capacities, including providing assessment, treatment, and consultation services to young offenders in the Saskatoon Health Region and with adult federal offenders in the Correctional Service of Canada. Dr. Olver's research interests include offender risk assessment and treatment, young offenders, psychopathy, and the evaluation of therapeutic change. He is the codeveloper of the Violence Risk Scale-Sexual Offender version (VRS-SO) and he provides training and consultation services internationally in the assessment and treatment of sexual, violent, and psychopathic offenders.

Jesus Padilla earned his doctoral degree in psychology in 1994. He subsequently worked within State Hospital systems treating, evaluating, and conducting research on sex offenders. He was a member and then chair of the team that designed the treatment program for California's Sexually Violent Predators and was cochair of the research committee within this team. He presented research findings to California's Department of Mental Health, the American Psychological Association, and the California District Attorney's Association. To our dismay, Dr. Padilla is now deceased.

Cameron C. Page, J.D., has practiced law in California since 1977. He began civil practice for 2 years in Santa Barbara, followed by 9 years as a Public Defender. Beginning in 1989, he was a Deputy District Attorney with San Bernardino County, in a variety of assignments, including narcotics, arson, and career criminal and gang prosecutions. He was the supervising attorney in their Civil Commitment Unit for 12 years, handling all types of civil commitment cases (e.g., Sexually Violent Predators, Mentally Disordered Offenders, and Insanity Extension proceedings). He was actively involved in California District Attorney's Association, serving twice as Cochair of the SVP Committee. He also participated in training state evaluators for court testimony in both Sexually Violent Predator and Mentally Disordered Offender proceedings. Mr. Page is now retired.

I. Jacqueline Page, Psy.D., is an Associate Professor at the University of Tennessee Health Science Center in Memphis, Tennessee. Her specialty areas include adolescents who have engaged in sexually abusive behavior, children with sexual behavior problems, and victims of sexual abuse. Dr. Page served on the Association for the Treatment of Sexual Abusers Executive Board and is cochair of the Adolescent Best Practices Committee for the Association. She is an experienced presenter at a state, regional, and national level. Dr. Page works with the Tennessee Department of Children's Services in their efforts toward effective management of sexually abusive youth and juvenile justice youth through implementation of best practices including evidence-based assessment and interventions.

Amy Phenix, Ph.D., is a licensed clinical and forensic psychologist in California in private practice. Her expertise includes sex offender evaluation and risk assessment. She completes evaluations pursuant to the Sexually Violent Predator/Persons Statutes and serves as an expert witness in those cases in several states with similar laws. In her capacity as a trainer, she provides instruction in sex offender risk assessment, the use of the Static-99R, report writing, and issues in court testimony. She has served as Consulting Psychologist for the California Department of Mental Health Sexual Offender Commitment Program from its inception in 1996–2008.

Christopher A. Ralston is a coauthor of the *Juvenile Sexual Offender Recidivism Risk Assessment-II* (JSORRAT-II). He graduated from Iowa State University with a Ph.D. in Counseling Psychology, and his dissertation investigated the predictive validity of the JSORRAT-II in Utah. Dr. Ralston is currently serving as an assistant professor in the Department of Psychology at Grinnell College in Grinnell, Iowa.

Marnie E. Rice was a Fellow of the Royal Society of Canada, Canada's senior national body of distinguished Canadian scientists and scholars. She worked at the Mental Health Centre, Penetanguishene (now called Waypoint Centre for Mental Health Care) for 35 years, as a clinical psychologist, researcher, and, for 14 years, Director of Research. Most recently, she was Research Director Emerita at Waypoint, where she continued her research part-time. She was also Professor of Psychiatry and Behavioural Neurosciences (part-time) at McMaster University, Professor of Psychiatry (adjunct) at the University of Toronto, and Associate Professor of Psychology (adjunct) at Queen's University. She had over 150 scientific publications, including six books. She was the recipient of many awards, including the American Psychological Association's Award for Distinguished Contribution to Research in Public Policy and the Career Contribution Award from the Criminal Justice Section of the Canadian Psychological Association. She was a Fellow of both the American and the Canadian Psychological Associations. Dr. Rice was a mentor, adviser, and source of encouragement to many professionals in several fields. Sadly, she passed away this past summer.

Robert G. Riedel, Ph.D., is a forensic and clinical psychologist. He was a professor of psychology and department chair at various colleges. Dr. Riedel is professor emeritus and former chair of the Social Sciences Department at Southwestern State University in Minnesota. He has taught courses and/or published various areas including psychological testing and measurement, statistics, and aging. Currently, he practices exclusively as a forensic psychologist, primarily in the evaluation of sexual offenders.

Jessica Schilling, Ph.D., works as a licensed psychologist at the Essentia Health-Polinsky Medical Rehabilitation Center in Duluth, Minnesota. She received her doctorate in clinical psychology from Loyola University Chicago, with a subspecialty in child/adolescent psychology. Her clinical work centers around psychotherapy and psychological assessment and evaluations with children, adolescents, and families with neurodevelopmental disorders, including Fetal Alcohol Spectrum Disorder (FASD).

Anita Schlank, Ph.D., A.B.P.P., is a licensed clinical psychologist and certified sex offender treatment provider who received her doctorate in clinical psychology with a forensic specialty from the Law-Psychology program at the University of Nebraska-Lincoln. She is also board certified in Forensic Psychology from the American Board of Professional Psychology. Dr. Schlank has worked evaluating and treating sexual offenders since 1986, and was the Clinical Director of the civil commitment program for the State of Minnesota (The Minnesota Sex Offender Program) from 1995 to 2003, and has served as a consultant to the sex offender civil commitment programs in nine other states. Dr. Schlank was Past President of the Minnesota

Chapter of the Association for the Treatment of Sexual Abusers and is currently the clinical director of the SVP program for the Commonwealth of Virginia.

Michael C. Seto is a registered clinical and forensic psychologist and is the Director of the University of Ottawa Institute of Mental Health's Forensic Research Unit and the Director of Forensic Rehabilitation Research at the Royal Ottawa Health Care Group. He also has adjunct cross-appointments in psychology and/or psychiatry at four universities: the University of Toronto, Ryerson University, Carleton University, and the University of Ottawa. Dr. Seto has published extensively on pedophilia, child pornography, and sexual offending and regularly presents at scientific meetings and professional workshops on these topics. He published a well-reviewed book on pedophilia and sexual offending against children in 2008 and is the author of a new book on internet sex offenders, released June 2013.

Shoba Sreenivasan, Ph.D., is Clinical Professor of Psychiatry and the Behavioral Sciences, University of Southern California, Keck School of Medicine, and a former forensic evaluator for the California and Washington State Sexually Violent Predator Panels. Her publications include issues relevant to sexually violent predator evaluations, including a book chapter (*Actuarial methods for violence and sex—offender risk assessment*) in R. Rosner (Ed.) Principles and Practice of Forensic Psychiatry NY: Oxford University Press, 2003) and peer-reviewed articles (e.g., *Actuarial risk assessment model: A review of critical issues related to violence and sex offender recidivism assessments; Expert testimony in sexually violent predator commitments: Conceptualizing legal standards of mental disorder and likely to reoffend; The impact of surgical castration on sexual recidivism risk among sexually violent predatory offenders;* and *Predicting likelihood of future sexual recidivism: Pilot study findings from a California Sex Offender Risk Project and cross-validation of the Static-99*).

Skye Stephens, M.A., is a doctoral candidate in clinical psychology at Ryerson University. To date her research has focused on the role of sexual deviancy in the onset and maintenance of sexual offending and victim selection in sexual offending, with her dissertation focused on hebephilia and sexual offending. She is also interested in the criminal trajectories of sexual offenders and the treatment efficacy for those found not-criminally responsible on account of mental disorder. Her clinical interests lie in the assessment and treatment of adolescents and adults in conflict with the law.

Jill D. Stinson, Ph.D., is a clinical psychologist and Assistant Professor with the Department of Psychology at East Tennessee State University. Her research interests include self-regulation and maladaptive regulatory behaviors, sex offenders with serious mental illness, rural reentry needs for sexual and violent offenders, and Safe Offender Strategies, an original sex offender treatment protocol. Dr. Stinson's clinical interests additionally include Dialectical Behavior Therapy and the treatment of individuals with suicidality and self-harm behavior. She has published two books and numerous articles and chapters, presented at national and international conferences devoted to forensic mental health and sex offender prevention and treatment, and serves on a variety of professional and administrative committees within the field of sex offender treatment and management.

David Thornton, Ph.D., is currently research director for Wisconsin's program for sexually violent persons and a professor in the department of clinical psychology at the University of Bergen in Norway. He has developed and managed treatment programs for sexual offenders in both correctional and forensic mental health settings and in both the United Kingdom and the United States. He has published on evidence-based standards for effective correctional programs and on the importance of therapist style in sexual offender treatment. He has been involved in the development of static actuarial risk assessment for sexual offenders, contribut-

ing to the development of scales such as Static-99, Static-2002, Static-99R, Static-2002R, and Risk Matrix 2000. He has been involved in the development of psychological risk assessment, creating the Structured Risk Assessment (SRA) framework and contributing to the development of various implementations of this scheme such as the Structured Assessment of Risk and Need (SARN) and the SRA-Forensic Version (SRA-FV). David Thornton has published three books, 14 chapters in edited books, over 50 papers in peer-reviewed scientific journals, and 11 Internet publications.

Greig Veeder has been working in the mental health field since 1974. He worked with adolescents at the Menninger Clinic and delinquent boys sentenced state group homes prior to working with batterers in the Abusive Men Exploring New Directions (AMEND). He began treating adult sex offenders in 1983 and founded Teaching Humane Existence (T.H.E.), the first program in Colorado to use the "containment approach" and one of the original "offense specific" sex offender treatment programs in the state. In 1984, he began using shared living arrangements (SLAs) for offenders, a positive therapeutic milieu that creates residential settings in the community. He introduced the therapeutic use of polygraph to Colorado. He served as board members to the Colorado Association for Sex Therapy and the Rape Assistance and Awareness Program. He contributed to the first edition of standards of practice promulgated by the Association for the Treatment of Sexual Abusers (ATSA) and served for 7 years on the Colorado Sex Offender Management Board. He received his Masters Degree in Social Work from the University of Denver in 1980.

Tony Ward, Dip.Clin.Psyc., Ph.D., is Professor of Clinical Psychology at Victoria University of Wellington, New Zealand. He has taught clinical and forensic psychology at the universities of Canterbury, Deakin, Melbourne, and Wellington. Professor Ward is the creator of the Good Lives Model of offender rehabilitation. He has over 370 academic publications and his research interests include offender rehabilitation, forensic and correctional ethics, and cognition in sex offenders.

Linda E. Weinberger, Ph.D., is a Professor of Clinical Psychiatry in the Department of Psychiatry at the University of Southern California. She is also the Chief Psychologist at the USC Institute of Psychiatry, Law, and Behavioral Science, where she trains postdoctoral psychiatry and clinical psychology fellows in how to conduct forensic evaluations for the courts and attorneys as well as how to evaluate and treat sex offenders. Among her publications, she has coauthored numerous articles on risk assessment and legal evaluations of sex offenders. Finally, she has served as a forensic psychological consultant to various health, mental health, criminal justice, and legal agencies.

Robin J. Wilson, Ph.D., A.B.P.P., is a researcher, educator, and board-certified clinical psychologist who has worked with sexual and other offenders in hospital, correctional, and private practice settings for more than 30 years. He presently maintains an international practice in consulting psychology based in Sarasota, Florida, and is an Assistant Clinical Professor (Adjunct) of Psychiatry and Behavioural Neurosciences at McMaster University in Hamilton, Ontario. Robin's current interests are focused on collaborative models of risk management and restoration as persons of risk are transitioned from institutional to community settings. He has published and presented internationally on the diagnosis and treatment of social and sexual psychopathology, in addition to being a member of the editorial boards of *Sexual Abuse: A Journal of Research and Treatment,* the *Journal of Sexual Aggression*, and the *Howard Journal of Criminal Justice*.

Stephen C.P. Wong, Ph.D., is currently Professor at the Institute of Mental Health, Nottingham, UK, and Adjunct Professor, Department of Psychology, University of Saskatchewan, Canada. He was the Chief of Psychology and Research and then Director of Research at the Regional

Psychiatric Centre in Saskatoon, Saskatchewan, where he carried out research on the assessment and treatment of high-risk offenders and psychopaths for over 25 years. Together with his colleagues and students, he developed the Violent Risk Scale (VRS) and the Violence Risk Scale-Sexual Offender (VRS-SO) version that are now used internationally in the assessment and rehabilitation work of high-risk and violence-prone forensic clients.

Pamela M. Yates is a psychologist and researcher who has worked extensively in correctional and forensic settings as a clinician, researcher, program developer, program evaluator, and trainer. She has worked with youth and adults, including adult sexual offenders, violent offenders, and individuals with substance abuse problems, as well as with victims of violence. She has developed treatment programs for various offender groups, including accredited programs for sexual offenders, and is a certified trainer in various actuarial risk assessment instruments. Her research and clinical interests and publications include assessment and treatment of sexual offenders, the Good Lives and Self-Regulation Models of offending, risk assessment, program evaluation, and treatment effectiveness. She has written and coauthored numerous reports and presentations in the areas of offender rehabilitation, sexual offending, sex offender assessment and treatment, psychopathy, sexual sadism, denial, phallometric assessment, treatment effectiveness, and program accreditation and evaluation.

Gary Zinik, Ph.D., is a clinical forensic psychologist in private practice who received his training at Harvard and the University of California. He has specialized in the evaluation and treatment of sexual deviancy since 1987. He is a Certified Sex Offender Treatment Provider in California, and he has performed risk assessments of Sexually Violent Predators in California, Washington State, and for Federal District Courts. He frequently testifies as an expert witness. He has presented at professional conferences and published articles on the nature of sexual orientation and erotic arousal.

An Integrated Theory of Sexual Offending

Tony Ward, Stephanie Fisher, and Anthony Beech

Introduction

The empirical and theoretical achievements in the sexual offending field have been considerable, and researchers have formulated a number of rich and insightful accounts of sexual offending (Ward, Polaschek, & Beech, 2006). The foci of these theories have been broad and included biological, psychological, and social/cultural levels of analysis. An important implication of this theoretical work is that a satisfactory explanation of sexual abuse is likely to be multifactorial in nature and allows for a diversity of etiological pathways leading to the onset and maintenance of sexual offending. The types of causes canvassed in the research literature include *genetic predispositions* (Siegert & Ward, 2003); *adverse developmental experiences* (e.g., abuse, rejection, attachment difficulties; Beech & Ward, 2004); *psychological dispositions/trait factors*, e.g., empathy deficits, attitudes supportive of sexual assault, deviant sexual preferences, emotional skill deficits, and interpersonal problems (Thornton, 2002); *social and cultural structures and processes* (Cossins, 2000); and *contextual factors*, such as intoxication and severe stress (Hanson & Harris, 2000, 2001).

In the spirit of advancing theory construction, we propose that it is timely to present a comprehensive etiological framework that is capable of encompassing the clinical phenomena evident in offenders and all the causal mechanisms asserted by leading theorists. Our aim is to knit together a number of areas said to be causally implicated in the occurrence of sexual abuse into an integrated theory of sexual offending (ITSO). It is a broad etiological framework that arguably has the capacity to inform the construction of more specific theories of particular types of sexual offending (e.g., rape, child sexual abuse). It is important to note here that the research in this area is based on those few sexual offenders who are actually detected and for those offenses that they actually report; there are limitations in this area and so the development of theory in this area is based on only the available information.

In brief, according to the ITSO, sexual abuse occurs as a consequence of a number of a network of causal factors: biological (evolution, genetic variations, and neurobiology), ecological (social and cultural environment, personal circumstances, physical environment), and core neuropsychological systems. The ITSO, we will argue, is able to explain how clinical phenomena observed in sexual offenders arise from the interaction between these diverse sets of factors. It also has the ability to absorb competing theories of sexual offending and to generate new and exciting lines of research.

The Integrated Theory of Sexual Offending

The ITSO has both horizontal and vertical depth and therefore is able to provide a comprehensive framework to account for the development of sexual offending. *Horizontal depth* refers to the ecological and multisystemic nature of the theory while *vertical depth* denotes the ability of the ITSO to provide a multilevel analysis of sexual offending. According to our approach [after Pennington (2002)], a neuroscientific account of human behavior/psychopathology requires consideration of four levels of analysis, an *etiological level*, *brain mechanisms*, *neuropsychological* analysis, and a *symptom* level. The *etiological level* is concerned with the influence of genetic and environmental factors in causing psychopathology, while the *brain mechanisms level* is concerned with the effects of etiological factors on the development of the brain and its subsequent

functioning (e.g., prolonged abuse; Sapolsky, 1997). *Neuropsychological* analysis is concerned with the brain-based psychological systems generating human behavior, (e.g., spatial perception and language production), and the *symptom* level of analysis is concerned with the clinical phenomena thought to characterize the various forms of psychopathology under investigation (e.g., deviant sexual arousal, mood disturbances, hallucinations). It is the third level given above, *neuropsychological* functioning, that is particularly important from an explanatory perspective as it directly informs researchers of the possible psychological mechanisms generating offenders' psychological symptoms and problems. Following Pennington, we propose that all four of these levels are mutually constraining, and theories at the different levels need to be consistent with each other (Tables 1 and 2).

We will now systematically outline the ITSO, which is shown in schematic form in Fig. 1.

We propose that there are three sets of factors which converge to cause sexual offending and its associated problems: *biological* factors (influenced by genetic inheritance and brain development), *ecological* niche factors (i.e., social, cultural, and personal circumstances-learning), and *neuropsychological* factors. According to the ITSO, sexual offending occurs through the ongoing convergence of *distal* and *proximal* variables, which then interact in a dynamic way. Genetic predispositions and social learning have a significant impact upon brain development and result in the establishment of three interlocking neuropsychological systems (Pennington, 2002), each associated with distinct functions and brain structures: *motivation/emotional*; *perception and memory*; and *action selection and control* (Luria, 1966).

We would further argue that genes, social learning, and neuropsychological systems work together to generate the clinical problems evident in offenders, i.e., deviant arousal, offense related thoughts and fantasies, negative/positive emotional states, and social difficulties. These state factors, as shown in Fig. 1, directly result in sexually abusive actions. The consequences of sexually abusive behavior (on an offender) then act to maintain and entrench the offender's vulnerabilities, and this occurs through the impact of these vulnerabilities on the offender's environment and psychological functioning, i.e., the consequences of sexual offending will function to maintain and/or escalate further sexually deviant actions. This maintenance or escalation is hypothesized to occur through the modification of environmental factors and the reduction or enhancement of the individual's psychological functioning (e.g., their mood, sexual arousal and satisfaction, feelings of powerlessness). For example, an offender might reduce their negative mood state through the use of a maladaptive emotion regulation strategy, such as using coerced sex to regulate their negative mood. The reduction of the negative mood state through the use of this maladaptive strategy is then likely to negatively reinforce the strategy used, while the improvement in mood as a result of these actions will function as a positive reinforcer for the maladaptive strategy. So, the use of coerced sex will be positively reinforced by the improvement in the offender's mood, increasing the likelihood that the offender will repeat this behavior.

Therefore, in our theory brain development (influenced by biological inheritance and genetics) and social learning interact to establish individuals' level of psychological functioning. This functioning may be compromised in some way by poor genetic inheritance, biological damage, or developmental adversity to make it difficult for the individual concerned to function in an adaptive manner. This compromised functioning may lead to problematic psychological functioning and subsequent clinical symptomatology. We will now examine each of these areas in more detail.

Table 1 Neuroscientific account of human behavior

Etiological level	Concerned with the influence of genetic and environmental factors in causing psychopathology
Brain mechanisms	Concerned with the effects of etiological factors on the development of the brain and its subsequent functioning
Neuropsychological analysis	Concerned with the brain-based psychological systems generating human behavior
Symptom level	Concerned with the clinical phenomena thought to characterize the various forms of psychopathology under investigation

Table 2 Factors that converge to cause sexual offending

Biological factors	Influenced by genetic inheritance and brain development
Ecological niche factors	Social, cultural, and personal circumstances, and learning
Neuropsychological factors	The nature of the physical processes associated with the functioning of the brain including motivation, emotions, goals, beliefs, action directed behavior, information processing

Brain Development

The first source for offense related vulnerabilities is brain development. There are a wide variety of biological variables associated with abnormal brain development, ranging from the existence of biologically inherited mating strategies that are maladaptive (i.e., the acquisition of aggressive or problematic strategies—Buss, 1999), the modulation of sexual behavior by hormonal activity in normal and abnormal contexts, and, for example, the biological processes associated with attachment (Nelson & Panksepp, 1998).

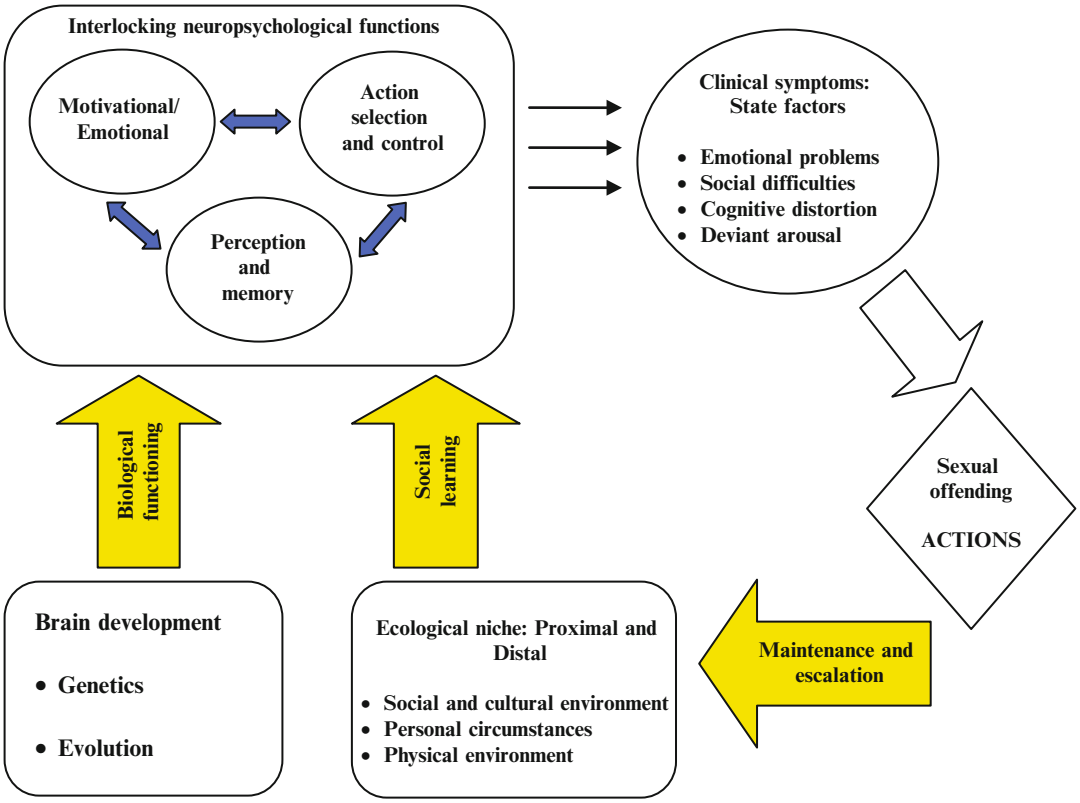

Fig. 1 A schematic representation of the integrated theory of sexual offending. The authors would like to thank Elsevier Science for permission to use figure 1, originally published in Ward, T., & Beech, T. (2006). An integrated theory of sexual offending. Aggression and Violent Behavior, 11, 44–63

The Role of Evolution in Brain Development

The fundamental idea in evolutionary theory is that organisms slowly evolve over time and through a process of natural selection either adapt to environmental challenges or become extinct. The process of change is gradual, comprised of small, incremental modifications in existing organs or characteristics, which can lead to the emergence of new characteristics or even a new species. Through the processes of natural selection and sexual selection, animals that are the winners in the evolutionary struggle develop specific physical and psychological adaptations that enable them to meet these challenges.

There are three fundamental elements in Darwin's (1859) theory of natural selection. First, individual members of a species vary with respect to their physical and psychological traits. Second, some members of a species will demonstrate variations which make them better able to survive or adapt to changing environmental conditions. Third, those individuals who are better equipped to survive will be more likely to breed and in doing so will pass on these characteristics to their offspring. Consequently, these inherited characteristics will become more common within that species. In addition to natural selection, Darwin also discerned one other important process in evolution—*sexual selection*. This is the idea that male and female members of a particular species will demonstrate distinct preferences in their choice of mates based upon the physical or behavioral characteristics of potential partners. Some of these genetically based predispositions may be linked to the sex of the individual, and so there are gender linked vulnerabilities. These gender linked vulnerabilities include the tendency for males to engage in impersonal sex (Brennan & Shaver, 1995) and for males to rape if they cannot attract a sexual partner (Thornhill & Palmer, 2000).

Genetic Determinants of Brain Development

An evolutionary approach to human behavior that is able to incorporate the malleability of human beings and their capacity for culture is gene-culture coevolution theory (Odling-Smee, Laland, & Feldman, 2003). This is a flexible evolutionary model claiming that genetic, individual learning, and cultural processes propel the evolution of human beings. Because of this, the explanation of human traits is likely to involve these three sets of processes (Odling-Smee et al., 2003). *Genetic factors* may result in a predisposition to seek certain types of basic goods (e.g., relationships, sexual satisfaction, autonomy, mastery), while *learning events*,

within a particular cultural context, provide *socially constructed* ways of achieving these valued experiences, activities, and outcomes. For our integrated theory, this means that the causes of sexually aggressive behavior are likely to have a naturalistic basis, and that motivational and cognitive biases lead individuals to seek basic human needs in socially unacceptable ways. An important aspect of this idea is the powerful influence of genetic and cultural processes; neither dominates the other, giving both biological and social learning oriented researchers an important role in accounting for sexually abusive behavior.

Neurobiological Functioning

The neurobiological level of analysis is concerned with the nature of the physical processes associated with the functioning of the brain, such as type and levels of neurotransmitters, the existence of neural pathways, and the integrity of neural structures. There are at least two ways such brain processes impact on the neuropsychological systems underpinning human actions: (a) functional systems may be *disrupted* by brain-based abnormalities, and (b) the *calibration* of the systems may be directly influenced by physical processes. An example of a functional system being disrupted is when high levels of stress hormones, such as cortisol, compromise the operation of the action selection and control system, and this may manifest itself as the individual behaving impulsively (Bremner et al., 1997; Sapolsky, 1997). An example of the second type of relationship is when the individual experiences persistently high levels of stress hormones and this in turn increases the salience and availability of sexual goals and strengthens their influence on the individual, and this may manifest itself as the person becoming preoccupied with sexual goals and needs.

Neurobiological research reveals that structural brain damage and/or neurotransmitter malfunction can impact adversely upon sexual behavior. For example, we suggest that for some individuals the motivation/emotional system can be compromised by dysfunctional neurotransmitter mechanisms. This may lower the threshold for sexually aggressive behavior by increasing the strength, salience, and duration of sexual goals and desires, and additionally, by weakening the action selection and control systems. Put simply, the presence of extremely intense sexual feelings might override an individual's ability to control his sexual behavior.

Ecological Niche: Proximal and Distal Factors

A second source for offense related vulnerabilities is the ecological niche (social and cultural roles of the offender) and habitat (environment in which a person lives) that the individual is exposed to. In certain circumstances, vulnerabilities in these areas may cause a person to commit a sexual offense in the absence of any significant psychological deficits or vulnerabilities. We have used the term "ecological niche" to refer to the set of potentially adverse social and cultural circumstances, personal circumstances, and physical environments confronting each person as he or she develops throughout their life, e.g., growing up in a low socioeconomic status family.

The content and functional integrity of a person's psychological system is determined by a combination of biological inheritance and social learning. Once acquired, psychological vulnerabilities related to sexual offending are thought to function as a predisposition, making it more probable that an individual will struggle to effectively meet specific environmental challenges and therefore make it more likely that he or she will commit a sexual offense at some future time. These psychological vulnerabilities can be regarded as a more *distal* dimension of risk. An individual's current ecology or physical environment is also an important contributor to the etiology of sexual offending through making available potential victims, and by creating the specific circumstances that trigger the psychological deficits involved, this is a *proximal* or current dimension of risk. For example, the experience of fighting in a war (Henry, Ward, & Hirshberg, 2004), being subject to social circumstances such as the erosion of one culture by another, or the death of a partner may sometimes lead to individuals committing a sexual crime that they would under other circumstances have found abhorrent. In these kinds of extreme circumstances, individuals can behave in ways they would not normally consider and may even engage in actions that they would view as utterly reprehensible in their normal environments.

In other words, sometimes the major causal factors resulting in sexual offending reside in the ecological niche rather than within the person. The offending may be quite opportunistic, or the consequence of circumstances that effectively erode an individual's capacity to behave in an ethical, and typical, manner (Marshall & Barbaree, 1990). Consideration of these factors leads us to an understanding that sexual offending emerges from a network of relationships between individuals and their local habitats and niches and is not simply the consequence of individual psychopathology. Furthermore, an individual's unique circumstances are hypothesized to influence his/her psychological and social development by virtue of their influence on core functional systems. For example, Watkins and Bentovim (1992) report evidence that the long-term effects of childhood sexual victimization are psychological disorder, with marked risk for the development of alcohol and drug misuse. In a similar vein, Beitchman et al. (1992) state that the long-term effects of childhood sexual victimization include disturbed adult sexual functioning, poor social adjustment, confusion over sexual identity, inappropriate attempts to reassert masculinity, and recapitulation of the abuse by the victim on new victims. Each of these problems is associated with impaired psychological skills and competencies.

Table 3 Neuropsychological functioning

The motivation/emotional system	The perception and memory system	The action selection and control system
Associated with the cortical, limbic, and brainstem brain structures	Associated with the hippocampal formation and the posterior neocortex	Associated with the frontal cortex, the basal ganglia, and parts of the thalamus
Allows goals and values to influence both perception and action selection	Major function is to process incoming sensory information and to construct representations of objects and events, and make them available to the other two systems	Major function is to help the organism plan, implement, and evaluate action plans, and to control behavior, thoughts, and emotions in service to higher-level goals
Also allows adjustment of motivational state to fit changing environmental circumstances	Problems in this system can lead to maladaptive beliefs, attitudes, and problematic interpretations of social encounters	Implement plans designed to achieve the individuals' goals
Example: Person may, through poor learning, lack the skills to be able to develop interpersonal relationships, and this deficit may result in social isolation and psychological deficits which could lead to sexual offending	Example: A person with maladaptive beliefs will likely activate problematic goals and emotions, which can make it difficult for the individual to control his sexual behavior, possibly leading to sexual offending	Example: A person with problems in this system will present with problems of self-regulation such as impulsivity, failure to inhibit negative emotions, and inability to adjust plans to change

Neuropsychological Functioning

Both biological inheritance and social learning can have a significant impact on individuals' developing brains and have an impact upon on the three interlocking neuropsychological systems: *motivation/emotional*, *perception and memory*, and *action selection and control* (Luria, 1966; Pennington, 2002) that arguably underpin psychological functioning. Although the systems may be differentially compromised in some ways, it is likely that problems in any of the systems will adversely affect the others in some respects. We will now examine each of these systems and consider how they can be involved in specific aspects of dysfunction in more detail (Table 3).

The Motivation/Emotional System

This system is associated with the cortical, limbic, and brainstem brain structures. According to Pennington (2002), a major function of this system is, '…to allow goals and values to influence both perception and action selection rapidly and to adjust motivational state to fit changing environmental circumstances' (p. 79). Problems in an individual's genetic inheritance, cultural upbringing, or negative individual experiences may lead to defects in the motivational/emotional system. For example, someone who was brought up in an emotionally impoverished environment might find it difficult to identify his emotions in an accurate manner and also become confused when confronted with emotionally charged interpersonal situations. Such an individual might become angry and act in an antisocial manner on occasions. Another type of problem could be related to the range of needs or goals sought by such a person. Poor early learning could lead to an individual lacking the skills necessary (internal conditions) to establish strong interpersonal relationships and result in social isolation and further psychological and social deficits that could lead to sexual offending, such as intimacy problems (Marshall, 1989) or attachment problems (Baker & Beech, 2004; Ward, Hudson, & Marshall, 1996). These deficits in interpersonal functioning are exactly the kinds of problems that Thornton (2002) and Hanson and Harris (2001) regard as a particular type of stable dynamic risk factor for sexual offending, i.e., causal psychological risk factors (Beech & Ward, 2004; Ward & Beech, 2004). Our point here is that psychological vulnerabilities that have been previously described in the sexual offending literature as a stable dynamic risk domain can be reconceptualized as dynamic disturbances in the motivation/emotional system.

The Action Selection and Control System

The action selection and control system is associated with the frontal cortex, the basal ganglia, and parts of the thalamus. A major function of this system is to help the organism to plan, implement, and evaluate action plans, and to control behavior, thoughts, and emotions in service of higher-level goals. The action selection and control system is concerned with the formation and implementation of action plans designed to achieve the goals of the individual. It draws heavily upon the *motivation/emotional* system for the goals that effectively energize behavior and the *perception and memory* system for procedural and declarative knowledge (i.e., knowledge about how to do certain things, and relevant facts and information pertaining to a given situation). Problems that might arise from malfunctions in the action control and selection system essentially span self-regulation problems such as impulsivity, failure to inhibit negative emotions, inability to adjust plans to changing circumstances, and poor problem solving skills.

Again these deficits in self-management/self-regulation are exactly the kinds of problems that in the sexual offending literature have been described as stable dynamic risk factors (Hanson & Harris, 2000, 2001; Thornton, 2002). As we have argued above, it is possible to view these "vulnerability factors" as essentially disturbances in the action selection and control system—in conjunction with input from the

other two neuropsychological systems comprising the ITSO. In other words, the "self-control" theoretical constructs involved in many theories/descriptions of sexual offending (e.g., Ward & Hudson, 1998) can be reformulated in terms of the interlocking neuropsychological systems. Thus, we are not simply *relabeling* clinical phenomena but rather are showing how these factors can be produced by the casual mechanisms comprising the ITSO.

The Perception and Memory System

This system is associated primarily with the hippocampal formation and the posterior neocortex. A major function of this system is to process incoming sensory information and to construct representations of objects and events and make them available to the other two systems. Problems in the perceptual and memory system can lead to maladaptive beliefs, attitudes, and problematic interpretations of social encounters. The presence of maladaptive beliefs that are frequently available to guide information processing is likely to cause the subsequent activation of problematic goals and emotions, which in relation to sexual offending make it difficult for a person to effectively control his sexual behavior. We hypothesize that these cognitive structures can function as preattentive filters biasing the processing of social information and resulting in a variety of personal and social difficulties.

These problems may underlie the kinds of offense-supportive cognitions that Thornton (2002) and Hanson and Harris (2000, 2001) regard as another type of stable dynamic risk factor for sexual offending. The ITSO proposes that what have been termed cognitive distortions (Abel et al., 1989) are arguably caused by entrenched beliefs and subsequent biased information-processing originating in the perception and memory system. An intriguing aspect of the ITSO is that different types of cognitive distortions are predicted to have their origins in different neuropsychological systems.

Clinical Phenomena

Problems in any of the neurological systems outlined above will comprise a person's adaptive functioning in any number of ways, depending on the specific dysfunction in question, e.g., if there are problems in the *action selection and control* system it will make it more difficult for an individual to adequately regulate his mood. Exposure to antisocial models is also likely to teach individuals maladaptive ways of solving personal and interpersonal problems and result in problematic values and attitudes which will have an impact upon the *perception and memory* system. It is hypothesized by the ITSO that the three functional systems will always interact to cause a sexual offense but that this interaction will be different for each person depending on that individual's specific problems within these systems. In addition, there are numerous types of problems that can occur within the three systems and these can also result in different clinical presentations and treatment needs. The fact that the three functional systems can individually, or collectively, create offense related vulnerabilities, means that different types of deficits in these systems will be associated with different offense variables. That is to say, individuals will commit sexual crimes for quite different reasons and therefore present with varied clinical problems, but these all lead back to problems with the three functional systems. That is, each individual will have their own offense pathway, but this will be influenced by their own interaction of the three functional systems.

According to the ITSO, deficits in neuropsychological functioning interrelate with individuals' current *ecology* or physical environment (proximal dimension) to cause the emergence of four groups of symptoms or clinical phenomena that are directly associated with sexual offending. These clinical phenomena can be usefully viewed as acute risk factors (Hanson & Harris, 2000, 2001) or the *acute state* of Thornton's (2002) dynamic risk domains, which are self-management problems, socio-affective functioning problems, distorted attitudes, and deviant sexual interests. These clinical phenomena are then expressed in a state form, such as: powerful emotional/behavioral expression, need for intimacy/control, offense-supportive cognitions (deviant thoughts and fantasies), and deviant sexual arousal, and it is from this expression that they are likely to lead the individual concerned to commit a sexual offense, depending of course on the availability and accessibility of a potential victim (an ecological variable). We will now examine each of these clinical phenomena in more detail.

Emotional/Behavioral Regulation Problems

The first set of clinical symptoms/problems include the commission of impulsive acts, poor emotional control (tendency to explosive outbursts), and other behavioral expressions of emotional impulses. These phenomena may arise from problems in two different neuropsychological systems. For example, problems in an individual's *motivation/emotional* system may manifest at a psychological functioning level as mood problems, while a problem in the *action selection and control* system will present as impulsive behavior. Therefore, the causes of what Thornton describes as problems in self management (Domain 4 problems), have their roots in more than one neuropsychological system.

We would suggest that these problems occur due to exposure to sexual activities such as compulsive masturbation during early adolescence, and the absence of alternative means of increasing self-esteem or mood, which can create a profound link between sex and emotional well-being (Cortoni & Marshall, 2001). Emotional competency deficits are likely to produce powerful negative emotional states, say for example, an individual may have an argument with a partner or may experience a stressful life event, such as

losing a job, and if they have emotional competency deficits then they will experience a powerful negative emotional state as a result. This is particularly the case if the individual lacks the ability to dampen down, or communicate, their emotions in a "healthy" way. Such an inability to efficiently manage mood states may result in a loss of control, which, in conjunction with sexual desire, can lead an individual to either become disinhibited or else opportunistically use sex as a soothing strategy to meet his or her emotional and sexual needs. This may be especially likely when confronted with triggering risk factors (Beech & Ward, 2004; Ward & Beech, 2004) such as substance abuse, anger, hostility, and emotional collapse.

Need for Intimacy and Control

The second set of clinical symptoms revolves around social difficulties and includes: emotional loneliness, inadequacy, low self-esteem, passive victim stance, and suspiciousness. Problems in this area are arguably a reflection of dysfunction in the *motivation and emotional* system and can be viewed in terms of attachment insecurity leading to problems establishing appropriate adult intimate relationships (Ward et al., 1996). Attachment style is a relatively enduring set of characteristics for making sense of one's life experiences (Young, Klosko, & Weishaar, 2003), where either one has a positive or negative view of self and others. Beech and Mitchell (2005) have outlined how distal ecological factors such as adverse childhood experiences are highly significant for neurological systems (especially events such as abuse, stress, and rejection), which can produce biochemical changes in the neuropsychological systems that underlie and modulate attachment behaviors (Kraemer, 1992).

There are a number of different kinds of attachment style that have been identified in sexual offenders, each reflecting different types of motivation/emotional system dysfunction. Ward et al. (1996) have argued that there are three insecure attachment styles in the four-category model that would be related to different types of sexual offending given the particular environmental triggers. The three insecure attachment styles are proposed as follows: *Dismissive* individuals would be more likely to demonstrate hostility to others, making them likely to offend violently against adult women; *preoccupied* individuals would tend to seek approval from others and sexualize attachment relationships, leading them to engage in sexual contact with children; Further to these ideas, Burk and Burkhart (2003) note that individuals with a *Disorganized* style of attachment are likely to use sexual offending as one of several possible strategies of externally based control in response to the intense negative emotional states which are the consequence of such a attachment style. Further to this idea, Smallbone and Dadds (1998, 2000) suggest that for intra-familial abusers—if an individual has some level of disorganized attachment, then in reaction to distress they may activate their sexual systems rather than their attachment system and so in response to a nonsexual need they may employ sexual tactics. This individual may use sex to achieve nonsexual needs because their attachment style has their sexual needs tied in with attachment. Taken together these ideas would suggest that the relative levels of need for intimacy and control would vary depending upon the type of attachment style an individual has.

Offense-Supportive Cognitions

The third set of clinical symptoms associated with committing sexual offenses in child molesters and rapists are offense-supportive cognitions, i.e., cognitive distortions. The type of cognitive distortions that child abusers typically report reflect the views that children are sexual beings and that sex does not cause harm to children (Ward & Keenan, 1999). The kinds of offense-supportive cognitions evident in rapists include the beliefs that heterosexual encounters are inherently conflict ridden, that women seek to deceive men about what they really want, and that women are constantly sexually receptive to men's needs (Polaschek & Ward, 2002). Ward and Keenan proposed that underlying these surface level cognitions are a set of schemas which are utilized by individuals to explain, predict, and interpret interpersonal phenomena. These schemas can be regarded as "implicit theories" in that they are part of the process by which offenders explain and interpret the actions of others. Implicit theories are likely to have been formed during an offender's early life and therefore exert their effects through the filtering of perceptual information. In other words, implicit theories are located in the *perception and memory system*.

Sexual Interests

It is commonly thought that child molesters sexually abuse children because they have a deviant sexual interest in children, and that rapists prefer forced sexual contact with women to consensual sex. In other words, the expression of deviant, sexual behavior is thought to be the direct product of a deviant sexual preference. These deviant sexual preferences (or paraphilias) are thought by many to have become entrenched prior to the initial deviant act (Abel et al., 1987; Marshall, Barbaree, & Eccles, 1991). Paraphilias have been defined as, "recurrent intense sexually arousing fantasies, sexual urges or behaviors generally around children or non-consenting persons, the suffering or humiliation of oneself or others, or nonhuman objects" (DSM-IV-TR, APA 2000, p. 522). More recently, those who have described the acquisition of deviant sexual preference have suggested a more sophisticated description of how such paraphilias are acquired. Here, fantasy is seen as being important in the maintenance of deviant interests. Leitenberg and Henning (1995) define sexual fantasy as almost any mental imagery that is sexually arousing or erotic to the individual. Sexual fantasies do not have to

be accompanied by masturbation, although they often are. The role of sexual fantasy in the etiology of sexual offending is described by Abel et al. (1987), who report that in a sample of 400 outpatient sexual offenders, 58 % stated that they had experienced, prior to the age of 18, sexual arousal to deviant ideas that were later translated into deviant acts. Additionally, Marshall and Eccles (1991) report that 41 % of men who had molested extra-familial male children had experienced deviant fantasy prior to the age of 20. Hence, it is hypothesized that deviant fantasies precede deviant arousal, which, in turn, leads to sexual offending.

We would suggest these problems arise through an interaction between the three areas of dysfunctional psychological functioning discussed above. That is, the inability to effectively manage attachment issues and mood problems (problems in the *motivation/emotional system*) system, in the presence of dysfunctional schemas/implicit theories (problems in the *perception and memory* system) may lead to the occurrence of deviant sexual fantasies and sexual preoccupation. These problems coupled with a failure to regulate sexual desire (a basic physiological drive—*motivation/emotional* system) might lead an individual to use sex to meet their emotional and sexual needs. Specifically, if an individual has problems with sexual control (problems in the *action selection and control* systems), in conjunction with high levels of sexual arousal, driven by deviant interests, this would mean that deviant sexual arousal could easily occur in particular situations, given certain triggering factors, such as anger, hostility, or the presence of a potential victim. That is, situations where due to personal circumstances and/or the nature of the physical environment, an individual would become deviantly aroused to children or to the thought of coercive sex with a woman. We will now describe how such "deviant" arousal and the other three types of clinical problems are maintained and can escalate.

Maintenance and Escalation of Clinical Factors

The ITSO accounts for the maintenance and escalation of sexual offending by virtue of its impact on the ecology of the offender and on his psychological functioning. The sexual abuse of a child might result in a person becoming further socially isolated from his normal social supports and lessen his chances of forming appropriate intimate relationships. If an individual in this situation also has problems with his mood, then sex with a child may become increasingly a powerful way of regulating problematic emotional states. In other words, the consequences of sexually abusive actions can modify, entrench, or worsen the personal circumstances of an offender and in this way, increase or maintain the offending behavior.

From the perspective of the ITSO, cultural factors interact with biological and individual learning to create situations that support or discourage sexual offending. An example of a relevant cultural process might be the portrayal of females as essentially sexual objects and males as sexually entitled to have sex with whom they want and when they want (Polaschek & Ward, 2002). For some males, a weak genetic predisposition toward sexual promiscuity may interact with a learning environment where females are routinely ridiculed and presented as inferior and a culture where females are not valued and are underrepresented in positions of power and influence. In this situation, it is probable that males will grow up with pro-rape attitudes and beliefs. Furthermore, continued exposure to a social environment characterized by sexist and hostile attitudes to women, and dysfunctional sexual norms, can help to maintain and even escalate sexual offending.

Relationship to Other Theories of Sexual Offending

We propose that the ITSO has the theoretical resources to unify other prominent theories of sexual offending. We do not have the space in this chapter to demonstrate this for every theory, so we have chosen what we see as two of the most promising etiological theories in order to illustrate how this can be done. The theories we have selected are Finkelhor's (1984) precondition theory and Marshall and Barbaree's (1990) Integrated Theory. We will limit ourselves to a brief description of each theory and a few comments about how it could be incorporated within the ITSO.

Finkelhor's Precondition Theory

Finkelhor (1984) suggests that four underlying factors have typically been used to explain the occurrence of child sexual abuse, usually in the form of single factor theories. These theories are based on the following claims: sex with children is emotionally satisfying to the offender (emotional congruence); men who offend are sexually aroused by a child (sexual arousal); men have sex with children because they are unable to meet their sexual needs in socially appropriate ways (blockage); and finally, these men become disinhibited and behave in ways contrary to their normal behavior (disinhibition). He argues that the first three factors explain why some individuals develop sexual interest in children and the fourth why this interest manifests as sexual deviance.

In Finkelhor's theory, these four factors are grouped into four preconditions that must be satisfied before the sexual abuse of a child occurs. The first precondition implies that the offender must be motivated to sexually abuse a child, and encompasses three of the four factors (i.e., emotional congruence, sexual arousal, and blockage). The second precondition involves overcoming internal inhibitions (e.g., which can be achieved through alcohol, impulse disorder, senility,

psychosis, severe stress, socially entrenched patriarchal attitudes, or social tolerance of sexual interest in children), and is related to the disinhibition factor. The third precondition involves overcoming external inhibitions or conditions that increase the possibility of offending (e.g., maternal absence or illness, lack of maternal closeness, social isolation of family, lack of parental supervision, unusual sleeping conditions, or paternal domination or abuse towards mother). The final precondition states that the offender must overcome a child's resistance to the abuse (e.g., giving gifts, desensitizing a child to sex, establishing emotional dependence, using threats or violence). The two remaining preconditions are associated with the how of the offense process and do not relate to the four causal factors. Finkelhor hypothesizes that the preconditions occur in a temporal sequence with each being necessary for the next to occur.

The four factors or motives in Finkelhor's theory can be subsumed within the three psychological systems outlined earlier: the motivation/emotional, perception and memory, and action selection and control systems. Emotional congruence and sexual arousal are motivational constructs and have affective aspects to them. In the ITSO, they would both be incorporated within the motivation/emotional system. The constructs of blockage and disinhibition can be seen as reflecting faulty planning or self-regulation and can be viewed as parts of the action and control system. The preconditions of overcoming both external and a child's resistance can also be viewed as reflecting control strategies and would also involve the retrieval of information from strategies from the perception and memory systems.

Marshall and Barbaree's Integrated Theory

Marshall and Barbaree's Integrated Theory (1990) proposes that the sexual abuse of children occurs as a consequence of a number of interacting distal and proximal factors. Specifically, this theory states that individuals experiencing developmentally adverse events (e.g., poor parenting, inconsistent and harsh discipline, physical and sexual abuse) are likely to exhibit distorted internal working models of relationships, particularly, with respect to sex and aggression, resulting in poor social and self-regulation skills from an early age.

For these individuals, the transition into adolescence is a particularly critical period. It is at this stage that individuals are most receptive to acquiring enduring sexual scripts, preferences, interests, and attitudes. Furthermore, the massive increase of sex hormones during this period increases the salience and potency of these sexual cues. According to Marshall and Barbaree, sex and aggression originate from the same neural substrates (e.g., hypothalamus, amygdala, septum, etc.) and are thought to cause qualitatively similar experiences. If an individual comes from an adverse background and, therefore, is already predisposed to behaving in an antisocial manner, the pubertal release of hormones may serve to fuse sex and aggression and to consolidate or enhance already acquired sexually abusive tendencies.

As a young adult, the lack of effective social and self-regulation skills makes it more probable that relationships, or attempted relationships, with women will be met by rejection and result in lowered self-esteem, anger, and negative attitudes toward females. These powerful negative emotions may fuel the intensity of sexual desires and the development of deviant sexual fantasies. Masturbation to these fantasies will increase their strength and also function as mental rehearsals in which future sexual offenses are planned. Young children may be viewed as more inherently trustworthy and to constitute a "safe haven" for the individual. The individual may therefore see deviant sex or fantasies as meeting a multitude of needs, including releasing sexual tension, and increasing personal effectiveness and control, interpersonal closeness, self-esteem, and masculinity.

According to the integrated theory, the above vulnerability factors interact with more transient situational elements such as stress, intoxication, strong negative affect, sexual stimuli, and the presence of a potential victim to impair an individual's ability to control their behaviors, resulting in a sexual offense. The reinforcing effects of deviant sexual activity and the development of cognitive distortions maintain offending. This reinforcement may be positive (e.g., sexual arousal, sense of power) or negative (e.g., reduction of low mood) in nature.

Marshall and Barbaree's Integrated Theory is a very sophisticated and powerful theory and its accommodation within the ITSO requires considerable thought. In order to ease, the task we will simply take each of the three systems comprising the trait factors of the ITSO and consider its relationship to key ideas in the Integrated Theory. With respect to the trait or vulnerability factors, the following analysis is feasible: (a) The motivation/emotional system can incorporate the sexual attachment, intimacy, emotional, and needs constructs of the Marshall and Barbaree theory. (b) The action selection and control aspect of our theory can absorb the impulsivity, social skills, and self-regulation components of the Integrated Theory. (c) The perception and memory system is able to integrate the entrenched beliefs, strategies, identity, and values referred to in the Integrated Theory. Concerning the other variables comprising this elegant theory, the emphasis on ecological, social learning, circumstantial, and biological factors are all easily dealt with. For example, early learning events are viewed as part of the developing offender's social ecology. One of the virtues of the Integrated Theory is that it explicitly addresses the role of biological and hormonal variables in the genesis of sexual abuse. With its strong neurobiological orientation, the ITSO is also able to take these factors in account without neglecting the important role of psychological agency and identity.

Future Directions and Conclusions

In this chapter, we have sketched out a possible framework for integrating many of the factors identified in research and theory determinants of sexual offending. In our view, the ITSO shows considerable potential for bringing together theories from different levels of theory, including the major multifactorial theories of sexual abuse (strong unifying power). It incorporates the insight from the comprehensive etiological theories that there are multiple trajectories to sexual offending. It also provides a useful way of incorporating single factor theories in terms of the three psychological systems outlined earlier. Individually and collectively, the three systems can be utilized to explain specific problems evident in sexual offenders such as emotional loneliness or deviant sexual arousal. It is also possible to create a unified or integrated account such as the one sketched out in this chapter. Finally, theories of the offense and relapse process are easily accommodated by virtue of the ITSO's stress on self-regulatory capacities and the role of ecological factors in facilitating sexual crime. Cultural factors are considered to be both a developmental resource and also part of the offender's current ecology.

Furthermore, the ITSO provides a clinically useful framework for the assessment and treatment of sexual offenders. Its ability to account for multiple offense trajectories and varying clinical presentations means it will help clinicians to focus on offenders' unique problems. The multisystemic nature of the ITSO prompts therapist to take into account a range of causal variables when formulating a case, to think dynamically with respect to their interaction, and to appreciate the role of ecological (i.e., social, cultural, circumstantial) variables in both creating the conditions for abuse and in shaping offender vulnerabilities. In our view, the use of the ITSO by clinicians will facilitate the construction of tailored treatment programs and avoid the mistakes inherent in a-one-size-fits-all perspective.

Finally, the ITSO is really an abstract framework for thinking systematically about sexual offending and its constituent causal variables. It is necessary for researchers to unpack its assumptions in greater detail and apply it to different types of sexual crimes, for example, rape, exhibitionism, or child molestation (i.e., to achieve greater explanatory depth and to improve upon its existing heuristic value). The abstract nature of the ITSO allows for variety in the types of goals, strategies, contexts, beliefs, emotions, and biological mechanisms involved in different sexual crimes. In other words, the ITSO possesses both horizontal and vertical depth. The former by virtue of its strong ecological orientation and the latter because it assumes human beings are embodied beings whose actions are conjointly influenced by a network of causal influences. Like all of us, sexual offenders are psychological agents who seek to realize their personal goals and animals whose evolved capacities allow them the possibility of changing their lives.

Part I

Disorders and Types of Sexual Offending

Pedophilic Disorder

Jill D. Stinson and Judith V. Becker

Pedophilia, or a sexual interest in young children, has long been recognized as unusual and deviant, often linked with sexual behaviors involving youth and prepubescent children. Even early cultures which condoned the marriage of older men to adolescent females, or sexual relationships between older males and adolescent males (i.e., pederasty), largely condemned and questioned individuals who engaged in preferential sexual practices with very young children who had not yet reached the age of puberty (e.g., Suetonius, 121/1989; see also Quinsey, 1986; Seto, 2008a). Early works dedicated to the discussion of aberrant sexual behaviors as a form of mental illness (e.g., Krafft-Ebing, 1886/1997) also noted the peculiarity of individuals who chose to engage in sexual behavior with infants and young children. It seems that despite cultural variations in marriageable age and perceptions of sexual development, sexual interest, and arousal associated with infants and very young children are almost universally perceived as unconventional and at the same time, inappropriate.

Diagnosis and Diagnostic Considerations

Pedophilia first appeared in the context of mental disorder in the late nineteenth century, when it was labeled *paedophilia erotica* by Krafft-Ebing (1886/1997). It was later included in the diagnostic nomenclature for mental health professionals with the publication of the *Diagnostic and Statistical Manual for Mental Disorders, 2nd edition* (American Psychiatric Association, 1968) and has continued to be defined as a mental illness in subsequent revisions of diagnostic criteria related to problematic sexual interest and behavior.

Our most current diagnostic definition of pedophilia comes from the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM 5, American Psychiatric Association, 2013). Termed pedophilic disorder, this diagnosis connotes not simply sexual interest in prepubescent children but also the presence of significant distress, interpersonal impairment, or other difficulty as a result of these sexual interests. The DSM 5 contains a number of key diagnostic elements that were similarly present in the previous 4th edition and text revision of the Diagnostic and Statistical Manual (DSM-IV-TR, American Psychiatric Association, 2000). Within this definition are several crucial features: (1) recurrent and intense sexually arousing fantasies, urges, or behaviors involving prepubescent children, (2) acting on the urges or experiencing clinically significant distress or interpersonal impairment, and (3) time-related criteria, including a duration of at least 6 months for fantasies, urges, or behaviors and an age of 16 for the individual in question, with at least 5 years' difference in age between the individual and the children of interest. Additional specifiers include child gender preference, incestuous sexual interest, and whether or not the individual is also attracted to adults as well as children. While it is noted that the sexual interest involves a prepubescent child, this is merely defined as "generally 13 or younger," given that signs of pubescence are fluid throughout early pubertal development and vary from child to child. Diagnostic criteria for pedophilia described in the *International Statistical Classification of Diseases and Related Health Problems, 10th Revision, 2007 Version* (ICD-10; World Health Organization, 2007) are relatively brief, stating only that it reflects a sexual preference for children of prepubertal or early pubertal age. This remains the key feature with regard to most definitions of pedophilia—that it connotes a sexual interest in young children.

Oftentimes, the term "pedophile" is used rather loosely within a general context, referring broadly to individuals

who have committed sexual crimes against children and used interchangeably with "child molester." However, it is important to note that given current diagnostic labels, not everyone who has engaged in sexual acts involving children would meet criteria for pedophilia, nor have all individuals diagnosed with pedophilia necessarily engaged in acts of child molestation or child sexual abuse. This is an important distinction, as much of the literature on pedophilia may be clouded by the inclusion of individuals who have not met specific criteria categorizing their sexual interest and behavior as a mental illness (Seto, 2008a). It is noted that individuals may engage in sexual behavior involving children without clear pedophilic interests, for reasons such as impulse control problems, dysfunctional relationship models stemming from histories of sexual abuse and trauma, intimacy deficits with adults (e.g., Beech & Fisher, 2002; Bumby & Hansen, 1997; Marshall, 1989, 1993), or self-regulatory deficits (e.g., Stinson, Sales, & Becker, 2008).

Victim research indicates that as many as 20 % of females and 10 % of males have been sexually victimized as children (Finkelhor, 1994), and that approximately 90,000 cases of child sexual abuse were reported to the authorities in the USA in 2000, though there appears to have been a decrease in actual offending, reporting, or both in recent decades (Finkelhor & Jones, 2004). From this, however, it is difficult to determine the exact number of pedophilic offenders, given that many sexual offenders against children may not demonstrate these characteristics or that some of the children represented in these numbers may have been victimized by the same perpetrator.

With regard to the prevalence of pedophilia, we do not currently know how many individuals are afflicted with this disorder. We do know that it is infrequent and that on surveys eliciting responses regarding sexual fantasies involving young children, approximately 3–5 % of individuals surveyed report some sexual interest and arousal associated with prepubescent children [as reported in Seto (2008a, 2008b)]. Even fewer individuals have reported acting on their sexual interest or fantasies in these same surveys. However, it becomes clear that despite the relative rarity of cases of pedophilia, it is more common among some groups than others. Not surprisingly, cases of pedophilia are most often identified among groups of known sexual offenders against children. Research regarding sexual interest and arousal patterns among adult men who have committed known acts of child sexual abuse reveals that between 40 and 50 % of these men would meet DSM-IV-TR (American Psychiatric Association, 2000) criteria for pedophilia (Blanchard, Klassen, Dickey, Kuban, & Blak, 2001; Maletzky & Steinhauser, 2002; Seto, 2008a; Seto & Lalumiere, 2001).

Recent attention to the use of child pornography, particularly given its availability on the internet, highlights the reality that not all individuals with sexual interests in young children are known offenders, and that little is in fact known about pedophilic individuals who have not acted on their sexual interests. In a study by Wolak, Finkelhor, and Mitchell (2005) describing the content of pornographic materials associated with a sample of child pornography offenders, 85 % possessed pornography involving children under the age of 12, in addition to pornography depicting post-pubertal adolescents. In this same sample, 17 % possessed depictions of prepubertal children exclusively. Thus, while approximately half of child sexual abusers may meet criteria for pedophilia, perhaps more than half of individuals who collect images of underage youth may demonstrate significant sexual interest in prepubertal children.

Sexual development and age of onset of pedophilic sexual interests do not appear to be substantially different from the sexual development or age of first sexual interests and experiences in non-pedophilic males (Seto, 2008a), though these individuals do differ in terms of the nature of their sexual interests. It is therefore likely that pedophilic sexual interests first manifested themselves in adolescence, along with the advent of puberty, for these individuals. Additional research does suggest higher rates of sexual abuse or trauma in the histories of adolescent and adult sexual offenders against children than those against adults, perhaps implying some early disturbances in normative sexual experiences and development (see Seto, 2008a).

With regard to comorbidity with other sexual disorders, pedophilia is often associated with comorbid diagnoses of exhibitionism, voyeurism, and frottage, as well as acts of rape (Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988; Raymond, Coleman, Ohlerking, Christenson, & Miner, 1999). Although criteria used to define pedophilia were predominantly behavior-based, findings from Abel et al. (1988) additionally reveal that 80–95 % of individuals with pedophilic interest in male children met criteria for one or more additional paraphilias, with the same being true for 60–85 % of individuals with pedophilic interest in female children. Similar results were obtained by Raymond et al. (1999), in that 53 % of the individuals in a sample of pedophiles met diagnostic criteria for at least one other paraphilia.

In terms of comorbidity with other psychiatric symptoms and diagnoses, individuals with pedophilia are often diagnosed with other Axis I and II conditions at a significant rate. In one study of individuals diagnosed with pedophilia (Raymond et al., 1999), current and lifetime rates of other Axis I disorders were 75 % and 93 %, respectively. The most common of these were mood disorder (31 % current; 67 % lifetime), anxiety disorder (53 % current; 64 % lifetime), and substance use disorder (4 % current; 60 % lifetime). Rates of Axis II personality pathology were reported at 60 % in this same sample. Few other studies have examined rates of psychopathology specifically among pedophiles, but other

empirical research denoting comorbid psychiatric disorder among individuals who meet criteria for one or more paraphilias reveal similar levels of psychopathology (e.g., Kafka & Hennen, 2003), particularly with regard to mood-disordered and personality-disordered symptoms.

Etiology of Sexual Interest in Children

Initial efforts to describe the causal mechanisms of pedophilia categorized pedophiles into two typologies—fixated and regressed (e.g., Groth & Birnbaum, 1978). These terms originate from a psychodynamic conceptualization of pedophilia and refer to an assumption that individuals who show some sexual interest in or behavior related to children are relying on sexual impulses from an earlier developmental stage. The fixated pedophile is an individual who is "fixated" in an earlier developmental stage and who identifies him- or herself with children. The fixated pedophile demonstrates poor or limited social interactions with adults and a lack of intimate relationships with adult partners. He or she will presumably engage in immature behaviors and associate more frequently with children. It is also hypothesized that the primary targets of a fixated pedophile are male children, and that this represents intrapsychic resolution of difficulties with achieving later stages of adult maturity. The regressed pedophile, on the other hand, is primarily sexually interested in same-aged adult partners and has likely engaged in such relationships during adulthood. However, under conditions of extreme stress, or when adult sexual partners are unavailable, the regressed pedophile may "regress" to an earlier developmental stage and select a child sexual partner to fulfill intimacy needs. This substitution of sexual partners may be situational or dependent on the moment and often does not reflect the degree of planning which is assumed in the sexual offenses characteristic of the fixated pedophile. Further, the regressed pedophile is presumably more likely to select female child victims, as this does not reflect conflicts in prior developmental stages of the offender himself. These views of pedophilia eventually fell out of favor as many researchers and clinicians moved away from psychodynamic personality explanations of sexual deviance and other maladaptive behaviors and adopted theoretical perspectives incorporating cognitive-behavioral, learning, and biological approaches.

A later conceptualization of pedophilia focused on the role of childhood experience, proposing that many sexual abusers of children are themselves former victims of childhood sexual abuse. This idea, labeled the abused–abuser hypothesis (Burgess, Hartman, & McCormack, 1987; Burton, Miller, & Shill, 2002; Freeman-Longo, 1986; Freund & Kuban, 1994; Garland & Dougher, 1990), adopts a social learning theory framework and assumes that modeling and internalization of sexual roles for adult and child following experiences of sexual abuse may lead to subsequent sexual interests in children or in adult–child sexual relationships. Three key components to this process are the child victim's initial interpretation of the abuse (e.g., beliefs in the normality of the behavior, belief that it is not harmful) which may serve to normalize the experience, factors specific to the relationship between victim and perpetrator, such as the age of the victim, the identity of or relationship with the perpetrator, or the frequency, severity, and type of abuse, and the initial response of the victim or the reactions of others who may become aware of the abuse. It was believed that through a specific confluence of these factors, some individuals who were victims of childhood sexual abuse would develop sexual preferences of their own which reflected sexual interest in adult–child sexual relationships, thus leading to more lasting pedophilic interest and arousal. Several problems with this hypothesis have limited its usefulness in describing the process through which pedophilic interests form, however. This includes discrepancies between the number of individuals who are victims of child sexual abuse and those who develop pedophilic interests, the rate of pedophiles with no known instances of sexual abuse during childhood, and the lack of empirical research to support many of the hypothesized factors which are believed critical to this process (e.g., Benoit & Kennedy, 1992; Haapasalo & Kankkonen, 1997; Jonson-Reid & Way, 2001).

Some research has considered the role of biological processes in the development of pedophilic sexual interests. Early efforts explored intellectual differences between pedophiles and other sexual offender groups, suggesting that perhaps intellectual or cognitive impairments might characterize the majority of adult individuals who manifest sexual interests in children. Studies comparing intellectual assessment results of sexual offenders with child victims and other offenders have noted some important differences (e.g., Hucker et al., 1986; Langevin, Wortzman, Wright, & Handy, 1989), while others have noted low rates of intellectual impairments among pedophilic or general sex offender samples (e.g., Lambrick & Glaser, 2004; Lindsay, 2002). Other neurological research has considered the possibility of structural brain impairments among pedophilic sexual offenders. Initial research utilizing brain scanning techniques identified abnormalities in the left temporal lobe differentiating pedophilic sexual offenders from other sex offender groups (Galski, Thornton, & Shumsky, 1990; Lang, 1993; Langevin et al., 1988; Langevin, Wortzman, Dickey, Wright, & Handy, 1988; Wright, Nobrega, Langevin, & Wortzman, 1990). Similar research has also identified significantly lower levels of cerebral blood flow, particularly within the frontal and left temporal lobes, of individuals with sexual interest in children as opposed to other sexual offenders or non-offenders (Hendricks et al., 1988; Raine & Buchsbaum, 1996).

Unfortunately, these biologically based theories have failed to provide a specific causal mechanism through which these neurological impairments or differences lead to pedophilic sexual interests, and still only a portion of individuals with sexual interests in children demonstrate these differences. Further, the biological explanations of pedophilia fail to account for important social, cognitive, and behavioral factors which can influence the development of sexual behaviors involving children.

Other etiological conceptualizations have relied on a cognitive-behavioral framework, emphasizing the role of offense-supportive beliefs, cognitive schemas and information processing, behavioral reinforcement contingencies which may strengthen pedophilic arousal, and patterns of sexually deviant interest and arousal. These principles have been utilized to shape a variety of integrated cognitive-behavioral theories, including Finkelhor's Precondition Model (Finkelhor, 1984), Marshall and Barbaree's integrated theory of sexual offending (Marshall & Barbaree, 1990), and other models which use cognitive-behavioral theory to not only explain pedophilic offenses but other sexual offenses as well [e.g., Hall and Hirschman's Quadripartite Model, Hall and Hirschman (1991); the Pathways Model, Ward and Siegert (2002)]. Important components of these theories include sexual beliefs about children (e.g., "Sexual activity between adults and children isn't harmful" or "Children know about sex and benefit from sexual experiences") which may facilitate sexual offending against them, ways of processing interpersonal information which overemphasize sexual interaction or sexual interest (e.g., perceiving that a child asking for a hug from an adult is in fact sexually interested in that adult, interpreting questions about sex or sexual activity as sexual interest or a desire for sexual activity), or beliefs about the world which may suggest sexual entitlement or sexual expectations of others. Other factors which are relevant from a cognitive-behavioral perspective include intimacy deficits, limited social skills or social competence, loneliness, empathy deficits, or antisociality. Theories emphasizing these principles suggest that sexual interests in children thus develop through a combination of experience, cognitive beliefs about sexuality and children, and the gradual reinforcement of sexual arousal in response to children over time. These theories inform perhaps the majority of current treatment approaches, though few of them have been rigorously empirically tested from a causal perspective (Seto, 2008a; Stinson, Sales & Becker, 2008).

More recent etiological considerations have examined the role of self-regulatory processes in the development of pedophilia and other sexual pathology and problematic sexual behaviors [Multi-Modal Self-Regulation Theory, Stinson, Sales, and Becker (2008); Self-Regulation Model, Ward and Hudson (2000)]. While these do not specifically focus on only the development of pedophilia or sexual interest in children, they do propose relationships between deficits in self-regulatory functioning and the use of sexual goals as a regulatory strategy. Important components of these conceptualizations as related to pedophilic interests include difficulties with regulating mood or thoughts, deficits in adaptive functioning with regard to relationships, reinforcement of specific sexual behaviors or interests, and goals consistent with sexual offending. As noted, these ideas are relatively recent and have thus been subjected to only limited empirical evaluation (e.g., Stinson, Becker, & Sales, 2008; Stinson, Robbins, & Crow, unpublished manuscript).

Assessment Strategies

Mental health professionals are often called upon to do various forms of assessment with individuals who have committed sexual offenses, many of whom have engaged in sexual activity with children and who might meet criteria for pedophilia. Some of these evaluations are for legal purposes. Some are for treatment. Others involve mitigation of legal culpability or even determinations of treatment progress. This section of the chapter will focus on those assessments which occur prior to beginning treatment. These assessments focus on a variety of issues, including diagnosis and history, description of the offense process, and identification of treatment needs.

Pretreatment assessments for individuals who have engaged in sexual offenses against children or who have demonstrated pedophilic interests should be comprehensive and include many of the following elements. A first step includes review of collateral materials, including victim statements, criminal and/or juvenile justice records, and any other legal documents related to prior offenses that the individual might have committed. A thorough clinical assessment also involves describing developmental and family history, education, medical history, school history, substance abuse history, any history of abuse, or neglect. One should also obtain information regarding the individual's living situation, hobbies or interests, and available supports. It is critical to ascertain whether or not the individual has ever received prior psychological or psychiatric counseling and if that was helpful. It might also be beneficial to obtain prior therapy records, if potentially related to the assessment question at hand.

Personality characteristics or traits may additionally be useful in determining important factors related to the client's offending, responses to treatment, and possible risks for future sexual offenses. There are numerous personality inventories which could be used as part of a comprehensive assessment. Such measures might include the Personality Assessment Inventory (PAI; Morey, 1991), the Minnesota

Multiphasic Personality Inventory, 2nd Edition (MMPI-2; Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), or the Millon Clinical Multiaxial Inventory, 3rd Edition (MCMI-III; Millon, Davis, & Millon, 1997). Since psychopathy has been found to be predictive of recidivism (e.g., Hanson & Harris, 1998; Hanson & Morton-Bourgon, 2005; Hemphill, Hare, & Wong, 1998) as well as success in treatment (Seto & Barbaree, 1999), it is recommended that adults also be assessed using the Psychopathy Checklist, Revised (PCL-R; Hare, 1991).

Regarding sexual interests, a comprehensive and thorough sexual history is essential. This includes a history of "normative" (age appropriate consensual sexual behaviors) as well as paraphilic fantasies and behaviors. A number of specialized instruments are available to assist the clinician in assessing the nature of the individual's sexual interests. Physiological assessments of sexual arousal, particularly related to children, include penile plethysmography and the Abel Assessment of Sexual Interest (AASI; Abel, Huffman, Warberg, & Holland, 1998), which assesses sexual interest via viewing time technology. Research has indicated that viewing time measures are able to distinguish pedophiles from non-pedophiles (Abel et al., 1998, 2004; Abel, Jordan, Hand, Holland, & Phipps, 2001), who have targeted male child victims from those who have targeted female child victims (Abel et al., 2004; Worling, 2006), and different types of paraphilic sexual interests (e.g., Gray & Plaud, 2005; Stinson & Becker, 2008). However, despite these successes, others have questioned the use of these instruments, as they are often expensive, invasive, and do not always lead to definitive findings of sexual interest (e.g., Freund, Watson, & Rienzo, 1988; Gray & Plaud, 2005; Howes, 1995, 2003; Looman, Abracen, Maillet, & DiFazio, 1998; Stinson & Becker, 2008).

Some have also used the polygraph as a physiological measure of sexual activity involving children. While this cannot be used to diagnose pedophilia or corroborate sexual fantasies involving children, it may be used to validate historical instances of sexual behavior involving children (e.g., Abrams, 1991; Ahlmeyer, Heil, McKee, & English, 2000). However, there are few articles in the literature attesting to the validity of polygraphy with a pedophilic population or other sex offender populations.

Other measures of sexual interest and related cognitions and behaviors may include combination of self-report and historical variables, such as the Multiphasic Sex Inventory, 2nd edition (MSI-II; Nichols & Molinder, 2000), Clarke Sexual History Questionnaire (Langevin & Paitich, 2002; Paitich, Langevin, Freeman, Mann, & Handy, 1977), the Abel and Becker Cognition Scale (Abel et al., 1989), and the Abel and Becker Sexual Interest Cardsort (Abel & Becker, 1985). Interestingly, recent research has indicated that some self-report instruments, such as the MSI-II (Nichols & Molinder, 2000) or self-report sexual fantasy content, may be more accurate predictors of sexual interests in children or other targets than the traditional physiological measures in some populations of sexual offenders (Stinson & Becker, 2008). Thus, these instruments, which are perhaps more cost-effective, easy to administer, and less invasive, might provide much valuable information for those interested in examining sexual interest in children [For a more detailed list of assessment inventories that have been used in assessing sexual offenders, readers are referred to Prentky and Edmunds (1997)].

Treatment Models

Historically, a variety of treatment theories have governed the development of treatment models or treatment strategies for working with pedophiles. Individuals have used psychodynamic therapy, eclectic approaches, and generic group therapy. More recently, cognitive-behavioral interventions, the relapse prevention model, and in some cases, psychopharmacologic interventions have been the predominant methods of providing sex offender treatment. Cognitive behavior therapy utilizes a multicomponent approach and targets both cognitive treatment needs, such as deviant sexual arousal, distorted cognitions, pro-offending attitudes, impulse control deficits, social skills deficits, poor emotional regulation, environmental triggers, and behavioral components like masturbatory reconditioning, covert sensitization, or olfactory aversion therapy (e.g., Marshall & Eccles, 1996; Marshall & Fernandez, 1998; McGrath, Hoke, & Vojtisek, 1998). An important part of these therapies also involve assisting the client in overcoming the denial and minimization and developing empathy. With regard to pedophilia and offenders with sexual interest in children, the goal of cognitive-behavioral sex offender treatment would be to reduce offense-supportive beliefs (e.g., "Ancient societies encouraged sex between adults and children," or "Children need to have sex to learn about it."), develop empathy for children, improve relationships with adult consenting sexual partners, and reduce deviant arousal to child stimuli. Although the majority of treatment programs in North America utilize cognitive-behavioral techniques, the effectiveness of such programs has been questioned (e.g., Kirsch & Becker, 2006; McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2010; Rice & Harris, 2003). Empirical research evaluating the effectiveness of cognitive-behavioral treatment in reducing violent sexual recidivism among general sexual offenders has produced minimal, mixed, or even negative effects (Hanson, Steffy, & Gauthier, 1993; Marshall, Jones, Ward, Johnston, & Barbaree, 1991; McGrath et al., 1998; Quinsey, Harris, Rice, & Lalumiere, 1993; Quinsey, Khanna, & Malcolm, 1998; Rice, Quinsey, & Harris, 1991).

Relapse prevention is a type of cognitive-behavioral intervention which has been continually dominant in North American sex offender treatment programs (McGrath et al., 2010). Relapse prevention relies on the identification of high-risk situations, triggers which may initiate the sex offense process, and the development of a relapse prevention plan. These high-risk situations or triggers may include environmental factors, "seemingly unimportant decisions" which can lead to offending or beliefs or thoughts which are supportive of the offense process. The ultimate goal of relapse prevention is to develop a comprehensive plan to assist the client with accurately identifying these precursors and minimizing risk. Though many programs have used a relapse prevention approach, recent research regarding its outcome has been less than encouraging and suggests that there are few differences between treated and untreated offenders (Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005).

Psychopharmacologic interventions are frequently used in some treatment programs as an adjunct to treatment. Hormonal treatments such as medroxyprogesterone acetate, cyproterone acetate, and leuprolide acetate have been used in the treatment of individuals with pedophilia. These medications are used to lower the individual's testosterone levels and consequently reduce sexual drive, though they do not redirect the individual's patterns of sexual interest (i.e., sexual interest in children or minimal erectile capacity may remain despite treatment). However, these forms of medication can cause unwanted side effects, including weight gain, increased blood pressure, impaired glucose tolerance, and gallbladder disease (Meyer, Walker, Emory, & Smith, 1985) and may be subject to continuing compliance problems, as is the case with other pharmacological interventions. Others have questioned the use of these medications on ethical grounds (e.g., Meyer & Cole, 1997; Stinneford, 2006), while others have noted their failure to reduce sexual recidivism (Rice & Harris, 2003). Other pharmacological treatments have involved the use of Selective Serotonin Reuptake Inhibitors (SSRIs) for the treatment of paraphilic and non-paraphilic sexual disorders (e.g., Greenberg & Bradford, 1997; Greenberg, Bradford, Curry, & O'Rourke, 1996). As noted by Becker and Johnson (2008), it is possible that these medications may decrease sexual obsessions, improve disordered mood symptoms, and perhaps decrease impulsivity.

While it does not endorse a specific treatment approach, the risk-needs-responsivity model (Andrews, Bonta, & Hoge, 1990; Bonta & Andrews, 2007) has been applied to the treatment of pedophilic sex offenders as well as other offender groups. This model emphasizes discriminating high from low risk offenders and offering treatment to those most at risk, targeting criminogenic needs related to the individual's sex offending behavior, and considering responsivity factors such as motivation, special needs, or barriers to treatment [see further Hanson, Bourgon, Helmus, and Hodgson (2009a, 2009b), Becker and Stinson (2011)]. This approach calls for continued research in identifying those at highest risk and thus in most need of treatment, targeting treatment needs which may be most relevant for reducing risk and producing a better outcome for offenders, and tailoring treatments so as to have the greatest preventative impact on future sexual offending.

As can be seen from the previous discussion, many problems remain with current approaches to sex offender treatment. This may be due to a number of factors, including a rather atheoretical approach to sex offender treatment (i.e., that our theories of what causes sex offending behaviors and pedophilic interests do not match our strategies for treating these behaviors and interests; Kirsch & Becker, 2006), problems with treatment duration or delivery, a lack of comprehensive and integrative treatment targets, or poor aftercare and follow-up once treatment has been completed. With regard to pedophilic sexual offenders, given the high rates of comorbidity with other paraphilias and other psychiatric disorders, it is possible that traditional treatments are less successful for this population given the psychiatric complexity of individuals with this disorder, and the corresponding adaptive and functional deficits which may be seen accompanying this diagnosis.

Recidivism and Risk Assessment

With regard to known recidivism among pedophilic sexual offenders, research indicates that anywhere from 5 to 42 % of individuals studied have engaged in further acts of sexual violence after release (Hanson et al., 1993; Hanson & Bussiere, 1998; Langan, Schmitt, & Durose, 2003; Moulden, Firestone, Kingston, & Bradford, 2009; Prentky, Knight, & Lee, 1997). Interestingly, one recent study of recidivism among offenders against children under the age of 16 utilized phallometric testing and the Screening Scale for Pedophilic Interest (Seto & Lalumiere, 2001) to differentiate pedophilic from non-pedophilic offenders and found no significant differences between the recidivism rates of these two groups (Moulden et al., 2009). This suggests that much about the nature of sexual recidivism among pedophiles, and whether or not it differs from other sex offender groups, remains unknown. There is also some research to indicate that a small subgroup of sexual offenders against children continue offending until later in life (e.g., Hanson et al., 1993), though this may not be the case with the larger population of pedophiles and sexual offenders against children (Barbaree, Blanchard, & Langton, 2003).

The assessment of risk for individuals who have committed sexual offenses focuses primarily on determining the risk of future sexually violent recidivism upon release into the community. This may include determining risk in order to

assign an offender to treatment and emphasize treatment needs in accordance with the risk-needs-responsivity model (Andrews et al., 1990; Bonta & Andrews, 2007), to assess dangerousness according to specific legal standards or criteria, or to make placement or risk management decisions. Few studies of risk have differentially focused on individuals who are at greater risk of sexually offending against children as opposed to other victim groups, though some risk factors specific to pedophilic sexual interests have been implicated as crucial determinants of risk. For example, general risk factors for the detection of known sexual recidivism include offender age, history of arrest for sexual and nonsexual offenses, patterns of violence associated with sex offending behavior, antisocial lifestyle characteristics, poor mood or affect regulation, anger control, and cooperation with supervision requirements (Hanson & Bussiere, 1996; Hanson & Harris, 1998, 2000; Hanson, Harris, Scott, & Helmus, 2007; Hanson & Morton-Bourgon, 2005). Risk factors more specific perhaps to individuals with pedophilia or sexual offenses against children may include certain victim characteristics (e.g., age), deviant sexual interests, problems with sexual self-regulation, and attitudes or beliefs which are supportive of sexual offending (Hanson et al., 2007; Hanson & Harris, 1998, 2000; Hanson & Morton-Bourgon, 2005). Individuals with pedophilic sexual interests may thus be at greater levels or risk with regard to these factors due to the age of their victims, sexual interests in children, and attitudes or beliefs which are related to their sexual behaviors involving children.

The way in which this risk is determined typically involves the use of actuarial instruments designed to predict risk among a diverse population of sexual offenders. These instruments, developed by determining the known recidivism rates of large groups of sexual offenders post-release and statistically calculating characteristics of these individuals most predictive of their recidivism, have demonstrated predictive superiority over clinical judgment alone (e.g., Meehl, 1954). Because these measures rely on statistical relationships, they do not inform us as to causal mechanisms behind an individual's risk; in other words, they do not tell us why a certain factor is predictive of risk nor will they give us a true estimate of risk on an individual basis. Instead, they predict risk based on a set of characteristics which were significant for a group of individuals who had engaged in additional acts of sexual violence. A combination of static and dynamic risk variables have been incorporated into these instruments, including the Static-99 and Static-99R (Hanson & Thornton, 2000; Helmus, 2009), the Static-2002 (Hanson & Thornton, 2003), the Rapid Risk Assessment for Sex Offense Recidivism (RRASOR; Hanson, 1997), the MnSOST-R (Epperson, Kaul, & Hesselton, 2005), the Sex Offender Risk Appraisal Guide (SORAG; Quinsey, Harris, Rice, & Cormier, 1998), the Sexual Violence Risk-20 (SVR-20; Boer, Hart, Kropp, & Webster, 1997), and the Stable-2000/Acute-2000 and Stable 2007/Acute 2007 (Hanson et al., 2007). As noted above, many of these instruments contain items which may rely on a history of pedophilic sexual behaviors and interests, including sexually deviant interests, youthful victim age, and offense-supportive beliefs.

Though actuarial instruments are typically considered the most precise and objective means of measuring risk of future sexual offending, some research has evaluated the utility of using clinical adjustments to static actuarial measures. Unfortunately, some research suggests that the addition of clinical or discretionary material makes no impact on actuarial prediction (e.g., Krauss, 2004) or may actually worsen it [Barbaree, Seto, Langton, and Peacock (2001), for further discussion, please see Seto (2008a)]. Other recent work regarding the use of clinical data to supplement actuarial decision making involves the development of structured clinical and actuarial assessment tools, including the Historical Clinical Risk—20 (HCR-20; Webster, Douglas, Eaves, & Hart, 1997) and the Structured Anchored Clinical Judgment—Minnesota (SACJ-Min; Grubin, 1998). Again, though these instruments do not exclusively address risk concerns related to pedophilia, a number of the risk items do relate to specific sexual interests or behaviors which may be relevant for individuals with pedophilia.

With regard to individuals who have demonstrated pedophilic sexual interests but who have not yet been known to act on them (e.g., individuals who utilize child pornography but who have not been arrested for sexual acts involving children), few available resources exist to describe their future risk of engaging in sexual behaviors with child victims. Many of the above-described risk assessment actuarial instruments rely heavily on history of arrest or known offense behaviors in order to make determinations of an individual's potential risk. Seto (2008a) and Seto and Eke (2005) have noted that men who utilize child pornography but who have not committed contact sexual offenses against children are perhaps less likely to commit future sexual offenses involving children than men who utilize child pornography but who have already engaged in child sexual offenses, again suggesting that history of behavior is a highly predictive factor. Whether or not the presence of pedophilia alone may be predictive of future offending when compared with non-pedophilic individuals who have been found with child pornography has yet to be determined.

Policy Issues

In an effort to make for safer communities, legislators have enacted numerous laws that impact or regulate the behavior of sexual offenders, particularly offenders who have targeted child victims. Such laws have included longer sentences, sex offender registration, community notification and residency restrictions, and long-term post-incarceration civil commitment.

These laws apply to both juvenile as well as adult sexual offenders. In many cases, the impetus for the development of these laws was a particularly heinous and public case where a child was sexually assaulted and/or murdered by an individual with a history of sex offending behavior. In fact, many of these laws have been named after the very victims in these cases (e.g., Megan's Law, the Jacob Wetterling Act). While some policies have been criticized as being unconstitutional (e.g., Sexually Violent Predator civil commitment), the U.S. Supreme Court and other courts have often upheld them (e.g., *Kansas v. Hendricks*, 1997). However, several states' efforts to enact the death penalty for cases of child molestation did result in a reversal by U.S. Supreme Court decision (*Kennedy v. Louisiana*, 2008).

Many of these policies, particularly those involving community registration and notification, are predicated on the assumption that knowing who the offenders are will prevent future sexual violence. This also presumes that these individuals are unknown to the victims and their families, whereas much of the research has indicated that perpetrators of sexual violence against children are often known or even related to the victims (e.g., Snyder, 2000), thus perhaps negating the effectiveness of prior registration and notification. Policies instead should perhaps focus on education regarding child sexual abuse or decreasing stigma for victims of child sexual abuse which may in turn increase willingness to report such offenses.

Though few research efforts have been conducted to evaluate the efficacy of many legislative policies directed toward sexual offenders against children, some recent data have examined recidivism rates of both adults and juveniles who are impacted by registration and notification policies. Evaluation of several states' registration and notification policies as well as related residency restrictions reveal somewhat mixed results, in that there were no significant effects on juvenile sexual recidivism (Letourneau & Armstrong, 2008; Letourneau, Bandyopadhyay, Armstrong, & Sinha, 2010), but some initial deterrent impact on adult sexual offending (Letourneau, Levenson, Bandyopadhyay, Armstrong, & Sinha, 2010). However, examination of a change in trajectory of adult offending (i.e., differentiating different offender risk groups) following the implementation of registration and notification laws (Tewksbury & Jennings, 2010) and of recidivism and child offenders' proximity to schools and daycare centers (Zandbergen, Levenson, & Hart, 2010) failed to find significant effects.

Other research has assessed the impact of sex offender registration and notification policies on offenders, their families, and the reduction of recidivism. Levenson, D'Amora, and Hern (2007) examined the impact of community notification on 239 registered sex offenders from one state and 148 from another state. The offenders were surveyed as to outcomes including job loss, housing disruption, assault victimization, property damage, harassment, and suffering on the part of their family members. They were also queried as to psychosocial effects such as stress, isolation, fear for their safety, shame, and embarrassment and as to whether or not having community notification helped them manage risk and prevented reoffense. The majority of the sex offenders reported negative consequences; for example, 21 % reported they lost a job because their boss or coworker discovered their registration status. Ten percent were forced to move from their homes, and 21 % had been threatened or harassed by neighbors. Eighteen percent experienced property damage. The majority of offenders experienced psychosocial distress in relation to the public disclosure, and nearly half were afraid for their safety because their sex offender status was known. Specifically, 62 % reported that the community notification made recovery more difficult by causing stress, 58 % reported shame and embarrassment, 54 % reported feeling alone and isolated, and 55 % reported less hope for the future now that they would be a registered sex offender. Given the role of negative affect and lifestyle instability in the determination of an offender's risk to reoffend, these effects are concerning.

Levenson and Tewksbury (2009) examined the stress experienced by family members of adults who were registered sex offenders. Sixty-eight percent of survey respondents reported frequent stress due to their family member's registration as a sex offender. Almost half of the respondents reported fearing for their safety due to their loved ones being registered as a sex offender, and 31 % of the respondents reported they were forced to move due to residential restriction laws or community pressure. Stress levels were high among the family members of registered sex offenders, as were isolation, loss of friends, and relationships and fear for their safety.

Thus, it would appear that there are a number of unintended consequences either to sex offenders who are made to register or to their family members. Since family members are a potential source of support for individuals who have committed sexual offenses, it is important to identify strategies which might be helpful in aiding relatives who are in relationships with individuals who must register or who are involved in community notification. Finally, though some initial research has demonstrated perhaps small, though inconsistent, effects of registration and community notification on recidivism, more research is clearly needed to determine if other policies are achieving their goals relative to reducing recidivism and enhancing community safety.

Future Directions

As has been highlighted throughout this chapter, a number of areas still remain relatively unexplored with regard to understanding individuals with pedophilic sexual interests. In order

to provide the most effective assessment, treatment, risk management, and prevention, we should continue to focus on these unknowns in our research and clinical practice with pedophilic sexual offenders.

First, we must gain a more complete understanding of the causal mechanisms underlying etiology and risk. For example, recent theoretical and empirical findings have implicated self-regulation and self-regulatory deficits as not only important etiological considerations (Stinson, Becker & Sales, 2008; Stinson, Sales & Becker, 2008; Ward, Polaschek, & Beech, 2006) but also as significant predictors of risk (Hanson et al., 2007; Hanson & Harris, 1998). However, this work is still relatively new and lacks comprehensive empirical study. And while research has determined many significant factors which may precede sexual offending or predict risk, the causal mechanisms explaining these statistically significant relationships remain elusive. In other words, in order for us to truly understand not only how pedophilic sexual interests develop but also how they impact continued sexual behavior, we must know more about why certain constructs or factors are significant and how they impact and interact with one another.

A related concern involves the need for more effective integration between theory and practice. Many current treatment interventions for pedophilia, including those which involve chemical or biological solutions, are predicated on the belief that treating outward symptoms of the disorder (e.g., sexual arousal, sexual beliefs about children) will ultimately reduce sexual interest in children and related behaviors. However, the etiological link between these concepts and offending behavior remains unclear (e.g., Stinson, Sales & Becker, 2008). In order to remain effective, our practices of assessing and treating pedophilia must match what is known from empirical evaluation of causal theory. In this way, we can ensure that we are truly addressing those causal or maintenance factors most related to risk and prevention of sexual violence.

Similarly, we must focus efforts on developing and researching the most effective treatment interventions for individuals with pedophilia and pedophilic sexual interests. Emerging criminal justice trends in the detection of users of child pornography suggest that a number of individuals with pedophilia who were previously unidentified will now be in need of treatment intervention. Most treatments for sexual offending thus far, including those aimed at reducing sexual interests and behaviors involving children, have focused primarily on contact pedophilic offenders. And while much remains to be improved with regard to these treatments [e.g., limited treatment effectiveness noted by Marques et al. (2005)], even greater need lies in the treatment of these increasingly salient pornography offenders with clear sexual interests in children, but whose behaviors and clinical presentation may be different from that of the traditional contact child sexual offender seen in correctional samples.

With regard to improvements in our understanding of risk, we should perhaps place greater emphasis on the changing or dynamic nature of risk, particularly within the community following treatment. While several risk assessment instruments have incorporated dynamic factors, such as treatment progress, understanding of risk, or compliance with supervision requirements, the ability to capture the rapid and situational factors impacting risk on a daily basis in other settings is still largely absent from our risk prediction tools. Some in this area have made distinctions between risk status and risk state, noting that while status may remain relatively constant, the state of risk is constantly changing and building over time (Douglas & Skeem, 2005). Others have likened risk prediction to weather prediction (Monahan & Steadman, 1996), comparing the prediction of dangerousness to the prediction of the weather, where conditions are variable and can only be known for short periods of time. Future research with regard to pedophilia and risk of sexual offending should incorporate many of these principles.

Finally, we have voiced concerns that many legislative efforts in the area of prevention and treatment for sexual offenders against children have resulted from reactive public outcry rather than sound empirical research. Thus, an obvious area for future research includes education and empirically informed legislative policies. This may involve a change in emphasis from reactive deterrence measures to those aimed at prevention, treatment, and reintegration into the community. It also may include more rigorous evaluation of the effectiveness of current legislative practices, including community registration and notification, civil commitment for dangerous sexual offenders, and sentencing practices for sexual crimes, as well as identifying proactive research contributions to proposed legislation.

Hebephilic Sexual Offending

Skye Stephens and Michael C. Seto

Introduction

This chapter focuses on sexual offenses committed by hebephilic individuals (see also Stephens & Seto, 2015). The literature on sexual offenses committed by pedophilic individuals is reviewed in depth in Seto (2008). *Hebephilia* refers to a sexual preference in pubescent children (Tanner stages 2 or 3 in terms of physical maturation; see Table 1), typically ages 11–14. In hebephilia, the focus of the sexual interest is on girls or boys who are just beginning to show secondary sex characteristics (Blanchard, 2010; Blanchard et al., 2009). Hebephilia is differentiated from *teleiophilia*, a sexual preference for physically mature persons (Tanner stage 5), and *pedophilia*, a sexual preference for prepubescent children (Tanner stage 1, generally younger than 11) who show no signs of sexual development (Blanchard et al., 2009). The term hebephilia was first introduced by Glueck (1955) and in the early writings of Freund (1965), who discussed hebephilia in the context of phallometric assessment of sexual arousal.

Although approximate age ranges are specified, it is the physical stage of sexual development as opposed to chronological age that truly matters in this distinction. For example, it is not the case that an individual is attracted to a girl because she is 13 years old; it is that the person is attracted to girls who are beginning to show signs of sexual development—breast budding, growth spurt, emergence of pubic and axillary hair—rather than prepubescent girls, who do not show any such signs, or older adolescent girls, who are postpubescent or appear sexually mature.

The typical age ranges associated with pedophilia and hebephilia are approximate, because people vary in the age of onset of puberty and their maturation rates. Pediatric research has shown, for example, that the average age of onset of puberty has decreased steadily over the past century for both boys and girls, possibly as a result of better nutrition and physical health (Herman-Giddens et al., 1997, 2011). Pubescence typically occurs between the ages of 11 and 14 (e.g., Herman-Giddens et al., 2011). For girls, pubic hair and breast budding appear at an average age of 11 years; for boys, pubic hair appears and physical changes in the penis and scrotum begin at an average age of 11 (Roche, Wellens, Attie, & Siervogel, 1995). The pubertal growth spurt begins at an average age of 10 for girls and 12 for boys (Grumbach & Styne, 1998) and the mean age for first menses is 12.88 (SD = 1.20) for Caucasian girls and 12.16 (SD = 1.21) for African American girls (Herman-Giddens et al., 1997). Herman-Giddens and colleagues (2011) found that boys typically begin stage 2 genital development between the ages of 9 and 10 and stage 3 development between 11 and 13. For boys, stage 2 pubic hair development starts between 10 and 12, and for stage 3 it occurs between 11 and 13. For testicular volume increases to 3 ml or higher start on average between 9 and 10 and this starts to increase to 4 ml between 11 and 12. In both males and females, adult-typical pubic hair patterns are established between the ages of 13 and 16, female breast development is mostly complete between the ages of 14 and 16, and the genitals approach their adult size and shape between the ages of 14 and 16 (Grumbach & Styne, 1998; Herman-Giddens et al., 2011). Hebephilic sexual offenders would be most interested in pubescent children, based on their physical appearance, rather than a particular age range.

In the clinical literature, hebephilia has often been (imprecisely and thus confusingly) equated to a sexual preference in adolescents, which is typically defined as the developmental period between the ages of 12 and 18. This wide age range is problematic as it would include pubescent children

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_3

Table 1 Tanner stages

Tanner stage	Brief description	Typical age range	Preference
1	No secondary sex characteristics have developed	Under 11 (prepubescent)	Pedophilia
2	Breast buds develop and areola begins to widen. Male genitalia change. Small amount of pubic hair growth	11 (pubescent)	Hebephilia
3	Male genitalia continue to change and the penis begins to lengthen. Breasts start to develop and extend past the areola. Pubic hair becomes coarser	12–14 (pubescent)	Hebephilia
4	In females, the breasts continue to develop and the areola and nipple becomes an additional mound. Testicular volume continues to change and the penis continues to lengthen in males. Pubic hair extends across the pubis bone	15–16 (adolescent)	Ephebophilia
5	Secondary sex characteristics reach full maturity	17 and older (sexually mature)	Teleiophilia

Note: The changes regarding secondary sex characteristics are briefly described, and interested readers should consult Tanner (1978) to receive a full description of each stage

along with sexually mature teenagers who could be easily confused with young adults. A sexual preference in those in late adolescence who show many signs of sexual maturity (Tanner stage 4) or who are sexually mature (Tanner stage 5) is not representative of hebephilia; instead, it can be described as *ephebophilia* or *teleiophilia* (Hames & Blanchard, 2012). The distinction is important in both conceptual and practical ways. Conceptually, hebephilia is a paraphilia, reflecting an atypical (statistically rare) sexual age interest in pubescent children (see Seto, 2010). In contrast, a sexual preference in older adolescents (ephebophilia) would probably not meet Wakefield's (1992) definition, given older adolescents are reproductively viable and the fact that typically men are sexually attracted to older adolescents, as reflected in self-report, psychophysiological, and pornography use studies (Freund, Seeley, Marshall, & Glinfort, 1972; Symons, 1979).[1] Practically, acting on hebephilic sexual interests by viewing child pornography or engaging in sexual acts with pubescent children would violate laws in most jurisdictions regarding age of sexual consent, whereas the same is not necessarily true of ephebophilia.

The present chapter will briefly review the research literature on pedophilia, because hebephilia and pedophilia have a number of similarities. Additionally, there is an established literature on the etiology, assessment, and treatment of pedophilia among sexual offenders that may serve as a useful framework for thinking about hebephilic sexual offending. We will discuss ways in which hebephilia may be a distinct sexual age preference while reviewing the debate about the inclusion of hebephilia in *DSM-5*. We then discuss the etiology, assessment, and treatment of hebephilia.

Pedophilia and Hebephilia

Unlike hebephilia, pedophilia is an accepted clinical diagnosis and is currently part of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM: American Psychiatric Association, 2000) and *International Classification of Diseases* (ICD: World Health Organization, 1997) diagnostic nosologies. In the most recent version of the *DSM* (*DSM-5*), a person can be diagnosed with pedophilia if they have intense and recurrent sexual interests in prepubescent children—as reflected in their thoughts, urges, fantasies, sexual arousal, or behavior—and they are clinically distressed or impaired as a result of this sexual interest. The definition remained unchanged between the DSM-IV-TR and the DSM-5, though the diagnosis will be relabeled "pedophilic disorder" to distinguish the disorder from paraphilic sexual interest in the absence of distress or impairment (American Psychiatric Association, 2013). In the *ICD-10*, the latest version of the international diagnostic system, pedophilia represents a sex-

[1]The sexual interests of women in adolescents has been much less studied, and the sexual interests of women in prepubescent or pubescent children even less so.

ual preference for boy and/or girls usually of "prepubertal *or early pubertal age*" (emphasis added). As such the international classification system includes both pedophilic and hebephilic sexual interests under the category of pedophilia, and the description in the ICD-10 is similar to how we have defined it in this chapter.

Pedophilia is generally accepted as a paraphilia and mental disorder [though see the December 2002 special issue of the *Archives of Sexual Behavior* for a series of articles and commentaries arguing this point, e.g., Seto (2002)]. Hebephilia, on the other hand, has not been widely accepted, for several possible reasons: (1) it cannot be reliably distinguished from pedophilia, given the liminal nature of puberty and problems with the reliability of age estimation; (2) hebephilia may not meet Wakefield's (1992) definition of a harmful dysfunction; and (3) because of political and social concerns about how a diagnosis of hebephilia might be used (or misused) in legal and clinical decision-making. We discuss these arguments in the next section.

The Debate About Hebephilia

Writers have been deeply divided on whether hebephilia should be included in *DSM-5* (e.g., Green, 2010; Plaud, 2009; Rind & Yuill, 2012; Tromovitch, 2009; Wakefield, 2012). In some cases, authors have evoked the culturally relative criteria used in determining dysfunction, which is similar to arguments that have been made about pedophilia as a mental disorder. Franklin (2010) suggested hebephilia is a novel concept, advanced by small group of researchers driven by personal interests. These criticisms were devastatingly refuted by Cantor (2012), who points out the many errors made by Franklin in her critique.[2]

Others have argued that a sexual interest in pubescent girls[3] is normal; in its most extreme form, the argument has been made that hebephilia has been evolutionarily "hardwired," at least for heterosexual men with regard to pubescent girls (Franklin, 2009; Rind & Yuill, 2012). The common thread in these arguments is that men without psychopathology would show some sexual interest in pubescent children. Franklin (2009) also argued that sexual activity between men and pubescent girls has occurred in other time periods and in other cultures, signifying that it is not always socially proscribed. Green (2010) noted that the age of consent in some European countries falls within the age range originally proposed in the *DSM-5* revisions for pedohebephilic disorder, which suggested the typical pubescent age range was 11–14 (e.g., Spain's age of consent is 13). Others have suggested that a sexual interest in pubescent girls was historically accepted; Rind and Yuill (2012) reported that girls between the ages of 12 and 14 were married to older men in Ancient Egypt. Janssen (2009) went further and argued that the entire concept of paraphilias, not just hebephilia, is flawed because these labels are social constructions that reflect societal norms as opposed to actual psychopathology.

Rejoinders

It is readily apparent when reading arguments against hebephilia that many authors have focused on a critique of the idea that a sexual interest or behavior involving adolescents in the age range mentioned in early DSM-5 documents (ages 11–14 and sometimes expanded to include adolescents as a whole) is maladaptive or abnormal. This occurs even though hebephilia refers specifically to pubescent children as defined by maturation status. Blanchard and colleagues as well as other researchers have responded in depth to these critiques of hebephilia [see Blanchard (2010) for a response to arguments against the diagnosis of hebephilia and Cantor (2012) for a detailed response to Franklin's (2010) critique]. In considering these responses and the legitimacy of hebephilia, it is important to first consider the definition of what would constitute a mental disorder as reflected in *DSM-IV-TR*.

Harmful Dysfunction Wakefield (1992) definition of a mental disorder as harmful dysfunction is widely cited and serves as the basis for their definition of a mental disorder in *DSM-IV-TR* (American Psychiatric Association, 2000, 2013). According to Wakefield, a harmful dysfunction involves (1) evidence of a malfunctioning biological mechanism that (2) results in significant distress or impairment. In terms of the first criterion, one perspective would suggest that hebephilia (and pedophilia) represent exaggerations or other dysfunction in the male-typical interest in cues of youthfulness, including neotenous facial features, smooth skin, and lustrous hair (Seto, 2008). Though typical men are sexually interested in youthfulness, they are also sexually interested in cues of sexual maturity, including adult size, full breasts, and waist-to-hip ratio approaching 0.70 (Buss, 1994). As a result, men are most sexually attracted to older adolescent and young adult women (Kenrick & Keefe, 1992), not pubescent or prepubescent children. The combination of youthfulness and sexual maturity indicates a high likelihood that the female is healthy and fertile. Pedophiles and hebephiles respond strongly and positively to cues of youthfulness, but negatively to cues of sexual maturity (e.g., Blanchard et al., 2009; Seto & Lalumière, 2001). As further evidence that a sexual interest in pubescent (i.e., sexually

[2]This includes evidence that hebephilia has been discussed for decades, is mentioned in at least 100 texts (http://individual.utoronto.ca/james_cantor/page21.html), and has been examined by multiple research groups (http://individual.utoronto.ca/james_cantor/page19.html).

[3]Of note, these critics have focused on adult male interest or behavior involving pubescent girls and have not discussed sexual interest in or behavior involving pubescent boys in any sustained way.

immature) children is maladaptive, Ryniker (2012) argued that in cultures where marriage between adult men and pubescent girls occurs, it is usually as a result of economic and social considerations rather than the adult's sexual interest in the girl. In other words, the marriages served nonsexual purposes, and sexual activity might or might not have occurred in these contexts. Hames and Blanchard (2012) reviewed the anthropological literature and argued that sexual activity did not begin until the girl had completed, or almost completed, the pubertal process.

Additionally, Blanchard (2010) found that heterosexual pedophiles and hebephiles currently have fewer children than teleiophiles, which is not consistent with the argument that hebephilia is evolutionarily adaptive or neutral in its effect on fitness (though that contention is an inference from current environments to the much different environments found in the ancestral past, where humans lived in small hunter-gatherer clans with fewer mate options). Taken together, these arguments would suggest that a sexual preference for pubescent children is maladaptive, similar to a sexual preference for prepubescent children (see Seto, 2002, 2010).

Regarding the second criterion in Wakefield's (1992) definition, a sexual preference in pubescent children could result in significant distress or impairment. In many jurisdictions contact between adults and pubescent children is illegal and would result in criminal charges. Legal problems stemming from a mental disorder would constitute a form of impairment, even if the individual was not concerned with the symptoms, as it has broad implications for the individual's quality of life (e.g., job loss, relationship difficulties). Even in the absence of a criminal charge or conviction, there could still be other impairment in an individual's life (e.g., disrupted adult relationships) or a clinically significant amount of distress because sexual behavior involving pubescent children violates social norms in most if not all contemporary cultures. For example, Beier et al. (2009) recruited pedophilic and hebephilic men from the community who were not required to participate in treatment but were motivated to seek treatment due to the impact their sexual interests were having on their lives. This demonstrates that some pedophilic or hebephilic men are sufficiently distressed as to seek treatment. In the absence of large-scale epidemiological research, it is not known how many non-distressed pedophiles or hebephiles there might be. Seto (2008, in press) has suggested that the prevalence of pedophilia may be 1–3 % based on nonrepresentative surveys and studies of clinical or criminal justice samples. In clinical samples, hebephilia may be more prevalent than pedophilia (Blanchard et al., 2009), though this has not been a consistent finding (e.g., Beier et al., 2009).

Responding to one of Franklin's (2009, 2010) criticisms, showing some sexual response to pubescent or prepubescent children is less important than the *relative* response to pubescent children. Most heterosexual men are most interested in adult women, followed by adolescent girls and then

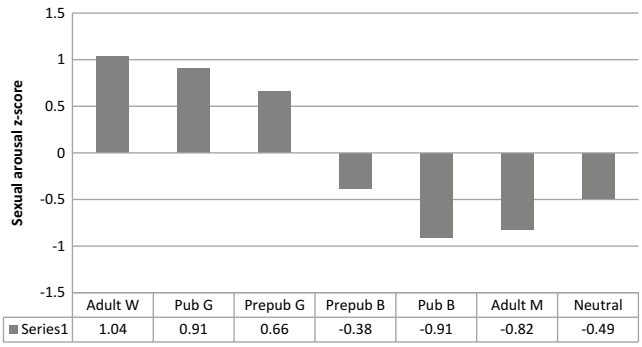

Fig. 1 Sexual Response Gradient. The figure represents the level of sexual arousal to each of the stimulus categories during phallometric assessment. Labels are as follows: Adult W = adult women stimuli; Pub G = pubescent girl stimuli; Prepub G = prepubescent girl stimuli; Prepub B = prepubescent boy stimuli; Pub B = pubescent boy stimuli; and Adult M = adult men stimuli. The figure represents the classic sexual response gradient for those interest in adult women. These indivudal show their greatest response to adult females, followed by pubescent and prepubescent females. The scores for male stimuli are negative, which means that the level of sexual arousal is below their mean level of sexual arousal. The neutral category is comprised of scenery and is used as a control condition

pubescent and prepubescent children followed by males [referred to by Seto, Lalumière, and Kuban (1999), as the sexual response gradient; see Fig. 1]. Given that teleiophilic men still show sexual response to non-preferred age categories, showing some response to pubescent children is normative. Showing more arousal to pubescent children than to adults, or not discriminating between these two categories, is *not* normative. Different clinics would use different cutoffs in order to determine how much of a greater response would be needed towards prepubescent or pubescent children relative to adults (Lalumière & Harris, 1998).

Assessment of Hebephilia

Self-Report

The simplest way to assess hebephilic sexual interests is to ask an individual directly, either in interviews or using questionnaires. However, as with pedophilia there are obvious reasons for any individual to deny sexual interest in pubescent children, given the intense stigma associated with being sexually interested in children in contemporary societies. Though some hebephiles may admit their sexual interest in pubescent children, many others might not, especially if they face more punitive legal consequences (e.g., more severe sentencing if they have committed a sexual offense). Due to the likely stigma and possible negative consequences such as ostracism, prejudice, and even violence, an admission of sexual interest in pubescent children is likely to be true, whereas denial of any such sexual interest might well be false in order to avoid legal consequences or other social

sanctions. It is important to consider that there may be rare occasions when someone might have good reasons to lie about having hebephilic sexual interests; one possibility is when someone would rather claim hebephilia than pedophilia, given some listeners may confuse hebephilia with a sexual interest in older adolescents.

Hebephilic sexual interests might also be inferred from information about someone's sexual history, preferably with multiple, independent sources. For pedophilia, Seto and Lalumière (2001) developed a screening scale comprised of four simple items related to one's sexual offence history: multiple child victims, any boy victim, any victim under age 12, and any unrelated child victims. Sex offenders with any history of sexual offending involving children could obtain a score from 0 to 5 on this scale (having a boy victim had twice the weight of the other items). This screening scale score was positively correlated with phallometrically assessed sexual arousal to prepubescent children in multiple samples (Seto, Harris, Rice, & Barbaree, 2004; Seto, Murphy, Page, & Ennis, 2003). As such, in the absence of a reliable and honest client, information from their sexual offence history can be used to confirm the diagnosis. Although the measure is specifically designed to detect pedophilia, a similar scale could be developed to screen for hebephilia, with items defined in terms of pubescent children.

Phallometry

Phallometry is used to assess penile responses (in terms of circumference or volume change) in response to sexual stimuli, such as descriptions of sex with different aged persons (see Laws, 2009). In the original phallometric test designed by Freund (1965) to assess erotic age-gender preferences, pubescent stimuli were included alongside prepubescent stimuli and adult stimuli. In subsequent research, Freund clearly distinguished pedophilic and hebephilic arousal patterns (e.g., Freund, Chan, & Coulthard, 1979). As previously discussed, this literature uses the term hebephilia if someone shows his greatest responses to pubescent children over the other age categories. Based on phallometric assessment, if an individual's greatest response is to pubescent children relative to their sexual response to adults, hebephilia could be present. Relative responding means that the examiner would take into account whether the response to pubescent aged stimuli was significantly greater [the significant threshold is set by individual clinics resulting in variability across phallometric labs; e.g., Howes (1995)] than the response to adult stimuli. Relative response is important as it leads to greater diagnostic accuracy than absolute response (Lykins et al., 2010b).

Classification Accuracy Like other diagnostic methods, phallometry produces both false negatives (e.g., not detecting the presence of pedophilia or hebephilia when the condition is in fact present) and false positives (e.g., incorrectly indicating pedophilia or hebephilia is present when the condition is not in fact there). Due to the negative consequences of being identified as pedophilic or hebephilic, assessors might conservatively set their clinical cutoffs for interpreting results such that specificity (minimizing false positives) is high, even though that necessarily comes at the expense of the sensitivity (minimizing false negatives) of their test. For pedophilia, Blanchard, Klassen, Dickey, Kuban, and Blak (2001) have shown that their phallometric testing procedure has high specificity (greater than 90 %) with good sensitivity (61 %). As such, the test is better equipped to identify men without pedophilia or hebephilia, than those who have it, which means that a negative test result does not necessarily mean that the individual does not have pedophilia or hebephilia. That is, a lack of response to pedophilic or hebephilic stimuli during phallometric testing does not rule out the possibility of pedophilia or hebephilia. This highlights the important role of collateral information (e.g., criminal records, previous assessment results, reports by others, child welfare reports, interview data) in these types of assessments. Research specifically focused on the sensitivity and specificity of tests focused on detected hebephilic sexual interests is needed.

Standardization One difficulty with phallometry is that there is no standardization across laboratories. This results in variability in both its administration and the interpretation of results (Howes, 1995); this has led to criticisms (e.g., Fedoroff, Kuban, & Bradford, 2009; O'Donohue & Letourneau, 1992). These concerns are particularly salient in the assessment of hebephilia, as labs have more experience with assessing pedophilia. For example, some laboratories may not include stimuli depicting pubescent children. This is an important consideration as it means that these labs would be unable to detect the presence of hebephilia, as hebephiles can appear nondeviant (respond greatest to adults) if pubescent stimuli are not included (Harris, Rice, Quinsey, Chaplin, & Earls, 1992). Additionally, some labs may use stimuli that include adolescents in Tanner stage 4, which means that they would only be able to detect the presence of ephebophilia, which is not a paraphilia (Hames & Blanchard, 2012). This highlights the important role of considering the stimuli used in phallometric assessment when interpreting the results. Another issue is that phallometric testing is expensive, requiring specialized equipment and trained assessors, and is perceived as intrusive, such that some individuals will refuse to participate. Also, phallometric assessment is not permitted in some European countries (e.g., Germany), leaving clinicians to rely on other types of assessments. Regardless of whether a professional has access to a phallometric lab, as with other types of diagnoses, multiple assessment methods are required in order to increase diagnostic accuracy.

Other Methods of Assessment

Cognitive measures (e.g., viewing time) have been used in the detection of sexual deviancy. One example of a cognitive measure that has been used to detect sexual interest in children among sexual offenders is the Implicit Association Tasks [IAT; see Gray, Brown, MacCulloch, Smith, and Snowden (2005)]. The IAT is a computerized task involving five trials, whereby offenders are presented with 32 words across four different categories: sexual (e.g., breasts), nonsexual (e.g., elbow), adult (e.g., grown-up), and child (e.g., infant). During initial trials, offenders are asked to classify words as sexual or nonsexual and adult or child. On subsequent trials they are to separate words in to child/nonsexual and adult/sexual (congruent condition) categories. Offenders would complete an incongruent trial where they are instructed to categorize words as child/sexual and adult/nonsexual. Results are interpreted as indicative of a sexual interest in children if offenders have a faster reaction time during the incongruent condition.

Brown, Gray, and Snowden (2009) used the IAT task to assess whether potentially pedophilic offenders (having victims younger than 11), potentially hebephilic offenders (having victims ages 12–15), and a control group of nonsexual offenders would perform differently on the IAT. There were significant group differences on IAT performance, with potentially pedophilic offenders more likely than potentially hebephilic offenders or the control group to show evidence of an association between children and sex in the task. They found no difference between the control group and potentially hebephilic offenders. Although a promising application of the IAT, there were two limitations of this research. First, the offenders were distinguished by victim age rather than maturation status of victims, which would likely increase misclassification. For example, some 14 year olds and more 15 year olds would be expected to be postpubescent, and thus offenders who had an ephebophilic or teleiophilic sexual preference could be misclassified as potentially hebephilic. Second, offenders were classified according to their youngest victim, which meant offenders could have had victims from other age groups. Based on these limitations, more research is needed on whether the IAT can be specifically used to distinguish among offender types and whether IAT performance corresponds with phallometric responses.

Diagnostic Considerations

Based on self-reported sexual interests, Blanchard et al. (2009) categorized offenders as follows: two pedophilic groups (interested in children ages 0–5 or 6–10), two hebephilic groups (interested in children aged 11 or 12–14), an ephebophilic group (interested in adolescents 15–16), and a teleiophile group (interested in adults). They used these groupings to examine how self-reported interests corresponded to phallometrically assessed sexual arousal to prepubescent, pubescent, and adult stimuli. Focusing on their results pertaining to hebephilia, they found a high correspondence between a self-reported sexual interest in pubescent girls and sexual arousal to pubescent children, as heterosexual hebephiles responded more to the pubescent category than to prepubescent or adult categories. Unexpectedly, the self-reported heterosexual pedophile group (who reported interest in 6–10-year-old girls) responded most to pubescent rather than prepubescent girls, whereas the self-reported heterosexual pedophile group who reported attraction to children from infancy to age five responded most to prepubescent child stimuli.

For those attracted to males, both self-reported pedophile groups (i.e., to younger or older prepubertal children) responded most to prepubescent stimuli as hypothesized. However, the self-reported hebephiles did not show a significant difference in their sexual response to pubescent and prepubescent males. The male-attracted ephebophile group had the greatest response to pubescent children, which could be due to the absence of older adolescents in Tanner stage 4 in the stimulus set. These results suggest that self-reported hebephilic sexual interest corresponds to phallometric assessment results, at least in the case of heterosexual men. Blanchard and colleagues reported that their results for hebephiles attracted to men could have resulted from a number of factors: (1) small sample size of this subgroup which could have resulted in a decreased ability to detect statistical differences, (2) prepubescent female models ranged from 3 to 11, whereas the prepubescent male models were slightly older, ranging from ages 5 to 11, and (3) the pubescent male models were slightly more physically developed than the female pubescent models. Blanchard et al. also suggested that their results could signify there is a characteristic difference between same-sex and opposite-sex-attracted hebephiles. Another possibility is that there are fewer physical differences between pictures of prepubescent and pubescent boys than between prepubescent and pubescent girls; breast budding is a relatively obvious cue to pubescent status, unlike changes in genital appearance or the onset of the pubertal growth spurt.

After initially indicating that hebephilia would be added to the DSM-5, the APA Task Force in charge of the *DSM-5* revision process decided not to include hebephilia as a diagnosis in the DSM-5. Clinicians could still consider hebephilia as a paraphilia, however, using the diagnosis of Other Specified Paraphilic Disorder. To make this diagnosis, a comprehensive assessment is required. This can include in-depth clinical interviews regarding sexual and relationship histories, review of collateral information such as police or court accounts of any sexual offenses, phallometric assessment of sexual age interests, and the use of alternative objective measures such as viewing time. An important issue

is the limits of self-report, because there are obvious reasons to lie about being sexually interested in pubescent children; collateral and ideally objective assessment data are crucial. A second issue to keep in mind is the distinction between interest and behavior: some hebephiles may never have acted upon their interest by accessing pornography depicting pubescent children or by having sexual contact with pubescent children. Additionally, some proportion of offenders with pubescent victims will not be hebephiles, motivated instead by other factors such as antisociality (see below discussion on victim age polymorphism in offenders against adolescent victims). Freund et al. (1972) suggested hebephilia was likely to be present if there is evidence of repeated sexual contacts with pubescent children, especially as the age difference between adult and minor increased.

A third issue to keep in mind regarding assessment is that pedophilia and hebephilia may be difficult to distinguish. This may partially account for the results of Blanchard and colleagues (2009), who found that men who self-reported pedophilic or hebephilic interest responded to categories that were unexpected (e.g., self-reported pedophiles interested in girls appearing to be between the ages of 6 and 10 had their greatest response to pubescent children). A challenge is that the Tanner stage of any known sexual offense victims is unlikely to be known; instead, clinicians will generally have information about the age of past victims and must use this to infer victim maturation status. For example, a 12-year-old girl might be showing signs of puberty onset, but might also be part of the population that does not begin puberty until the age of 13 or 14; it is not clear if offending against this girl might be evidence of pedophilia (prepubescence), hebephilia (pubescence), or neither. Another possibility that needs to be explored in further research is the comorbidity of pedophilia and hebephilia, where someone is sexually interested in both prepubescent and pubescent children (just as nonexclusive pedophiles can be sexually attracted to both children and adults; American Psychiatric Association, 2000; Freund et al., 1972) and whether they represent distinct psychological constructs.

Etiology

Etiological research on pedophilia and hebephilia has relied on retrospective research, looking for historical correlates of pedophilic or hebephilic sexual interests that might have etiological significance. This includes group comparisons of pedophilic or hebephilic individuals with others who do not have these interests and by correlating indices of sexual interest (e.g., self-reported interest, phallometrically assessed sexual arousal to children, number of child victims) with historical factors. Limitations of this research include the typical limits of self-report, the preponderance of studies of individuals who have been seen in clinical or criminal justice settings (as opposed to community settings), and incomplete historical information. Prospective research studies—following very large samples using repeated assessments with multiple measures over time to see who develops sexual interests in prepubescent or pubescent children—have not been done, though there have been some smaller studies of potentially at-risk individuals (e.g., children who have been sexually abused and who might be at risk of acting out sexually towards children; Salter et al., 2003). Etiological candidates that have been examined in research include nonspecific prenatal factors (as indicated by markers such as left-handedness, which appears during the first trimester), neurocognitive functioning, and sexual abuse history. Each of these candidates is reviewed in the following sections.

Prenatal Factors Pedophiles and hebephiles are more likely to be non-right-handed than those with teleiophilia, at a rate much higher than what is observed in the general population (Cantor et al., 2004, 2005). Cantor et al. (2005) found that the rate of non-right handedness in their group of pedophiles was tripled in comparison to teleiophilic men, even after accounting for potential confounds such as IQ and age (see also Blanchard et al., 2007). They argued that this is a crucial finding given that handedness develops in the very early stages of gestation. This could provide support to the argument that precursors to the development of atypical age sexual interests may be present before birth. Further indirect evidence is reported by Cantor et al. (2007), who found that both pedophilic and hebephilic offenders were shorter, on average, than teleiophilic offenders. Both of these findings imply that early developmental factors were sufficiently potent as to affect physical development.

Neurocognitive Functioning Recent sexological research has suggested that pedophiles and hebephiles show distinct differences when compared to teleiophiles in a number of neurocognitive domains. Regarding overall cognitive abilities, Cantor et al. (2006) investigated the educational histories of a sample of pedophilic, hebephilic, and teleiophilic men. They found that in comparison to teleiophiles, pedophiles and hebephiles were twice as likely to have failed a grade or to have required special education (encompassed under the term educational difficulties), even when controlling for other variables such as intelligence and parental education. Cantor et al. (2004) found that both pedophiles and hebephiles had lower IQs when compared to teleiophiles, with hebephiles' scores as intermediate between the groups. They also found that both pedophiles and hebephiles exhibited memory deficits in comparison to teleiophiles in the area of memory recall, though this effect disappeared when IQ was controlled for. Additionally, both pedophiles and hebephiles were more likely to suffer a head injury before the age of 13

when compared to teleiophiles (Blanchard et al., 2003). Interestingly, the difference was not found for head injury after the age of 13, suggesting it is head injury during a particular critical developmental period (before puberty) that might be important.

The empirical evidence on the neurocognitive and physical anomalies to date has been used to assert that both pedophilia and hebephilia result from an underlying neurodevelopmental perturbation (Blanchard et al., 2002; Cantor et al., 2006). According to this hypothesis, the fetus is exposed to something teratogenic in the gestation period that would cause the cognitive, physical, and behavioral deficits alongside the atypical sexual age interest. However, without longitudinal research the nature of this link is not clear nor is whether a third variable causes both the atypical sexual interests and the markers that have been found in the research (Blanchard et al., 2002). Regardless, the hypothesis has continued to gain traction in the field, largely based on recent studies that have examined the biological underpinnings of atypical age interests.

In further support of the neurodevelopmental hypothesis, Cantor and colleagues (2008) utilized magnetic resonance imaging (MRI) and found white matter differences between pedophilic and hebephilic men compared to teleiophilic men. These white matter deficiencies were localized to both the temporal and parietal lobes of the brain in both pedophilic and hebephilic men (Cantor et al., 2008; Cantor & Blanchard, 2012). Cantor et al. (2008) argued that their findings suggest a disconnection in the brain network that recognizes and responds to sexual cues, which may occur in a period of neurodevelopment leading to deviant sexual preferences such as pedophilia and hebephilia.

Sexual Abuse History There is a long-standing belief that experiencing sexual abuse as a child or young adolescent increases the likelihood that someone will sexually offend against minors in the future (the so-called *abused–abuser* hypothesis). Indeed, meta-analytic reviews show that both adolescent and adult sex offenders are substantially more likely to have experienced sexual abuse than their nonsexually offending counterparts (Jespersen, Lalumière, & Seto, 2009; Seto & Lalumière, 2010). The group differences were much smaller for physical abuse history, suggesting a specific sexual abuse to sexual offending link. This result is bolstered by longitudinal data showing that sexually abused children are more likely than other children to get into trouble for sexual offending (Salter et al., 2003; Widom & Ames, 1994) and cross-sectional data from the community showing an association between experiencing sexual coercion and engaging in sexual coercion (Seto et al., 2010). Moreover, both Jespersen et al. (2009) and Seto and Lalumière (2010) found that sex offenders with child victims were more likely to have sexual abuse histories than sex offenders with adult victims, suggesting a potential link with sexual interest in children. Consistent with this idea, Becker, Kaplan, and Tenke (1992) found that sexually abused adolescent sex offenders showed greater sexual arousal to children when assessed phallometrically. Greenberg, Bradford, and Curry (1993) found that men with sexual abuse histories who victimized children and adolescents chose victims of similar age to the age of their own sexual victimization.

Summary The research conducted to date on hebephilia is important as it has established a small body of literature on the cognitive, physical, and behavioral deficits seen in hebephilic offenders. Further, it has advanced our understanding of a possible etiological pathway in the development of both pedophilia and hebephilia. Although hebephilic offenders have been found to be distinct in their arousal patterns (e.g., Blanchard et al., 2009), the research literature to date has often found that hebephilic men are intermediate between pedophilic and teleiophilic men in a number of regards. Unfortunately, in many of the above cited studies, pedophiles and hebephiles were not directly compared. It is possible that hebephiles would be similar to pedophiles in some regards, but they may differ in regard to other correlates. One area where hebephilia is especially relevant would be in sexual offending.

Hebephilia and Sexual Offending Against Children and Adolescents

Contrary to public perception, sexual offending victim choice does not always equate to sexual interests or preferences. For example, Seto (2008) concluded that 50–60 % of men with child victims were not pedophilic, which suggests that sexual offenders can victimize children for reasons other than a sexual preference (e.g., antisociality). As such, sexual offending against pubescent children may not necessarily correspond to hebephilia.

Many researchers have found that, as a group, sexual offenders against adolescents are often intermediate on the variable of interest when compared to offenders against children and offenders against adults (e.g., Kalichman, 1991). Cohen, Frenda, Mojatabai, Katsavdakis, and Galynker (2007) found that when compared to child molesters and rapists, sexual offenders with adolescent victims were intermediate in the likelihood of having a male victim and in their use of violence during the commission of the offence. One study found that offenders with adolescent victims were twice as likely to have been diagnosed with a mood disorder as offenders with child or adult victims (Carlstedt et al., 2009). Firestone, Dixon, Nunes, and Bradford (2005) compared incest offenders with victims younger than six and incest offenders with victims who were 12–16. They found

significant differences in that those with younger victims were more likely to abuse drugs and alcohol, come from a family with a history of criminal behavior, exhibit poor sexual functioning, and suffer from greater levels of psychopathology. In regards to their offending, those with adolescent victims were less likely to have two or more victims, to have abused a male, to have abused a relative, or to have used violence during the commission of their offence. In a study of victims of extrafamilial sexual assaults, adolescents (13–18 years old) were compared to adult (25–44 year old) victims. Adolescent victims were less likely to be victimized by a stranger, less likely to sustain physical injuries, and more likely to be drinking or using drugs at the time the offence occurred (Muram, Hosteler, Jones, & Speck, 1995).

It is not clear whether sexual offenders with adolescent victims differ in their sexual response to prepubescent or pubescent children. Firestone et al. (2005) found no difference in phallometric response to prepubescent children between those who victimized adolescents and children. A possible reason for the absence of meaningful differences may be attributable to the composition of their sample, as incest offenders are less likely to be pedophilic (e.g., Seto et al., 1999). In other studies that have examined more heterogeneous groups of sexual offenders, sexual offenders with adolescent victims do not differ from offenders with adult victims in their sexual response to prepubescent children, whereas both of these groups differ from offenders with child victims (Baxter, Marshall, Barbaree, Davidson, & Malcom, 1984; Malcolm, Andrews, & Quinsey, 1993). These findings could be due to the absence of pubescent and adolescent stimuli, which would be what hebephiles would show the greatest response to.

Another potential reason for these findings is that offenders with adolescent victims show the highest levels of victim age polymorphism among offenders who have multiple sexual victims (Guay, Proulx, Cusson, & Ouimet, 2001). Victim age polymorphism is a term used to denote inconsistency across offenses in the ages of victims, for example, if an offender has both child and adult victims. Adolescent victims may serve as viable option for an opportunistic offender when the offender's preferred victim type is not accessible (Guay et al., 2001; Lussier, Leclerc, Healey, & Proulx, 2007). This can be viewed as a behavioral example of the sexual response gradient, wherein teleiophilic offenders might still offend against adolescent or pubescent victims, and pedophilic offenders might offend against pubescent or early adolescent victims (Seto et al., 1999) as they most closely resemble their ideal victim type (Heil, Ahlmeyer, & Simons, 2003).

Lykins and colleagues (2010a) explored the sexual response gradient idea in a study of sexual arousal in nonoffending heterosexual teleiophilic men. During phallometric testing, these men had the greatest response to women, followed by pubescent girls and prepubescent girls. They showed the lowest levels of sexual arousal to males of any age group. Similar results have been found in studies of sexual offenders (e.g., Blanchard et al., 2009; Seto & Lalumière, 2001). It is possible that hebephilic offenders are less likely to have exclusive sexual age interests. Beier et al. (2009) found that in their sample of self-identified hebephiles, 41 % were exclusively interested in a specific group, in comparison to 61 % of pedophiles and 100 % of teleiophiles. Thus, distinguishing hebephilia from other types of arousal patterns would be a more challenging task, given that they may be less likely to exhibit an exclusive pattern of sexual responding. Though they might show strong responses to stimuli depicting pubescent children, they could also exhibit substantial responses to depictions of pubescent children or of postpubescent adolescents and young adults.

In one of the few studies to directly examine the relationship between hebephilia and sexual offending, Studer, Aylwin, Clelland, Reddon, and Frenzel (2002) examined the phallometric responses among child molesters with intrafamilial and extrafamilial child victims. Among hebephilic (based on phallometric assessment) sexual offenders with child victims, there was no difference in whether they selected related or unrelated victims. Further, no differences emerged in the hebephilic intrafamilial group on their selection of biological or nonbiological family members as victims. This pattern differed from what was found in teleiophiles, who tended to have intrafamilial child victims, and pedophiles, who were more likely to have extrafamilial child victims. This suggests that hebephiles may be equally likely to be intrafamilial or extrafamilial offenders, which is in contrast to pedophiles or teleiophiles who victimize children.

Clinical Applications

Risk Assessment

Atypical sexual interests are a psychologically meaningful risk factor, meaning sexual interest in prepubescent or pubescent children ~~are~~ is a robust predictor of sexual recidivism and play a prominent role in theoretical models of sexual offending (Hanson & Morton-Bourgon, 2005; Mann, Hanson, & Thornton, 2010; Seto, 2008). Atypical sexual interests are indicated by phallometrically assessed sexual arousal to children, having multiple child victims, and other sexual offending characteristics (e.g., having unrelated child victims or having boy victims). Studies have typically not distinguished between pedophilia and hebephilia, however, and an important theoretical and clinical question is whether these two age interests differ in their associations with sexual recidivism. Eke and Seto (2011) conducted a study of child pornography offenders in order to examine the factors that

influenced child pornography offenders to recidivate. Included in their examination of different risk factors was admitted pedophilic and hebephilic sexual interest. Admitted hebephilic interest was an important factor in predicting future contact sexual recidivism, but not admitted pedophilic interest. Based on their findings, it may be that hebephilia may be more important than pedophilia in sexual recidivism, at least among child pornography offenders. It is not known whether hebephilia plays less of a role among men who have primarily committed contact sexual offenses.

Although pedophilic and hebephilic interests have usually not been distinguished in risk appraisal research, hebephilia is already represented in many established risk measures because maturation status is not specified. For example, the *Sex Offender Risk Appraisal Guide* has 14 items, one referring to *any* deviant phallometric results and the second asking whether the offender has only offended against girls under the age of 14 (Quinsey, Harris, Rice, & Cormier, 2006). Deviant phallometric results would include showing relatively greater sexual response to stimuli depicting prepubescent or pubescent children while victimizing girls under 14 could include both prepubescent and pubescent victims. To take a second example, the Screening Scale for Pedophilic Interests is significantly and positively correlated with sexual arousal to prepubescent children in the phallometric laboratory and is also a significant predictor of serious recidivism among sex offenders with child victims (Seto et al., 2004; Seto & Lalumière, 2001). This measure is comprised of only four items referring to sexual child victim history: any boy victims, multiple child victims, any victim under the age of 12, and any unrelated child victims. Someone who has offended against pubescent children only would score points on this measure, which was originally developed to assess pedophilic interests among any individuals with victims under the age of 14.

Treatment and Prevention

Treatment

Psychosocial Treatment Pedophilia can be viewed as akin to a sexual orientation that emerges early in life and is stable over time (see Seto, 2012). Hebephilia could be viewed this way as well, because of its conceptual and clinical similarities with pedophilia, though its evidence base is much less developed. There is no strong evidence to support the idea that any sexual gender or age preferences can be changed using existing treatment technologies (see Barbaree, Bogaert, & Seto, 1995; Seto, 2008). Thus, the focus of treatment for pedophilia (and, by extension, hebephilia) is on increasing self-management of pedophilic thoughts, fantasies, urges, sexual arousal, and sexual behavior. Sexual self-regulation deficits have been identified as an important psychologically meaningful risk factor for sexual reoffending (Mann et al., 2010). These skills can be taught using cognitive-behavioral techniques and form a core aspect of the most common sex offender treatment programs in operation (McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2009). Voluntary control over sexual arousal can be addressed using behavioral conditioning techniques that teach offenders how to suppress their sexual arousal to undesirable stimuli (children); behavioral techniques have been less successful at increasing sexual arousal to normative stimuli (Lalumière & Quinsey, 1998). An unanswered question is to what extent behavioral conditioning of sexual arousal can be robustly demonstrated, because the evidence has mostly been limited to small sample studies and/or uncontrolled evaluation designs. If there is a robust effect, it is likely that the effects fade over time and thus sex offenders will need "booster" sessions to maintain potential gains achieved.

More broadly, treatment of paraphilic offenders appears likely to be the most effective when it adheres to the Risk Need Responsivity (RNR) model of correctional rehabilitation (Hanson, Bourgon, Helmus, & Hodgson, 2009). The RNR model posits that correctional interventions are more likely to be effective when they are true to a core set of principles (Andrews & Bonta, 2010). The risk principle states that interventions are most effective when they are titrated to the risk posed by offenders, with the most intense interventions for high risk offenders and low intensity or even no intervention for low risk offenders. The needs principle states that interventions are more effective in reducing recidivism when they focus on so-called criminogenic needs, that is, dynamic risk factors that are associated with recidivism. Research with sexual offenders suggests dynamic risk factors include general and specifically sexual self-regulation deficits, noncompliance with rules, antisocial attitudes and beliefs, and association with delinquent peers. Finally, the responsivity principle states that interventions are more likely to be effective when they are tailored to individual learning styles. For offenders, this typically means programs that are cognitive-behavioral in their approach emphasize concrete skills training over insight or learning abstract principles, and use classic teaching techniques such as modeling, role play, and rehearsal. Hanson et al. (2009) examined data from 23 sex offender treatment outcome studies. Treated offenders had lower recidivism rates overall than offenders in the comparison groups. Programs that adhered to the risk, need, and responsivity principles to a greater degree produced larger differences than programs that addressed them to a lesser degree.

Medication For those with intense sexual urges, who have a history of self-regulation problems and who are therefore at higher risk of sexually reoffending, anti-androgen medications

have been used in treatment (Thibaut et al., 2010). These medications reduce circulating androgen levels, and several smaller-scale clinical trials have demonstrated substantial reductions in sex drive and behavior as a result. There is no evidence that anti-androgens can change the direction of sexual interests; instead, they can be viewed as turning down the intensity of existing interests. A significant problem for anti-androgen medications is the risk of serious side effects, including osteoporosis and liver damage. Perhaps as a result of these undesired effects, compliance with anti-androgen medication can be a problem (Hucker, Langevin, & Bain, 1988). For individuals who will not accept or cannot tolerate anti-androgen medications, there may be a role for selective serotonin reuptake inhibitors (SSRIs), which are commonly used in the psychiatric treatment of depression and other mental conditions. SSRIs can also reduce sex drive and may also benefit clients by improving mood. Randomized clinical trials are needed to test medication effects, because most of the evidence base consists of open trials or other less rigorous designs.

Circles of Support and Accountability (COSA) The COSA model was developed to support offenders who had served their prison sentence and were being released to the community despite continuing to be at high risk of reoffending (Wilson, Picheca, & Prinzo, 2007; Wilson & Prinzo, 2001). Given the higher recidivism risk associated with men with a sexual interest in children, especially when combined with antisocial tendencies, those with either pedophilia or hebephilia could benefit from such a program. In the model, four to six members of a volunteer support group visit the offender daily, assist him with fundamental living tasks such as obtaining and keeping housing and employment, and mediate if necessary with police, media, and concerned members of the public. These volunteers are given training regarding the patterns of sexual offending and warning signs and are able to consult with professionals such as police officers or mental health clinicians as needed. Preliminary evaluation results are encouraging: Wilson et al. (2007) followed 60 sex offenders involved with COSA in Canada and compared them to 60 sex offenders who were released at the end of their prison sentence without a circle; the two groups were matched on risk to reoffend, length of time in the community, and prior involvement in sex offender treatment. After an average follow-up time of 4.5 years, 5 % of the offenders involved in COSA had sexually reoffended compared to 17 % of the comparison offenders. A similar result was obtained in a replication study conducted by Wilson, Cortoni, and McWhinnie (2009). Duwe (2012) recently published the results of a small randomized clinical trial to evaluate a Circles of Support and Accountability model in Minnesota and found positive effects on recidivism for those who went through the program.

Randomized Clinical Trials Systematic or meta-analytic reviews of sex offender treatment have concluded that it can be effective in reducing sexual recidivism (Hanson et al., 2002; Lösel & Schmucker, 2005). However, there is an ongoing and vociferous debate about the efficacy of sex offender treatment given the paucity of randomized clinical trials and the discouraging results of the best clinical trial, the Sex Offender Treatment Evaluation Project or SOTEP (Marques, Wiederanders, Day, Nelson, & van Ommeren, 2005; Marshall & Marshall, 2007; Seto et al., 2008). Randomized clinical trials are important because of obvious and subtle biases inherent in less rigorous designs. For example, many of the studies we reviewed in the Hanson et al. (2002) meta-analysis compared treated offenders with offenders who had dropped out of treatment or refused treatment. Given that dropout is associated with greater risk of recidivism, this means treated offenders are being compared to a higher-risk group, on average, even if the two groups are matched on risk using an established risk measure (because some of the variance in risk associated with risk might not be captured). Studies are considered to be incidental assignment designs, where treated offenders were compared to offenders who did not receive treatment [e.g., because the clinic was too far away: Marshall and Barbaree (1988)]. The problem, again, is that offenders who were not able to attend treatment might differ in risk-related ways (e.g., the offenders could have made arrangements to participate in treatment if they were more motivated).

For these kinds of reasons, randomized clinical trials are considered the gold standard of treatment evaluation by organizations such as the United States Food and Drug Administration, the Cochrane Collaboration for systematic reviews in health care (cochrane.org), and the Campbell Collaboration for systematic reviews in education, social welfare, and criminal justice (campbellcollaboration.org). Other study designs have methodological or analytic issues that limit the inferences that can be drawn about treatment efficacy. In the most recent Cochrane review of trials involving adults who have sexually offended or are at risk to do so, Dennis and her colleagues stated matters clearly and succinctly: "The inescapable conclusion of this review is the need for further randomized controlled trials" (Dennis et al., 2012, p. 1). The current state of adult sex offender treatment evaluation can be contrasted to the encouraging results of small randomized clinical trials that support cognitive-behavioral, ecologically sensitive treatment for adolescents who sexually offend, and for children with sexual behavior problems (Borduin, Schaeffer, & Heiblum, 2009; Carpentier, Silovsky, & Chaffin, 2005; Letourneau et al., 2009). More methodologically sound research relying on randomized clinical trials is needed regarding both psychosocial (including social interventions such as Circles of Support and Accountability) and medical treatments for adults who sexually offend against youth.

Prevention

A disadvantage of offender treatment is that it is provided after victimization has already been taken place. In the following section, we discuss some of the innovative prevention efforts that have been implemented in an effort to prevent sexual offenses from occurring in the first place. The first effort is a clinical outreach program in Germany that used mass media campaigns to recruit self-identified pedophiles and hebephiles living in the community [Dunkelfeld Prevention Project: Beier et al. (2009)]. The second effort is an information clearinghouse and hotline available to individuals who are concerned about their sexual interest or behavior involving children (Stop It Now!).

Project Dunkelfeld Beier et al. (2009) developed a secondary prevention program in Germany to address men in the "Dunkelfeld" (translation: dark field), that is, individuals who are sexually interested in children but are unknown to authorities because they are not seen in clinical settings and are not involved with the criminal justice system. Interested persons contacted a sexology clinic offered at the Charité hospital in Berlin, Germany, and underwent a comprehensive assessment. This Berlin clinic offers treatment free of charge to individuals who use child pornography or are attracted to children. Treatment is aimed at teaching individuals skills to prevent child sexual abuse. Individuals who were diagnosed with pedophilia or hebephilia were offered treatment, as long as they were not currently involved in a criminal proceeding for sexual offending. Clients learned to increase victim empathy, to employ cognitive strategies aimed at problematic attitudes and beliefs about sex with children, and learned self-regulation strategies that they could use to prevent the occurrence of child sexual abuse. In many cases, medication was also available and used to help clients better control their sexual impulses (Amelung, Kuhle, Konrad, Paulsa, & Beier, 2012; see also, dont-offend.org).

Unlike Canada or the United States, Germany does not have a mandatory child sexual abuse reporting law, except where homicide is considered to be a risk, which was likely an advantage in recruiting community clients who were not already known to the authorities. The original Berlin clinic has now expanded to include other clinics in Germany, with government funding. Beier et al. (2009) provided further details about the sample of men they recruited to the program. They found that of the 358 men who were assessed, approximately 75 % of them had committed a prior sexual offence (many of which were undetected). Of those assessed, 12 % were not diagnosed, 60 % were diagnosed with pedophilia, and 28 % were diagnosed with hebephilia. Based on descriptive information about their sample of hebephiles, 58 % were primarily interested in females, 38 % in males, and 5 % in both males and females. Approximately, 15 % of them met criteria for another mental disorder, and 14 % had another paraphilia. Approximately, 80 % had committed a prior contact sex offence or child pornography offence.

Stop It Now! Stop It Now! is a nonprofit organization that began in the United States but now has sister organizations in other countries, including the United Kingdom (stopitnow.org). Stop It Now! provides online resources, links, a clinical directory service, and a confidential, toll-free number for individuals who are concerned about their sexual interests or behavior involving children. The goals of Stop It Now! are prevention, education, and outreach. Both Stop It Now! and the Association for the Treatment of Sexual Abusers maintain directories of clinicians who can provide assessment and treatment of individuals for their sexual interests or behavior, even if they are not currently involved in the criminal justice system (or have not committed any sexual offenses). Ideally, efforts such as Stop It Now! and the Dunkelfeld Project would reach individuals before they had committed any sexual offenses.

Conclusion

Research suggests that hebephilia is a valid psychological construct, representing a distinct sexual interest in pubescent children (e.g., Blanchard et al., 2009). Though the debate continues as to whether it should be formally recognized as a mental disorder, we agree with the logic of Blanchard (2010): If pedophilia is accepted as a mental disorder in standard nosologies such as the *DSM-IV-TR* and *ICD-10*, then hebephilia should be included as well because they are similar conceptually and clinically in terms of the relationship between sexual interests and behavior, evidence of links between phallometrically assessed sexual arousal and victim selection, and group differences from offenders with prepubescent child victims and offenders with adult victims.

There are many questions that need to be addressed in further research. A fundamental question is how common hebephilia is in the general population and how many hebephilic individuals act on their sexual interest either by accessing illegal pornography depicting pubescent children or by initiating sexual contacts with pubescent children. Epidemiological surveys are needed to address this question, which also applies to pedophilia. The sexual response gradient hypothesis would lead us to predict that there are more hebephilic men than pedophilic men.

Other research goals should include how to best distinguish hebephilic from pedophilic and other sexual offenders, further group comparisons and follow-up studies using a more precise definition and assessment of hebephilia (pubescent children, not adolescents more broadly), and research to determine if hebephilia shares etiological factors with

pedophilia. Focusing on clinical applications, it is important to know if hebephilic offenders differ in risk from other sex offenders and if they respond differently to interventions. To illustrate the importance of these questions, it may be the case that hebephilic sex offenders pose a greater risk to sexually offend because they are less likely to be exclusive than pedophilic or teleiophilic offenders and thus may have a larger potential victim pool. At the same time, this lower non-exclusivity of sexual age interests may provide opportunities for clinicians to support a shift towards legal and more socially appropriate aged partners through behavioral conditioning and self-management techniques.

Rape and Paraphilic Coercive Disorder

Gary Zinik and Jesus Padilla

History and Controversy of a Rape Paraphilia

There has never been a diagnostic category in any edition of the *Diagnostic and statistical manual of mental disorders* (APA, 1952, 1968, 1980, 1987, 1994, 2000, 2013) that describes an individual who is persistently aroused by coercive sex and repeatedly commits acts of rape. Despite this, clinicians generally hold that such individuals do suffer from a sexual disorder or paraphilia, and that the paraphilia has specific dimensions. Most often characterized as paraphilic coercive disorder (PCD), this paraphilia has long been the subject of clinical treatment and sexuality research.

Paraphilic coercive disorder has a long and controversial history. It was considered and ultimately rejected for inclusion into the Paraphilias section of the revised third edition of the Diagnostic and Statistical Manual of Mental Disorders (*DSM-III-R*, APA, 1987) but is now being reconsidered for inclusion in the next edition of the diagnostic manual (*DSM-5*), which is scheduled for publication in 2013. With the passage of sex offender civil commitment laws in 20 states since 1990, along with recent research findings, paraphilic coercive disorder has generated new interest—and new controversy.

Paraphilias Defined

It has generally been proposed that paraphilias (e.g., pedophilia) are psychologically characterized by an internalized set of deviant sexual urges and/or fantasies that lead to the expression of overt paraphilic behavior. Paraphilic behavior is assumed to reflect underlying deviant arousal patterns that have become deeply imprinted into an individual's sexual arousal system. These fixed mental and emotional patterns have been described as *love maps*, *sex prints*, *erotic signatures*, and *sexual scripts*. The origin of the word *paraphilia* is constructed from two Greek roots: *para* means beyond and *philia* means love, reflecting that paraphilias are construed not only as sexual disorders but *as disorders of loving*.

In this sense, paraphilias have been characterized as disorders of courtship (Freund, 1988; Freund, Scher, & Hucker, 1983) because they can interfere with normal pair bonding, mating, and biological reproduction. In *Lovemaps*, John Money (1986) famously catalogues over 60 different paraphilias which result from the "vandalism of sexuoerotic development of the vulnerable male" (p. 1). Paraphilias are not exclusive to males, but males with paraphilias are thought to vastly outnumber females. Thus, as with the current work on PCD, research has primarily been limited to males. Statistically, paraphilias occur at low levels of frequency in the population and are abnormal—a deviation from the norm—and are thus considered forms of sexual deviancy. In its extreme or exclusive form, the paraphilic stimulation is required for sexual arousal and inhibits the ability to form suitable and sustainable sexually intimate relationships.

A Suggested Definition of Paraphilic Coercive Disorder

Paraphilic coercive disorder is defined as a mental disorder characterized by persistent urges, fantasies, or behavior involving coercive sexual acts toward nonconsenting persons. It reflects an underlying deviant sexual arousal to forced sex and is conceived as the sexualizing of power, control, and dominance over nonconsenting persons. The eroticizing of coercive sex is thought to develop psychologically such that physical force and/or the nonconsent of the sexual situation become established "turn ons" that are pursued in either fantasy or reality for repeated sexual gratification. Money and Lamacz (1989) used the terms *raptophilia* (Latin

derivative) or *biastophilia* (Greek derivative) to describe what we believe is comparable to PCD: "Genitoerotic arousal and, eventually the orgasm, that are contingent on having a partner who, as a captive, is forced to yield sexually under condition of threat, assault, and injury" (p. 48).

The essential elements of Paraphilic Coercive Disorder could then be described as follows:

(A) Over a period of at least 6 months, recurrent sexually arousing fantasies, urges, or behaviors involving coercive sexual acts with nonconsenting persons, typically including genital contact.
(B) The experience of power, dominance, and control are sexually arousing because the sexual behavior is forced upon a person who is deprived the liberty of consent and would otherwise refuse the sex if given a free choice.
(C) The individual has acted on these sexual urges (committed sexual assault), or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
(D) The disorder is distinguished from sexual sadism in which the physical suffering and/or psychological humiliation of the nonconsenting person is the source of sexual arousal.

To summarize, PCD as a diagnosis applies to serial rapists who demonstrate *persistent*, *repetitive* acts of coercive sex over time with multiple victims. At the core of PCD is the deviant arousal to the abusive power of sex with a nonconsenting person. Note that the nonconsenting person need not be actively physically resisting the sexual assault (fighting, struggling, etc.). In some rape situations a fearful victim may "surrender" and never physically resist, accepting that she or he would lose the struggle, and passively submit to the rape. This is particularly true of vulnerable victims who are small in stature, elderly, physically disabled, or when the perpetrator uses weapons. In addition, PCD cam be present in serial rapists who target unconscious or mentally incompetent victims who are incapable of consent due to their lack of awareness that a sexual assault is being committed upon them. Whereas sexual sadists are erotically aroused by the use of force greater than necessary to subdue the victim, the need for excessive force or the infliction of pain are not necessarily characteristic of PCD.

Sexual Deviance, Paraphilias, PCD, and the *DSM*

The original edition of the *Diagnostic and statistical manual of mental disorders* (*DSM*, APA, 1952) was designed to develop a uniform nomenclature of mental diseases and a method for coding and statistically tracking their prevalence. The *DSM* was also based on the premise that all disease—including mental disease—had a biological basis, and advancing science would ultimately shed light on both the origins and treatments for disease. However, the *DSM* catalogue of disorders was also influenced by psychodynamic and Freudian notions that were popular at the time, particularly the concept of *neurosis*. The only sexual disorders listed in the *DSM* were termed *sexual deviations* and appeared as a subcategory under *sociopathic personality disturbance*. Sexual deviations included cases formerly classified as "psychopathic personality with pathologic sexuality," but offered little guidance as to signs, symptoms, or criteria for diagnosis. Rape and sexual assault are mentioned but appear to be features of sexual sadism as a type of sexual deviation (which also included mutilation).

The second edition of the diagnostic manual (*DSM-II*, APA, 1968) was designed to more closely follow the World Health Organization's eighth edition of the *International classification of diseases* (ICD-8, 1996; WHO, 1966). The numerical classification scheme was revised, and eight specific sexual deviations were listed as personality disorders that included homosexuality, fetishism, pedophilia, transvestitism, exhibitionism, voyeurism, sadism, and masochism. The list also included "Other Sexual Deviation" and "Unspecified Sexual Deviation." Sexual deviations as a diagnostic class were "for individuals whose sexual interests are directed primarily toward objects other than people of the opposite sex, toward sexual acts not usually associated with coitus, or toward coitus performed under bizarre circumstances … This diagnosis is not appropriate for individuals who perform deviant sexual acts because normal sexual objects are not available to them" (APA, 1968, p. 44).

The third edition of the manual, *DSM-III* (APA, 1980), produced a major shift in which the psychodynamic and biological views were abandoned in favor of a descriptive model that characterized each mental disorder as a clinically significant behavioral or psychological syndrome or collection of symptoms. Rather than focusing on etiology, mental disorders were defined as those disorders associated with distress, disability, or impairment in functioning. A multiaxial system was created to rank the degree of impairment, and diagnostic criteria were offered for each disorder based on specific behavioral signs and subjective symptoms.

The term *paraphilia* first appeared in *DSM-III*, and it is here that we first see the more familiar definition as recurrent, intense sexual urges, fantasies, or behaviors lasting at least 6 months—a time frame that was arbitrarily selected by the authors (Frances, 2007). The paraphilias included the sexual deviations listed in the *DSM-II* with the addition of zoophilia and a residual atypical class called paraphilia, not otherwise specified (NOS). Ego dystonic homosexuality—though not a paraphilia—replaced sexual orientation disturbance, which was introduced in 1973 as a replacement for the prior listing of homosexuality as a personality disorder and sexual deviation in the *DSM-II*.

A paraphilia diagnosis for non-sadistic rape, called sexual assault disorder, was first introduced for consideration in the *DSM-III*. However, sexual assault disorder was withdrawn

after the American Academy of Psychiatry and the Law and other groups voiced opposition that it could be used to promote an insanity defense by defendants facing prosecution for rape (Kutchins & Kirk, 1989). Nevertheless, advocates continued to maintain the need for a separate diagnostic category for paraphilic rape.

Work on the revised edition of *DSM-III* began in 1983 and eventually produced the *DSM-III-R* (APA, 1987). One significant change between the revised edition and its predecessor was that a paraphilia diagnosis no longer required the deviant acts or sexual object to be the preferred or exclusive means of achieving sexual pleasure. In the *DSM-III-R*, paraphilias could be either the *Exclusive* or *Nonexclusive* type, provided they had a duration of at least 6 months. In this way, a nonexclusive paraphilic diagnosis did not necessarily eliminate normative sexual interests (Person, 2005), suggesting that pathological and non-pathological sexual preferences could coexist side by side within the same individual—though not necessarily of equal strength and potency.

It was also during the formulation of the *DSM-III-R* that the term "paraphilic coercive disorder" was officially introduced by the Paraphilias Work Group. The proposed diagnostic criteria were as follows:

(A) Over a period of at least 6 months, preoccupation with recurrent and intense sexual urges and sexually arousing fantasies involving the act of forcing sexual contact (e.g., oral, vaginal, or anal penetration; grabbing a woman's breast) on a nonconsenting person.
(B) It is the coercive nature of the sexual act that is sexually exciting and not signs of psychological or physical suffering of the victim (as in sexual sadism).
(C) The individual repeatedly acts on these urges or is markedly distressed by them.

The diagnosis of PCD was proposed for inclusion in the *DSM-III-R* along with two other controversial diagnoses: masochistic personality disorder and premenstrual dysphoric disorder. As news spread of these proposed changes in the diagnostic manual, strong opposition was heard from both the popular press and various professional organizations (The American Psychological Association, the American Orthopsychiatric Association, the National Association of Social Workers, and the National Organization for Women). Objections were voiced for a number of reasons, not the least of which was how the three diagnoses were perceived to unfairly affect women. Premenstrual dysphoric disorder could apply only to women, masochistic personality disorder was perceived as disproportionally applying to (and thus discriminating against) women, and it was believed that PCD would help rapists to avoid prosecution (at the expense of their female victims) because they allegedly suffered from a psychiatric disorder.

The newly proposed diagnoses provoked a firestorm of debate in the mental health community, and the response from feminist psychologists was particularly passionate (Capalan, 1995; Kutchins & Kirk, 1989, 1997). For example, in a meeting with one of the *DSM-III-R* committees, psychologist Lynne Rosewater from the Feminist Therapy Institute (Georgetown, Maine) threatened to sue the American Psychiatric Association if they included the three controversial diagnoses in the *DSM* (Capalan, 1995). But the proposed paraphilic coercive disorder diagnosis by far generated the most debate. Indeed, Zander (2008) contends that PCD was one of the most hotly debated and widely publicized issues ever considered by the drafters of the *DSM*, second only to the internationally publicized debate about the inclusion of homosexuality in the early 1970s. (For a discussion of the debate over homosexuality in the *DSM*, see Bayer (1981).)

Broad cultural and political trends in the mid-1980s clearly influenced the debate over PCD as a legitimate diagnosis. To begin with, feminist literature promoted the perspective that rape was a violent assault motivated by the rapist's desire for power and dominance rather than by sexual arousal. The motto that "rape is a violent crime, not a sexual crime" was popularized by leaders of the feminist movement (Brownmiller, 1975; Dworkin, 1981; Wells & Motley, 2001). This new thinking influenced the reform of rape laws and the rules of evidence for prosecuting rapists. Prior to this time, rape victims were discouraged from prosecuting because their sexual histories were allowed as evidence, and this information, along with their identities, was typically published by the media. By the early 1980s, most jurisdictions in the United States had adopted rape shield statues to protect the victim's identity and personal history.

During this same period of rape law reform, a separate but overlapping judicial concern was developing about the effects of pornography. In 1969, the United States Supreme Court ruled that all forms of adult pornography were legal and could be viewed by people in the privacy of their own homes. This prompted President Lyndon Johnson to organize the first government inquiry into the effects of pornography in 1970. The 1970 President's Commission on Obscenity and Pornography concluded that there were no antisocial or adverse effects from exposure to sexually explicit material.

By the mid-1980s, the production and distribution of pornography was proliferating at an unprecedented rate. This was in part due to the affordability and widespread use of videotape technology that allowed for home viewing of sex movies. In addition, an underground market developed for porn videos with extremely violent content ("snuff films" and "slasher flicks"). This prompted President Ronald Regan to commission the second government inquiry into the effects of pornography, headed by then Attorney General Edwin Meese. Some felt the Meese Commission, as it was called, was padded with antipornography crusaders, which prompted considerable controversy before its results were even released (Hertzberg, 1986). Predictably, the Meese

Commission produced very different results from the first President's Commission on Pornography in 1970. The Meese Commission concluded that there was a causal link between viewing pornography and sexual violence toward women (Attorney General's Commission on Pornography, 1986). According to the report, viewing pornography changes perceptions of typical sexual behavior, trivializes rape, promotes rape myths, and directly leads to male aggression toward women. (Subsequent research on the effects of pornography has challenged the Meese Commission findings; see Ferguson and Hartley (2009) for a comprehensive review.)

It was within this political climate in the mid-1980s that a groundswell of opposition against the proposed diagnosis of PCD was heard, both inside and outside the American Psychiatric Association. The controversy was covered by news media internationally, and the American Psychiatric Association received hundreds of letters and petitions containing thousands of signatures from mental health professionals and others who objected to the validity of PCD as well as the other two proposed diagnoses (premenstrual dysphoric disorder and masochistic personality disorder). Even the U.S. Department of Justice (USDOJ), which rarely takes a public position on mental health issues, argued that the proposed diagnosis of PCD would be used by criminal defendants to avoid legal responsibility in criminal prosecutions for rape (Kutchins & Kirk, 1997). Although controversial, the position taken by USDOJ was less surprising considering that Attorney General Edwin Meese was heading the Department of Justice at the time, and the *Meese commission report on pornography* was published in July 1986, only a few weeks after the American Psychiatric Association Board of Trustees, by a vote of ten against and four in favor, rejected PCD for inclusion in the *DSM* on June 28, 1986.

Nevertheless, there was a growing consensus among clinicians who treated sex offenders that Paraphilic rapism did exist in a subsample of serial rapists (Fuller, Fuller, & Blashfield, 1990). At the same time, there were good reasons why a diagnosis of PCD was not ready for inclusion in the *DSM*. There was little evidence-based research on its reliability and validity, raising problems with differential diagnosis and distinguishing paraphilic rapists from the vast majority of rapists who commit sexual assault for non-paraphilic reasons. But the clamor to exclude PCD from the *DSM* went beyond these scientific concerns, and the decision to reject it was not without its critics. Psychiatrist Fred Berlin, one of the original proponents of PCD, supported the position that some serial rapists were turned on by the coercive rather than the sadistic elements of rape (Berlin et al., 1997). Psychologist Judith Becker (who also was a dissenting member of the Meese Commission on Pornography) estimated that the proposed PCD diagnosis would apply to approximately 20 % of rapists (Holden, 1986).

After the *DSM-III-R* was published in 1987, the controversy over PCD remained quiet for a time. No proposal to insert a rape-related paraphilia was raised during the drafting of the *DSM-IV* (APA, 1994) or *DSM-IV-TR* (APA, 2000). It wasn't until the mid-1990s, after several states passed sex offender civil commit laws and the subsequent surge in sex offender research, that the controversy over rape paraphilia resurfaced.

Paraphilia NOS and Civil Commitment of Sex Offenders

A new generation of civil commitment laws emerged in the 1990s designed to protect society from a small number of high-risk sex offenders, called sexually violent predators (SVP) or sexually dangerous persons (SDP), who were likely to reoffend after release from prison.

In 1997, the U.S. Supreme Court upheld the constitutionality of the civil commitment of sex offenders who were deemed to be dangerous by virtue of a mental disorder (Kansas v. Hendricks, 1997). To date, 20 states and the federal government have passed SVP laws in which dangerous sex offenders can be detained by civil commitment after their prison sentence has expired. Despite some state-to-state variations, all SVP laws share four basic elements (Prentky, Janus, Barbaree, Swartz, & Kafka, 2006). To be committed the offender must (a) have some mental disorder or abnormality that (b) causes or is related to (c) an elevated risk of future sexual violence and (d) treatment rather than punishment must be the purpose of commitment, though amenability to treatment or participation in treatment are not required.

States that allow for civil commitment of dangerous sex offenders require that individuals have a mental disorder that predisposes them to commit sexually violent crimes. One of the more common types of sex offenders within the SVP population is the repeat rapist who targets adolescent and adult victims (Abracen & Looman, 2006; Becker, Stinson, Tromp, & Messer, 2003; Jackson & Richards, 2007; Levenson, 2004). In the absence of a specific rape paraphilia diagnosis, the default diagnosis currently used to identify non-sadistic serial rapists is paraphilia not otherwise specified (NOS). The NOS diagnosis is usually followed with qualifiers such as paraphilia NOS *rape*, paraphilia NOS *nonconsent*, paraphilia NOS *sexual aggression toward nonconsenting females*, and paraphilia NOS *forced sex with adult victims*.

Jackson and Richards (2007) provide a breakdown of the diagnoses of 190 sex offenders civilly committed in Washington State, which includes 56.3 % pedophilia, 42.6 % paraphilic NOS nonconsent, 23.7 % other paraphilia NOS, and 16.8 % sexual sadism. Becker et al. (2003) reported that over half of their Arizona sample of 120 SVPs (56 %) were diagnosed with paraphilia NOS. Yet broad consensus about how best to define or standardize diagnostic criteria did not exist for repeat rapists, and use of paraphilia NOS for this purpose has been criticized as overbroad and lacking reliability and valid-

ity (First & Halon, 2008; Frances, Sreenivasan, & Weinberger, 2008; Miller, Amenta, & Conroy, 2005; Polaschek, 2003; Prentky et al., 2006; Zander, 2005, 2008). In contrast, however, other experts contend that the paraphilic rapists can be reliably diagnosed under the NOS category with the absence of a specific listing in the *DSM* (DeClue, 2006; Doren, 2002; Packard & Levenson, 2008; Sachsenmaier, 2009). Indeed, the current debate over use of Paraphilia NOS as a qualifying mental disorder in civil commitment trials echoes the controversy concerning the inclusion of paraphilic coercive disorder in the *DSM* in the mid-1980s. Susan Sachsenmaier (2009) notes the historical irony: PCD was criticized in the 1980s when it was believed the diagnosis would be used by rapists to *avoid* prosecution for their crimes, whereas, under current civil commitment laws, the rape paraphilia NOS diagnosis is criticized for *promoting* the prosecution of rapists.

Much of the disagreement concerns whether the wording of proposed diagnostic criteria allows for the diagnosis of a paraphilia in the absence of direct evidence for deviant urges or fantasies, which was apparently not the intent of its authors (First & Francis, 2008). Like biblical scholars deciphering Holy Scripture, two camps emerged in this debate. One camp (e.g., First & Francis, 2008; Zander, 2005, 2008) holds a literalist view of *DSM* criteria as final and authoritative and cautions that "tinkering with criteria wording should be done only with care … because of the potential unforeseen consequences … and because of the disruptive nature of all things" (First & Francis, 2008, p. 1241). The other camp holds the more liberal view that *DSM* criteria represent "guidelines," which allow room for interpretation (Doren, 2002; Elwood, 2009; Sachsenmaier, 2009). This hair-splitting distinction becomes critical in SVP civil commitment cases because many rapists deny rape urges and fantasies, and the diagnosis must therefore be based on rape behavior alone.

Paraphilic Coercive Disorder and the *DSM-5*

At the time of this writing, efforts are under way to compile the next edition of the *Diagnostic manual* (the *DSM-5*, which is scheduled for publication in May 2013), and paraphilic coercive disorder has been reintroduced for consideration. The official website of the *DSM-5* (APA, 2010, at www.dsm5.org) lists the following diagnostic criteria for PCD:

(A) Over a period of at least 6 months, recurrent, intense sexually arousing fantasies or sexual urges focused on sexual coercion.
(B) The person is distressed or impaired by these attractions or has sought sexual stimulation from forcing sex on three or more nonconsenting persons on separate occasions.
(C) The diagnosis of Paraphilic Coercive disorder is not made if the patient meets criteria for a diagnosis for Sexual Sadism Disorder.

The *DSM-5* website adds the following statement:

> In clinical practice, especially under the adversarial conditions that commonly apply during forensic evaluations, convicted sexual offenders will commonly do their best to conceal coercive sexual interests. Consequently positive evidence from any source (self-report, laboratory tests, or patterns of behavior) may be taken as indicative … The reliance on "forcing sex on three or more nonconsenting persons on separate occasions" in indicating that the paraphilia rises to the level of a disorder will also likely have the effect of increasing the accuracy of the ascertainment of this paraphilic interest. It is probable that this degree of repetition is in itself partially indicative of a specific interest in coercive sexual behavior (as opposed, for example, to those rapes where situational or opportunistic factors play a larger role) (APA, 2010, at www.dsm5.org).

The *DSM-5* proposed criteria for PCD based on behavior alone is not without its critics, however. Warnings have been issued concerning unreliability, misuse, and risk of misdiagnosis similar to those raised over PCD in the mid-1980s and more recently, by the use of Paraphilia NOS in civil commitment cases (Frances, 2010). Indeed, First and Halon (2008) state, "Concluding that an individual's behavior is driven by paraphilic rapism based entirely on a history of committing repeated rapes within a circumscribed period of time is never justified" (p. 446). At a recent presentation to the California Department of Mental Health (2009), when asked by an evaluator whether he would diagnose a rapist who had 100 victims with a coercive paraphilia, Dr. First answered that he would not do so without evidence ruling out alternative explanations for the rape behavior. First (2007) also stated he would not conclude a serial rapist was aroused by forced sex even if the offender had ten cycles of sexual offending in which he was incarcerated for rape, released, then raped again, repeating this cycle ten times. Yet when considering rape behavior of this magnitude, what possible alternative explanations could there be?

Certainly, the need for caution and supportive research is appropriate, but so is common sense. Establishing behavioral criteria for distinguishing paraphilic from non-paraphilic rapists may be difficult, but that does not mean the effort should be abandoned. It seems reasonable, both clinically and empirically, that at some point, increasing numbers (victims, arrests, and convictions) begin to matter and become a diagnostic indicator. Persistence of offending in sexual criminals is also a well-established risk factor for recidivism identified in sex offender literature (Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004; Harris, Phenix, Hanson, & Thornton, 2003; Phenix, Doren, Helmus, Hanson, & Thornton, 2008). Nevertheless, the *DSM-5* website offers the following caveat: "The reason for diagnosing specific paraphilic disorders from multiple, similar offenses in uncooperative patients is to achieve a level of diagnostic certitude closer to the certitude in diagnosing these disorders from self-reports in cooperative patients. It is not derived from legal theory or practice" (APA, 2010, at www.dsm5.org).

Epidemiology and Prevalence of Rape

Rape appears to be a universal phenomenon across societies that has existed throughout human history and appears to exist in some animal species (Lalumiere, Harris, Quinsey, & Rice, 2005). In modern industrialized societies, rape is an abhorrent crime that devastates victims, violates the values and legal norms of those societies, and inevitably results in severe social sanctions (e.g., incarceration).

Studies on the demographics of crime have clearly established that rape is underreported in the United States and abroad, and that reliance on recorded crime statistics greatly underestimates the actual occurrence of this and other sex crimes (Abel, Becker, Mittelman, Cunningham-Rathner, & Rouleau, 1987; Ahlmeyer, Heil, McKee, & English, 2000; Doren, 1998; Freeman-Longo & Knopp, 1992; Groth, Longo, & McFadin, 1982; Marshall & Barbaree, 1988; Prentky, Lee, Knight, & Cerce, 1997; Romero & Williams, 1985). For example, a 1992 study sponsored by the National Victims' Center indicated that only 16 % of all rapes are reported to police. A 2007 English government report notes similar findings: between 5 % and 25 % of rapes are reported to police. According to a 2000 Bureau of Justice Statistics study (Tjaden & Thoennes, 2000—described below), about 40 % of actual rapes or sexual assaults were reported to police. It is estimated that only about half of those individuals who are reported are arrested, about 80 % of those arrested are prosecuted, and about 58 % of those prosecuted are convicted (Rape, Abuse, and Incest National Network: www.RAINN.org, 2010). This suggests that only a very small proportion (less than 10 %) of rapists are incarcerated and that the vast majority go undetected.

Because of underreporting, the actual occurrence of rape in the United States is typically estimated from victim and perpetrator surveys and the estimates of the *incidence* (the number of rapes occurring during a given period of time) and *prevalence* (the percentage of persons who have been raped) vary depending on the definition used, the population studied, and the methods used to gather the data (Muehlenhard, Sympson, Phelps, & Highby, 1994). In 2000, the National Institute of Justice and the Centers for Disease Control and Prevention sponsored the National Violence Against Women (NVAW) Survey (Tjaden & Thoennes, 2000). This highly cited survey included a demographic cross section of 8,000 men and 8,000 women who were interviewed by telephone about their experiences with violence, including rape. In the study, completed rape was defined as an event that occurs without the victim's consent and involves the use of threat or force to penetrate the victim's vagina or anus by penis, tongue, fingers, or object or the victim's mouth by penis. Included in the survey was a measure of attempted rape that included force and threat without the actual completion of the act. The study found that 14.8 % of women reported having been raped or had been the victims of attempted rape (2.8 %) in their lifetime. About half (54 %) of these victims reported the rape occurred when they were under 18 years of age. The study also found that about 3 % of men reported attempted or completed rape (see also Baumer, 2004).

The reasons given by victims for not reporting a rape vary but typically involve victims' stating that the rape was a personal matter (23.3 %), fear of reprisal (16.3 %), police bias (5.8 %), and, in the case of attempted rape, to protect the offender (9.9 %) (Tjaden & Thoennes, 2000). This study further found that only about a fourth of rapes or sexual assaults were reported if the victim was the current or ex-wife or girlfriend of the perpetrator. In contrast, when the offender was a stranger, about half of the rapes (46 %) and two-thirds of the sexual assaults (66 %) were reported. It has been found that physical injuries and the use of a weapon were primary factors associated with increases in reporting (Bacheman, 1998).

Studies of perpetrators have found self-reported rates of rape, attempted rape, or sexual assault range from 9.0 % (Koss, Gidycz, & Wisniewski, 1987) to 14.9 % (Lisak & Roth, 1988). Findings from studies that have only assessed rape and attempted rape ranged from 6.5 % (Lisak & Miller, 2002) to 14.8 % (Merrill et al., 1998). Studies restricted to perpetrator's admissions of rape alone have ranged from 4.8 % (Weiss & Zverina, 1999) to 6.1 % (Kosson, Kelly, & White, 1997). In the United States, most rapists are male, below the age of 30, slightly older than their victims, tend to be more accepting of violence in general, have a more authoritarian approach to relationships, and display more hostility toward women (Drieschner & Lange, 1999).

The finding that most rapists go undetected is not unimportant because the most often studied samples of rapists are those that are or have been incarcerated and those in civil commitment custody. As such, research findings on detected rapists may not generalize to the population of all rapists. Lisak and Miller (2002), for example, argue that the majority of undetected rapists are serial rapists. In a community sample of 1,882 non-offending males, Lisak and Miller (2002) identified 120 undetected rapists. Seventy-six (63 %) were found to be serial rapists who reported an average of 14 victims and were responsible for 439 rapes and attempted rapes, 49 sexual assaults, 277 acts of sexual abuse against children, 66 acts of physical abuse against children, and 214 acts of battery against intimate partners. Lisak notes that undetected rapists he studied premeditate the sexual assaults and are extremely adept at identifying "likely" victims and testing their boundaries; typically they groom victims using sophisticated strategies such as physical isolation, use only enough psychological and physical violence (threats, assaults) sufficient to coerce the victim (i.e., do not exhibit the gratuitous violence one might expect from a sadistically

oriented perpetrator), and use drugs or alcohol to render the victim vulnerable or unconscious.

In summary, rape is a greatly underreported crime and the rapists that are detected may not be representative of the general rapist population.

Rapist Typologies

When clinicians began studying the psychology of rape, it immediately became clear that perpetrators of sexual aggression were a heterogeneous group and that rape was committed for a variety of reasons. Clinicians and the courts understood that identifying the motivation for sexual coercion was significant for legal dispositions of rape crimes and, when appropriate, clinical interventions. Early descriptive models represented the clinicians' best guess about what were the most discriminating characteristics among these offenders.

The first typology of rapists was proposed by Nicholas Groth in the late 1970s. Groth, Burgess, and Holmstrom (1977) ranked accounts from 133 rape offenders and 92 victims on the dimensions of power, anger, and sexuality. All three dimensions operated in every rape, but the proportions varied and power and anger always predominated. In their seminal book *Men Who Rape*, Groth and Birnbaum (1979) summarize their findings:

> Rape, then, is a pseudosexual act, a pattern of sexual behavior that is concerned much more with status, hostility, control, and dominance than with sensual pleasure or sexual satisfaction. It is sexual behavior in the primary service of nonsexual needs. (p. 13)

However, Groth's rape typology was heavily influenced by both psychoanalytic concepts (Stoller, 1975) and the politically correct view of rape promoted by feminist literature at the time (Brownmiller, 1975). It also had significant problems with reliability and validity assessment (Hazelwood, 1987; Hazelwood & Burgess, 1989; Knight, 2010b), and no estimates of inter-rater reliability have been provided.

A particularly influential topology for rapists has been produced by Raymond Knight and colleagues based on four decades of research at the Massachusetts Treatment Center at Bridgewater (Knight, 1999, 2010a; Knight & Guay, 2006; Knight & Prentky, 1987, 1990; Knight, Rosenberg, & Schneider, 1985). One of the critical questions guiding Knight's work was whether rapist types were dimensional or operated as discrete naturally occurring taxons that "carved nature at its joints" (Knight, 1999). The core sample on which the original rapist typology was based included all sexually dangerous offenders civilly committed to the Massachusetts Treatment Center (MTC) between 1959 and 1991. A rapist was defined as an adult male whose sexual offenses were committed against victims 16 years of age or older. Data for the MTC rapist typology program was gathered from several sources including archival records, criminal histories, and the *Multidimensional assessment of sex and aggression* (MASA). The MASA is a self-report inventory designed to assess the domains for classifying rapists (Knight, 1999; Knight, Prentky, & Cerce, 1994). The original impetus for creating the MASA was because of the paucity of information related to offenders' sexual behavior, cognitions, and fantasies in the archival records. Like all self-report inventories, the MASA has the same inherent problems with under and overreporting, which may be even more pronounced when surveying individuals about potentially embarrassing or illegal sexual behavior. The MASA began as a paper-and-pencil inventory and has undergone several revisions to improve reliability, one of which was computerized administration. Participants were guaranteed confidentiality, but even with guarantees of confidentiality and immunity from prosecution, questions remain as to whether sex offenders are the most accurate historians of their own sexual behaviors and fantasies. Nevertheless, after conducting reliability and validity studies on a wide variety of samples (including college students, community noncriminals, and non-sex offending criminals), the authors conclude that "the inventory shows promise as a useful assessment instrument for sex offenders" (Knight & Cerce, 2001, p. 2).

The original MTC rapist typology (MTC:R1) has gone through two major revisions and Knight claims the third version, the MTC:R3, "is the best available published typological model for discriminating among rapists" (Knight, 2010b, p. 3). The latest version of the MTC:R3 (Knight, 2010b) includes five major types of rapists that range along dimensions of violence, sexualization, and impulsivity. Sexualization was defined as high rates of sexual preoccupation, compulsivity, sexual drive, sexual fantasy, and paraphilic fantasy and behavior.

The MTC:R3 rapist types are: (1) sadistic, (2) pervasively angry type, (3) vindictive types, (4) opportunistic type, and (5) sexual non-sadistic type. Knight reports that discriminating between types is problematic and incorrect classifications are sometimes made (Knight, 2010b; Knight & Guay, 2006). For example, "contrary to expectations, both the Vindictive and the Pervasively Angry types achieved more extreme scores than the Sadists on the Sadistic Fantasies factor [on the MASA]" (Knight, 2010b, p. 7), and these three types were statistically similar on the bondage and "Synergism of Sex and Aggression" factors. In addition, non-sadistic rapists were easily discriminated from sadistic rapists, but non-sadistic rapists were sometimes confused with opportunistic rapists during the classification process.

Originally, the MTC:R3 was a linear model, and the sexualization dimension was believed to operate independently from the violence domain. However, this proved not to be the case. In order to assess the relationship between sexualization and sexual aggression, rapists were compared to

community and criminal controls. This included community sample of men who denied ever committing acts of sexual coercion, men who admitted committing undetected acts of sexual aggression, and criminal offenders with no history of sex offending. Compared to noncoercive males, the composite group of sexually aggressive males (convicted rapists and self-admitted community and criminal sexual aggressors) reported significantly higher frequencies of sexual preoccupation, compulsivity, sexual drive, and paraphilic fantasies and behaviors. These findings suggest the important role for sexualization or "hypersexuality" in sexual coercion against women in both criminal and undetected rapists (Knight, 2010b; Knight & Guay, 2006). In other words, as sexualization increased across groups, so did sexual aggression. Likewise, as impulsivity and antisocial behavior increased, so did sexual aggression in both criminal and noncriminal samples.

In an effort to correct conceptual problems and misclassification of rapist types, Knight reorganized the MTC:R3 typology into a "circumplex dimensional model" (Knight, 2010b, p. 23) with sexualization, impulsivity, and violence dimensions superimposed over the circumplex of rapist types. We would argue that PCD rapists are most similar to the pervasively angry, vindictive, and sadistic types, all of which are high on the impulsivity, violence, and sexualization dimensions.

Knight (2010a) argues against the existence of PCD rapists—at least as a "preferential taxon" and a diagnostic entity distinguishable from sexual sadism. Knight bases his conclusions on several lines of evidence, including the creation of a PCD scale from items on the MASA. Knight examined the responses of 186 adult male sex offenders. The PCD scale was composed of the following four items: masturbating to thoughts of forcing someone to have sex, being sexually aroused by making a woman do what the respondent wants sexually, by having a woman struggle, and by thoughts of overpowering someone. Knight's PCD scale does not include items that reflect a serial rape strategy, for example, data on number of victims, relationship to victims (stranger versus acquaintance), rape when consenting partners are available, or persistence of offending over time (e.g., number of rape arrests)—all factors relevant to PCD as motivating rape behavior. Knight's PCD scale was then correlated to the item "having thoughts of forcing someone to have sex." While the correlation reached significance ($r = .75$, $p < .001$), Knight also found that the PCD scale's correlation with the "sadism fantasy scale" on the MASA was slightly higher ($r = .76$, $p < .001$), and he concluded that the majority of the PCD scale variance is associated with sadism. However, as noted above, Knight has reported that the vindictive and pervasively angry rapists types also scored higher than the sadists on the sadistic fantasy scale, so these findings are not surprising given our view that PCD is related to these three rapist types as defined by Knight.

Persistence of Sex Offending and Paraphilic Coercive Disorder

There is some evidence of relationship between arousal to sexual coercion and serial rape. Hazelwood, Reboussin, and Warren (1989) studied 41 incarcerated serial rapists who had each raped a minimum of ten victims. Collectively, the sample was found to be responsible for 837 rapes, more than 400 attempted rapes, and over 5,000 "nuisance" sexual offenses. Data was collected concerning the subjects' first, middle, and last rapes. Results showed that while the amount of force used by the rapist did not change from first to last rape overall, there were ten individuals for whom the amount of force did increase from first to last rape. Four correlates were identified that distinguished these "increasers" from the "nonincreasers." The data also indicated that when the victim resisted, the amount of self-reported arousal experienced by the rapist was greater, and the duration of the rape was longer.

Mieth, Olson, and Mitchell (2006) examined *specialization* and *persistence* in the criminal careers of sex offenders. The data for their study was originally supplied by the U.S. Department of Justice and the Bureau of Justice Statistics (Langan & Levin, 2002; Langan, Schmitt, & Durose, 2003). The sample included more than 38,000 inmates released from prison in 15 states in 1994 representing about two-thirds of prisoners released across the entire country in that year. From that group, a sample of about 10,000 male sex offenders was collected based on arrest histories for a sexual offense, and a subsample of 2,291 offenders arrested for rape was further identified. Criminal specialization was then examined. It was defined as three or more arrests for the same sex offense during the offender's criminal career. Of the 2,291 rapists in the sample, only 7 % were *serial specialists* with three or more rape arrests demonstrating this pattern of sex offense specialization. Of those serial rapists, approximately one quarter (27 %) were found to be *persistent specialists*, meaning that they had at least one arrest for rape during the beginning (first third), middle (second third), and last (third third) stages of their criminal careers. Sachsenmaier (2009) suggests (and we agree) that the method developed by Mieth et al. (2006) to identify *persistent specialist offenders* can be useful to identify rapists who would meet the criteria for paraphilic coercive disorder.

Several individual case studies exist giving detailed descriptions of PCD (Berlin et al., 1997; Kafka, 1991; Spitzer, Gibbon, Skodol, Williams, & First, 2002). Kafka (1991) offers an interesting case report of a 30-year-old male who was referred for treatment after an aborted attempt to rape his mother. The man began having rape fantasies at age 18, and that became his primary means of achieving orgasm with masturbation. In his fantasies, a woman was physically restrained, perhaps bound by the extremities, and forced to

be orally, anally, or vaginally penetrated. The fantasies did not include unnecessary pain, suffering, or humiliation of the victim. The fantasy victims were always women that he knew. According to the case report, the man had been rejected by a female peer he wanted to date, and he got intoxicated. The urge to rape his mother had been on his mind for several days, and he finally decided to attack her, and they struggled for several minutes. Approximately 2 days after assaulting his mother, he went alone to the younger woman's apartment while intoxicated with a clear intent to rape her. He backed down from his plan while waiting in hiding, and soon afterwards admitted himself to the hospital for treatment of substance abuse. Kafka reports this individual suffered from multiple impulse control disorders including alcohol and marijuana abuse, compulsive gambling, kleptomania, voyeurism, and PCD.

Rape and Antisocial Behavior, Including Psychopathy

The core features of psychopathy include a deceptive and manipulative interpersonal style, lack of guilt and remorse for misdeeds, and an impulsive, irresponsible, and antisocial lifestyle (Cleckley, 1941; Hare, 1991, 2003). The relationship between psychopathy, deviant sexual behavior, and sex offending has been well established in both criminal and non-offender samples (Knight, 2010b; Knight & Guay, 2006; Lalumiere et al., 2005; Rice & Harris, 1997). Psychopathy was positively related to admissions of unreported sexual aggression by men in noncriminal community samples (Knight & Guay, 2006; Williams, Cooper, Howell, Yuille, & Paulhus, 2009). In a study of non-offender college males, Williams et al. (2009) found that deviant sexual fantasies translated into sexually deviant behavior only for individuals scoring high in psychopathy, and this interaction was most pronounced for sexual assault. These researchers also found that the link between pornography consumption and deviant sexual behavior held only for individuals high in psychopathy, and they conclude that "rather than serving a cathartic function, pornography may activate or escalate the deviant sexual behavior of psychopaths" (Williams et al., 2009, p. 215).

Clinical observation and literature reviews show that serial rapists tend to be antisocial individuals, and rapists are likely to be psychopaths more than any other category of sex offenders (Lalumiere et al., 2005; Lalumiere, Fairweather, Harris, Seto, & Suschinsky, 2009; Lalumiere, Harris, & Seto, 2009; Lalumiere, Quinsey, Harris, Rice, & Trautrimas, 2003). Higher PCL-R scores have been found among rapists than among child molesters, and still higher scores have been found among men who offend sexually against both adult and child victims (Porter et al., 2000; Porter, Campbell, Woodworth, & Birt, 2001; Quinsey, Rice, & Harris, 1995; Rice & Harris, 1997; Serin, Malcolm, Dhanna, & Barbaree, 1994; Sreenivasan et al., 2007). Several studies using the psychopathy checklist-revised (PCL-R) have found that between 12 % and 40 % of rapists, depending on the risk level of the sample, meet the criteria for a diagnosis of psychopathy (Brown & Forth, 1997; Prentky & Knight, 1991; Serin, Mailloux, & Malcolm, 2001). Recidivism studies of the relationship between psychopathy and sexual deviance also show that sex offenders who were both psychopathic and paraphilic by phallometric assessment exhibited higher rates of sexual reoffense than other offenders (Harris et al., 2003; Hildebrand, de Ruiter, & de Vogel, 2004; Rice & Harris, 1997).

Harris, Rice, Hilton, Lalumiere, and Quinsey (2007) studied 512 sex offenders and found that psychopathy was associated with early, frequent, and coercive sex. This research group looked at the relationship between psychopathy, sexual recidivism, and the following five juvenile variables: (1) having had sexual contact with an adult before age 15; (2) age at first sexual intercourse (including sex offense perpetration); (3) number of sexual partners before age 15; (4) forcing someone into sexual activity before age 15; and (5) Cormier–Lang score for sex offense criminal charges before age 18. These researchers found that the juvenile variables are a group correlated with psychopathy, particularly with a subset of PCL-R Factor two items (parasitic lifestyle, proneness to boredom, irresponsibility, impulsivity, and lacking realistic goals). Indeed, the cluster of variables describing "precocious coercive sexuality" were more strongly associated with psychopathy than the two items on the PCL-R specifically tapping sexual behavior: promiscuous sexual behavior and many short-term marital relationships. The juvenile variables also improved the prediction of recidivism for sexual offending. The authors theorize that psychopathy is a form of "life course antisociality" selected by evolution that reflects a genetically programmed non-pathological reproductive strategy characterized by "cheating," "high adult mating effort," and "minimal parental investment." They conclude, "Based on the present analysis … we propose that interpersonal sexual and nonsexual aggression are not best conceived of as the consequence of psychopathic personality traits but as fundamental aspects of the condition itself" (Harris et al., 2007, p. 18; See also Knight & Guay, 2006; Lalumiere, Mishra, & Harris, 2008; Mealey, 1995 for discussions of coercive sexuality as an inherent component of psychopathy). The authors also suggest that the coercive and precocious sexuality component of psychopathy is not merely a function of indifference to the suffering of others (the failure-of-inhibition hypothesis) or a variant of sexual sadism. It is, rather, a "sexual preference for coercion that does not result in serious injury" (p. 20), which (like sadism) would interfere with reproductive success.

In the MTC:R3 typology of rapists described above, Knight and Guay (2006) concluded that there was a strong

convergence between sexual aggression and the construct of psychopathy in both criminal and noncriminal populations. This was particularly true of impulsiveness/antisocial deviance assessed by Factor 2 on the PCL-R. Indeed, these converging lines of evidence suggest a "unified theory of sexual coercion" (Knight & Guay, 2006). These researchers found that rapists high in psychopathy generally rated higher in sexualization, and they hypothesize that the proposed underlying evolutionary processes that would select for psychopathy (maximum mating effort with minimal parental investment) are theoretically congruent with the potential for sexually coercive behavior.

Rape and Measured Deviant Sexual Arousal

In addition to clinical and self-report information, important evidence for the presence of PCD comes from phallometric studies using the penile plethysmograph (PPG). The PPG is a device that directly measures sexual response by the use of a mercury strain gauge (a wire loop or flexible band) that is placed around shaft of the penis that provides electrical feedback measuring penile tumescence. The subject's sexual response is recorded while he views images (slides or videos) or listens to auditory recordings of various sexual scenes in which the experimenter controls the type of stimuli (adults, children, male, female, consensual or nonconsensual sex, etc.). PPG data is preferred over self-report because it is less likely to be biased, and the specific nature of sexual deviance can be studied in a systematic fashion.

One of the early attempts to generate empirical evidence of rape as a paraphilia was initiated by forensic sexologist Kurt Freund, who coined the term *courtship disorder*. (Freund was also responsible for the invention of volumetric phallometry.) Freund's use of the term *courtship* has nothing to do with courting or romantic dating; rather, it refers to the ethnological study of animal behavior in the wild. Freund observed that human sexual behavior follows a sequential pattern divided into four primary phases of human courtship labeled as partner location, pretactile interaction, tactile interaction, and genital union (Freund, 1988, 1990). Freund's concept of courtship disorder derived from the notion that a specific set of five paraphilias appeared to reflect an exaggerated or distorted form of normal male response for a particular phase. The specific paraphilias are voyeurism, exhibitionism, frotteurism, telephone scatologia, and paraphilic rape. For example, voyeurism is a disruption of the partner location phase. Based on his phallometric studies of sex offenders, Freund found that many of the courtship paraphilias tended to co-occur (Freund et al., 1983; Freund, Scher, Racansky, Cambell, & Heasman, 1986; Freund, Seto, & Kuban, 1997; Freund & Watson, 1993). Instead of being independent paraphilias, Freund theorized that deviant sexual interests, including *rape proneness*, as he called it, were symptoms of a single underlying courtship disorder. Freund and Seto (1998) found phallometric evidence that "preferential rape" (a paraphilic preference for coercive sex) was associated with other expressions of courtship disorder and suggests that the presence of other paraphilias, particularly exhibitionism, may serve as a behavioral marker for paraphilic rape-proneness. On the other hand, Lalumiere et al. (2005) discuss Freund's findings and point out that the courtship paraphilias, especially rape proneness, also tend to be associated with paraphilias that seem to have nothing to do with phases of normal courtship and reproductive intercourse, including pedophilia (Freund, 1990) and transvestic fetishism (Freund & Watson, 1993).

PPG research is fallible, of course, because men can to some extent manipulate their penile response. Moreover, the findings are limited because assessments are preformed in the laboratory rather than in the real world. However, despite noted limitations, the PPG allows us to explore the conceptual boundaries of PCD and helps to answer the following questions:

(1) Are the sexual arousal patterns of rapists different from normal nonsexual offenders?
(2) Are the sexual arousal patterns of rapists different from violent nonsexual offenders who assault women?
(3) Are the sexual arousal patterns of rapists different from sexual sadists?

In research on PCD, the use of PPG data typically entails the construction of a "rape index," which is defined as the ratio of average sexual responses to stimuli depicting coerced sex divided by the average sexual responses to stimuli depicting consensual sex. In other words, the rape index is a single number index that reflects the strength of arousal to coercive sex compared to consenting sex.

It has been repeatedly shown that rapists as a group score higher on the rape index than non-offender community subjects (Hall, Shondrick, & Hirschman, 1993; Lalumiere & Quinsey, 1993), and the difference between rapists and non-rapists is moderate to large. A more recent and comprehensive meta-analysis (Lalumiere et al., 2003) reported moderate-high effect sizes ($d = 0.82$) and found that the difference between rapists and non-rapists is greater when very violent material is used. PPG studies consistently report that about 60 % of rapists show equal or greater arousal to audio presented rape stories than to consenting sex stories. This pattern is rarely obtained among non-rapists (Lalumiere et al., 2003, 2005; Lalumiere, Harris, 2009; Quinsey, 2009) and is more likely in rapists with more extensive histories of prior rape and violent crime. The meta-analysis by Lalumiere et al. (2003) was especially interesting because it compared PPG data on rapists, nonsexually violent offenders against women, and non-offender community participants. The results from that study found that (1) rapists show stronger

overall responses when listening to rape stories than to the consenting sex stories; (2) men recruited from the community showed a clear preference for consenting sex (especially when told from the female point of view); and (3) the nonsexual assaultive offenders produced response patterns that were virtually indistinguishable from that of the normal community sample.

It has been hypothesized that normal non-offenders might be aroused by the sexual elements of rape stories in phallometric assessment but that such arousal is simultaneously inhibited by the violent elements. Rapists, like non-rapists, are thought to be aroused by the sexual elements of rape but, in contrast to non-rapists, fail to be inhibited by the violent elements (Barbaree & Marshall, 1991). Because paraphilias are defined as sexual disorders, a failure to inhibit a sexual response could be attributed to an antisocial tendency rather than to a paraphilia per se. (For further discussion of this view, see Knight (2010a).) If this hypothesis is true, then it could be correctly concluded that PCD would not exist as a genuine paraphilia (persistent arousal to forced sex) but that all rape behavior results from a failure to inhibit arousal and, thus, PCD operates merely as the sexual expression of a more general proneness to antisociality. Experimental studies have shown that it is possible to *disinhibit* normal men—for example, by intoxicating them, by inducing anger at a woman, or by exposing them to pornography prior to testing so that their relative arousal to rape stimuli is increased (Barbaree, 1990; Lalumiere et al., 2005; Lalumiere, Fairweather, 2009). Similarly, the introduction of coercive elements into a sexual story that began as mutually consenting does not appear to inhibit the arousal of sexually coercive men (Bernat, Calhoun, & Adams, 1999; Lohr, Adams, & Davis, 1997).

This insensitivity hypothesis (Lalumiere et al., 2005) suggests that rapists, as part of a general antisocial lifestyle, lack empathy and are insensitive to the feelings and interests of others, especially in a sexual context. Because of their insensitivity, rapists fail to be inhibited by the violence and lack of consent portrayed in rape scenarios presented during phallometric assessments. If the sexual elements are arousing, and the violence and brutality do not inhibit arousal, this dynamic should be especially true of men who score high on measures of antisociality such as the psychopathy checklist-revised (*PCL-R*, Hare, 1991, 2003). However, the relationship between the rape index and psychopathy as measured by the *PCL-R* tends to be mixed (Firestone, Bradford, Greenberg, & Serran, 2000; Harris, 1998; Rice, Harris, & Quinsey, 1990; Serin et al., 1994; Thornton, 2010).

In another review, Thornton (2010) concludes that available PPG research assessing the relationships between the rape index and antisociality or psychopathy is too small to conclude that rapists are motivated by a general antisocial set. Thornton cites further evidence that violent nonsexual offenders against women do not show a deviant PPG rape index (Lalumiere et al., 2003), even though they show equal levels of general antisociality and psychopathy. Also, there is a small percent of normal men in community samples (approximately 10 %) who have a positive rape index (in which their arousal to coercive sex is stronger than consenting sex), but this subgroup was comprised of community males who self-reported past undetected acts of sexual aggression and who admitted the willingness to commit rape provided they would not get caught (Malamuth, Check, & Briere, 1986).

In addition to the arguments that PCD is simply an expression of general antisocial tendencies, another suggestion is that PCD is merely a variant of sexual sadism, clinically defined as a persistent sexual arousal to the physical suffering or psychological humiliation of another person. Knight (2010a) argues that there is little or no support in the PPG data for a category of PCD independent of sadism. If rapists are prone to sexual assault because physical pain and injury are the focus of their sexual interest, one might expect that phallometric stimuli emphasizing sadistic elements would elicit higher responding even with consenting partners.

Findings concerning the relationship between sexual sadism and the Rape Index have shown inconsistent and sometimes insignificant results but lean toward a lower relationship for sexual sadists than for rapists (Barbaree, Seto, Serin, Amos, & Preston, 1994; Langevin et al., 1985; Seto and Kuban 1995; Marshall, Kennedy, & Yates, 2002; Proulx, 2001). Unfortunately, rape stories used in most PPG research have confounded violence and nonconsent cues by including elements of both. In order to better measure the effects of these variables, researchers (Harris et al., 2009; Seto, Lalumiere, Harris, & Chivers, 2009) recently developed a new set of PPG stimuli to distinguish dimensions of sexual arousal theoretically linked to rape and sexual sadism. These were audio stories describing an interaction between a man and woman whose content varies along three dimensions: (1) violence involving physical injury (present or absent); (2) sexual behavior (present or absent); and (3) consent versus coercion.

The first study (Seto et al., 2009) compared a normal community sample with self-identified sadists; both groups were recruited as community volunteers without criminal histories. The authors found that compared to normal controls, the self-identified sadists had stronger sexual responses to stories containing the injury dimensions, but the two groups showed similarly low responding to the coercion dimensions. Thus, for example, the sadists showed stronger sexual responses than controls to stories depicting consenting sadistic activity (injury and sex), consenting nonsexual violence (injury), nonconsenting nonsexual violence (coercion and injury), and sadistic rape (coercion, injury, and sex). In contrast, sadists actually showed weaker arousal to nonsadistic rape stories (coercion and sex only). In the second study, Harris et al. (2009) compared a sample of 164 rapists to normal controls. The rapists showed markedly stronger arousal than controls to stories depicting non-sadistic rape

and markedly weaker arousal than controls to stories depicting consensual non-sadistic sexual activity. In contrast, rapists showed only small differences from controls on stimuli depicting either consensual sadistic sex or sadistic rape. In a review of these new PPG studies, Thornton (2010) concludes that two distinct paraphilias are supported by the data: (1) a non-sadistic paraphilia in which the salient focus is coercing another into sexual activity; (2) a sadistic paraphilia in which the salient focus is injury (consensual and nonconsensual). The sadistic paraphilia may include some kinds of rape (with injury) but also includes nonsexual sadistic activities. Thornton concludes: "There is significant empirical support for the existence of a distinctive coercive paraphilia among men convicted of rape. This paraphilia involves preferential sexual arousal to forcing sex upon a woman in a way that she obviously experiences as coercive. Development of the paraphilia may depend, in part, on a failure of inhibitory processes but it also involves this erotic focus being a positive excitatory source of sexual arousal" (Thornton, 2010, p. 6).

Clearly, there continues much to be learned about PCD, but the most recent PPG data appears to reflect what clinicians have long reported, that PCD describes a distinct pattern of sexual arousal different from the normal sexual interest of non-offending males and different from both sexual sadists and nonsexual violent (antisocial) offenders.

The Paraphilic Coercive Disorder Checklist

The authors are conducting a study to explore and establish the conceptual boundaries of the construct of paraphilic coercive disorder with the further goal of creating a standardized measure, the Paraphilic Coercive Disorder Checklist (PCDC), for use in applied settings for research, assessment, and treatment of sex offenders. The goal was to create a instrument that could be scored based on behavior documented in an offender's criminal records even when the offender is uncooperative and unwilling to self-disclose sexual information. The procedure for developing the PCDC is a three-step process: (1) item generation; (2) scale development; and (3) scale evaluation. In this chapter, we report on the first step in the process.

Method

Materials

Following an extensive literature review, input from numerous professionals whose work is exclusively or primarily with sex offenders, and author-defined theoretical dimensions of PCD, a set of 83 items reflecting these dimensions was constructed. The set of items included some that were thought to be most reflective of PCD (e.g., "The individual possesses evidence of a *rape kit*"), items that were theoretically negatively related to the concept of PCD (e.g., "The individual has a history of coercive sexual crimes but has lived offense free in the community for 15 or more years"), and items that were felt to be neutral (e.g., "The individual is severely mentally ill"). To further assess the content validity, the 83-item list was given to an impartial judge, highly experienced in the treatment and evaluation of sexually violent predators, who reviewed the list and provided feedback. After deleting redundant or poorly constructed items, the final list of 70 items was produced. The list included items that were designed to establish theoretical cutoff points for determining the presence (or absence) of PCD. For example, the six items reflecting number of victims were constructed in hierarchical fashion, so that we would be able to learn about the number of victims required to increase evaluator certainty of the diagnosis of PCD.

Procedure

A survey containing the list of 70 items and demographic questions, termed the paraphilic coercive disorder rating scale, was constructed and made available to sex offender treatment and evaluation professionals (see Appendix). The survey was disseminated in two ways; the first was to invite, via e-mail, known sex offender professionals who work with high-risk sex offenders from, among others, the states of California, Washington, Iowa, Wisconsin, and Florida, to participate in the survey. Second, invitations to participate in the survey were placed on the Association for the Treatment of Sexual Abusers (ATSA) and California Coalition on Sexual Offending (CCOSO) listserv emailing lists. To insure anonymity and thus promote open and honest participation, the *Survey Monkey* website was used to gather the data (http://www.surveymonkey.com/s/JGTC76K). Participants were asked to rate each item on a 5 point Likert-type scale on the manner in which the item is related to PCD (−2 strongly negates, −1 negates, 0 neutral, +1 supports, and +2 strongly supports). To ensure that as much of the PCD content domain as possible was surveyed, each item also contained a section in which the respondent could comment. In addition, a section for open comments was made available at the end of the survey.

Results

Respondent Characteristics

To the present, 130 professionals have participated in the survey and 126 have fully completed it. Five (4 %) of the 126 surveys were deleted because the respondents indicated

disagreement with the construct of PCD and/or produced response sets (e.g., all zeroes or all ones). The rest of the respondents (121 or 96 % of the original sample) did not voice such opinions nor did they produce response sets. This finding is not unimportant because it suggests that of those surveyed, the vast majority were of the opinion that PCD is a valid construct. In fact, many voiced approval of this work.

The overall response rate is considered to be strong, and the opinions expressed are considered to be representative of the sex offender treatment, evaluation, and research community in the United States. Review of demographic data indicates that the vast majority of respondents were highly trained professionals (107 of the 111 who answered the question were psychologists, psychiatrists, or licensed clinical social workers). The majority of the respondent group was male (66.4 %), over 50 (60.4 %), and worked in public or private settings in which they performed forensic evaluations (80.4 %). Eleven respondents identified themselves as sex offender researchers, six as community supervision professionals, five as criminology researchers, and four as legal counselors.

With an average of 16.6 years experience in evaluating or treating sex offenders (80 of the respondents (62 %) reported 10 or more years' experience), the respondent group was clearly knowledgeable about the topic. The average number of sex offender evaluations performed by individual respondents was 679 with a range between zero and 8,000. With regard to experience with sexually violent predators (SVPs), the average number of years working with SVPs was 9.37, and the average number of SVP evaluations performed by the respondent group was 174 with a range between zero and 1,000.

A few respondents added comments, some of which spoke to the overlap between the constructs of PCD and sexual sadism. This suggests that, as with most mental disorders, when behaviorally measured, the constructs appear to be dimensional in nature.

Findings

The scored items of the PCD checklist were categorized according to mean ratings across respondents, and a hierarchical listing was created (see Appendix). The average scores of items that were greater than positive one (+1 Supports/Rules in PCD) or less than negative one (−1 Negates/Rules out PCD) were pooled into theoretical domains as noted in Table 1. The thresholds of positive and negative one (+1 and −1) were thought to reflect a considerable amount of agreement among the expert respondents. Although important, items that had average scores within the "neutral" range (between negative .99 and positive .99) were not considered in the present analysis.

Table 1 List of items with mean rankings greater than 1.0 grouped by domain

Mean score	Victim domain
1.74	The individual has committed documented acts of coercive sex with 15+ victims
1.70	The individual has committed documented acts of coercive sex with 11–14 victims
1.64	The individual has committed documented acts of coercive sex with 8–10 victims
1.59	The individual has committed documented acts of coercive sex with 5–7 victims
1.24	The individual has committed documented acts of coercive sex with 3–4 victims
1.11	The individual engages in coercive sex with a wide range of victims including two or more of the following: male, female, children, adolescents, adults, elderly, or disabled
Persistence of offending domain	
1.54	The individual has three or more sentencing dates for coercive sexual offenses prior to the index coercive sexual offense
1.27	The individual reoffends quickly and commits a new coercive sex offense within 1 year following sanction/release for a prior coercive sex offense
1.16	The individual has two sentencing dates for coercive sexual offenses prior to the index coercive sexual offense
1.15	The individual committed coercive sexual acts as a minor and as an adult
1.13	The individual displays a pattern of recurrent coercive sexual behavior with persons over a period of at least 6 months
1.06	The individual was arrested/charged for coercive sex as a juvenile and again as an adult
Behavioral correlates domain	
1.41	The individual possesses evidence of a "rape kit": rope, bindings, tape, blindfold, scissors, tools, binoculars, lubricants, etc.
1.39	The individual engages in stereotyped rituals or repetitive patterns of behavior during coercive sex, as if scripts are being enacted, repeated "M.O."
1.30	The individual exhibits advanced planning or premeditation prior to committing coercive sexual acts
1.13	The individual collects and saves victim's memorabilia (photos, jewelry, hair, items of clothing) gathered during coercive sex
1.20	The individual commits acts of coercive sex despite the presence of an available consenting sexual partner
1.16	The individual drives around cruising for victims with whom to engage in coercive sex
1.11	The individual shows physical signs of arousal (erection, ejaculation) during coercive sex
1.09	The individual video or audio records the coercive sex
1.03	The individual reads, watches, or writes pornography with themes of coercive sex
Sexual deviance domain	
1.19	The individual reports having rape impulses or fantasies with masturbation
Items contraindicating PCD	
−1.24	The individual stops the coercive sex when he sees the victim cry or scream
−1.07	The individual loses his erection when the victim complains or otherwise resists

As noted in the "victim domain," the average number of victims of coercive sex required for an average rating supportive of a diagnosis of PCD was 3–4. The mean ratings of the other "number of victims" items were remarkably consistent: The greater the number of victims, the greater the agreement that the individual likely has PCD. Starting with the "three victims" item, the mean rating increased as the number of victims increased across items, reaching +1.74 (the highest ranked item on the entire scale) for the item describing the individual who "commits documented acts of coercive sex with 15+ victims." In addition, having a wide range of victims (including two or more of the following victim types: male, female, children, adolescents, adults, elderly, or disabled) was seen as increasing the likelihood that the assessed individual would be diagnosed with PCD.

In the "persistence domain," the following items were rated as supporting a diagnosis of PCD: A pattern of coercive sex for 6 months (which is the standard durational criteria for a diagnosis of any paraphilia found in the *DSM-IV-TR* (APA, 2000)), coercive sex offenses as a juvenile and as an adult (e.g., early onset of offending), having at least two prior sentencing dates for coercive sex offenses prior to the index sex offense, and quick reoffense (within a year) following sanctions.

Other "behavioral" indicators supportive of a PCD diagnosis include possessing a "rape kit," showing stereotyped rituals or repetitive patterns, advanced planning, collecting and saving victim memorabilia, cruising for victims, committing coercive sexual crimes when a consenting sex partner is available, showing physical signs of arousal during coercive sex, video or audio taping of coercive sexual behavior, and using or creating pornography with themes of coercive sex. In the "sexual deviance domain," having rape impulses or fantasies with masturbation was found to support the diagnosis of PCD.

Discussion

As noted above, the survey items were naturally grouped into the following four descriptive domains: victims, persistence of offending, behavioral correlates, and sexual deviance.

Victim Domain

Six victim items received mean ratings greater than +1.0 (range 1.11–1.74), supporting the finding that PCD involves coercive sexual acts over time with multiple victims. A minimum of three victims (mean = +1.25) was the cut-point, since two victims received a significantly lower ranking (mean = +0.70). Another victim item that experts agreed is supportive of PCD is coercive sex with a wide range of victims. Elsewhere in the literature, mixed victim types (usually defined as child and adult victims) has been identified as both a marker of sexual deviance and associated with increased recidivism among sex offenders (Rice & Harris, 1997; Sreenivasan et al., 2007).

Persistence of Offending Domain

Early onset of sex offending, usually defined as arrest for a juvenile sex offense followed by sexual offending as an adult, is also a well-documented risk factor in recidivism research and a useful predictor of future sex offending (Hanson & Helmus, 2008; Helmus, 2007; Phenix et al., 2008). Most juvenile sex offenders do not reoffend and do not continue a pattern of sexual assault into adulthood; however, for the few who do, repeated sex offenses might reflect an underlying paraphilia for coercive sex. The suggestion here is that early sex offending is the precursor to a life pattern of sexual misconduct that is driven by an underlying arousal to forced sex. Two items describing coercive sexual behavior committed as a minor and an adult were rated as supporting a finding of PCD. This included being arrested/charged for coercive sex as a juvenile and as an adult (mean = +1.06) as well as uncharged coercive sexual conduct as a minor and as an adult (mean = +1.15). These findings are consistent with the literature on the development of paraphilias as well as sexual recidivism research. Many experts believe that paraphilias typically begin in adolescence when deviant sexual interests get reinforced by repeated fantasy and sexual behavior. Early deviant experiences can have an imprinting effect that directs future sexual interests. Images and memories of the deviant experience may be incorporated into masturbation fantasies and further reinforced. Eventually, these deviant preferences become entrenched by adulthood. Individuals who are sanctioned for sex offending as juveniles and then continue to reoffend as adults have higher rates of recidivism than adults who do not have juvenile sex offending histories. This demonstrates a persistence of sex offending that was not deterred by sanctions.

In a similar sense, having two or more prior sentencing dates for coercive sexual offenses was also identified as indicating PCD. When an individual continues to commit coercive sexual acts despite suffering prior legal sanctions for sexual assault, it suggests an underlying deviant arousal to forced sex may be driving the behavior, particularly if this cycle is repeated multiple times. Punishment is intended to inhibit the behavior that caused it, and incarceration is typically a wake-up call for rapists, most of who never reoffend. When they repeatedly do, two factors may be operating suggestive of PCD: (1) persistent urges for coercive sex and (2) a lack of control to inhibit acting on those urges. In this case, PCD becomes a sexual compulsion that overrides the deterrent effects of punishment

and the offender continues to rape to satisfy his sexual desire for power, control, and domination.

Persistence of offending is demonstrated by individuals who commit a coercive sexual act, get caught and sanctioned (sentenced), and then commit another coercive sexual act for which they are caught and sanctioned/sentenced. The more times this offense–sanction–reoffense cycle is repeated, the more strongly respondents to the survey were likely to say that PCD may be driving the coercive sexual behavior. When the cycle occurs only once (one prior sentencing date), the mean rating was only +0.81. For example, the offender who is incarcerated for rape, gets released, then rapes again was less likely to be identified as suffering from PCD than the offender who repeats the cycle a second time (has two priors). By the third sentencing date, the mean rating of this item increased to +1.16. By the fourth sentencing date, (three priors) the mean rating increased to +1.54. Interestingly, the number three was found to be a cut-point between both the number of victims and the number of sentencing dates. This makes sense since three sentencing dates would almost always involve convictions for sexual assaults of at least three different victims. (A possible rare exception would be the offender who gets convicted of raping the same victim at different times.)

It is noteworthy that the number three is emerging as a benchmark for rapists whose behavior is likely to be driven by a paraphilia in contrast to offenders who rape for nonparaphilic reasons. Three was the cut-point in our study for items measuring both number of victims and number of sentencing dates as indicators of PCD. As mentioned earlier, three is also the number of rape arrests identified by Mieth et al. (2006) that defined *serial sexual specialists*, which comprised only 7 % of the rapist sample ($N = 2{,}291$). Finally, seeking "sexual stimulation from forcing sex on three or more nonconsenting persons on separate occasions" is found in criterion B of the proposed diagnosis for paraphilic coercive disorder in the *DSM-5* (APA, 2010 at www.dsm5.org), which was published after our data was collected. We have referred to this numerical congruence as the "magic number three" and suggest that once an offender has sexually assaulted three victims—particularly when these acts result in separate arrests and/or convictions—that a diagnosis of PCD should be strongly considered.

Finally, rapid reoffending (defined as committing a new coercive sex offense within 1 year following sanction/release from a prior coercive sex offense) is perhaps the clearest example of persistence of offending. This item was rated +1.27. These offenders are usually on probation or parole in the community, but the conditions of supervision fail to deter further acts of sexual coercion. As noted by Dennis Doren (2002), "Conceptually, these 'ex-cons' may literally be driven toward nonconsensual sexual contacts with others. The fact that they just experienced a significant period of incarceration does not ultimately alter their behavior even in the short run, when the memory of prison is still presumed to be fresh" (p. 73). What's more, some offenders with PCD continue to commit acts of coercive sex even while incarcerated. They may target female officers or other male inmates and may receive institutional violations or be charged with new sexual crimes in custody.

Behavioral Correlates Domain

Nine items were rated strongly supporting PCD that can be described as behavioral correlates that are often evident by the individual's self-report or may be documented by victim or witness reports or in other criminal records. Several of these items form a cluster indicating premeditated coercive sexual acts. Premeditation or planning a sexual assault—conceived as a "preparation phase"—may accompany a buildup of impulses and sexual tension that culminates in coercive sexual behavior. The items in this group include carrying a "rape kit" (+1.41), advanced planning of coercive sexual acts (+1.30), driving around cruising for victims (+1.16), collecting and saving victim's memorabilia (+1.13), and video or audio recording the coercive sexual act (+1.09). Paraphilic sexual behavior may be ritualized and stereotyped, as if following a script or "MO" (modus operandi). Ritualistic sex offending is also called the "offense signature" that is evident from clues and patterns left behind by the offender. This item assessing ritualized, scripted, sexually coercive behavior was found supportive of PCD (mean +1.39). Finally, committing coercive sexual acts despite the presence of an available consenting sexual partner (+1.20), physical signs of arousal (erection, ejaculation) during coercive sex (+1.11), and involvement with rape pornography (+1.03) were all considered indicators of PCD. (Also see Doren, 2002, for descriptive accounts of these indicators.)

Sexual Deviance

The item describing individuals who self-report rape impulses or fantasies with masturbation (mean +1.19) is conceptualized as an indicator of sexual deviance. Men typically access sexual imagery (fantasies and memories) with private masturbation, and a man's masturbation fantasies usually reflect his favorite or preferred method of sexual arousal. When men report persistent rape fantasies with masturbation, it suggests a sexual preference for coercive sex. Sex offenders often deny rape fantasies or refuse to discuss their sexual interests or masturbation habits, though they may be more inclined to discuss these matters after commitment to and participation in sex offender treatment. Finally, multiple victim types, as noted above, is also considered an indicator of sexual deviance that is associated with increased risk of sexual reoffense.

Items Negatively Related to PCD

There were two items negatively related to PCD that had mean scores lower than −1.0: When the individual stops a coercive sexual act when he sees the victim cry or scream (mean −1.24), and if he loses erection when the victim complains or resists (mean −1.07). These items are consistent with the definition of PCD used in this study in which a male is sexually aroused by a victim's nonconsent or resistance and his ability to overpower that resistance. If the man shows signs of decreased arousal (loss of erection) resulting from the nonconsent, or if he stops the coercive sexual activity due to the victim's signs of nonconsent (crying, screaming), this would suggest a lack of sexual arousal to nonconsent and negate a finding of PCD. This finding is also consistent with PPG literature showing that it is the reaction to the coercive elements of the sexual assault that distinguish rapists from normal men (rapists' sexual arousal is not inhibited by the coercive nature of the rape).

At the time of this writing, the PCD checklist is still in the research stage. We have developed a method for combining and weighting items and a coding manual for scoring. Interrater reliability and construct validity of the checklist are yet to be determined, but at least one reliability study is underway. Nevertheless, we feel the current results can be useful for defining the parameters of PCD in clinical practice because they represent the collective opinion of clinicians, researchers, and evaluators in the field and are thus superior to any currently available diagnostic scheme for assessing PCD.

PCD Case Study

Below is a case study of a sex offender evaluated for civil commitment by one of the authors who we believe characterized Paraphilic Coercive Disorder. Every effort was made to accurately describe the case, while at the same time, disguise and protect the identities of the offender and the victims. The case description is followed by a discussion of the items from PCD checklist that suggest Roger's rape behavior was motivated by PCD.

Roger

> Roger's criminal career began at age 10, and by early adolescence he had been arrested for multiple burglaries, robberies, battery, and assault. He committed his first rape at age 14 with a male peer. This was a home invasion assault of an elderly female stranger. The crime started as a burglary, but both boys ended up raping the victim. This was Roger's first sexual experience with another person in which he penetrated the victim and ejaculated. He was caught and spent an unknown amount of time in custody. His next rape was another home invasion of an 70 year-old female stranger committed when he was 17. After the rape he robbed the victim and fled. Within the following month Roger committed three more rapes of elderly female strangers in a similar fashion. He also became more violent, slapping one victim in the face, choking another, and throwing a third victim on the floor and covering her face with a towel. Roger was subsequently arrested for charges not related to the rapes and sent to a work camp. After one month he escaped and the next day committed another home invasion rape and robbery of an elderly year-old female stranger. He was arrested a few days later and identified by all five victims. They all reported that he achieved erections and ejaculated during the rapes. Roger was remanded to adult court and sentenced to state prison for three years. During his term he received several disciplinary violations for "sexually pressuring" and "sexually molesting" other inmates. One incident was submitted to the local district attorney's office that was rejected for prosecution, but the violation was found true and additional time was added to Roger's prison sentence. Roger was age 20 when he paroled. Five months later he committed two sexual attacks two days apart. The first attack involved an adolescent year-old female stranger riding a bicycle. Roger approached the victim from behind and grabbed her around the waist but she was able to struggle free and rode away. Two days later Roger drove behind an adult female stranger who was walking and carrying a bag of groceries. She noticed that he was following her slowly in his car and a cloth was placed in such a manner as to cover the car's license plate. Roger pulled up and forced the victim into his vehicle and drove away. A few moments later he was stopped by police for driving in a suspicious manner and the victim was discovered. Roger was sentenced to state prison for kidnapping, attempted rape, and annoying/molesting a child. He paroled four years later at age 26. He spent the next four years in and out of custody for multiple parole violations, property crimes, and weapons charges. He was never out more than a few months. At age 30, Roger forced entry into the house of a 13 year-old female stranger after she arrived home from school and then raped her. Six weeks later he committed another sexual assault of a 13 year-old female stranger in a similar fashion. The records note that the victim resisted until she was choked into submission. Both victims report Roger achieved vaginal penetration and ejaculation. Roger was convicted of both assaults and spent nineteen years in prison. He was age 49 when referred for evaluation for civil commitment.

Based on the facts of Roger's case, he demonstrates many characteristics of PCD discussed above that also appear in Table 1 (Appendix). He shows a *persistence of sexual offending* that began as a minor and resulted in both juvenile and adult convictions. He has *four sentencing dates* for assaulting female victims. He was also sanctioned with added prison time for molesting a male victim in custody, which could be considered another sentencing date. He has assaulted *multiple victims* (11+) and *mixed victim types* that include male adults and female adolescent, adult, and elderly victims. He also demonstrates *rapid reoffending*; in one example, he was paroled at age 20 and 5 months later committed two sexual attacks separated by two days. Roger demonstrates *behavioral correlates of PCD* that include *advanced planning* and *driving around cruising for victims* in his car. He demonstrates *physical signs of arousal during coercive sex* (erection and ejaculation). His choice of six elderly women victims as a juvenile suggests *stereotyped behavior* and a *repetitive pattern* or *modus operandi*, though he shifted to

younger victims as he became an adult. In sum, Roger's case highlights many characteristics identified in this study that were strongly associated with paraphilic coercive disorder.

Conclusion

The purpose of this chapter was to discuss the epidemiology of rape with special focus on the construct of nonsadistic paraphilic serial rape known as paraphilic coercive disorder. We believe that there is sufficient theoretical, clinical, and scientific basis for the mental health and criminal field to recognize PCD as a legitimate diagnostic entity. As noted, PCD has a long and controversial history in the mental health community that dates back to the 1980s when the proposal to include it in the *DSM* was derailed primarily for political rather than scientific reasons. However, mental health professionals treating and evaluating sex offenders continued to identify serial rapists who appeared to demonstrate a paraphilic arousal to coercive sex. With the introduction of a new generation of sex offender civil commitment laws in the mid 1990s, PCD reappeared of sorts under the rubric paraphilic disorder not otherwise specified, nonconsent. Partly due to renewed legal interest, but also due to the ongoing need to diagnose, manage, and treat dangerous sex offenders, PCD is now proposed for inclusion in the next edition of the diagnostic manual, the *DSM-5*. Yet the controversy in the psychiatric community over PCD is no less heated now than during the original debate in the 1980s. Despite the legal and political ramifications, there is a growing consensus among sex offender professionals that PCD exists and motivates sexual aggression among some serial rapists. We have not discussed etiology and theories of how PCD develops, which goes beyond the scope of this paper.

New lines of research, including PPG studies and recidivism research, support the existence of a subgroup of rapists who are erotically aroused by power, dominance, and control over a nonconsenting victim. But unlike sexual sadists, PCD rapists stop short of injury and do not employ force greater than necessary to subdue the victim. Furthermore, PCD occurs not merely as a failure to inhibit arousal to the violent elements of violent sex, as in normal males. Rather, the sexual and aggressive elements in coercive sex fuse in an additive fashion to enhance arousal in PCD.

Trends in the research suggest that there may be several types of rapists who are the product of different developmental pathways leading to an erotic interest in coercive sex (Harris et al., 2007; Knight, 2010b; Knight & Guay, 2006; Thornton, 2010). The first form is a fixated sexual deviance in men who are not otherwise highly antisocial or criminally oriented. The second form is coercive sexuality as an inherent component of life course persistent antisociality. A third pathway may be a blended form of the these two. Diagnostically, they may appear the same in terms of serial rape behavior, but their amenability to treatment and intervention may be different.

In this respect, persistent arousal to forced sex by serial rapists (PCD) is a *mental disorder* as defined in the *DSM*, because it creates *dysfunction* and *disability* in the individual that, in the very least, results in an "important loss of freedom" (incarceration) (APA, 2000, p. xxxi).

PCD may be controversial and hard to identify and discriminate from other rapist types. This is all the more true because incarcerated rapists are typically uncooperative and not inclined to reveal their private sexual fantasies and urges. While the effort to identify the existence of PCD among persons who commit repeated rapes is difficult, clearly it should not be abandoned. Behaviorally based criteria, informed by the consensus of sex offender professionals, and supported by laboratory findings, appears to offer a promising direction. As discussed previously, the proposed *DSM-5* criteria for PCD includes forcing sex on three or more nonconsenting persons on separate occasions. In addition to PCD, the *DSM-5* trend toward behaviorally based diagnosis of paraphilic disorders has also been proposed for voyeuristic disorder (three nonconsenting persons), exhibitionistic disorder (three nonconsenting persons), sexual sadism disorder (two nonconsenting persons), and pedohebephilic disorder (two children if both are prepubescent, three children if one or more are pubescent). This change also addresses the past criticism that the word "recurrent" in the *DSM-IV-TR* criterion "A" of the paraphilias says nothing beyond "more than once" and is too vague to be clinically useful (from www.dsm5.org).

It would be reasonable to expect that all paraphilias (including PCD) at this point can be best described in dimensional terms, and cutoffs need to be established to discriminate them from non-paraphilic sexual interests. For example, at what point does an arousal to sex with women wearing high heels develop into a shoe fetish? Or when does spanking one's partner during sex cross the threshold into sexual sadism? Indeed, all human sexuality can be viewed as dimensional ranging along a continuum from nondeviant (statistically common and "normal") to deviant, rare, and disordered.

There are no bright lines separating PCD from nonparaphilic rape, and diagnostic criteria are to some extent arbitrary. With this problem in mind, determining cutoffs for PCD will be a major focus of future research and should take into consideration the consequences for both false positive and false negative decisions. We concede that there will always be disagreement about where the line should be drawn, but getting consensus data is an important beginning. In this spirit, we offer our empirical findings from the first stage of constructing the PCD checklist.

Appendix

Mean respondent ratings of the final 70 items of the paraphilic coercive disorder rating scale

Item	Mean score
1. The individual has committed documented acts of coercive sex with 15+ victims	1.74
2. The individual has committed documented acts of coercive sex with 11–14 victims	1.70
3. The individual has committed documented acts of coercive sex with 8–10 victims	1.64
4. The individual has committed documented acts of coercive sex with 5–7 victims	1.59
5. The individual has three or more sentencing dates for coercive sexual offenses prior to the index coercive sexual offense	1.54
6. The individual possesses evidence of a "rape kit": rope, bindings, tape, blindfold, scissors, tools, binoculars, lubricants, etc.	1.41
7. The individual engages in stereotyped rituals or repetitive patterns of behavior during coercive sex, as if scripts are being enacted, repeated "M.O."	1.39
8. The individual exhibits advanced planning or premeditation prior to committing coercive sexual acts	1.30
9. The individual reoffends quickly and commits a new coercive sex offense within 1 year following sanction/release for a prior coercive sex offense	1.27
10. The individual has committed documented acts of coercive sex with 3–4 victims	1.24
11. The individual commits acts of coercive sex despite the presence of an available consenting sexual partner	1.20
12. The individual reports having rape impulses or fantasies with masturbation	1.19
13. The individual drives around cruising for victims with whom to engage in coercive sex	1.16
14. The individual has two sentencing dates for coercive sexual offenses prior to the index coercive sexual offense	1.16
15. The individual committed coercive sexual acts as a minor and as an adult	1.15
16. The individual collects and saves victim's memorabilia (photos, jewelry, hair, items of clothing) gathered during coercive sex	1.13
17. The individual displays a pattern of recurrent coercive sexual behavior with persons over a period of at least 6 months	1.13
18. The individual engages in coercive sex with a wide range of victims including two or more of the following: male, female, children, adolescents, adults, elderly, or disabled	1.11
19. The individual shows physical signs of arousal (erection, ejaculation) during coercive sex	1.11
20. The individual video or audio records the coercive sex	1.09
21. The individual was arrested/charged for coercive sex as a juvenile and again as an adult	1.06
22. The individual reads, watches, or writes pornography with themes of coercive sex	1.03
23. The individual reports having rape impulses or fantasies without masturbation	0.98
24. The victim makes statements that indicate the perpetrator was sexually aroused by her nonconsent to coercive sex	0.97
25. The individual commits acts of coercive sex when he is fully sober (i.e., not under the influence of alcohol or drugs)	0.94
26. The individual is a "sexual specialist" (virtually all criminal behavior is sexual)	0.94
27. The individual engages in home invasion (breaking and entering) to commit coercive sex	0.91
28. The individual has PPG results showing sexual arousal to rape scenes	0.91
29. The individual uses restraints or blindfold during coercive sex	0.89
30. The individual commits acts of a coercive sex that involve the element of surprise (e.g., "Lying in wait")	0.88
31. The individual kidnaps victim and moves/transports victim to a different location to commit coercive sex	0.87
32. The individual shows a trend of escalating violence with successive instances of coercive sex	0.86
33. The individual has engaged in coercive sex with strangers (known less than 24 h)	0.85
34. The individual has one sentencing date for a coercive sexual offense prior to the index coercive sexual offense	0.81
35. There is evidence that the individual is not aroused by sex with a consenting partner	0.80
36. The individual commits coercive sex in a public place (suggesting lowered inhibitions and greater risk of getting caught)	0.79
37. The individual lures the victim to a secluded area to commit coercive sex	0.76
38. The individual stalks victim before committing coercive sexual act	0.76
39. The individual uses more force than necessary to subdue the victim during coercive sex	0.76
40. The individual uses weapons during coercive sex	0.75
41. The individual makes verbal statements of feeling sexually out of control before, during, or after coercive sex	0.74
42. The individual has committed documented acts of coercive sex with two victims	0.70
43. The individual seriously injures or kills the victim during coercive sex	0.61
44. The individual enjoys being watched while committing coercive sex	0.55
45. The individual engages in coercive sex with victims who are asleep, intoxicated, unconscious, developmentally delayed, or otherwise particularly vulnerable and unable to resist	0.53

(continued)

(continued)

Item	Mean score
46. The individual has been arrested more than once for a coercive sexual offense but never convicted of a coercive sexual offense	0.45
47. The individual displays attitudes of hostility toward women	0.41
48. The individual has engaged in coercive sex with a male victim	0.41
49. The individual has coercive sex only with children	0.40
50. The individual shows indicators of other paraphilias (pedophilia, exhibitionism, voyeurism, fetishes)	0.39
51. The individual enjoys consenting sex but also pursues nonconsenting sex	0.37
52. In addition to committing acts of coercive sex, the individual has a criminal history of prowling, loitering, attempted burglary, or trespassing	0.28
53. The individual reports excessive masturbation (i.e., every day for many days or several times a day)	0.25
54. The individual expresses distress, remorse, or guilt for coercive sex behaviors or fantasies	0.24
55. The victim does not cooperate with the coercive sex and actively fights and resists	0.21
56. The individual demands that the victim tell him she loves him and/or she enjoys the coercive sex	0.20
57. The individual uses alcohol or drugs to subdue the victim during coercive sex	0.20
58. The individual engages in coercive sex in concert with others (gang rape)	0.19
59. The individual displays nonsexual violence toward females (battery, assault, domestic violence)	0.16
60. The individual and the victim consume alcohol or drugs after which the individual commits coercive sexual acts	−0.02
61. The individual robs the victim in addition to coercive sex	−0.11
62. The victim initially consents to sexual activity but later withdraws consent, says "no" or physically resists further coercive sex	−0.33
63. The individual is severely mentally ill (e.g., psychotic)	−0.40
64. The individual has a history of coercive sexual crimes but has lived offense free in the community for five or more years	−0.46
65. The individual has a history of coercive sexual crimes but has lived offense free in the community for 15 or more years	−0.83
66. The individual has a history of coercive sexual crimes but has lived offense free in the community for 10 or more years	−0.88
67. The individual shows physical signs of non-arousal (such as inability to achieve an erection) during coercive sex	−0.96
68. The individual's preference is for noncoercive sexual acts with children	−0.99
69. The individual loses erection when the victim complains or otherwise resists	−1.07
70. The individual stops the coercive sex when he sees the victim cry or scream	−1.24

Drug-Facilitated Sexual Assaults

Jain Ashok, Mohan Nair, and Robert Friedman

The terms *sexual assault* and *rape* are used indiscriminately in medical literature, often causing confusion over statistical numbers reported. Sexual assault describes a broader range of sexual offenses involving touching or penetration of an intimate part of a victim's body without due consent, while rape is generally defined as forced or nonconsensual sexual intercourse.

The U.S. Department of Justice Bureau of Justice Statistics reported that there were 260,940 rapes/sexual assaults in 2006 that were reported to law-enforcement agencies in the United States (RAIN, 2009; U.S. Department of Justice, 2008). These numbers are under-representative as evidenced by a study documenting that almost 59–84 % of victims did not report being raped (Tjaden & Thoennes, 2000).

Assaults are not reported for various reasons that include feelings of shame, embarrassment, guilt, confusion, uncertainty of being sexually assaulted, or uncertainty regarding the definition of rape (Fitzgerald & Riley, 2000). In the majority of sexual assault cases, the perpetrator is an acquaintance of the victim. Spousal and date rapes are often not considered by many victims to be sexual assault because the perpetrators are acquaintances of the victims (Koss, 1993; Rickert & Wiemann, 1998).

Drug-Facilitated Sexual Assault

Drug-facilitated sexual assault (DFSA) simply implies the use of a mind altering chemical being used in the course of a sexual assault. Emergency room physicians, law enforcement, toxicologists, forensic psychologists, lawyers, and judges may be confronted with the scenario of a subject who may have been sexually assaulted while under the influence of a substance that affected their ability to resist or, in some cases, even to recall the assault (Goulle & Anger, 2004; LeBeau & Mozayani, 2001).

Drugs incapacitate victims physically as well as mentally, rendering them powerless to resist an attack or unable to provide conscious, valid consent. The ability to consent is affected even though the victim may be in a state of vigilant consciousness but experiencing muscle paralysis or weakness due to the ingested chemicals or drugs (LeBeau & Mozayani, 2001; Linden, 1999).

A large number of drugs are used to facilitate sexual assault. The choice of drugs depends on ease of administration and availability. These drugs are usually odorless, tasteless, and colorless so that a beverage or food can be covertly spiked. Some like "Spanish fly" may have aphrodisiac properties. (It may be argued that the active ingredient of Spanish fly, cantharidin, does not induce drowsiness, but rather causes inflammation of urogenital structures causing swelling and stimulation and, therefore, is not an aphrodisiac per se.) Others drugs like MDMA ("Ecstasy") may act by lowering sexual inhibitions, thereby decreasing the threshold of an unwanted sexual act. Steroid use may also contribute to the higher number of athletes who commit sexual assault by increasing aggression called "roid" rage. The most common class of drugs used in DFSA are central nervous system depressants, primarily hypnotic sedatives. Drugs like Rohypnol have become notorious for causing lack of recall of the sexual assault, but all benzodiazepines and even the "safer" imadazopyridine drugs like zolpidem (Ambien),

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_5

eszopiclone (Lunesta), and zaleplon (Sonata) can cause anterograde amnesia.

By impairing the consciousness and inducing sedation, assailants can subdue and dominate their victims. These drugs are also capable of depersonalizing their victims, altering the victim's ability to judge, impairing motor skills, and rendering their muscles relaxed. The victims usually describe being in a dreamlike state. The anterograde amnesia caused by these drugs results in inability of the victims to recall the details of the assaults, sometimes in their entirety. This fragmented recall of the events during the attacks makes victims unreliable witnesses for the prosecution of rapists.

Due to the lack of reporting and incomplete recall abilities, actual numbers of DFSA victims are not available. Many of the factors that lead to the well-recognized underreporting of sexual assault are even greater concerns in these cases, especially when the victim has recall problems. A significant proportion (as much as two-thirds noted by some studies) of sexual assault victims show evidence of voluntary intoxication (ElSholay, 1999; Slaughter, 2000). A recent study, conducted in 2007, of sexual assault on college campuses suggested that about one in twelve undergraduate women had been victims of at least one completed sexual assault since entering college; 7.8 % of women were sexually assaulted during voluntarily intoxication, and 0.6 % were sexually assaulted after being drugged surreptitiously (Krebs, Lindquist, Warner, Fisher, & Martin, 2007).

DFSA does not mandate a covert administration of the chemical agent and can also occur without deliberately spiking beverages or food by the assailant. Social lubricants like alcohol and drugs like LSD, MDMA, GHB, marijuana, uppers, and downers are all popular and freely used in night clubs, bars, and disco-dance/rave parties (Fendrich, Wislar, Johnson, & Hubbell, 2003). The victim's use of alcohol or other recreational drugs as well as prescription and OTC medications make them vulnerable to sexual assault (Abbey, Zawacki, Buck, Clinton, & McAuslan, 2001). (Assailants tend to prey on susceptible victims.) The use of ethanol alone increases the risk of sexual assault as it produces paradoxical disinhibition resulting in increased sociability at lower doses, while causing amnesia and sedation at higher doses. Perpetrators are often under the influence of alcohol or drugs, which may eliminate physical and psychological inhibitors, thereby enabling them to carry out these acts of violence. About half of all sexual assaults occur under the influence of alcohol or drugs. Most often these intoxicants are used voluntarily by the victim and assailant. The stereotypical drug-facilitated rape (i.e., the deliberate, covert drugging or drink spiking) is much less common than the media leads the public to believe and probably represents around 2 % of reported DFSA cases (Beynon, McVeigh, McVeigh, Leavey, & Bellis, 2008; Juhascik et al., 2007; Scott-Ham & Burton, 2005).

Commonly Encountered Drugs in DFSA

At least 20 different substances are commonly encountered and implicated in DFSA. The chemical substances used to subdue victims of DFSA could be licit or illicit. The most common legal substance encountered in DFSA victims is alcohol. The use of alcohol by the perpetrator increases the perpetrator's aggression and the severity of the physical injury to the victim. The recent practice of making alcoholic beverages more palatable by mixing with fruit juices (energy drinks and fruit-flavored alcoholic beverages, called "alcopops") targets underage adolescents. The other commonly used licit substances are prescription medications belonging to the class of anxiolytic, sedative, hypnotic drugs includes benzodiazepines, barbiturates, chloral hydrate, codeine, propoxyphine, antihistamines, muscle relaxants, and others. Among these prescription medications, Flunitrazepam (Rohypnol), diazepam, triazolam, tetrazepam, clonazepam, lorazepam, zolpidem, zopiclone, eszopiclone, zaleplon, and ketamine are the most commonly implicated medications. Concurrent use of alcohol with these medications intensifies the effects of these prescription medications (Anglin, Spears, & Hutson, 1997; Bechtel & Holstege, 2007).

The commonly implicated illicit drugs are familiar recreational drugs (cannabinoid, cocaine, opioids, and amphetamines, including MDMA and LSD) as well as present day "knockout" drugs (GHB, ketamine, rohypnol, scopolamine, and datura). Recently, reported cases have involved use of datura as a plant extract called burundanga (should have a citation if available).

GHB ("Liquid X", Blast, G3, Sulcel-B, V35), a drug commonly used at all night dance parties or "raves," has been implicated in up to 7 % of DFSA cases (Stillwell, 2002). GHB produces euphoric intoxication and is perceived to enhance sexual experience. Rohypnol or "roofies," while highly publicized, has been found in less than 1 % of these victims. About 35 % of the victims who test positive have multiple drugs in their system. Sixty to sixty-five percent of victims have alcohol in their screening tests. The presence of alcohol alone is reported in about 40 % of these victims. Following alcohol, the second most common drug found in these victims is cannabinoids, reported in up to 30 % of victims. Cocaine and amphetamines have been discovered in about 10–15 % and 10 % of victims, respectively. Benzodiazepines are involved in about 10–13 % of these cases. Opiates are found in about 5–10 % while Barbiturates are found in only 1–2 % of these victims. Thus, implicated drugs in order of frequency are:

- Alcohol
- Marijuana
- Cocaine
- Amphetamines that include MDMA

- Benzodiazepines
- Opiates
- GHB
- Barbiturates
- Rohypnol

About 10–12 % of sexual assault victims in emergency rooms are suspected to be DFSA victims. Among these, about 60 % are positive for drugs, while 40 % are negative. The inability to detect a drug in the biological specimen of the suspected DFSA victim does not rule out DFSA. Late presentations to the healthcare facility and the inability to screen for all potential drugs have lead to falsely negative results for drugs among many of these victims. This makes it difficult to prove drug-facilitated sexual assault.

As new drugs and chemicals, including prescription as well as illicit drugs, are constantly creeping into society, one should be vigilant about such products when a case of suspected DFSA is being investigated. Recently, cases of DFSA were reported implicating the therapeutic form of GHB (Xyrem) (Akins, Miranda, Lacy, & Logan, 2009) and OTC ocular solution containing tetrahydrozoline (Visine) (Spiller, Rogers, & Sawyer, 2007).

Traditionally, drugs in cases of DFSA have been delivered to the victims by surreptitious administration into a beverage or food. Recently, cases have been reported in which volatile agents were delivered via the respiratory route. In one case it was chloroform and in another case it was mixture of aromatic solvents delivered via a soaked cloth placed over the mouth of the victim (Gaillard, Masson-Seyer, Giroud, Roussot, & Prevosto, 2006; Martínez & Ballesteros, 2006).

Even old drugs may resurface for facilitating sexual assault for their amnesic and other desirable properties. Scopolamine was recently being reported to have been used for such purpose, although it has been extensively used for robbery in Columbia in the form of Burundanga powder.

Forensic evaluators also need to consider the possibility that commonly used general anesthetics and hypnotic drugs, such as chloroform, midazolam, and propofols, can, in some instances, produce sexual hallucinations (Balasubramaniam & Park, 2003; Brahams, 1990; Thomson & Knight, 1988; Weller, 1933). Clinicians may become victims of allegations stemming from these hallucinogenic effects if not handled carefully (Hansen-Flaschen & Adler, 1999).

Index of Suspicion Factors Regarding DFSA

Less likely to resist, DFSA victims have less serious physical injuries (genital or extragenital), when compared to other sexual assault victims. They can also involve multiple perpetrators involving a single victim (Marc, 2008). The victims' altered mental status during and post-sexual assault makes it less likely for them to involve law-enforcement officials. The delayed presentation to the emergency room by these victims as a result of the drug effects and the subsequent delay in collecting forensic specimens reduces the probability of detecting many drugs commonly seen in these offenses (McGregor, Lipowska, Shah, Du Mont, & De Siato, 2003).

DFSA victims may present various symptoms that provoke suspicion. DFSA should be investigated when the following historical clues are noted:

- Intoxication or hangover disproportionate to the amount of alcohol consumed
- Witnessed to have been acting inconsistent to the amount of alcohol or drugs used and one's personality
- Unexplained dizziness, disinhibition, impaired judgment, impaired motor coordination, slurred speech, impaired vision, nausea, and vomiting
- Altered mental states including confusion, partial or total amnesia, dreamlike state, delirium, or hallucinatory state
- Drowsiness, loss of consciousness or blackouts, recurrent lapses of consciousness and flashes of memory ("cameo appearances"), conscious paralysis
- Inexplicable genital, anal, oral, or bodily soreness and injuries
- Sudden awakening in a strange place or in compromised circumstances or with clothing in disarray or with uninvited person in bed
- Unexplained discovery of body fluid or used condom
- Vague sensation of being sexually assaulted

Forensic Evaluation of DFSA Victims

Sexual assault victims may often present to hospital emergency rooms for an initial evaluation. A thorough and systematic history must be taken, which includes a physical examination and evidence collection. Appropriate treatment including prophylaxis and crisis intervention should be provided. Some cities have rape crisis or sexual assault centers that are dispatched to hospitals when rape victims are seen in the emergency room. Hospitals may provide a sexual assault resource service (SARS) or a sexual assault response team (SART) that use trained sexual assault nurse examiners (SANEs). In most of these cases, however, an emergency physician performs the initial evaluation. SANEs work closely with medical staff and coordinate with sexual assault crisis centers, law-enforcement agencies, social services, and forensic laboratories.

The priority during the initial evaluation is to recognize life threatening physical injuries and provide appropriate medical care to DFSA victims. A detailed history of the events surrounding the assault and other medical complaints should be obtained in a safe and secure environment. A thorough physical examination must be performed and appropriate evidence should be collected, after obtaining consent.

For evidence collection and storage, physicians must use the standardized "rape kit." All personal items including clothing and debris should be placed in paper bags. During initial history taking, the physical examination, and evidence collection, it is prudent to have an advocate or rape crisis counselor present. It is advised to use patients' direct quotes when notating history: provide details about the patient's mental status, not only at the time of presentation to the emergency room but also during and prior to the incident.

During the physical examination, medical professionals must look for the subtle signs of trauma, suggesting use of force (e.g., echhymotic areas on the inner aspect of thighs). The collection of evidence and appropriate documentation is of paramount importance in the evaluation of sexual assault victims (Gray-Eurom, Seaberg, & Wears, 2002). Consent should be obtained before the examination and evidence collection. Significant (biologic) evidence can be collected from the victim up to 5 days after the sexual assault. Victims should be persuaded to consent to evidence collection, with the reassurance that this does not mandate them to press charges.

A thorough pelvic examination should be performed, preferably including a colposcopy, which increases detection of more subtle injuries. The examiner must look carefully for the evidence of trauma, not only on the involved orifices (oral, rectal, vaginal) but also in the area of back, buttock, breasts, etc. for bruises, lacerations, abrasions, cuts, swelling, and tenderness. A Wood's lamp (ultraviolet light) is used to identify semen, saliva, and other body fluids on skin and belongings. A moistened cotton swab is used to collect suspicious specimens (suspect's saliva, dried blood, semen, etc.) from the victims' bodies and belongings for forensic examination that includes DNA testing. Swab samples are also collected from oral, rectal, and vaginal orifices for forensic examination. Other biological specimens collected may include head and pubic hair combings, fingernail scrapings, or other situation specific evidence depending on the circumstances of the attack.

A recent sexual act can be determined by the sperm acid phosphatase test. Urine and blood samples should be collected as soon as possible for determination of blood typing, drug screening, DNA, or other evidence. A strict chain of custody procedures for collection and storage of the evidence must be maintained. Once history, physical examination, and evidence collection are completed, a physician must make decisions regarding treatment and prophylaxis for sexually transmitted diseases (STDs) and pregnancy. At the conclusion of the initial evaluation in the hospital emergency department, it is of paramount importance that victims get appropriate emotional support and follow-up care arranged by hospital special services (rape counselor, psychologist, and physician) to lessen the ensuing psychological trauma of rape.

In suspected DFSA victims, additional collection of special biological specimens may be required to detect certain classes of drugs. This is dictated by the nature of the suspected chemical, as well as the time elapsed since assault. Specific tests for metabolites with long half-lives, such as ethyl-glucuronide (alcohol) and trichloroacetic acid (chloral hydrate), may be needed. In special situations, such as a delayed presentation, scalp hair and sweat may be needed to test for cumulative toxins.

Drug Detection in DFSA Victims

In suspected cases of DFSA, 60–100 cc of urine needs to be collected as soon as possible, but at least within 4 days of alleged incident. At least 30 cc of blood is required within the first 24 h of the suspected drugging. Additionally, for the forensic investigation, it is preferred to have a urine specimen because it allows a longer window of detection for the drugs and their metabolites commonly encountered in these victims.

Blood should be collected in containers with preservatives such as sodium fluoride and potassium oxalate and stored in a refrigerator promptly. If a drug is detected on the screening immunoassays, it must be confirmed by gas chromatography, mass spectrometry, or other advanced methods. If the drug is identified in urine, it should also be determined in the blood specimen, as this helps when determining the time period since ingestion.

The absence of a drug in either urine or blood specimens does not rule out DFSA. Negative findings can come from a failure to look for all potential drugs involved. Poorly cross-reacting immunoassay antibodies of the same class of drugs may cause false negative results. Drugs or alcohol are often not detected in the blood or urine because the subjects present late in the course after the chemicals have been eliminated. This absence of evidence is particularly common when attackers use rapidly metabolized and short half-life drugs as their weapon to subdue victims. Drugs not administered by the assailant may be found in victims that are using over-the-counter or prescription drugs recreationally or those who have a legitimate prescription for the medication found in their system.

Sweat and hair are other biological specimens used for drug detection particularly when presentation is delayed to detect chemically unstable compounds and low dosage drugs. A sweat patch, which is removed after a few days, can be used for the analysis of suspected drugs excreted in sweat. Hair analysis is of great value in cases of sexual assault victims presenting weeks to months later as the window of drug detection is significantly longer due to stability of the deposited drug. Hair analysis is never an alternative method to blood and urine analysis but should be considered as

complementary and adjunctive testing. This procedure has been used in DFSA cases to detect drugs of abuse such as GHB, MDMA, and heroin, as well as therapeutic drugs like Rohypnol (Negrusz et al., 2001), Zolpidem, lorazepam, Zopiclone, thiopental (Frison, Favretto, Tedeschi, & Ferrara, 2003), and phenobarbital (Villain, Chèze, Tracqui, Ludes, & Kintz, 2004).

One should wait for about a month after the assault to collect the hair for analysis. Segmental hair analysis may also help to differentiate single vs. multiple exposures. In case of multiple positive segments, difference in levels among different segments of hair may indicate possible timing of administration of the drug based on rate of hair growth. For collection of the hair sample, a tuft of hair is clipped as thick as a pencil close to the scalp. In rare cases, pubic hair may also be analyzed particularly if there is significant time delay and scalp hair is not present (Kintz, Villain, & Ludes, 2004; Rossi, Lancia, Gambelunghe, Oliva, & Fucci, 2009).

Many state forensic laboratories use a three-tier chain of testing to analyze drugs used in these cases. The first tier of testing quantitatively screens for blood ethanol using GC-FID or GC-MS (gas chromatography-mass spectrometry or gas chromatography with flame ionization detection). The second tier of testing quantitatively screens for drugs of abuse using immunoassays and fluorescent polarization assays. Then positives are confirmed by GC-MS or HPLC-MS/MS (high pressure liquid chromatography linked to tandem mass spectroscopy). The drugs included are benzodiazepines, barbiturates, cannabinoids, cocaine, amphetamines, opioids, GHB, LSD chloral hydrate, and dextromethorphan. The third tier of testing analyzes a broad array of 300–400 amine containing compounds by advanced methods which are highly sensitive and specific. In many cases, once first-tier testing determines alcohol levels to be higher than 0.08 in the victim, further testing is not done unless specifically suspected by medical histories. Thus, it is important for the physician to document suspected drugs involved in DFSA case so that justification for further testing is documented.

Selected Drugs Requiring in Depth Forensic Interpretation

Ethanol

Alcohol levels in blood and urine are confirmed by GC-FID or GC-MS. By these methods one can detect concentrations as low as or even lower than 1 mg/dL, thus extending the widow of detectability. Reverse extrapolation based on rate of elimination may establish levels at the time of assault.

Chloral Hydrate

Chloral hydrate is metabolized by reduction to trichloroethanol by alcohol dehydrogenase. Trichloroethanol has a half-life of about 6–10 h. The trichloroethanol is further metabolized to trichloroacetic acid by chloral hydrate dehyrogenase, which has a half-life of about 4–5 days. Trichloroethanol is also conjugated to glucuronic acid. Thus in a patient who present days after overdose, one can look for trichloroacetic acid in urine as an indication of past overdose.

Currently, chloral hydrate is used occasionally in pediatric dentistry. It is also present in medications used for migraines and can give positive results on victims using these drugs for migraines. If alcohol is consumed along with chloral hydrate, the effects of alcohol will be exaggerated. Spiking of alcoholic beverages with chloral hydrate is known as "Mickey Finn" and has been used in criminal activities for theft as well as in drug-induced rape. As alcohol dehydrongenase is utilized for chloral hydrate metabolism, the levels of ADH decrease, thus reducing the metabolism of alcohol. This prolongs alcohol's effects. Alcohol also reduces the conversion of trichloroethanol to trichloroacetic acid, as chronic alcoholic has a reduced ratio of NAD/NADH. Thus, the elevation of trichloroethanol would result in exaggerated effects of chloral hydrate. Thus, a combination of chloral hydrate and alcohol would increase the effect of alcohol, as well as the effect of chloral hydrate.

Chloral hydrate is rapidly metabolized to trichloroethanol and, therefore, to detect the presence of chloral hydrate, one measures the levels of trichloroethanol, which is also an active metabolite. In the early state of overdose, both free trichloroethanol and conjugated trichloroethanol levels need to be measured. Part of trichloroethanol is conjugated to glucuronic acid. These levels should be measured in plasma as well as in urine. In the case where the ingestion occurred several days prior, one should measure levels of trichloroacetic acid. Increased trichloroacetic acid in the absence of trichloroethanol indicates past exposure to chloral hydrate. Levels of trichloroethanol could be also positive in patients who had exposure to trichloroethylene (which is used as a solvent in garment industry and is also produced during the chlorination of water). Trichloroethylene is metabolized to trichloroethanol, hence gives false positive results for chloral hydrate ingestion (Larson & Bull, 1989).

GHB

GHB is present endogenously, but the concentration is so low (less than 1 mg/L) that it is usually not detected in urine and blood. The usual concentration in overdosed patients is equal to or more than 100 mg/L in blood and equal to or

more than 1,000 mg/L in urine. Urinary concentrations are usually much higher than blood concentrations. GHB is metabolized rapidly and has a half-life of around 30 min; blood must be collected within 6–8 h and urine within 12 h of ingestion to render tests positive. The most common method utilized to detect GHB is by GC employing flame-ionization, electron-capture, or mass spectrometry. Simple qualitative spot tests have been employed in some studies. Sweat collected by a "sweat patch" can be used to document exposure when sampling is done 12 h after the crime. In delayed presentations, segmental hair analysis could document presence of GHB. It is believed that small quantities are transferred from the circulation to hair follicles and sweat and consequently incorporated in the hair structure. GHB is normally present in the hair because of endogenous presence. As the physiological concentration is stable along the entire hair shaft, one would expect similar concentration in all the segments of the hair. In case of exogenous exposure, the segment corresponding to the time period of exposure would have marked increase in the concentration of GHB. While interpreting, one must be careful to the potential contamination by sweat. Hence, it is advised that in such situations, one should wait for a few weeks before the collection of hair, so that this time period would allow the migration of GHB spot along the length of the hair shaft. Hair analysis is also useful if one needs to identify the source of GHB. If the precursors of GHB are sought as the source (1,4-Butanediol or GBL), then the parent compound would also be detected in the hair shaft and will confirm the source.

Rohypnol

Flunitrazepam ("Roofies," "Mexican Valium"). Chemical structure: $C_{16}H_{12}FN_3O_3$—5-(2-Fluorophenyl)-1,3-dihydro-1-methyl-7-nitro-2H-1,4-benzodiazepin-2-one. Rohypnol is a white solid, colorless, odorless, and tasteless compound with a melting point between 166 and 167 °C, a molecular weight of 313.3, and is soluble in ethanol. Flunitrazepam is a benzodiazepine that takes effect as quickly as 10 min after ingestion. Peak plasma concentrations occur after 45 min. Flunitrazepam takes effect within 20–30 min of administration and lasts up to 8 h. It acts as a sedative by inducing amnesia, relaxing the muscles, and slowing down psychomotor responses. It has a synergistic effect with alcohol. Decreased blood pressure, severe drowsiness, visual disturbances, dizziness, confusion, gastrointestinal disturbances, and urinary retention are noted.

MDMA

MDMA (also known as Ecstasy) is a phenylethylamine related to methamphetamine that has stimulant and psychedelic effects. Rapidly absorbed with a half-life of about 7 h, MDMA is metabolized to MDA which is the only metabolite reported in blood and plasma. There is no clear correlation between MDMA blood concentrations and effects. Peak concentrations of MDMA and MDA are observed within 1.5–2 h and 4 h, respectively. Effects of the drug are noted in 20–30 min and last an hour or more, depending on the dosage. Other general effects last for approximately 2–3 h. Doses used vary between 50 and 700 mg, averaging about 150 mg (Jacobs, 1987).

Burundanga

Burundanga is light yellow powder from a raw plant extract of Borrochio (drunken) tree belonging to the genus of Brugmansia that is found in Columbia, South America. Burundanga has the reputation of being used in voodoo rituals and induces waking-trances like zombies. This plant genus is a close cousin of the Datura found in North America. The active toxins are scopolamine and other yet unknown amines have also been extracted. The drug is widely used in Columbia mainly as a weapon for robberies and kidnappings as well as sexual assault. Most Americans are unaware of its existence, although it can be found here in the United States (Gold & Hofheinz, 2000). Several deaths have been reported in the northeastern United States as a result of mixing scopolamine with heroin (MMWR, 1996). Blood and urine scopolamine analysis will confirm its presence along with clinical anticholinergic syndrome.

Case Examples

Case examples illustrate the necessity for and the process of thorough history taking, adequate evidence collection, and careful evaluation of the results.

Case 1

A 22-year-old female was evaluated in the emergency room for DFSA. The subject visited the suspect at his apartment for a photo shoot for a book. Around 5:30 p.m., the suspect provided her with a glass of wine. Between 6.00 p.m. and 6:30 p.m. she recalled walking around the suspect's apartment. From 6:30 p.m. to 10:00 p.m. her memory of the events is vague, but she does remember coming in and out of a comatose state. Around 10:00 p.m., she suddenly awoke, and completely aware of her surroundings, found herself fully dressed, in the living room of the suspect's apartment. At that point, she suspected that something was wrong. She called a friend, left the apartment, and went to the emergency room. The subject arrived to the hospital emergency department

around 11:30 p.m. but was not examined until 4:00 a.m. at a rape crisis center. Toxicological analysis of the urine for metabolites of cocaine and cannabinoids, amphetamines, PCP, ketamine, and rohypnol were negative. As there was a strong suspicion of drug-facilitated sexual assault, additional tests were performed on the urine after consultation with a toxicologist. High levels of trichloroethanol, a metabolite of chloral hydrate, were found in her urine. Further investigation including review of medical records revealed that the patient had a history of migraine. It was determined that the victim had high levels of trichloroethanol secondary to the use of drug Midrin, a drug commonly used in treating migraines. Further analysis of urine for the Midrin associated ingredients were also discovered strongly suggesting that positive trichloroethanol results must be from Midrin drug and not from pure chloral hydrate. Based on analysis of various ingredients in Midrin, it was determined that each 100 mg Midrin pill would contain 64 mg of chloral hydrate. Based on the levels in her urine, it was concluded that the victim must have consumed four to five tablets of Midrin. Consumption of four to five tablets of Midrin during a migraine headache is considered medically appropriate. Forensic investigation revealed assailant's salivary amylase to be positive on a swab taken from the victim's breast area, but was negative from the swab taken from her vaginal area. It was concluded the victim may have suffered a sexual assault, but the assailant did not give the drug to the victim.

Case 2

The 42-year-old victim alleges that around 11:00 p.m. the suspect gave her a sport drink. The victim stated that soon after drinking the sports drink, she lost consciousness and then remembers waking up in the early hours the next day. She woke up to find the suspect choking her with a rope. The suspect left the scene immediately. The victim passed out again, then woke up a few hours later and went to the hospital. She arrived at the hospital around 4:00 p.m. and the blood samples were drawn around 5:00 p.m. (18 h after the alleged drug ingestion). Significant history indicated that the victim had consumed methamphetamine at approximately 8:00 p.m. and was also drinking alcohol.

A blood sample was collected and analyzed but no urine samples were collected. A blood test by radioimmunoassay was negative for cocaine, barbiturates, and opiates, but was positive for amphetamines and methamphetamines. By GC analysis, the amphetamine levels were 37 ng/mL, methamphetamines 247 ng/mL, and MDMA 84 ng/mL. In addition, ethanol levels were measured which were 0.12. Blood was also analyzed for flunitrazepam, norflunitrazepam, 7 aminoclonazepam, and clonazepam. All these tests were negative. A blood test was also done for GHB, which was positive and revealed the concentration of 3.5 mg/L.

Considering the half-life of GHB to be a maximum of 1 h, it was determined that 18 h earlier, her levels would have been so high that it would be impossible to consume that amount of GHB. Considering the presence of other drugs and alcohol, it was concluded that this victim had probably taken GHB prior to arriving at the hospital and not at the time of the alleged assault.

Legal Considerations in DFSA Cases

Since the mid-1990s, DFSA has been under particular law enforcement and legislative scrutiny with the implication that it is surging public danger. The Drug-Induced Rape Prevention and Punishment Act of 1996 provides penalties of up to 20 years imprisonment when rape involves providing the victim with a controlled substance without the victim's knowledge, making such a charge extremely serious. The majority of American jurisdictions explicitly include rape of intoxicated or drugged victims in their sexual offenses. Enhanced punishment of these offenses is provided by laws that (1) grade sexual offenses committed by giving intoxicants as higher crimes, (2) enhancing penalties for the use of drugs, (3) noting victim incapacity as an aggravating factor in sentencing guidelines, or (4) making DFSA as SVP qualifying offenses (Falk, 2002).

Rape is a serious crime with significant impact on victims, up to 2/3 of whom may go on to develop Posttraumatic Stress Disorder, a serious, potentially chronic psychological disorder. Charges of rape can be devastating to the alleged offender since convictions draw long prison sentences. Individuals convicted of multiple rapes may face indeterminate civil commitment under Sexually Violent Predator or Sexually Dangerous Persons (SVP/SDP) laws after they serve the criminal sentence. While rape is an underreported crime, false accusations of rape are not uncommon, even given poor statistical data (Greer, 2000; Kanin, 1994; Katz & Mazur, 1979; Torrey, 1991). The assessment of drug-facilitated rape is more complex than a nondrug involved rape. Distortions in the media create the impression that DFSA is of epidemic proportions when, in fact, they constitute a very small portion of rapes. The picture in the minds of most juries is of a man (usually) moving, positioning, and penetrating the various orifices of an apparently lifeless victim (most commonly a female) can be very prejudicial to the defendant. In 1997, Max Factor heir Andrew Luster was sentenced to 128 years in prison on multiple counts of rape of unconscious victims. His videotaped activities showed him positioning his victim(s) "limp as a rag doll" in various sexual positions and inserting objects such as a marijuana cigarette and a candle in the victim's vagina. The victim was described wincing in pain as Luster sodomized her. Another victim is described as "audibly snoring" while he sexually assaulted her. Luster was reported to have commented,

"I dream about this; a strawberry blonde passed out on my bed, waiting for me to do with her what I will."

Yet many cases of DFSA allegations are far removed from this scenario and may simply be variations of individuals getting intoxicated and having sex with varying levels of consent or lack thereof. One of the concerns is that DFSA laws can take commonplace behavior between individuals and mistakenly or intentionally reframe the acts as heinous crimes.

False reporting can occur with individuals who are confused, delirious, hallucinating, delusional, or from misidentification. Elderly nursing home residents constitute a special high risk population for both actual and mistaken drug-facilitated rape given the occurrence of medically induced delirium, multiple psychotropic medications, and dementia coupled with constant need for hands on care by others. False accusations can be intentional, for the purpose of revenge, extortion, or to mislead a significant other. False victimization claims may also occur in individuals who are pathologically attention seeking. Clues to the presence of false victimization include discrepancy between victimization history and clinical findings; evidence of self-inflicted injury; allegations that are bizarre or highly improbable; allegations that change constantly and/or take on new details with repetition; individuals more focused on receiving attention (i.e., from the media), than getting help; improbable claims of serial victimization; victims who go "shopping" trying to convince law-enforcement officers, attorneys, and/or therapists about being sexually victimized; individuals with a history of frivolous litigation.

The litigation of DFSA cases presents many obstacles for both the prosecution and defense attorneys. There appears to be no requirement that the prosecution identify the specific drug used because the conduct involved in DFSA cases is, by its very nature, surreptitious and will usually be difficult to identify the precise substance administered. For example, in *People v. Wojahn* (1959), the victim consulted the defendant, a physician, for chest pains because she feared tuberculosis. The defendant administered a shot, which he said was to remove the mucous in her throat and gave her a capsule to quiet her nerves. After receiving the drugs, the victim was unable when standing against a wall with her eyes closed to touch her nose with her fingers. She felt light and relaxed, her feet felt glued to the floor, and she felt as though her body was swaying. Nevertheless, she became aware that the defendant had one or more acts of sexual intercourse with her. A neighbor that was assisting the victim observed her to be nervous, upset, red-eyed, her lipstick looked smeared, her hair mussed, and her legs shaky after the visit. The neighbor accompanied the victim to the police station where the police captain observed her hair to be disheveled, her eyes red, and crying hysterically. The victim appeared to be drugged. Later, she was examined by a doctor at the county hospital, but not tested for drugs. The doctor at the county hospital concluded that she had been sexually assaulted. The state expert testified that her presenting symptoms indicated that she was under the influence of drugs even if no drug testing had been done. The *Wojahn* court stated, "A rape by drugs may be proved by circumstances and surroundings. The fact that [the victim] was not given any test for drugs on the day of the attack is not fatal to the prosecution's case."

Several courts have held that an expert may testify to the symptoms described by an alleged victim of rape when they are consistent with the administration of a drug to facilitate the attack. For example, in *Sera v. State* (2000), the Arkansas Supreme Court rejected a sufficiency of the evidence claim regarding the defendant's conviction for administering a controlled substance, the date-rape drug Rohypnol, to the victim, and engaging in sexual intercourse with the victim, who was incapable of consenting due to the drugs. The victim testified that she went out to dinner with the defendant. She recalled having a glass of wine and a glass of water at dinner. At one point, the victim left the table to go the bathroom. When she returned, she finished her water and soon thereafter began feeling ill. After remembering leaving the restaurant and getting into the defendant's car, the victim could not recall any further details until the next morning, when she woke up in bed with the defendant.

In *Sera v. State* (2000), there was no specific testimony that the victim had ingested Rohypnol. In fact, one of the state's experts, after viewing a videotape secretly made by the defendant showing him having sex with the victim, and reviewing the victim's description of events, could only testify that the victim's behavior was consistent with the effects of Rohypnol. Another expert, a pharmacologist who had created a test to detect Rohypnol in urine, testified, after reviewing the videotape, that it was possible that the victim was under the influence of Rohypnol, but could not rule out different drugs as well. The Arkansas Supreme Court concluded that the evidence was not such that the jury was reduced to mere speculation and conjecture. In so holding, the court noted that the defendant was in possession of Rohypnol during a relevant time period and that the victim's symptoms and behavior on the videotape were consistent with the ingestion of Rohypnol.

Similarly, in *State v. Nunes* (2002) the defense argued against DFSA, because chloral hydrate was not tested for and there were significant inconsistencies between the victim's symptoms and the physician's testimony regarding the effects of chloral hydrate. Expert medical testimony was required to establish within a reasonable degree of medical certainty that the victim's symptoms had been caused by chloral hydrate. The Connecticut Supreme Court disagreed with the defense's contention. In *Nunes*, the victim self-reported several symptoms that included drowsiness, dizziness, fogginess, only partially recalled events, nausea,

vomiting, and lack of a hangover. The state's experts testified that these symptoms were consistent with the effects of chloral hydrate. The court held the fact that chloral hydrate was not tested for was not determinative. On the basis of the expert's testimony in the case, the court concluded that the jury could have found that the victim's symptoms and those attributed to chloral hydrate were consistent within a reasonable degree of medical certainty.

A typical defense to DFSA is that the sex was consensual. Typically, the defense will argue that there is no evidence of a date-rape drug particularly in cases where no testing was done. The court, in *State v. Sosa* (2008), allowed expert testimony about the effects of date-rape drugs even though none were tested. In *Sosa*, a medical doctor testified that a date-rape drug is a drug typically put in a drink, and it will generally not be detected by the person ingesting it because it renders a victim unconscious but leaves the system quickly, before the victim awakes. The expert also testified that a victim will generally have no memory of what happened and that she would not be surprised that a toxicology report on blood drawn several days after ingesting the drug would have no traces of the drug. The expert further testified that the victim's symptoms in this case, slurred speech, the feeling of a thickened tongue, and the loss of memory, reinforced the possibility that she was drugged.

On cross-examination, the defendant pointed out that the expert had not seen the toxicology report and that there were other ways of testing for drugs besides analysis of blood, namely analysis of urine and hair samples and perhaps by testing a person's vomit. The court held that since the expert opinion went only as far as describing typical date-rape drug symptoms, that were consistent with what the victim in this case had described, the testimony was admissible.

What is clear from the above appellate court decisions is that experts are permitted to testify about their analysis of the drug used to assault the victim, how the particular drug affects the human body in general, how the victim's symptoms are typical of someone who has ingested a particular drug, and explain the absence of a positive toxicological result in a particular case. Typically, these experts include toxicologists, pharmacologists, and medical doctors. An expert witness must be a medical doctor in order to testify as to matters of physical causation. Thus, a pharmacologist, whose training does not qualify him to do physical examinations, is not allowed to offer a medical opinion at trial concerning whether someone was the victim of drugging on the night of the alleged sexual assault. However, a pharmacologist does ordinarily possess the requisite degree of knowledge, skill, and education in order to provide general testimony about the usual symptoms produced by ingestion of a drug and to contrast it with the effects of other drugs or alcohol.

An alleged victim's ability to consent is often an issue in DFSA cases. Serious consideration should be given by the defense to request a *Daubert v. Merrell Dow Pharmaceuticals* (1993) or *Frye v. United States* (1923) hearing on the issue of whether a victim was incapable of consent. Expert medical testimony which is not based on any scientific analysis or data but is based merely on unsupported speculation or subjective belief should be excluded by the courts under the authorities of *Daubert v. Merrell Dow Pharmaceuticals* (1993) or *Frye v. United States* (1923). False accusations and wrongful convictions are a legitimate concern in sexual assault cases where the prosecution has framed the case as one involving an incapacitated victim. It is entirely possible for the prosecution's case to be based on a false hypothesis. While an alleged victim of a sexual assault may exhibit symptoms such as memory loss or nausea that are consistent with the administration of a drug by a defendant, this does not necessarily establish non-consent. A thorough inquiry should be made of any history of drug use, including prescription medication, or alcohol use or abuse by an alleged victim. Oftentimes, the morning after, an alleged victim may realize what they had done and an accusation follows.

Summary

Sexual assault and rape are not clearly differentiated in the medical literature reports. Significant number of sexual assaults are drug facilitated, although are highly underreported. Most of DFSA occurs from voluntary intoxication, and covert drugging is an uncommon occurrence. Although a large number of drugs are reported causing DFSA and the list keep growing, alcohol ingestion is responsible in at least half of cases. High index of suspicion and vigilant look out for DFSA in sexual assault cases by the initial evaluating healthcare provider can help provide a detailed history of assault and mental status of the victim at the time of presentation. Timely and appropriate physical examination and evidence collection by the initial evaluating physician is an important factor for the prosecution of the alleged perpetrator. An expert toxicologist can guide regarding type of biological specimen collection and methodology used to determine the chemicals involved. A thorough knowledge of pharmacokinetics/pharmacodynamics and clinical effects of various drugs is necessary for interpretation of drugs and/or their metabolites in biological specimens requiring expertise of medical/clinical toxicologist physician

Professional involvement in suspected DFSA cases requires the following steps in order to conduct thorough tests and derive relevant evidence:

- Careful review of a database: crime reports, victim/suspect accounts, emergency room records, and results of sexual assault examination findings
- Knowledge and familiarity of the various drugs that can be used in DFSA and their psychological and medical presentation

- Able to review and interpret toxicological findings
- Be cognizant of issues such as sexual deviance, false victimization and false memories, suggestibility, and eye witness identification

Noncontact Paraphilic Sexual Offenses

Richard B. Krueger and Meg S. Kaplan

Introduction

This chapter will review the noncontact crimes of exhibitionism, voyeurism, possession of child pornography, and interacting with children over the Internet. Epidemiology, comorbidity, offender characteristics, risk of recidivism, relevant diagnoses according to DSM-IV-TR and NB-DSM-5 including methods for making them, and relevant treatment modalities will be discussed. Diagnostic methods and issues are relevant to all of these disorders; so a brief discussion of methods and limitations of diagnosis relevant to all of these disorders will be made initially. Finally, conclusions and future directions will be given. It should be noted that while an attempt will be made to be thorough in literature selection, the broad scope of this chapter makes an exhaustive review, particularly of the psychometric properties of assessment and actuarial instruments, impossible. Literature will be confined to those aspects most salient to these noncontact offenses.

The class of sexual offenders which does not involve touching has traditionally been called "hands off" and thought to be relatively insignificant; such crimes are often prosecuted as misdemeanors. The Crime Classification Manual (Douglas, Burgess, Burgess, & Ressler, 1992) described in its chapter on Rape and Sexual Assault the category of "Nuisance Offense": "The defining characteristic is that the offense involves no physical contact between victim and offender. Police need to investigate and deal with these offenses given the amount of time and the priority they have available" (p. 202). Voyeurism and exhibitionism were mentioned as examples. Since this Manual was written in 1992, there has been a dramatic increase in individuals being arrested for child pornography or for attempting to meet children over the Internet. These crimes are also noncontact crimes, although the fact that they are usually felonies and that there are significant prison sentences associated with them suggest that these noncontact crimes are now considered to be me much more consequential.

The computation of the frequency of occurrence of the terms "exhibitionism" and "voyeurism" in subject headings, which are terms chosen for indexing done in major databases (Lane, 2010), has suggested less recent enquiry into these disorders than in the past. "Exhibitionism" was found in 312 references in PubMed between 1950 and 2004, but only 36 between 2005 and 2011; "voyeurism" was found in 82 references in PubMed between 1950 and 2004 and only 14 references between 2005 and 2011. This same pattern was true for PsycInfo.

Paralleling the growth of the Internet, the term "child pornography" has increased in subject headings. This term was found in 22 references in PubMed between 1950 and 2004 and in 30 references between 2005 and 2011. For subject headings relevant to crimes against children over the Internet, the terms "sex offenses" or "sex abuse" and "Internet" or "online" were used; in PubMed between 1950 and 2004, there were 15 references and between 2005 and 2011, 53 references. The same pattern for both child pornography and crimes against children over the Internet was found in PsycInfo. These figures substantiate a rapidly growing academic interest in studies involving child pornography and child sexual abuse involving the Internet.

Noncontact sex offenses also have relevance for assessing the risk of recidivism for more severe sexual crimes. The Static-99, for instance, has a category, Item #7, involving "Any Convictions for Non-contact Sex Offenses" (Harris, Phenix, Hanson, & Thornton, 2003). This category includes exhibitionism, voyeurism, illicit sexual use of the Internet, and possessing obscene material. Convictions for any of these offenses can increase a subject's score and risk of recidivism. Likewise, the term "sexual deviation," which would include exhibitionism, voyeurism, and possibly individuals involved with child pornography or meeting children over the Internet,

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_6

is a risk factor included in numerous other risk assessment and actuarial instruments (Boer, Hart, Kropp, & Webster, 1997; Hanson & Harris, 2000; Hanson, Harris, Scott, & Helmus, 2007; Harris & Hanson, 2003; Quinsey, Harris, Rice, & Cormier, 2009; Schlank & Cohen, 1999). Paraphilic fantasy and behavior have been identified as one factor in the histories of offenders who commit sexually motivated homicides (Harris & Pagé, 2008; Holmes, 1991), although the likelihood of an individual progressing from a noncontact offense to a lethal offense is unknown.

It should be noted that the courtship disorder hypothesis (Freund, Scher, & Hucker, 1983, 1984; Freund & Seto, 1998) has proposed that voyeurism, exhibitionism, frotteurism, and preferential rape (all representing distortions of typical courtship, which would usually involve visualization of a prospective mate, interacting with her, touching her, and then engaging in intercourse with her) could be viewed as expressions of a disturbance of an underlying regulatory system. Thus, it is asserted that these four disorders might be more likely to cluster together; however, evidence for this has been limited (Freund & Seto, 1998).

Several studies have also documented that men have multiple paraphilias, either sequentially or concurrently (Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988; Bradford, Boulet, & Pawlak, 1992; Freund & Watson, 1990), and have suggested either that noncontact paraphilias serve as a "gateway" to contact paraphilias or that individuals "cross over" from less severe noncontact paraphilias to more severe contact ones. There are many explanations or theories to account for such a progression, such as that an individual who might be thrill-seeking keeps looking for more exciting behavior or that an individual who engages in initial noncontact paraphilic behavior becomes disinhibited or inured to any adverse consequences and progresses to more severe paraphilic behavior. However, at this point such theories remain speculative, and we have confined the information in our chapter to reviewing the empirical evidence relevant to the risk of subsequent crimes, given the existence of at least one of the noncontact crimes discussed in this chapter, and have not presented an explanatory theory.

Finally, the biases inherent in the extant literature and the limitations of past research cannot be overemphasized. With few exceptions, all studies cited are from samples of convenience (i.e., from samples that are readily available and not from random samples drawn from the community or other populations). Thus, even statements of association have to be interpreted with extreme caution because the underlying population may itself be extremely skewed. Many studies are retrospective. Many studies do not use standard diagnostic criteria or structured diagnostic instruments. Objective assessment is likewise limited because of lack of validation of stimulus sets (Marshall, 2006) or use of polygraphy. Unfortunately, the paraphilias have not received much in the line of research funding; hopefully, this will change in the future.

General Comments on Assessment and Making Diagnoses

The Association for the Treatment of Sexual Abusers has set forth its set of standards and guidelines for the evaluation, treatment, and management of adult male sexual abusers (Association for the Treatment of Sexual Abusers, 2005), which details many aspects of the evaluation of sex offenders. Because evaluation of individuals involved with noncontact sexual offenses occurs mostly in a forensic context, it is especially important to obtain informed consent, which involves informing the person being evaluated about the nature and purpose of the evaluation, who requested the evaluation, who will receive the results of the evaluation, and the potential consequences of the evaluation. The person being evaluated should also be presented with an opportunity to participate or refuse to participate in the evaluation (p. 12). Written consent should be obtained. A comprehensive psychiatric and psychosocial history should be obtained with attention to developmental history, general psychiatric history, sexual history, and deviant sexual history (p. 13).

Given the forensic context, the tendency of most individuals being evaluated is to minimize or deny any deviant behavior (Kaplan, Abel, Cunningham-Rathner, & Mittleman, 1990). Thus, it is extremely important to have an official criminal record (to ascertain both current and previous sexual and nonsexual charges and offenses) and to obtain other official legal documents such as search warrants, arrest warrants, victim's statements, supporting depositions, or indictments in order not to rely solely on self-report. Collateral history from family or significant others is also important, when available. In the case of evaluations of individuals facing charges of child pornography or of enticement or coercion of children over the Internet, it is extremely important to have a report of the contents of the subject's media (computer hard drive, external hard drive, chats, and some idea of the organization of the hard drive). As a matter of interviewing technique, it is important not to ask close-ended questions which a patient can answer with "yes" or "no," but rather to present open-ended questions such as "How many times have you had sexual fantasies or masturbatory fantasies involving children?"

Abundant literature supports the utility of structured diagnostic instruments in increasing interrater reliability (Kranzler et al., 1995; Kranzler, Kadden, Babor, Tennen, & Rounsaville, 1996; Miller, Dasher, Collins, Griffiths, & Brown, 2001; Shear et al., 2000; Steiner, Tebes, Sledge, & Walker, 1995), and there is a large variety of written diagnostic instruments for diagnosing or assessing conventional sexuality (Davis, Yarber, Bauserman, Schreer, & Davis, 2000), deviant sexuality (Prentky & Edmunds, 1997), and psychiatric syndromes (Rush, First, & Blacker, 2008). While many of the diagnostic instruments used to diagnose and assess general psychiatric

syndromes (First, Spitzer, Gibbon, & Williams, 1997, 2008; Spitzer, Williams, Gibbon, & First, 1992) are validated, the many clinical interviews for the diagnosis of paraphilic disorders that have been written are not (Black, Kehrberg, Flumerfelt, & Schlosser, 1997; Grant, 2005; Kafka & Hennen, 2002; Marsh et al., 2010; Prentky & Edmunds, 1997; Raymond, Coleman, Ohlerking, Christenson, & Miner, 1999). A number of inventories contain questions concerning noncontact sexual behaviors (Abel, 1995a; Langevin & Paitich, 2002; Simkins, Ward, & Bowman, 1989), but these rely on self-report and have not been tested for their ability to discriminate groups with a disorder from control groups.

Neurological or medical causes of paraphilic behavior should always be part of the differential diagnosis (Berlin, 2008; Hooshmand & Brawley, 1969; Kafka, 2008; Kaplan & Krueger, 2010b; Krueger & Kaplan, 2000; Stein, Hugo, Oosthuizen, Hawkridge, & Heerden, 2000). We routinely administer a Mini-Mental State Examination to screen for cognitive impairment (Folsetin, Folstein, & McHugh, 1975).

While plethysmography and, more recently, viewing time have been used to assess sexual interest and arousal in patients, and its use is discussed in the Association for the Treatment of Sexual Abusers Guidelines (The Association for the Treatment of Sexual Abusers, 2005) (pp. 37–42), we have found only limited use for the evaluation of individuals presenting exhibitionism and voyeurism. Plethysmography has recently been criticized (Laws, 2003; Marshall, 2006) as lacking standardization (i.e., not all laboratories use the same stimulus sets or the same procedures) and thus not meeting satisfactory standards for reliability and validity. Furthermore, faking will always be a problem in assessing the validity of phallometric assessments (Marshall, 2006). While some stimulus sets which are used in Canada may have data which meets satisfactory standards for reliability and validity, the transportation of such sets across international borders is problematic because where these sets involve images, these images could be construed as consisting of child pornography, which is illegal to possess in the United States. In other instances, sets cannot be distributed because of issues of consent in the original acquisition of the images. Nevertheless plethysmography remains the best available measure of deviant sexual interest for male sex offenders (Seto, 2001) and, along with the Hare Psychopathy Checklist (Hare, 2003), the best predictor of recidivism (Gendreau, Little, & Goggin, 1996; Hanson & Morton-Bourgon, 2005; Hildebrand, De Ruiter, & De Vogel, 2004; Seto, 2008; Rice & Harris, 1997).

Viewing time assessment (Abel, 1995b; Abel & Wiegel, 2009; Krueger, Bradford, & Glancy, 1998; Laws & Gress, 2004) is a newer technology. One study (Abel, Huffman, Warberg, & Holland, 1998) found high reliability and validity in the use of visual reaction time and plethysmography in assessing 157 males who had admitted to inappropriate sexual behavior. Letourneau (2002) compared visual reaction time with penile plethysmography with audio stimuli on a sample of 57 sex offenders in a high-security prison; both measures were consistent and identified offenders against young boys, and the visual reaction time significantly identified offenders against adolescent girls. Generally speaking, however, the literature on viewing time assessment is much more limited than that of plethysmography, and no stimulus sets have been used to differentiate groups of voyeurs or exhibitionists from controls.

Polygraphy has been advocated mostly for post-conviction examination of convicted sex offenders (Sosnowski & Wilcox, 2009; The Association for the Treatment of Sexual Abusers 2005). While the National Research Council (Committee to Review the Scientific Evidence on the Polygraph, 2003) concluded that it could detect deception at odds well above chance, they noted that it was far from perfect. Polygraphic evidence is not admissible in US Courts under the Frye test, but was admissible, as of 2003, in 19 states in the United States (Wilcox & Madsen, 2009). This may still be useful on a case-by-case basis for negotiations with prosecutors or at times when an individual has agreed to be polygraphed in the presence of his or her attorney.

We will discuss each noncontact crime separately, presenting DSM-IV-TR critiera and NB-DSM-5 criteria where they exist. In the case of new hypersexual disorders relevant to child pornography offenders or offenders who victimize children over the internet, the Paraphilias Workgroup proposed diagostic criteria for Hypersexual Disorder (Kafka, 2010) which were not contained in DSM-IV-TR. However, the APA Board of Directors ultimately rejected the suggested diagnosis of hypersexual disorder. However, such a hypersexual diagnosis could still be made using the NB-DSM-5 diagnoses of Other Specified Disruptive, Impulse-Control, and Conduct Disorder, Unspecified Disruptive, Impulse-Control, and Conduct Disorder, Other Specified Mental Disorder, or Unspecified Mental Disorder. Diagnostic practices utilizing DSM-IV-TR would allow for the application of the diagnosis of a sexual disorder not otherwise specified, with further description as elaborated in peer-reviewed literature (Kafka, 2010a; Kaplan & Krueger, 2010a).

Finally, we would note that the NB-DSM-5 acknowledged the difficulty in making diagnoses in forensic contexts and at one point on its website suggested a specific victim number for the diagnoses of exhibitionism and voyeurism. The rationale section on the paraphilias on the NB-DSM-5 website stated:

> The second broad change applies to paraphilias that involve nonconsenting persons (e.g., Voyeuristic Disorder, Exhibitionistic Disorder, and Sexual Sadism Disorder). We propose that the B criteria suggest a minimum number of separate victims for diagnosing the paraphilia in uncooperative patients. This was done to reflect the fact that a substantial proportion—perhaps the majority—of patients referred for assessment of paraphilias is referred

after committing a criminal sexual offense. Such patients are not reliable historians, and they are typically not candid about their sexual urges and fantasies. The criteria have therefore been modified to lessen the dependence of diagnosis on patient's self-reports regarding urges and fantasies. This change also addresses the past criticism that the word "recurrent" in the DSM-IV-TR A criteria says nothing beyond "more than once" and is too vague to be clinically useful. The reason for diagnosing specific paraphilic disorders from multiple, similar offenses in uncooperative patients is to achieve a level of diagnostic certitude closer to the certitude in diagnosing these disorders from self-reports in cooperative patients. It is not derived from legal theory or practice.

It should be noted that ultimately the use of victim number as part of the B criterion was rejected by the workgroup.

The recognition of the importance of context is also apparent in the severity ratings, where there is a code 99 (Missing data), which designates that a rating cannot be assigned because of the patient's mental condition or the circumstances of the assessment (Sexual and Gender Identity Disorders Workgroup, 2010a); such a circumstance could be incarceration or supervision by probation or parole.

Exhibitionism

Epidemiological Samples

No questions regarding paraphilias or paraphilic behavior have been included in any of the national surveys of sexual behavior in the United States (Hite, 1976, 1981; Kinsey, Pomeroy, Martin, & Gebhard, 1953, 1975; Laumann, Gagnon, Michael, & Michaels, 1994) or in national surveys of mental disorders in the United States (Robins & Regier, 1991). Arrests for exhibitionism in the United States are usually classified as misdemeanors (Dietz, Cox, & Wegener, 1986) and thus not recorded in the national crime databases. Finally, most of the literature concerning exhibitionism comes from Europe or America. The only enquiry into exhibitionism outside of these countries was in 1973 by Rooth (1973a), who reported on a survey he sent to doctors and psychiatric facilities in 40 Asian, African, and South American countries; only 24 responded. He summarized his report saying that exhibitionism in general in these countries was very rare and that in Japan it was virtually unknown. There are also socially sanctioned forms of exhibitionism (Forsyth, 1992; Forsyth & Deshotels, 1997), such as parade strippers or nude dancers, which are not criminal.

Some epidemiological data on exhibitionism exists, which suggests that exhibitionistic acts are among the most common of potential law-breaking sexual behaviors. Långström and Seto (2006) analyzed a group of 2,450 Swedes (ages 18–60) who had been randomly selected and interviewed in a broad survey of sexuality and health. Seventy-six (3.1 %) of respondents reported at least one incident of being sexually aroused by exposing their genitals to a stranger. This behavior was associated with being male, having more psychological problems, lower satisfaction with life, greater alcohol and drug use, greater sexual interest and activity, more sexual partners, greater sexual arousability, higher frequency of masturbation and pornography use, and greater likelihood of having a same-sex partner. Respondents who reported greater exhibitionistic behavior had substantially greater odds of reporting other atypical sexual behavior, such as sadomasochistic or cross-dressing behaviors. It should be noted that this survey recorded acts only and not the presence of a diagnosed paraphilic disorder.

Clinical and Other Samples

Another way of obtaining information on the frequency of exhibitionism is to look at its frequency in samples of convenience, i.e., in clinical or other samples that are not randomly selected epidemiological samples but rather consist of samples which exist for other reasons, such as groups of patients who present for an evaluation or other groups who are studied. These studies suggest there is a substantial occurrence of exhibitionism and that those subjects who were diagnosed with exhibitionism also had other paraphilic diagnoses. Abel et al. (1988) reported on types of deviant sexual behavior of 561 nonincarcerated paraphiliacs in Memphis, Tennessee, and New York, New York. DSM-II and DSM-III criteria were used, with the modification that one completed act could qualify a subject as making a diagnostic category. Most subjects had a history of multiple paraphilias and most progressed through a variety of paraphilias to express one, which was preferred. Some expressed several paraphilias at the same time, and subjects could be diagnosed with multiple paraphilias simultaneously. One-hundred and forty-two subjects were diagnosed with exhibitionism; of these, only 7 % had this as a sole diagnosis. Forty-six percent were also diagnosed with female nonincestuous pedophilia, 28 % with voyeurism, and 25 % with rape.

Freund and Watson (1990) reported on a data gathered from 1,572 heterosexual males seen at a psychiatric teaching hospital; 1,198 were sex offenders and 374 individuals had no charges against them. Individuals were assessed by interview and by completion of an "Erotic Preferences Examination Scheme." Two-hundred and fifty-eight were exhibitionists; only 25 % of these had this as a sole diagnosis and the rest had co-occurring preferences consisting of voyeurism, exhibitionism, toucherism-frotteurism, and a preferential rape pattern, which together were termed courtship disorder.

Maletzky (1991) reported on the percentage of offenders in his clinic who were exhibitionists; between 1973 and 1978, 57 % of those attending his clinic were exhibitionists; from 1978 to 1990, this number had reduced to 15 %. A study

of 60 male college students in a rural setting in the United States (Templeman & Stinnett, 1991) reported that only one acknowledged exhibitionism.

Bradford et al. (1992) reported on a sample of 443 adult males consecutively admitted to the Sexual Behaviors Clinic at the Royal Ottawa Hospital for a forensic psychiatric assessment; the self-report Male Sexual History Questionnaire developed at the Clarke Institute was utilized. Sixty subjects admitted to exhibitionism. Of these, 52 % admitted to voyeurism, 30 % to frotteurism, and 22 % to scatologia (lewdness).

In a later sample of 2,129 patients evaluated at 140 sexual treatment clinics in North America reported as a personal communication in the volume *Dangerous Sex Offenders* (American Psychiatric Association, 1999), Abel reported that 13.8 % of this sample engaged in exhibitionism, presumably based on their responses to the questionnaire of the Abel Assessment of Sexual Interest (Abel, 1995a).

A recent update of this database (Abel & Wiegel, 2009), which contained 47,265 males and 1,684 females from throughout North America who had taken the Abel Assessment of Sexual Interest, revealed that 10.1 % (4,762) of males and 6.2 % (105) of females admitted to exhibitionism; 8.3 % (3,904) of males and 2.6 % (44) females to public masturbation, 23.8 % (6,525) of males and 2.6 % (43) of females to voyeurism; 29.4 % (13,901) of males and 15.9 % (268) of females to child sexual abuse; and 26.5 % (12,519) of males and 9.9 % (166) of females to problems with the use of pornography.

Kafka and Hennen (1999) reported on a sample of 206 consecutively evaluated males seeking help for paraphilias or sexual impulsivity disorders; semistructured intake questionnaires and sexual inventories were used. Of this group, 143 had paraphilias and 52, or 37 %, were exhibitionists. Eighty-six percent of the group with paraphilias had at least one lifetime paraphilia-related disorder, now known as a hypersexual disorder.

Marsh et al. (2010) reported on the prevalence of paraphilias in an adult inpatient psychiatric population, interviewing 112 consecutively admitted, voluntary male psychiatric inpatients recruited in Minnesota and Florida, using a Structured Clinical Interview for DSM-IV, Sexual Disorders Module; 5.4 % (6) had a diagnosis of exhibitionism.

Legal Samples

In an early report from Chicago (Arieff & Rotman, 1942), indecent exposure was the most common of all sex offenses (about 35 %) seen at the Psychiatric Institute of the Municipal Court of Chicago. A study from Britain (Taylor, 1993) reported on 98 cases admitted to Brixton Prison during 1946; this represented 32.2 % of sexual offenses, and 1.95 % of all offenses admitted into the prison during that year. In an extensive study of 1,356 white males who had been convicted for one or more sex offenses, along with control groups, Gebhard, Gagnon, Pomeroy, and Christenson (1965) reported that 135 (10 %) offenders were exhibitionists. Bancroft (2009) reported that the number of convictions for indecent exposure in England and Wales declined from 1990 to 2000; in 1990, the number was 1294; in 2000, it was 553. These figures are about 20 % of what they had been in 1970; no explanation was apparent for this decrease. Also, in the United States, reviewing the above data, it seems that exhibitionism represented a much higher percentage of all reported sexual crimes in the two studies in the 1940s (35 and 32 %), than would seem to be the case currently. Unfortunately, exact statistics are not available in the United States because often such crimes are misdemeanors and not captured in national databases, or such crimes are pled to nonsexual crimes and thus not captured at all. One could speculate that recently fewer resources are devoted to apprehending and prosecuting exhibitionists because such crimes are seen to represent low-risk or "nuisance" behavior and have been overshadowed by arrests for other more serious sexual crimes. It could also be the case that the incidence of exhibitionism is decreasing, perhaps because of the effects of general deterrence arising from the prosecution of other sexual crimes or from the growth of the Internet or other vehicles that have allowed for the expression of sexually impulsive or compulsive behavior that might otherwise find its expression in exhibitionism.

Victim Reporting of Exhibitionism

Another way of establishing the occurrence of exhibitionism is to examine the incidence of victim reports. In a survey of 13,551 women and 11,375 men in Great Britain (Walby & Allen, 2004), 12.8 % of women reported being the victim of indecent exposure, 8 % since the age of 16, and 0.5 % in the last 12 months; 1.2 % of men reported having been the victim of indecent exposure, 0.5 % since the age of 16, and 0.1 % in the past 12 months. Cox (1988) reported on a sample of 846 college women taking general psychology at nine universities randomly selected from across the United States; 33 % reported being victims of indecent exposure and one-third of these at least twice. Only 15 % of these episodes were reported to police (Cox, Tsang, & Lee, 1982).

Offender and Offense Characteristics and Comorbidity

An early report (Henninger, 1941) described 51cases of indecent exposure or open lewdness in Allegheny County in Pennsylvania; 1 was a woman, the rest men. 8 were psychotic,

19 "mentally deficient," 3 had "psychopathic personality," 1 marijuana intoxication, 4 chronic alcoholism, 4 were "organic unstable type," 2 psychoneurosis, and 19 were "normal, emotionally unstable." Smukler and Schiebel (1975) reported on an early chart review of 41 exhibitionists and found no definite character type or evidence of severe pathology.

Gebhard et al. (1965), in his study of incarcerated exhibitionists, reported that 31 % were married. Regarding their victims, 92 % were strangers, 5 % acquaintances, 2 % friends, and 1 % relatives. The exhibitionists frequently had committed other sex offenses prior to their exhibitionism. Thirty-eight percent were first offenders, slightly more than one-quarter second offenders; 13 % third time offenders, 7 % fourth time offenders, 6 % fifth time offenders, and 10 % six or more offenses. Only 3 % had a previous history of mental difficulty. "On the other hand, a substantial proportion (nearly one third) of the offenses involved drunkenness, and an additional 8 % involved mild to moderate intoxication. As usual, drugs were of no consequence. Only three offenses involved drug-users and none of them were using 'heavy' drugs" (p. 395).

Forgac, Cassel, and Michaels (1984) reported on the severity of psychopathology as measured by the MMPI in 84 exhibitionists and found that there was no relationship between the severity of psychopathology as measured by the MMPI and the chronicity of exhibitionistic activity. Dietz et al. (1986) in an early review reported that exposure incidents occurred most frequently in the spring, during daylight hours, and in public outdoor places. The age of exhibitionistic behavior showed a bimodal distribution, peaking in the age ranges of 11–15 and 21–24, with the most frequent age of arrest being in the mid-20s. 52–79 % of exhibitionists 21 or over were married at some time. It was cautioned that efforts to describe a "typical exhibitionist" with psychological testing or via other means had not been useful in predicting recidivism and that arrested exhibitionists were not necessarily representative of all exhibitionists.

Lang, Langevin, Checkley, and Pugh (1987) reported on a study of two offender groups, 34 "persistent" exhibitionists, and 20 nonviolent nonsex offender controls, comparing them on measures of gender identity and sexual and criminal variables. Forty-one percent of the exhibitionists were transvestitic, with masculine gender identity. They engaged in other paraphilic behaviors, including voyeurism (71 %), obscene telephone calling (32 %), frottage (38 %), toucherism (26 %), and attempted rape (18 %). Ninety-four percent of exhibitionists reported that they hoped the unsuspecting female would enjoy the experience; 56 % of them said they would have gone with their victims, if invited to do so. Twenty percent of exhibitionists had a history of violence-related offenses (5 charged with indecent assault, 2 with attempted rape, and 3 with common assault). The violent exhibitionists were older than the nonviolent sex offenders (mean 31.0 years vs. 25.4 years) and had significantly more sexual offenses (4.43 convictions vs. 2.30 convictions). The violent exhibitionists were more likely to make obscene phone calls, touch female strangers in a crowd and in lonely places, and use vulgar language when exposing. It was concluded that the violent subgroup tended to engage in a greater diversity of outlets more often.

Abel et al. (1988) reported that of those diagnosed with exhibitionism, only 7.0 % reported this to be the only paraphilia; 20.4 % of exhibitionists had 2 paraphilias; 22.5 %, 3; 15.5 %, 4; 7.0 %, 5; 7.0 %, 6; 9.2 %, 7; 4.9 %, 8; 2.8 %, 9; and 3.5 %, 10. Exhibitionists had an average of 4.2 paraphilias and a total of 596 paraphilias. Forty-six percent were diagnosed with female nonincestuous pedophilia, 22 % with male nonincestuous pedophilia, 22 % with female incestuous pedophilia, 5 % with male incestuous pedophilia, 25 % with rape, 28 % with voyeurism, 16 % with frottage, 1 % with obscene mail, 1 % with transsexualism, 8 % with transvestitism, 3 % with fetishism, 4 % with sadism, 4 % with masochism, 2 % with homosexuality, 9 % with obscene phone calls, 9 % with public masturbation, 4 % with bestiality, 1 % with urolagnia, 1 % with coprophilia, and 1 % with arousal to odors.

Bradford et al. (1992) reported that 20 % of exhibitionists reported heterosexual pedophilic activity, 20 % heterosexual hebephilic activity, 10 % homosexual pedophilic activity, 8 % homosexual hebephilic activity, 11 % transvestism, 51 % voyeurism, 21 % obscene telephone calls, 30 % frotteurism, 13 % attempted rape, and 6 % committed rape.

In the most detailed report on exhibitionists available, Grant (2005) reported on a group of 25 males with DSM-IV exhibitionism studied with structured clinical interviews. The reported mean age at onset of exhibitionism was 23.4 years. 56 % reported age of onset during adolescence. The mean duration of exhibitionism was 11.6 years. Episodes were frequent, with subjects reporting a mean number of 1.5 times per week. Subjects reported being unable to resist an urge to expose themselves 64.0 % of the time; 88 % reported that at least 50 % of the time they experienced an urge they were unable to resist. Triggers in descending order were boredom (reported by 44 %), stress (32 %), attractive person (28 %), interpersonal conflict (24 %), feeling down or sad (24 %), feeling inadequate (16 %), no precipitants (16 %), or a particular place (4 %). Sixty-eight percent reported they exposed themselves while driving, 48 % in stores or parking areas near stores, 40 % in parks, and 28 % in their own yards. Their social functioning, role limitations due to emotional problems, and mental health were all decreased compared with scores of a US population sample on a 36-Item Short-Form Health Survey. There was very substantial comorbidity with 36 % (9) of the sample being diagnosed with current major depressive disorder and 40 % (20) lifetime major depressive disorder, 8 % (2) with current obsessive-compulsive disorder, 20 % (5) with current alcohol abuse/dependence, 16 % (4) with current drug

abuse/dependence, 28 % (7) with current compulsive sexual behavior, and 12 % (3) with pathological gambling. Twelve percent (3) had lifetime pedophilia, 16 % (4) fetishism, 8 % (2) sexual sadism, 8 % (2) urophilia, 8 % (2) voyeurism, 8 % (2) male erectile disorder, and 56 % (14) any sexual disorder.

In a report focusing on the use of "deviant" fantasy, Dandescu and Wolfe (2003) gave a questionnaire to 25 exhibitionists; 24 % reported no masturbation to deviant fantasies prior to their first offense, but 76 % reported having had deviant masturbation prior to their first offense. Twelve percent reported no masturbation to deviant fantasies after their first actual offense, but 88 % reported deviant fantasies after their first actual offense. The average number of deviant masturbatory fantasies prior to the first offense was 93.9, and the average number of deviant fantasies after the first offense was 292.78. Exhibitionism has not been confined to men; there is one case described of a female (Hollander, Brown, & Roback, 1977).

Neurological and Biological Factors

Reports of neurological etiology for exhibitionism exist with Hooshmand and Brawley (1969) reporting on temporal lobe seizures causing exhibitionism and Comings and Comings (1982) reporting on a case of familial exhibitionism associated with Tourette's syndrome. Flor-Henry, Lang, Koles, and Frenzel (1988) reported on quantitative EEG assessment of 43 male genital exhibitionists and 46 normal controls. EEG power and coherence were significantly different in the exhibitionistic group, particularly during verbal processing, suggesting altered left hemispheric functions and disruption of interhemispheric relationships. Langevin, Lang, Wortzman, Frenzel, and Wright (1989) found subtle differences between a group of 15 male exhibitionists compared with 36 nonviolent, nonsex offender controls on CT brain scans, the Wechsler Adult Intelligence Scale, and the Halstead-Reitan Neuropsychological Test Battery, but no global differences. Lang, Langevin, Bain, Frenzel, and Wright (1989) reported on a hormonal study of 16 male exhibitionists compared with 15 controls and found that exhibitionists had lower estradiol and testosterone, but higher overall free testosterone. Overall, however, there have been no consistent biological markers or findings diagnostic of exhibitionism.

Diagnosis

The DSM-IV-TR diagnostic criteria for exhibitionism are (American Psychiatric Association, 2000):

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the exposure of one's genitals to an unsuspecting stranger.

B. The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty (p. 569)

Långström (2010) reviewed the empirical literature relevant to diagnostic criteria for exhibitionism for the upcoming Diagnostic and Statistical Manual of Mental Disorders (NB-DSM-5) and made several suggestions, some of which were adopted by the NB-DSM-5 Sexual Disorders Workgroup. The diagnosis of exhibitionism was changed to exhibitionistic disorder and the NB-DSM-5 criteria are as follows (APA, 2013).

Exhibitionistic Disorder

A. Over a period of at least 6 months, recurrent and intense sexual arousal from the exposure of one's genitals to an unsuspecting person, as manifested by fantasies, urges or behaviors.

B. The individual has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify whether:

Sexually aroused by exposing genitals to prepubertal children

Sexually aroused by exposing genitals to physically mature individuals

Sexually aroused by exposing genitals to prepubertal children and to physically mature individuals

Specify if:

In a controlled environment: This specifier is primarily applicable to individuals living in institutional or other settings where opportunities to expose one's genitals are restricted

In full remission: The individual has not acted on the urges with a nonconsenting person, and there has been no distress or impairment in social, occupational, or other areas of functioning, for at least 5 yeasts while in an uncontrolled environment (p. 689)

Many of the changes in NB-DSM-5 were criticized (Frances, 2009a, 2009b, 2009c; Hinderliter, 2010). In terms of making a diagnosis, it should be noted that this is a significant change from DSM-IV-TR, inasmuch as even if an individual does not admit to such sexual arousal, the text allows that such a diagnosis can be made if there is a criminal record or other evidence suggesting that a pattern of sexual arousal is present. In an individual who is willing to admit, self-report can be given substantial credence.

As far as the use of specialized testing, to our knowledge, no study involving psychological testing has isolated exhibitionists as a separate category with a clearly defined set of characteristic responses on any single or multiple reliable and validated psychological tests (Maletsky, 1997). This lack of assessment studies on exhibitionism alone is surprising because exhibitionists have comprised the largest diagnostic groups treated as sex offenders (Maletzky, 1991; McConaghy, 1993).

Plethysmography, viewing time assessment, and other laboratory examinations are not useful because of the lack of

validated stimulus sets, which would distinguish exhibitionists from controls. Freund et al. (1984) compared 16 exhibitionists with 16 sexually normal controls on penile responses to auditorily presented descriptions of the four phases of normal sexual interaction and found no differences between the two groups. Marshall, Payne, Barbaree, and Eccles (1991) reported on plethysmographic assessment of 41 men who were exhibitionists compared with 20 controls; exhibitionists had greater arousal to exposing tapes than did non-offenders, but the arousal of the exhibitionists did not correlate with the number of victims or chronicity and led the authors to question the value of erectile testing for this group. Indeed, Marshall and Fernandez (2003) reviewed 10 studies employing phallometry with exhibitionists and found that 9 of 10 suggested that exhibitionists in clinical settings did not have a preference for exposing themselves. Maletsky (1997) opined that the use of plethysmography to assess exhibitionists remained controversial. Differential diagnosis should focus on other paraphilias, sexual disorders, and other psychiatric disorders, including substance use and affective disorders given the very high occurrence of comorbidity cited in the above studies; the possibility of a neurological disorder should be kept in mind.

Risk for Other Crimes and Risk of Recidivism

Several early studies reported that exhibitionists also had histories of crimes of sexual violence. Radzinowicz (1957) in a large survey reported that exhibitionists accounted for about a third of recidivist sexual offenders in England and Wales and that about half of her sample had a prior history of a previous sexual assault. Rooth (1973b) reported on a series of 30 persistent exhibitionists, 3 also had histories of indecent assault against adults, but 11 had a history of offenses against minors. Myers and Berah (1983) compared psychiatric assessments of 65 pedophiles and 45 exhibitionists in Australia, all of whom had pled guilty and who were interviewed in a semistructured way over a 9-year period. Exhibitionists were younger, less likely to have problems with alcohol, remained in school longer, performed better educationally, and had better work histories.

Lang et al. (1987) found that 20 % of exhibitionists had a history of violence-related sexual offenses. Grassberger, cited in Sugarman, Dumughn, Saad, Hinder, & Bluglass (1994), in a 25-year study of a large sample of indecent exposures in Austria found that 12 % were later convicted of rape. Abel et al. (1988) found that 93 % of 142 sex offenders with exhibitionism had other paraphilias and had committed sexual assaults; for example, 25 % had committed rape. Freund (1990) found that 15 % of exhibitionists had committed rape. A serious drawback of these studies is a bias toward serious offenders, as many with exhibitionism first came to legal notice because of offenses involving physical contact. Another confound is the fact that different criteria are used for exhibitionism, ranging from DSM criteria of the period to as few as one instance of exhibitionism.

Berlin et al. (1991) reported on a 5-year follow-up survey of criminal recidivism in a treated cohort of 111 exhibitionists. The sexual recidivism rate for this group was 23.4 %; treatment compliant exhibitionists had a 12.5 % sexual recidivism rate. Exhibitionists who did recidivate generally did not commit more serious sexual offenses.

Sugarman et al. (1994) reported on a study in Great Britain of the case records of 210 subjects who were arrested for exhibitionism, with criminal record data extending for a follow-up period of 8–25 years. It was found that at least 26 % had at least one conviction for a contact sex offense. Unpublished data cited by Långström (2010) found that of all 16,000 men convicted of sexual offenses in Sweden between 1973 and 2004, 15 % had been convicted of sexual harassment offenses (which were heavily dominated by exhibitionistic acts), and at least one had a prior or subsequent conviction for a contact sexual offense (such as rape, sexual coercion, or child molestation).

Rabinowitz Greenberg, Firestone, Bradford, and Greenberg (2002) reviewed archival data from medical files and police files of 221 exhibitionists who were assessed at a university teaching hospital between 1983 and 1996. A mean follow-up period of 6.84 years was obtained; 11.7 % of exhibitionists were charged with or convicted of a sexual offense, 16.8 % a violent offense, and 32.7 % a criminal offense. Sexual offending recidivists had more prior sexual and criminal offenses and were less well educated. Hands-on sexual recidivists had higher PCL-R scores (Hare, 1990), higher pedophile and rape indices on plethysmography, and more prior sexual, violent, and criminal offenses than did hands-off counterparts.

Finally, looking at extremely serious sexual crimes, Ressler, Burgess, Hartman, Douglas, and McCormack (1986), in a study of 28 sexual murderers, reported that 25 % had indicated an involvement with indecent exposure. Dietz, Hazelwood, and Warren (1990) in a review of 30 sexually sadistic criminals reported that 20 % had a history of peeping, obscene telephone calls, or indecent exposure. Hill, Habermann, Berner, and Briken (2007), reviewing psychiatric and court records of 166 sexual murderers in Germany, found that 3.6 % (6) had a history of exhibitionism. Stermac and Hall (1989), in a review of the criminal histories of 50 sexual offenders from the Clarke Institute of Psychiatry, classified offenders as escalators, non-escalators, and first-time offenders and found that escalators committed more serious sexual assaults against strangers, were younger, and had a previous psychiatric history.

Another way of determining dangerousness is to examine diagnoses of individuals civilly committed in the United

States. Becker, Stinson, Tromp, and Messer (2003) reported on 120 men petitioned for civil commitment within the State of Arizona using DSM-IV criteria; 14 % had exhibitionism. Levenson (2004) reported on DSM-IV diagnoses of 450 men evaluated for Florida's civil commitment program. Of 229 recommended for commitment, 8 % had a diagnosis of exhibitionism; of 221 recommended for release, 4 % had a diagnosis of exhibitionism. Elwood, Doren, and Thornton (2010) reported on DSM-IV criteria for 331 men committed under Wisconsin's civil commitment program; 7 % had a diagnosis of exhibitionism. Jackson and Richards (2007) reported on a chart review of diagnoses of 190 civilly committed men in Washington State. Diagnostic criteria were not specified but 27 or 14.2 % of subjects received a diagnosis of exhibitionism.

Treatment and Risk Management

The above data suggest that exhibitionism, far from being a nuisance crime, can be associated with other paraphilias and violent sexual behavior. A careful assessment is the cornerstone of any treatment, with establishment of diagnoses and targets for treatment. Alcohol use disorder, drug use disorders, personality disorders, and psychotic disorders increase the risk of relapse of sex offenders (Langstrom, Sjostedt, & Grann, 2004), and it is important to treat these in order to reduce this risk. It also is important to perform a careful risk analysis using a clinical interview and appropriate actuarial instruments. Most treatment studies have been developed with other types of offenders and used with exhibitionists on the expectation that they will be effective (Morin & Levenson, 2008). Cognitive-behavioral treatment, covert sensitization, masturbatory satiation, and relapse prevention are all behavioral methods which can be employed (Abel et al., 1984; Abel & Osborn, 1996; Krueger & Kaplan, 2002a; Maletzky, 1991). Berlin et al. (1991) reported on a 5-year follow-up survey of criminal recidivism in a treated cohort of 111 exhibitionists and found a sexual recidivism rate for this group of 23.4 %; treatment compliant exhibitionists had a 12.5 % sexual recidivism rate. Treatment methods were not specified for the group of exhibitionists in particular, but for the entire cohort of 406 men; the primary mode of treatment was a 90-min group therapy; about 40 % had testosterone-lowering medications. Biological treatments are available but have not been studied on a group of exhibitionists. The largest open label study of androgen reduction therapy for the treatment of individuals with paraphilias was reported by Rosler and Witztum (1998) on a group of 30 males treated with triptorelin for 4 months to 4 years. No one relapsed while on treatment; 7 of these individuals had a diagnosis of exhibitionism. Open treatment of this group has continued, with the number being increased to 100 individuals and the period of follow-up to 15 years, with similar results (Rosler & Witztum, 2009). In our experience (Krueger & Kaplan, 2001) gonadotropin-releasing hormone agonists have worked very well for some exhibitionists who have a high frequency of sexual outlet.

Voyeurism

Epidemiology

Traditionally, individuals in the process of committing voyeuristic acts are arrested for other crimes, such as "trespassing" (in the United States) or "breach of the peace" or "being a public nuisance" (in Great Britain). Therefore, it has been difficult to assess the prevalence of voyeurism. However, in Great Britain in the Sexual Offenses Act of 2003, voyeurism was created as an offense, criminalizing those who watch people engaged in a private act without their consent (The Crown Prosecution Service, 2010). This protects against the installation of cameras in public changing areas or being spied upon inside public buildings where there is an expectation of privacy (Bancroft, 2009) (p. 468). In the United States, Simon (1997) reported on several cases of video voyeurs who had covertly videotaped unsuspecting victims and recommended the inclusion of appropriate criminal sanctions in privacy statutes; these exist in several states. The fact that voyeurism has been added as a separate offense category will make it easier to track its prevalence in the future. Långström and Seto (2006) reported in their study of 2,450 randomly selected 18- to 60-year-olds who were interviewed that 191 (8 %; 12 % of men and 4 % of women) reported at least one incidence of being aroused by spying on unsuspecting others having sex. Mann, Ainsworth, Al-Attar, and Davies (2008) commented that research on voyeurism has been "extremely limited," and there is not nearly the amount of literature on voyeurism that there is on exhibitionism.

Clinical and Other Samples

Clinical or forensic samples have generally found a high rate of voyeurism and of co-occurring paraphilias. Yalom (1960) reported that of 8 voyeurs, only 1 had engaged in exhibitionism; 6 of his patients had serious charges of assault. Gebhard et al. (1965) reported that of 56 voyeurs, 34 of the criminal convictions had been for sex offenses, and of these, 25 (45 %) had been convicted solely of sex offenses; 24 had been convicted of exhibitionism, and 11 had been convicted of offenses involving coercion.

Langevin, Paitich, and Russon (1985) reported on two studies, the first of 422 sexually anomalous men, none of whom were "pure" voyeurs. Of the 45 who admitted to

voyeurism, 33 had masturbated outdoors, 25 exhibited, 22 engaged in frottage, and 20 in toucherism. In a second study of 31 men who admitted to voyeuristic behavior, voyeurism was the dominant outlet for only 7; 24 had engaged in outdoor masturbation and 23 in exhibitionism.

Lang et al. (1987) reported that of 34 exhibitionists, 71 % (22) had peeped at solitary females disrobing, and 41 % (14) had peeped at intercourse. Freund and Blanchard (1986) reported that of 7 voyeurs, 2 had engaged in exhibitionistic behavior and of 86 exhibitionists, 22 were also voyeurs. In an additional analysis of 950 sexual offenders from their clinic, 87 % of those who admitted to voyeurism had at least one other sexual anomaly.

Freund (1990) reported that of 94 men who had admitted to voyeuristic activity, 77 (82 %) had also engaged in exhibitionism, 36 (38 %) had also engaged in toucherism or frottage, and 18 (19 %) had engaged in rape. Ninety percent of these men (85) had engaged in at least one other sexual anomaly. Freund and Watson (1990) reported that of 125 voyeurs, 50 were also exhibitionists, 52 touchers, and 73 (58 %) had other paraphilias (including rape).

Abel and Rouleau (1990) reported that of 62 voyeurs, only 1 was a "pure" voyeur. Six had one additional paraphilia, 17 two additional paraphilias, 9 three additional paraphilias, and the remaining 29 (46.8 %) had four or more additional paraphilias. In another report (American Psychiatric Association, 1999), Abel indicated that 20.2 % of 2,129 patients assessed acknowledged voyeurism. In a more recent report of 47,265 males and 1,684 females, Abel and Wiegel (2009) reported that 6, 525 males (13.8 %) reported voyeurism and 43 (2.6 %) of females reported voyeurism.

Bradford et al. (1992) reported that of 443 adult males studied, 115 admitted to voyeurism, and of these 30 % were diagnosed with heterosexual pedophilia, 30 % with heterosexual hebephilia, 15 % with homosexual pedophilia, 10 % with homosexual hebephilia, 15 % with cross-dressing, 20 % with scatologia (lewdness), 33 % with frotteurism, 23 % with attempted rape, 12 % with rape, and 27 % with exhibitionism.

A study by Templeman and Stinnett (1991) of 60 male college students in a rural town in the United States reported that 42 % had secretly watched others in sexual situations. When students were asked to rank order their preference in a variety of paraphilic behaviors, voyeurism and frotteurism were the most popular.

In a more recent study of 61 adults of both genders in a small town in South India, 41 % reported voyeurism (Kar & Koola, 2007). Rye and Meaney (2007) asked university students about the likelihood on a scale of 1–100 % that they would secretly watch two attractive people having sex or an attractive person undress. When the risk of being caught was changed from 0 to 25 %, the mean likelihood fell from 84 to 61 % for men and 74 to 36 % for women. We have found no reports enumerating the number of victims or victim accounts of voyeurism, although a substantial number must exist, given prosecution for this behavior or crimes, such as trespassing, associated with it.

Offender and Offense Characteristics and Comorbidity

Abel et al. (1988) reported on types of deviant sexual behavior of 561 nonincarcerated paraphiliacs in Memphis, Tennessee, and New York, New York. DSM-II and DSM-III criteria were used, with the modification that one completed act could qualify a subject as making a diagnostic category. Most subjects had a history of multiple paraphilias, and most progressed through a variety of paraphilias to express one, which was preferred. Some expressed several paraphilias at the same time, and subjects could be diagnosed with multiple paraphilias simultaneously. Sixty-two had this as a diagnosis, and only 1.5 % of these had this as a sole diagnosis. Voyeurs had an average of 4.8 paraphilias.

Kafka and Hennen (1999) reported on a sample of 206 consecutively evaluated males seeking help for paraphilias or sexual impulsivity disorders; semistructured intake questionnaires and sexual inventories were used. Of this group, 143 had paraphilias and 35, or 24 %, were voyeurs. Eight-six percent of the group with paraphilias had at least one lifetime paraphilia-related disorder, now known as a hypersexual disorder.

Långström and Seto (2006) additionally reported on association between voyeuristic behaviors and correlates and risk factors. Voyeuristic behaviors were weakly to moderately but positively associated with being male, having more psychological problems, lower satisfaction with life, greater alcohol and drug use, and greater sexual interest and activity in general (more sexual partners, greater arousability, and higher frequency of masturbation and pornography use and greater likelihood of having a same-sex sexual partner).

Diagnosis

The DSM-IV-TR diagnostic criteria for voyeurism are (American Psychiatric Association, 2000):

> A. Over a period of a least 6 months, recurrent, intense, sexually arousing fantasies, sexual urges, or behaviors involving the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity.
> B. The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty. (p. 575)

Långström (2010) reviewed the diagnostic criteria for exhibitionism, voyeurism, and frotteurism for the NB-DSM-5

and made a number of suggestions, some of which were adopted by the workgroup. NB-DSM-5 changed the diagnostic name from voyeurism to voyeuristic disorder. The NB-DSM-5 criteria for voyeuristic disorder are (APA, 2013):

> Voyeuristic Disorder
>
> A. Over a period of at least 6 months, recurrent and intense sexual arousal from observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity, as manifested by fantasies, urges or behaviors.
> B. The individual has acted on these sexual urges with a nonconsenting person, or the sexual urges or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
>
> *Specify if:*
> In a controlled environment: This specifier is primarily applicable to individuals living in institutional or other settings where opportunities to expose one's genitals are restricted.
> In full remission: The individual has not acted on the urges with a nonconsenting person, and there has been no distress or impairment in social, occupational, or other areas of functioning, for at least 5 yeasts while in an uncontrolled environment (p. 686-687).

Virtually all authorities recognize the importance of a clinical interview (Hanson & Harris, 1997; Mann et al., 2008). Freund, Watson, and Rienzo (1988) reported on the Erotic Preferences Examination Scheme (EPES) developed by Freund and others at the Clark, which contains 6 items addressing voyeurism. This scale appears to be clinically useful and has been psychometrically validated. Nichols and Molenda (1984) developed the Multiphasic Sex Inventory (MSI), which has face validity, but its ability to distinguish voyeurs from other groups has yet to be tested (Hanson & Harris, 1997). They have developed a Multiphasic Sex Inventory-II (Nichols and Molenda (2005) which contains items on voyeurism and exhibitionism. The Clarke Sex History Questionnaire (Langevin & Paitich, 2002) contains a six-item peeping scale, but has not yet been used to compare known groups of voyeurs with other paraphiliacs. The Abel-Becker Card Sort (Holland, Zolondek, Abel, Jordan, & Becker, 2000) contains 5 of 75 items targeting voyeurism; it showed a high level of reliability and concurrent validity. We have been unable to locate phallometric studies that differentiate voyeurs from controls, but, in theory, it would be possible to develop such stimuli (Hanson & Harris, 1997).

Risk for Other Crimes and Risk of Recidivism

Ressler et al. (1986) in a study of 28 sexual murderers reported that 71 % had indicated an involvement with voyeurism. Dietz et al. (1990) in a review of 30 sexually sadistic criminals reported that 6, or 20 %, had a history of peeping, obscene telephone calls, or indecent exposure. Hill et al. (2007) reviewing psychiatric and court records of 166 sexual murderers in Germany found that 10, or 6.0 %, had a history of voyeurism. Langevin (2003) reported on a study of 33 sex killers compared with 80 sexual aggressives, 23 sadists, and 611 general sex offenders examining a number of characteristics; he found that 42.42 % of the sex killers were diagnosed with voyeurism, 33.75 % of the sexual aggressives, 34.78 % of the sadists, but only 20.95 % of the general sex offenders.

Another way of determining dangerousness is to examine diagnoses of individuals civilly committed in the United States. Becker et al. (2003) reported on 120 men petitioned for civil commitment within the State of Arizona using DSM-IV criteria; 13 % had voyeurism. Levenson (2004) reported on DSM-IV diagnoses of 450 men evaluated for Florida's civil commitment program; of this group, only 12 had noncontact offenses (exhibitionism, voyeurism, and computer-related sex crimes). Voyeurism was not specifically reported on. Subjects could have more than one diagnosis. Elwood et al. (2008) reported on DSM-IV criteria for 331 men committed under Wisconsin's civil commitment program; voyeurism was not specified. Jackson and Richards (2007) reported on a chart review of diagnoses of 190 civilly committed men in Washington State. Diagnostic criteria were not specified but 12.6 % (24) of subjects received a diagnosis of voyeurism. It should be noted that no studies reported that they had used structured diagnostic instruments to establish paraphilic or other diagnoses and none utilized polygraphy.

Treatment and Risk Management

There are a number of case reports of voyeurs treated with behavior therapy which are described by Mann et al. (2008). Given the popularity of specific cognitive-behavioral treatment for sexual offenders (Marshall, Anderson, & Fernandez, 1999), it is surprising that there are no accounts that we have been able to find of comprehensive cognitive-behavioral treatment of voyeurs. Rather, methods developed on groups of sex offenders generally have been applied to voyeurs (Krueger & Kaplan, 2002a). Likewise, pharmacotherapy has been studied on heterogeneous groups of sexual offenders and used with voyeurs without any controlled documentation of effect for this specific disorder (Gijs & Gooren, 1996; Rösler & Witztum, 2000). Rosler and Witztum (1998) in their series of 30 males treated for 4 months to 4 years identified 2 as having voyeurism. Krueger and Kaplan (2001) in their series of 12 cases treated with depot-leuprolide acetate had 3 individuals whose deviancies included voyeurism; this treatment was given after individuals failed to respond to cognitive-behavioral treatment and in once case to depot-provera. A new algorithm for biological

treatment has been proposed (Thibaut et al., 2010) which may be consulted and which contains only suggestions for treatments for paraphilias in general but not for specific paraphilias such as voyeurism. As with all sex offenses, it is important to complete a comprehensive assessment using appropriate actuarial instruments and treat disorders which are related to the criminal behavior in order to reduce recidivism (Andrews & Bonta, 2006; Kutcher, 1982; Langstrom et al., 2004).

Possession of Child Pornography

Prevalence

The Internet has transformed child pornography into a lucrative criminal trade (Bryan-Low, 2006). *The Wall Street Journal* reported in 2006 an estimate that the child pornography business could bring in billions of dollars annually (Bryan-Low, 2006). Along with the growth of child pornography, there has been a growth of arrests for federal offenses against children. Motivans and Kyckelhahn (2007) reported that during 2006, 3,661 suspects were referred to US attorneys for offenses involving child sexual exploitation. Six in 10 child sex crime suspects were prosecuted in 2006, up from 4 in 10 in 1994. Child pornography offenses constituted 69 % of these referrals, followed by sex abuse (16 %) and sex transportation (14 %). Overall, 9 of 10 defendants were convicted and sentenced to prison, up from 8 in 10 in 1994. Wolak, Finkelhor, and Mitchell (2009) reported that including the Internet Crimes Against Children agencies and State and Local Agencies, the total number of arrests for online child sexual exploitation crimes (including both child pornography and exploitation of children) had increased from 2,577 in 2000 to 7,010 in 2006, an increase of 272 %. There was also an increase in the median prison sentence from 36 months to 63 months over this period; most suspects were white, male, US citizens, and had attended some college. Federal arrests for child sex offenses have grown at a 15 % rate, making these among the fastest growing crimes in the federal justice system (Motivans & Kyckelhahn, 2007). Under one federal statute (18 U.S.C. 2252) used to prosecute child pornography, convictions rose from 58 in 1994 to 442 in 2000 to 1295 in 2008 (Stewart, 2009).

Furthermore, sentences for such crimes are increasing (Hessick, 2010). In 1990, federal law punished the possession of child pornography by up to 10 years of imprisonment; in 1996, this was increased to 15. In 2003, a mandatory minimum of 5 years sentence was added, and the statutory maximum was raised to 20 years. All 50 states have specific provisions criminalizing the possession of child pornography, and 30 states have increased penalties for possession of child pornography since criminalizing it (Hessick, 2010).

Offender and Offense Characteristics and Comorbidity

Most studies to date have reported on demographic and psychological features of men arrested for child pornography or reported on the relationship between child pornography offenses and contact sexual offenses, but have not examined psychiatric diagnoses in this population. Galbreath, Berlin, and Sawyer (2002) reported on a review of cases of 39 outpatients who had entered their program for sexual problems involving the Internet. Of these, 54 % had looked at child pornography, and 33 % had tried to meet a minor over the Internet for sexual purposes. Of the whole group, 49 % received a diagnosis of paraphilia not otherwise specified (which was not further characterized), 23 % pedophilia, 8 % voyeurism, 3 % exhibitionism, and 18 % received no paraphilic diagnosis.

Quayle and Taylor (2002) reported on interviews of 13 men convicted of downloading child pornography; of these, 4 had also been convicted of assault on children. Frei, Erenay, Dittmann, and Graf (2005) reviewed files of 33 offenders convicted of child pornography in Switzerland; only 1 had a "relevant" criminal record, suggesting that most had not been arrested for sexual offenses before. Alexy, Burgess, and Baker (2005) reviewed 225 cases published in the news media, classifying these as "traders" (individuals who traded or collected child pornography), "travelers" (individuals who engaged in discussion with children online and used their skills at manipulation to try and meet a child for sexual purposes), and "trader-travelers" (individuals who engaged in both activities). They found no common profile and suggested that the classification of Internet offenders would be complicated.

Wolak, Finkelhor, and Mitchell (2005b) in a study regarding child pornography offenders reported that law enforcement agencies made an estimated 1,713 arrests nationally during the 12 months beginning July 1, 2000. Ninety-one percent of these men were white, 8 % older than 25, and 3 % younger than 18. Eighty-three percent had images of prepubescent children, 80 % of these graphically depicting sexual penetration. Twenty-one percent had images depicting sexual violence toward children, such as torture, rape, or bondage; 39 % had at least 1 video depicting child pornography. Forty percent of those arrested for child pornography were "dual offenders" who both sexually victimized children and possessed child pornography with both crimes discovered in the same investigation. In the overall study, 39 % of arrested offenders who met victims online and 43 % of offenders who solicited undercover agents were dual offenders. Ninety-six

percent of child pornography offenders were convicted or pled guilty, and 59 % were incarcerated.

Seto, Cantor, and Blanchard (2006) assessed 685 men referred to their clinic with penile plethysmography and found that possession of child pornography was a valid diagnostic indicator of pedophilia as represented by an index of phallometrically measured sexual arousal toward children. Indeed, as a group, child pornography offenders showed greater arousal to children than to adults and demonstrated greater arousal to children than did contact sex offenders against children, sex offenders against adults, and general sexology patients. Conversely, Blanchard et al. (2007), in an analysis of 832 males assessed in their clinic with plethysmography, reported the absence of any relations between output index (a measure of phallometric response to stimuli involving children) and child pornography offenders. The difference in the two studies can be explained by a difference in the two types of plethysmographic analyses. In the study by Seto et al. (2006), plethysmographic responses for each individual were ipsatively standardized, i.e., each subject's phallometric test scores were transformed to have a mean value of zero and a standard deviation of one, which allowed for the computation of the relative interest of a subject in various categories of stimuli. In the later study by Blanchard et al. (2007), absolute values (an output index) were used. These absolute values showed no relation to child pornography offenses. Given that men whose primary sexual interest is in adults can also have substantial responses to stimuli of prepubescent or pubescent children, relative ascertainment of interests is imperative (Blanchard et al., 2009). What is important is not that a patient or subject becomes aroused to a stimulus but how aroused they become to a particular category of stimuli compared with other categories of stimuli. Blanchard et al. (2007) also reported that child pornography offenders were more apt to be intelligent and better educated. Seto, Reeves, and Jung (2010) reported that about half of a combined sample of 84 child pornography offenders acknowledged that child pornography was sexually arousing. Wolak, Finkelhor, and Mitchell (2005a) reported the typical child depicted in child pornography is a prepubescent girl.

A study by Webb, Craissati, and Keen (2007) compared a group of 90 individuals convicted of charges involving child pornography with 120 child molesters. Internet offenders reported more psychological difficulties in adulthood and fewer prior sexual convictions. They were less likely to fail in the community and had fewer antisocial behaviors. A study by Elliott, Beech, Mandeville-Norden, and Hayes (2009) compared a group of 505 Internet sex offenders (convicted of charges involving child pornography) with 526 contact sex offenders on a range of psychological measures and found that the pornography offenders could be successfully discriminated from the contact offenders on 7 out of 15 measures, with elevated scores on scales of fantasy, underassertiveness, and motor impulsivity associated with the Internet offense type and an increase in scores of scales of locus of control, perspective taking, empathic concern, overassertiveness, victim empathy distortions, cognitive distortions, and cognitive impulsivity predictive of a contact offense type.

Bates and Metcalf (2007) compared psychometric test assessments of 39 men convicted of noncontact Internet sex offenses with 39 men convicted of contact offenses against a specific victim. The Internet group had higher rates of socially desirable responding, emotional loneliness, and underassertiveness and lower scores on external locus of control, sexualized attitudes toward children, emotional congruence with children, and empathy distortions with regard to victims of abuse.

Krueger, Kaplan, and First (2009) reported on a chart review of 60 males arrested for crimes against children involving the Internet; of this group, 63 % (38) were arrested for possession of child pornography, and the second group of 22 were arrested for attempting to meet a child (with 20 of 22 of this group also possessing child pornography). Of the entire group, 40 % had at least one paraphilia; 31 % had a diagnosis of pedophilia, and 18 % of a paraphilia not otherwise specified, characterized by a dysfunctional interest in teenagers. Thirty-three percent had a sexual disorder not otherwise specified or a hypersexual disorder. Individuals arrested for pornography only were significantly more likely to have a diagnosis of hypersexual disorder characterized by pornography dependence, and those arrested for trying to meet a child over the Internet were significantly more likely to have a diagnosis of hypersexual disorder characterized by cybersexual dependence. There was no significant difference in the frequency of paraphilic diagnoses in the group arrested for possession only compared with the group arrested for trying to meet a child. Of the entire group, only 1 had a conviction for a prior sexual crime (which involved trying to meet a child over the Internet) and 2 for prior nonsexual crimes. There was also a very substantial comorbidity, with 70 % having an active Axis I disorder associated with the criminal behavior leading up to their arrest. Thirty-seven percent had an associated mood disorder at the time of the commission of the crime and 23 % a substance use disorder. This high rate of comorbidity has been reported in previous studies of men arrested for crimes against children over the Internet (Galbreath et al., 2002), hypersexual males (Black, 1998, 2000), and contact sexual offenses (Dunsieth et al., 2004; McElroy et al., 1999; Raymond et al., 1999). The high rate of paraphilias and of hypersexual disorders has a direct relationship to the criminal behavior. The other comorbid disorders (primarily affective and substance use disorders) have a more indirect relationship. This may stem from some common underlying genetic diathesis, from common environmental or familial influences (such as familial sexual abuse

predisposing to depression, substance use disorders, and a higher likelihood to engage in sexual abuse) or from stressors in the environment impacting on both sexual and mood regulatory systems.

McCarthy (2010) reported on a record review of 107 adult male sex offenders who had participated in a sex offender treatment program in New York City. All offenders had a history of conviction for possession of child pornography, and each offender had passed a polygraph examination concluding that he either had or did not have a history of sexually abusing a minor. Additionally, offenders who admitted to sexually abusing a minor in the absence of a polygraph examination were included. The records were divided into two groups, noncontact offenders ($n=56$) and contact offenders ($n=51$). Diagnoses were made using DSM-IV criteria (American Psychiatric Association, 1994), and in addition, an Abel Assessment (Abel, 1995b), clinical interview, self-report, and records were used to make diagnoses. For the group as a whole, results showed that 82.2 % were white, and 55.1 % were single and had never married. Thirty-five percent had some college, 2 % completed undergraduate school, and 10 % graduate school. Twenty-seven percent of offenders had a history of drug use and 21 % of alcohol abuse, 29 % a history of depression, and 35 % a history of anxiety. Fourteen percent had more than one conviction for a sexual crime, and 21 % had a conviction for a nonsexual crime. Fifty-two percent received a diagnosis of pedophilia, with 26 % of those attracted to females, nonexclusive type. Comparing the two groups, there was no statistically significant difference in age, time at which offenders began viewing Internet child pornography, race/ethnicity, marital status, education attainment, or history of childhood abuse. However, contact offenders were more likely than noncontact offenders to have a history of drug abuse, more than one conviction for a sexual crime, and to receive a diagnosis of pedophilia. Contact offenders were more likely than noncontact offenders to masturbate to child pornography and download child pornography to an external medium. There were no significant differences between groups in trading, paying for, concealing, or organizing child pornography, but when these variables were combined, offenders who engaged in a combination of these behaviors were more likely to be part of the contact group. Contact offenders were more likely than noncontact to view child modeling websites and view erotic stories involving minors. Contact offenders had significantly more involvement with minors online than noncontact offenders, being more likely to chat in a sexual manner, send child pornography, adult pornography, and attempt to meet a minor. Contact offenders were more likely than noncontact to communicate both online and in person with others who shared their deviant interests. The percentage of offenders trading adult pornography online and paying for adult pornography online was higher for adult offenders. Contact offenders were more likely to engage in cybersexual behavior with adults than noncontact offenders.

Henry, Mandeville-Norden, Hayes, and Egan (2010) reported on a cluster analysis of 422 men who were Internet-based sex offenders; this sample was extracted from an initial group of 633 participants, with missing data precluding 211 offenders from the analysis. Of the initial sample, 594 (93.8 %) were convicted of making indecent images of children, 38 (6 %) of taking indecent images of children, and 1 (0.2 %) of inciting a child into sexual activity. Three clusters were identified, the apparently normal, the inadequate, and the deviant. Overall, the clusters were equivalent to contact sexual offender groupings.

Sheehan and Sullivan (2010) reported on an in-depth study of four males convicted of manufacturing indecent images of children. While all made reference to the Internet as having an impact on their sexual interest in children, analysis suggested that most had developed a sexual interest in children before using the Internet. All had downloaded indecent images of children prior to embarking on the manufacture of images.

Diagnosis

The DSM-IV-TR criteria for pedophilia are relevant for the assessment of individuals involved with child pornography. These are (American Psychiatric Association, 2000):

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger).
B. The person has acted on these sexual urges, or the sexual urges or fantasies cause marked distress or interpersonal difficulty.
C. The person is at least age 16 years and at least 5 years older than the child or children in Criterion A.

Note: Do not include an individual in late adolescence involved in an ongoing sexual relationship with a 12- or 13-year old.
Specify if:
Sexually Attracted to Males
Sexually Attracted to Females
Sexually Attracted to Both
Specify if:
Limited to Incest
Specify type:
Exclusive Type (attracted only to children)
Nonexclusive Type (p. 572)

Blanchard (2010a) reviewed the diagnostic criteria for pedophilia and recommended several significant changes; he wrote, "I recommend that, for diagnostic purposes, photographed children and impersonated children be treated the same as real children." His recommendations were discussed with the workgroup, posted on the NB-DSM-5 website, and modified. These suggestions have been the focus of criticism

and response (Blanchard, 2010; First, 2010; Moser, 2010). Ultimately Blanchard's suggestion for renaming Pedophilia to Pedohebephilic Disorder was rejected. The name of the diagnosis was changed from Pedophilia to Pedophilic Disorder, and the criteria used were drawn almost unchanged from DSM-IV-TR (the only change being the substitution of the word "individual" for the word "person." These criteria are as follows:

Pedophilic Disorder

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger.).
B. The individual has acted on these sexual urges, or the sexual urges of fantasies cause marked distress or interpersonal difficulty.
C. The individual is at least age 16 years and at least 5 years older than the child or children in Criterion A. Note: Do not include an indivdual in late adolescence involved in an ongoing sexual relationship with a 12- or 13-year-old.

Specify whether:
Exclusive type (attracted only to children)
Non exclusive type

Specify if:
Sexually attracted to males
Sexually attracted to females
Sexually attracted to both

Specify if:
Limited to incest

It should be noted that the new criteria now include the use of child pornography under B3. The occurrence of hypersexuality in association with the Internet (Bancroft, 2009), the co-occurrence of hypersexual and paraphilic disorders (Kafka & Hennen, 1999; Kafka & Prentky, 1992), and the study by Krueger et al. (2009) suggest that another diagnosis suggested by the NB-DSM-5 Workgroup would be relevant, that of hypersexual disorder.

The support for this possible diagnostic category was reviewed by Kafka (2010b). It has not been without its critics and debate (Kafka & Krueger, 2011; Kaplan & Krueger, 2010a; Moser, 2011; Winters, 2010; Winters, Christoff, & Gorzalka, 2010). The Paraphilias Workgroup proposed criteria which were posted on the NB-DSM-5 website of the APA; these criteria are no longer available on the APA website. The criteria proposed were quite similar to those originally suggested by Kafka (2010) in his review for the proposed diagnosis of Hypersexual Disorder and these criteria were as follows:

Proposed Diagnostic Criteria for Hypersexual Disorder

A. Over a period of at least 6 months, recurrent and intense sexual fantasies, sexual urges, or sexual behaviors in association with 3 or more of the following 5 criteria:
   (1) Time consumed by sexual fantasies, urges or behaviors repetitively interferes with other important (non-sexual) goals, activities and obligations.
   (2) Repetitively engaging in sexual fantasies, urges or behaviors in response to dysphoric mood states (e.g., anxiety, depression, boredom, irritability).
   (3) Repetitively engaging in sexual fantasies, urges or behaviors in response to stressful life events.
   (4) Repetitive but unsuccessful efforts to control or significantly reduce these sexual fantasies, urges or behaviors.
   (5) Repetitively engaging in sexual behaviors while disregarding the risk for physical or emotional harm to self or others.
B. There is clinically significant personal distress or impairment in social, occupational or other important areas of functioning associated with the frequency and intensity of these sexual fantasies, urges or behaviors.
C. These sexual fantasies, urges or behaviors are not due to the direct physiological effect of an exogenous substance (e.g., a drug of abuse or a medication).

Specify if:
Masturbation
Pornography
Sexual Behavior with Consenting Adults
Cybersex
Telephone Sex
Strip Clubs
Other: (p. 379)

Glasgow (2010) described the use of digital evidence to aid in risk assessment of Internet offenders; it can also be very useful for diagnosis, given the new criteria for pedophilia. A forensic analysis of the computer's content is exceedingly important. How many images are there? Are they still or moving? What dates do they span? Are they segregated or organized? What proportion of the images is of minors and what proportion is of adults? What proportion is prepubescent, pubescent, or older? What proportion is male or female? Is there any evidence that the individual has tried to communicate with minors? Is there any evidence that the individual being investigated has produced images of themselves? What sort of control does the individual report over urges/impulses to view images?

Obviously, here the use of plethysmography, viewing time, and polygraphy, as well as the usual instruments used to assess individuals with pedophilia, can be used to assist in diagnosis.

Risk for Other Crimes and Risk of Recidivism

Wolak et al. (2005b) reported on 429 cases of individuals where data was obtained by interviewing detectives about details of their cases of child pornography arrests made in the year 2000, only 14 % of which were prosecuted in federal courts. Eleven percent had a previous arrest for a sex offense against a minor, and only 3 % were diagnosed with a sexual disorder.

Seto and Eke (2005) identified a sample of 201 adult male child pornography offenders using police databases; 56 % had

a prior criminal record, 24 % a prior contact sexual offense, and 15 % prior child pornography offenses. During an average time at risk of 2.5 years, 17 % of the sample offended again in some way during this time, and 4 % committed a new contact sexual offense. Child pornographer offenders with prior criminal records were more likely to reoffend in any way during the follow-up period, and child pornography offenders who had committed a prior or concurrent contact sexual offense were most likely to reoffend, generally or sexually. In a follow-up study (Eke, Seto, & Williams, 2011), the follow-up time for this sample was extended to 5.9 years, and the same data were obtained for another 340 offenders, increasing the full sample to 541 men, with a total average follow-up tie of 4.1 years. In this new sample, 34 % of offenders had a new charge for any type of reoffense, with 6 % charged with a contact sexual offense against a child and additional 3 % charged with historical contact sex offenses (i.e., previously undetected offenses). There was a 32 % recidivism rate for any crime for the full sample; 4 % of offenders were charged with new contact sex offenses, an additional 2 % of offenders were charge with historical contact sex offenses, and 7 % of offenders were charged with a new child pornography offense. Predictors of new offending were prior offense history and younger offender age. Approximately one-quarter of offenders on probation were sanctioned for a failure on conditional release; in half of these failures, offenders were in contact with children or used the Internet to again access to pornography.

Webb et al. (2007) found that the Stable-2000 (Hanson et al., 2007; Harris & Hanson, 2003), which is an actuarial measure of potentially changeable risk factors, was able to significantly predict "risky sexual behavior" and probation failures in a group of online offenders (none of the child pornography offenders committed another contact offense in the 18-month follow-up period).

In an oft-cited study, Bourke and Hernandez (2009) reported on a group of 155 sexual offenders in an intensive, residential sex offender-specific treatment program at a medium-security federal prison. At the time of sentencing, 115 (74 %) of subjects had no documented hands-on victims. The treatment program was 18 months long, and 80 subjects (52 %) participated in voluntary polygraph examinations. Among these offenders, by the end of the study, 24 % indicated during treatment that they had victimized children of both genders, and 48 % said that they had abused both prepubescent and postpubescent victims. This study was severely criticized in a legal opinion (United States District Court, 2008) which opined, among other things, that the study was not credible, saying that it was "highly coercive" because there was testimony to the effect that unless offender continued to admit to further sexual crimes and say whether or not they had committed them, they were discharged from the program. Thus, they had an incentive to lie. Furthermore, 46 of 201 individuals (23 %) left due to "voluntary withdrawal, expulsion, or death," which was not reported and which would have skewed the results.

Endrass et al. (2009) reported on a group of 231 men in Switzerland who were charged with consumption of illegal pornographic material; the follow-up period was from 2002 to 2008. Two (1 %) members of this sample had a prior conviction for a hands-on sex offense involving child sexual abuse, 8 (3.3 %) for a hands-off sex offense, and 1 for a nonsexual violent offense. Applying a definition of recidivism that included charges and convictions, 9 (3.9 %) of the study sample recidivated with a hands-off sex offense and 2 (0.8 %) with a hands-on sex offense.

Babchishin, Hanson, and Hermann (2010) reported on a meta-analysis of online offenders and off-line offenders to examine the extent to which they differed on demographic and psychological variables. Twenty-seven distinct samples were identified, only 13 of which were classified as published materials; the online offenders were not partitioned into those involved with child pornography only and those involved with trying to meet a child over the Internet. Overall, online offenders were more likely to be Caucasian, slightly younger, had greater victim empathy, greater sexual deviancy, and lower impression management than off-line offenders.

Neutze, Seto, Schaefer, Mundt, and Beier (2010) reported on a sample of 155 self-referred pedophiles and hebephiles (individuals sexually attracted to pubescent children) in Germany. It was explained that a distinctive feature of German law is that there is no mandatory child abuse reporting in Germany unless there is evidence of an imminent risk of child sexual abuse and homicide. Thus, participants were free to report recent crimes. Two sets of group comparisons were conducted on sociodemographic variables and dynamic risk factors. The first was based on recent activity and compared men who had committed child pornography offenses only or child sexual abuse offenses only in the prior 6 months with men who had remained offense free in the same period. The second was based on lifetime offenses prior to the recent 6-month period and compared child pornography offenders with child sexual abuse offenders and men who had committed both kinds of offenses. For the recent offenders, the groups differed only with respect to risk awareness, with recent child sexual abuse offenders demonstrating significantly more awareness of risky situations than recent child pornography offenders or recently inactive participants. In the recent groups, recent child sexual abuse offenders were more likely to be unemployed than child pornography offenders or inactive participants, and the vast majority of recent child sexual abuse offenders admitted prior sexual abuse offenses. No group differences were found for lifetime offense history; child sexual abuse offenders were significantly older than child pornography-only offenders. The overall pattern of

findings was characterized much more by similarities across the groups than by differences.

Seto, Hanson, and Babchishin (2011) reported on two meta-analyses involving "online offenders." The first included both offenders involved with the possession or distribution of child pornography or other illegal pornographic content via the Internet and those who used the Internet to solicit minors for sexual purposes. Twenty-four samples with relevant data were included; 12 % had an officially known contact history at the time of their index offense and 55 % of online offenders admitted to a contact sexual offense in the six studies that had self-report data. The second meta-analysis included child pornography offenders only and included 12 samples; it revealed that 4.6 % of online offenders committed a new sexual offense during the 1.5–6-year follow-up period; 2.0 % committed a contact sexual offense, and 3.4 % committed a new child pornography offense. The authors suggested that there could be a distinct subgroup of online-only offenders who posed a relatively low risk of committing contact sexual offenses in the future.

Treatment and Risk Management

Treatment and risk management will again be guided by a comprehensive assessment including use of actuarial instruments. While many of the same static risk factors that underlie the Static-99 or Static-99R (Harris et al., 2003) apply to online offenders, these instruments would have to be modified before being used because current coding rules preclude their use with child pornography offenders with no identifiable victim (Seto, Hanson & Babchishin, 2011). It should be noted that the Static-99 and Static-99R can be used with offenders who have only committed exhibitionism, voyeurism, or lewd Internet chat with minors (Harris et al., 2003). It cannot be used if the offender only has a category B offense, which includes:

> Consenting sex with other adults in public places, crimes relating to child pornography (possession, selling, transporting, creating where only pre-existing images are used, digital creation of), indecent behavior without a sexual motive (e.g., urinating in public), offering prostitution services, pimping/pandering, seeking/hiring prostitutes, solicitation of a prostitute (p. 15) (Harris et al., 2003).

It can be used with child pornography offenders if they also have a category A offense involving a hands-on victim. In addition, other instruments are valid with this population. The Sex Offender Risk Appraisal Guide can be directly applied (Quinsey et al., 2006; Seto, Hanson & Babchishin, 2011), as can the Level of Service/Case Management Inventory (Andrews, Bonta, & Wormith, 2004). Should the offender be diagnosed with a hypersexual disorder, then treatment focused on that behavior is indicated; generally behavioral techniques have been borrowed from treatment of the paraphilias or substance abuse disorders, and there are not well-developed treatment standards (Kaplan & Krueger, 2010a; Krueger & Kaplan, 2002a). Twelve-step programs may be useful (Krueger & Kaplan, 2002b) for individuals who have contact offenses or who have been diagnosed with pedophilia, then the usual actuarial instruments and traditional methods of treatment may be employed (Seto, 2008). Software is regularly installed by probation to monitor for use of illicit or licit pornography or other communications that may be of concern, such as emails to minors.

Interacting with Children Over the Internet

Prevalence

In a telephone survey in 2000 of 1,501 youths ages 10–17, Finkelhor, Mitchell, and Wolak (2000) reported that approximately 1 in 5 had received a sexual solicitation or approach over the Internet in the prior year; 1 in 4 had an unwanted exposure to pictures of naked people or people having sex. A second telephone survey (Mitchell, Wolak, & Finkelhor, 2007; Wolak, Mitchell, & Finkelhor, 2007) in 2005 of 1,500 youths, 10–17 reported that 44 % had been exposed to online pornography in the previous year; of those, 66 % reported an unwanted exposure. The authors reported that there was a decline in the percentage of youth reporting sexual solicitations for both boys and girls in all age groups, except for minority youth and those living in less affluent households. Internet use had expanded rapidly among this age group from 25 % in 1999–2000 to 87 % in 2005.

Wolak et al. (2009) collected information from a national sample of law enforcement agencies about the prevalence of arrests for online sex crimes against minors during two 12-month periods for their National Juvenile Online Victimization Study. The first period was from July 1, 2000 through June 30, 2001 (Wave 1) and the second was for calendar year 2006 (Wave 2). Data from 612 interviews from Wave 1 and 1,051 interviews from Wave 2 were collected. In 2000, there were 508 arrests of offenders using the Internet to seek sex with minors; in 2006, there were 615, a 21 % increase. In 2000, there were 664 arrests of offenders by undercover agents posing as minors; in 2006, this increased to 3,100, an increase of 381 %. However, arrests of online offenders in 2006 only constituted approximately 1 % of all arrests for sex crimes committed against children and youth. Most online victims were adolescents, rather than younger children; 73 % percent were ages 13–15. Most victims were girls (84 %), but 16 % were boys. Sexual violence against victims was rare, occurring in 5 % of arrests in 2006. Seventy-three percent of cases with youth victims progressed from online contact to face-to-face meetings and illegal sexual

activity. There was a significant increase in arrests of young adult offenders. Only 4 % of those arrested were registered sex offenders. The authors concluded that offenders who victimized children previously known to them within networks or families were much more common than those who used the Internet to meet strangers.

Offender and Offense Characteristics and Comorbidity

Mitchell, Wolak, and Finkelhor (2005) presented a study of 124 offenders who were arrested during proactive investigations on the Internet (i.e., in the course of interacting with an undercover agent posing as a minor as opposed to actually having victimized a minor). Comparing demographic characteristics, all but one of those arrested was male, 7 (10 %) were age 18–25, 62 (61 %) were age 26–39, and 52 (33 %) were age 40 or older. One-hundred and ten (91 %) were white, 7 (4 %) Hispanic, and 3 (1 %) African American. Two (2 %) had not finished high school, 38 (26 %) were high-school graduates, 20 (13 %) had finished some college, and 11 (5 %) had a postgraduate degree. Forty-six (34 %) were single and/or never married, 39 (35 %) were married, 4 (3 %) were living with a partner, 8 (7 %) were divorced, and 26 (19 %) were separated. One-hundred and seven (91 %) were employed full time, 9 (6 %) part-time, 8 (4 %) were unemployed, and 4 (2 %) were in school. Case characteristics were very similar between proactive investigations that involved an undercover agent and juvenile victim investigations that involved an actual victim, except that the mean age of the victim was less for proactive investigations (13.8 years vs. 14.4 years). The Internet chat rooms that actual offenders met children in were less sexually oriented than chat rooms used by undercover operatives. Comparing offender characteristics in those arrested in proactive investigations with those arrested with actual juvenile victims, offenders were older in proactive investigations (mean age 37.7 vs. 34.7), and they were more likely to be employed full time. Offenders arrested with actual juvenile victims, on the other hand, were more likely to have committed violent behavior, to have a prior arrest for a nonsexual offense, and a prior arrest for a sexual offense against a minor.

Wolak, Finkelhor, and Mitchell (2004) in a telephone survey of 2574 law enforcement agencies conducted between October of 2001 and July of 2002 identified 129 sexual offenses against juvenile victims that originated with online encounters. Victims were mainly 13- through 15-year-old girls (75 %) who met adult offenders (76 % older than 25) in Internet chat rooms. Most offenders did not deceive victims about the fact that they were adults. Most of these victims had sex with the adults on more than one occasion, and half of the victims described themselves as being in love or feeling close to their offenders; almost all the cases of male victims involved male offenders. Violence was used in 5 % of episodes.

Krueger et al. (2009) reported that of a sample of 22 males arrested for attempting to meet a child, 8 (36 %) of this group were diagnosed with pedophilia by DSM-IV-TR criteria, 6 (27 %) with a paraphilia not otherwise specified, with an interest in adolescents, and only 1 (4.5 %) with another paraphilia. Eight (36 %) of this group had cybersexual dependence, which significantly differentiated them from the group arrested for child pornography only. None of this group had pornography dependence. Fourteen (64 %) of this group had a depressive disorder, 6 (27 %) had an alcohol use disorder, and 3 (14 %) had a substance use disorder. Thus, there was a high instance of comorbid psychiatric disorder in this group.

Diagnosis

The same DSM-IV-TR and NB-DSM-5 diagnoses used for child pornography offenders in the previous section are appropriate for this group of Internet offenders. Likewise, hypersexual disorder, described in the previous section, is appropriate, except the main types of possible relevant diagnosis would be cybersexual disorder and pornography dependence. Frequently, individuals arrested for trying to meet a minor on the Internet will also be found to have child pornography and may meet criteria for pornography dependence as well. The forensic evidence from the computer or other media (cell phones, blackberries) is important, especially transcripts and chat logs.

Risk for Other Crimes and Risk of Recidivism

Krueger et al. (2009) reported that 20 of 22 subjects arrested for trying to meet a child over the Internet also had charges involving child pornography. Mitchell et al. (2005) reported that 62 (41 %) of offenders arrested in proactive investigations and 53 (39 %) of offenders arrested with juvenile victims were found to be in possession of child pornography. Five percent of offenders arrested in proactive investigations and 14 % of offenders arrested with juvenile victims had a prior arrest for a sexual offense against a minor.

Treatment and Risk Management

Treatment and risk management should be guided by a thorough assessment. It is appropriate to use the Static-99 as well as other actuarial instruments if the offender believed that he was interacting with a minor (Harris et al., 2003). Should the offender be diagnosed with a hypersexual disorder, such as cybersexual disorder or pornography dependence, then treat-

ment focused on that behavior is indicated (Kaplan & Krueger, 2010a; Krueger & Kaplan, 2002a). Treatment should be guided by diagnoses and involve standard treatment offered to those with paraphilias or sex offenses (Abel et al., 1984; Marshall & Laws, 2003; Seto, 2008). Elliot, Findlater, and Hughes (2010) described a program in Great Britain using software that examined computers for specific inappropriate words and phrases, the results of which were monitored remotely by officers. Probation and parole officers in the United States regularly use monitoring software to survey for illicit pornography or communications.

Conclusions and Future Directions

The research reviewed above suggests that some "nuisance crimes" or "noncontact offenses" can be associated with more severe crimes and psychopathology. Clinicians should conduct a thorough assessment to determine risk when evaluating this population.

All of the studies except that by Långström and Seto (2006) are based on samples that are skewed or biased and that collect unrepresentative data. Some of the studies cited in this paper made diagnoses or established a paraphilia by as little as a single act, thus inflating the number of purported paraphilias that an individual has. Furthermore, generalizations from samples of convenience must be done with great caution. It is thus important to remember that much of the current information concerning these paraphilias is limited.

Several studies suggested that child pornography offenders are different from conventional sex offenders, with a lower risk for contact offenses. Given the very substantial penalties that exist for crimes involving child pornography, further research needs to be conducted with a focus on recidivism and on characteristics that predict recidivism. Actuarial instruments should be extended or developed for this population.

Currently, misdemeanors are not reported in any national crime database in the United States, and it is thus not possible to track the incidence of such crimes as exhibitionism or voyeurism; it would be advantageous to do so.

Epidemiological studies need to be done cross-nationally which can report on the prevalence of paraphilias. Metrics that would ascertain if someone has a paraphilia, diagnose a paraphilic disorder, and contain elements of duration, impact on functioning, and severity should be included in such studies.

Hypersexuality Disorders and Sexual Offending

Drew A. Kingston

Hypersexual Disorder is a clinical syndrome characterized by diminished control over excessive sexual fantasies, urges, and/or behaviors, which are accompanied by adverse consequences and/or personal distress (Gold & Heffner, 1998; Kafka, 2001). Hypersexual Disorder was considered for inclusion in the Sexual Disorders section of DSM-5 (www.dsm5.org) and then in the Appendix for disorders requiring further research. Hypersexual Disorder was ultimately rejected for inclusion in the Appendix. It is generally accepted that the incidence of hypersexual disorder is likely to be low, representing approximately 3–6 % of the general population (Black, 2000; Carnes, 1989; Coleman, 1992; Goodman, 1993), although higher rates are evident in specific populations, such as sexual offenders (Marshall & Marshall, 2006; Marshall, O'Brien, & Kingston, 2009).

Hypersexuality is particularly relevant in forensic settings because of its association with sexual aggression demonstrated in noncriminal sexual aggressors (Malamuth, 2003) and sexual offenders (Hanson & Morton-Bourgon, 2005; Kingston & Bradford, 2013; Knight, 2010). Unfortunately, problems defining and conceptualizing hypersexual disorder, and the lack of clear nosological criteria, have precluded effective assessment and treatment of this syndrome, particularly as it presents among sexual offending populations.

In this chapter, the extant literature on sexual behaviors that are considered excessive and problematic in both forensic and non-forensic populations is reviewed. Current perspectives regarding conceptualization, diagnosis, assessment, and treatment are also critically reviewed. Although excessive sexual behavior has been variously defined (e.g., sexual addiction, compulsive sexual behavior, sexual impulsivity), the term "hypersexual disorder" will be used throughout this review. As indicated below, features of hypersexual disorder are evident among paraphilic and normophilic sexual behaviors (i.e., sexual behaviors that are culturally sanctioned). This chapter is focused predominantly on culturally normative and excessive sexual behavior.

Defining and Conceptualizing Hypersexual Disorder

Hypersexual disorder is a controversial and elusive concept to define and measure (Giles, 2006; Gold & Heffner, 1998; Levine & Troiden, 1998; Rinehart & McCabe, 1997), and there has been a lack of consensus regarding terminology, definitional properties, symptomatology, and appropriate classification of this syndrome (Kingston & Firestone, 2008; Walters, Knight, & Langstrom, 2011). Historical descriptors have included nymphomania, Don Juanism, and erotomania and have coincided with predominant sociocultural attitudes of the time (Rinehart & McCabe, 1997). More recent labels have included sexual compulsivity, sexual impulsivity, and sexual addiction, which were based on the perceived psychopathological mechanisms guiding behavior (Kafka, 2007).

Despite such descriptive diversity, there is some agreement regarding the essential features of hypersexual disorder, such as the presence of volitional impairment over sexual fantasies, urges, and behaviors, and that these features are repetitive and persistent (Kafka, 2007, 2010; Kingston & Firestone, 2008). In addition, an essential component of the disorder is that the sexual thoughts or behaviors result in some form of personal distress and/or adverse consequences. Several personal distress features associated with hypersexuality have been identified, including social (e.g., relationship instability), emotional (e.g., anxiety, depression), physical (e.g., HIV infection), and legal consequences (e.g., incarceration) (Kafka, 2007; Kalichman & Rompa, 2001; Långström & Hanson, 2006; Schneider, 2004).

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_7

Hypersexual behaviors can manifest as impersonal and/or solo sexual activity (e.g., frequent masturbation, pornography use) or as relational sexual acts (e.g., sex with numerous partners over brief time periods) (Kingston & Firestone, 2008). A further distinction can be made between repetitive sexual fantasies, urges, and behaviors that are excessive but culturally sanctioned (e.g., masturbation, sex with several consenting adults over brief periods of time), referred to as normophilic, and fantasies or behaviors that are defined as paraphilic; that is, directed toward nonhuman objects, the suffering or humiliation of oneself or one's partner, or children/nonconsenting partners (Kingston, Firestone, Moulden, & Bradford, 2007; Kingston, Seto, Firestone, & Bradford, 2010; Kingston & Yates, 2008). As indicated earlier, this review focuses primarily on sexual behaviors that are culturally normative or normophilic (Kafka, 2007).

In terms of clinical presentation, normophilic hypersexual behaviors are more prevalent in males as compared to females (estimated at a 5:1 ratio) (Kafka, 2007), although this difference is less pronounced than the paraphilias (approximately 20:1). Moreover, the clinical phenomenology of hypersexual disorder is such that age of onset typically occurs in adolescence, the intensity of the behavior can increase during periods of intense, negative emotional states and can be either ego-dystonic or ego-syntonic. Such behaviors are often comorbid with other normophilic and/or paraphilic sexual behaviors (Cantor et al., 2013; Carnes, 1991; Kafka & Hennen, 2003).

Several manifestations of hypersexual disorder have been identified in the literature; however, there is a lack of a coherent or reliable classification system for these behaviors (Kafka, 2010; Kingston, 2009). Initial classification systems included several broadly defined categories of sexual behavior (including both paraphilic and non-paraphilic sexual behaviors) that were difficult to operationalize. Examples included fantasy sex, anonymous sex, exploitative sex, multiple sexual partners, voyeuristic sex, seductive role sex, and compulsive masturbation (Carnes, 1991; Wines, 1997).

Although many investigators have suggested different terminology for the many manifestations of hypersexual disorder, Kafka (2001, 2007) provided a relatively comprehensive list of normophilic and excessive sexual behavior, which he termed *paraphilia-related disorders* (PRDs). Kafka's typology included compulsive masturbation, protracted promiscuity, pornography dependence, telephone sex dependence, cybersex, and severe sexual desire incompatibility. Additional manifestations, such as *obsessional fixations* or *love addictions*, were encompassed in a not otherwise specified category.

Kafka and Hennen (2003) reported prevalence rates for the above-noted behaviors among 120 males presenting with a variety of diagnosed paraphilias. The three most common manifestations of hypersexual disorder evident within this sample were compulsive masturbation (72.5 %), pornography dependence (47.5 %), and protracted promiscuity (44.1 %). Other PRDs, such as telephone sex dependence and severe sexual desire incompatibility, were identified in a smaller subset of the population (25 % and 13.3 %, respectively). Reid, Carpenter, and Lloyd (2009) reported similar prevalence rates in a sample of 59 males seeking treatment for hypersexual disorder. Specifically, more than half of the sample reported compulsive masturbation and pornography dependence as the predominant sexual manifestation of concern.

Behavioral Indicators of Hypersexual Disorder

Hypersexual disorder is characterized by behaviors that are recurrent and persistent (Kingston & Firestone, 2008). It is generally acknowledged that behaviors must occur for a period of at least 6 months; a defining feature that conforms to current nosological assessment for other sexual disorders, such as paraphilic disorders. Furthermore, an adequate operational definition of hypersexual disorder includes some frequency of sexual activity and the degree of time consumed while engaged in the sexual act.

Kinsey, Pomeroy, and Martin (1948) described a quantifiable index of sexual frequency, termed total sexual outlet (TSO), which was defined as the number of orgasms achieved through any combination of methods (e.g., intercourse, masturbation) during a specific week. Several large-scale epidemiological studies have utilized this index to determine the normative range of sexual behavior, from which excessive levels of sexual activity may be determined. Based on the epidemiological data, Kafka (2007) proposed a TSO of seven or more orgasms per week to be characteristic of hypersexuality, as this would identify a relatively small portion of the population.

There have been several attempts to determine both normative and statistically excessive rates of sexual activity. In a convenience sample of American males ($n = 5{,}300$), Kinsey et al. (1948) reported that only 7.6 % of males, examined over a period of 5 consecutive years, had an average total sexual outlet of seven or more orgasms per week. Subsequent investigations have shown similar results to the Kinsey et al. study. Atwood and Gagnon (1987), for example, reported that 5 % of high school and 3 % of college age males exhibited a TSO (e.g., masturbation) of seven or more times per week. Laumann, Gagnon, Michael, and Michaels (1994) have conducted the most comprehensive and representative survey of sexual behavior among American adults between the ages of 18 and 59 ($n = 3, 432$). Survey questions covered a variety of sexual behaviors, such as early sexual experiences and masturbation. Results indicated that approximately 80 % of

adults reported having only one or no sexual partners in the previous year, whereas only 3 % of adults reported five or more sexual partners in the previous year. The results also showed that 7 % of males engaged in sex with another person four or more times per week for at least 1 year. With regard to masturbation, 5 % of men and 11 % of women reported to have never masturbated. Thirty-seven percent of men reported masturbating "sometimes," whereas 28 % reported masturbating one or more times per week. Almost 2 % of men reported masturbating on a daily basis for that particular year. In a more recent study, Pinkerton, Bogart, Cecil, and Abramson (2002) reported that undergraduate males ($n=223$) masturbated an average of 12 times per month.

Långström and Hanson (2006) analyzed data obtained from the 1996 national survey of sexuality and health in a large Swedish community sample ($n=2{,}450$). Several sexual outlets were examined, including masturbation and number of sexual partners, and behavioral infrequency was identified using an integer cut-point near the 90th percentile. A high rate of masturbation (defined as 15 times or more per month for men and five times or more per month for women) identified just over 10 % of the sample for each gender. In terms of number of sexual partners, a rate of three or more per year for men and two or more per year for women identified 10 % of men and 12.3 % of women.

There are several problems with purely behavioral definitions of hypersexual disorder. First, there is dissention among researchers regarding the pathological classification of frequent orgasms, suggesting that this endeavor is simply an attempt to classify conventional behavior as disordered (e.g., Giles, 2006). Interestingly, recent data have shown that a greater proportion of individuals may meet the criterion of seven or more orgasms per week than what has been suggested in previous survey studies (Winters, 2010). As such, a significant number of individuals may exhibit a relatively high sexual drive with numerous sexual outlets; however, a *diagnosis* of hypersexuality would not be warranted if their fantasies and/or behaviors do not result in some form of distress or significant impairment in functioning.

In addition, the number of orgasms in a given week is a relatively simplistic indicator of disordered behavior and fails to differentiate among the various ways in which sexual activity is expressed. In fact, both Långström and Hanson (2006) and Laumann et al. (1994), revealed that high rates of sexual activity with a partner (e.g., sexual intercourse) were associated with positive emotional states, whereas high rates of impersonal sexual activity (e.g., masturbation) were more likely associated with negative emotional states, suggesting that type of sexual outlet may be an important factor to consider in sexuality research.

Another problem pertains to the applicability of this criterion to women (Hyde, Delamater, & Byers, 2004), as many women experience difficulty in achieving orgasm, especially during intercourse (Laumann et al., 1994). Although frequent orgasms might indicate the presence of hypersexuality, they are clearly insufficient as a means of measuring or determining hypersexual disorder, as many individuals undoubtedly have frequent sexual activity without experiencing adverse consequences and some might be unable to experience orgasm but still engage in behavior consistent with hypersexual disorder. Additional features of hypersexual disorder, such as the role of negative emotional states (e.g., guilt, shame) and the importance of emotion regulation have been subsumed within various conceptual perspectives.

Conceptual Models of Hypersexual Disorder

Theoretical models are developed to provide heuristic utility for complex behaviors and are intended to explain etiological mechanisms that assist in the formulation of effective treatment. There are several pathophysiological models of hypersexuality that have emphasized the role of neurobiological mechanisms (Bancroft, Graham, Janssen, & Sanders, 2009; Kafka, 2003) or other motivational states related to behavioral addictions (Carnes, 1991), compulsivity (Coleman, 1992), and impulsivity (Schwartz & Abramowitz, 2003).

Neurobiological Models

With regard to neurobiological models, Bancroft and colleagues (Bancroft et al., 2009; Bancroft & Janssen, 2000) proposed a dual-control model of sexual response based on the interaction between principles of sexual excitation and sexual inhibition. In their description of the model, Bancroft and colleagues suggest that most brain functions involve elements of excitatory and inhibitory processes and that the interaction between these mechanisms determines species-specific patterns of sexual behavior. A central tenet of the dual-control model is that individuals vary in their propensity toward sexual excitation (e.g., sexual arousal in the presence of an attractive person) and sexual inhibition (e.g., sexual response becomes reduced when sexual activity is potentially dangerous). It is hypothesized that individuals who demonstrate a low propensity for sexual excitation and/or a high disposition for sexual inhibition are more likely to exhibit problems with sexual arousal and desire (i.e., sexual dysfunctions), whereas, individuals who have a high propensity for excitation and/or a low tendency toward inhibition are more likely to engage in behaviors that are analogous to hypersexuality.

The dual-control model has undergone extensive theoretical development and has received a fair amount of empirical support (Bancroft, 1999; Bancroft & Vukadinovic, 2004),

particularly with regard to sexual risk-taking. Indeed, several studies have shown that a high propensity for sexual excitation and and/or a low propensity for sexual inhibition, as measured by the sexual excitation and sexual inhibition scales, predicted the number of casual sexual partners and was associated with high-risk sexual activity (Bancroft et al., 2004; Carpenter, Janseen, Graham, Vorst, & Wicherts, 2008).

Excitatory and inhibitory mechanisms in the brain are presumed to be adaptive in both animals and humans, and the balance is considered a fundamental feature of neurophysiology. Studies with humans as well as nonhuman primates and rodents have provided support for the excitatory and inhibitory systems within the central nervous system (e.g., Bancroft, 1999). The limbic system, including neuropeptides, steroids, and monoamines, plays a central role in the organization of sexual behavior that includes specific excitatory and inhibitory processes (Bradford, 2000; Kafka, 2003). In a related neurobiological model of sexual dysregulation, Kafka (2003) emphasized the importance of the monoamines, particularly dopamine and serotonin, in the elicitation of the features characteristic of hypersexual disorder (i.e., recurrent and intense sexual urges and behaviors). In general, studies have shown that enhanced dopaminergic neurotransmission is correlated with sexual excitation and that enhanced serotonergic neurotransmission has been associated with sexual inhibition (Kafka, 2003; Maes et al., 2001; Paredes, Contreras, & Agmo, 2000).

In addition to the two neurobiological models indicated above, hypersexual behavior has been conceptualized as an addiction, an obsessive-compulsive disorder, and an impulse-control disorder (Kingston, 2009; also see Kingston & Firestone, 2008 for a review). Although each model contains similar features, such as the criterion for clinical significance (Spitzer & Wakefield, 1999) and the importance placed on disinhibited sexual behavior, the underlying motivational mechanism related to emotion regulation is the fundamental feature distinguishing among these three theoretical models.

Conceptual models of hypersexuality typically emphasize features of compulsivity and/or impulsivity as "driving" motivational states underlying sexual behavior. Although the terms compulsivity and impulsivity are often used interchangeably throughout the literature, these driving mechanisms are fundamentally different (Hollander & Rosen, 2002), such that the former describes individuals who are typically hypervigilant and who demonstrate a desire to avoid harm and reduce anxiety, whereas the latter characterizes individuals who are risk seekers and who are predominantly interested in increasing positive states (e.g., sexual pleasure) (Claes, Vandereycken, & Vertommen, 2002). The distinction between impulsivity and compulsivity has been empirically supported, and several studies have shown positive associations between trait impulsivity and positive emotional states (Abramowitz & Berenbaum, 2007; Claes et al., 2002). Obsessive-compulsive symptoms, conversely, have been associated with negative emotional triggers precipitating the criterion behavior (Ferrão, Almeida, Bedin, Rosa, & Busnello, 2006).

Sexual Addiction

Orford (1978) was one of the first researchers to suggest that hypersexuality was a behavioral syndrome that was characteristic of an addiction. The contemporary formulation of excessive sexual behavior as a behavioral manifestation of addiction, however, is most often attributed to Carnes (1983) book *Out of the Shadows: Understanding Sexual Addiction*. According to Carnes, sexual addiction was characterized as a pathological relationship with a mood altering experience.

The term "addiction" has been conceptualized as a progression from a state which is positive and rewarding, often associated with impulsivity, toward egodystonic experiences of compulsivity, associated with preoccupation, compulsive intoxication, and symptoms of withdrawal (Koob, 2006). Addictive states incorporate elements of physiological dependence on a particular substance that is characterized by tolerance (i.e., the need to use greater amounts of a substance to obtain the desired effect) and/or symptoms of withdrawal (e.g., insomnia) upon removal of the substance. Moreover, psychological dependence, which describes intense craving, compulsive behavior directed toward obtaining the substance, and loss of control, has been emphasized (Lubman, Yücel, & Pantelis, 2004).

Although the traditional notion of addiction has been utilized with substances (e.g., alcohol), there has been a movement in the research community toward the perspective of an overarching structure or underlying addictive process among several disorders (Peele, 1998; Potenza, 2006). According to this broad conceptualization of addiction, any behaviors used to regulate emotional states and that satisfy criteria for addiction (including associated features of tolerance and withdrawal) are potential behavioral manifestations of addiction. Schmitz (2005) and Joranby, Pineda, and Gold (2005) reported similar phenomenological characteristics between substance use disorders and other behavioral disorders, such as compulsive buying, pathological gambling, and eating disorders. With regard to hypersexual disorder, similarities between neurological substrates of addiction (e.g., dopaminergic dysregulation) and sexual appetitive behavior have been identified to support the conceptualization of excessive sexual behavior as a sexual addiction (Keane, 2004).

The movement toward categorizing behaviors, including sexual behavior, under a singular model of addiction has been challenged (Coleman, 1992; Keane, 2004), given the tendency for expansive models to oversimplify complex phenomena and to obscure key differences between disorders.

Although identifying commonalities across chemical and nonchemical addictions promotes heuristic utility, it neglects to elucidate key features among disorders and, therefore, results in decreased clinical utility.

Coleman (1990) argued that the expansive model of addiction failed to adequately differentiate between impulsivity and compulsivity and that each term was often used interchangeably in the literature. As described earlier, the defining characteristics of compulsivity and impulsivity are different and confusing; these terms have important treatment implications, especially when interventions that are designed for behavioral motivations associated with impulsivity are inappropriately applied to behaviors guided by compulsivity (Kingston & Firestone, 2008). Such criticisms have led to the formulation of hypersexual disorder as either a compulsive or impulsive-based disorder.

Compulsive/Impulsive Sexual Behavior

Coleman (1987, 1990, 1992) has been one of the primary advocates for conceptualizing hypersexual disorder as an obsessive-compulsive disorder, based on the shared phenomenological features between the two syndromes. In terms of these features, obsessions are intrusive, repeatedly experienced, and associated with anxiety and/or tension (Black, Kehrberg, Flumerfelt, & Schlosser, 1997). Moreover, the behaviors evident in both disorders are enacted to reduce feelings of anxiety and are often followed by feelings of distress (Coleman, 1992; Raymond, Coleman, & Miner, 2003).

Several studies have supported the predominant features of the sexual compulsivity model, such that individuals repeatedly experience intrusive thoughts that are associated with anxiety and that sexual behaviors are acted upon in order to reduce negative emotional states. Black et al. (1997), for example, reported that 42 % of individuals ($n=36$) exhibiting hypersexuality reported intrusive and repetitive sexual fantasies that were experienced as extremely distressful in nature. They also found that the majority of participants engaged in repetitive sexual behavior, which was initially resisted, and subsequent to the sexual behavior was followed by negative self-evaluation. Moreover, participants reported engaging in sexual behavior in response to specific negative emotional states (e.g., anxiety). Raymond et al. (2003) reported similar results, such that a significant proportion of individuals exhibiting hypersexuality attempted to resist sexual thoughts and urges and that behavioral action (e.g., sexual behavior) was intended to provide temporary relief from anxiety and tension.

The studies described above show important similarities between hypersexuality and obsessive-compulsive disorder and indicate some support for the compulsivity-based conceptualization (Claes et al., 2002).

However, there has also been contrasting evidence with regard to the predominant symptomatology exhibited by individuals with hypersexuality leading to the adoption of an impulsivity-based conceptualization. As indicated earlier, impulsive disorders are characterized by the failure to resist an impulse, drive, or temptation to commit an act that is harmful to oneself or others (APA, 2000). According to this conceptualization, there is often an increased sense of arousal prior to the behavior, a sense of gratification or relief during the behavior, and, for some, feelings of guilt following the act. In support of this conceptualization, Schwartz and Abramowitz (2003) examined a small sample ($n=12$) of patients referred to a clinic for "sexual obsessions." Results indicated that the sexual thoughts reported by patients exhibiting features of hypersexual disorder were predominantly associated with high levels of sexual arousal and low levels of fear and/or anxiety. Despite the small sample, Schwartz and Abramowitz concluded that the compulsivity model was insufficient and that impulsivity was, perhaps, a more accurate characteristic of individuals with hypersexual disorder.

Summary of Conceptual Models

Conceptual models of hypersexual disorder have focused on important neurological mechanisms as well as diverse motivational states driving behavior. With regard to motivational mechanisms, compulsivity and impulsivity have been essential constructs in the development of the sexual addiction, sexual compulsivity, and sexual impulsivity models.

Current data, in my opinion, do not currently support the sexual addiction, sexual compulsivity, or sexual impulsivity conceptualizations. In fact, several studies have explored motivational mechanisms of hypersexuality, and results have been largely inconsistent with regard to the primary mechanisms driving behavior. As indicated earlier, Black et al. (1997) found that negative emotional states (e.g., depression) were predominant reasons for some individuals engaging in sexual activity and that prior urges were distressful and unwanted, whereas, in contrast, Schwartz and Abramowitz (2003) reported that individuals with hypersexual disorder deliberately acted on their sexual urges to promote or achieve sexual gratification and that such behavior was associated with positive emotional states.

In addition to comparisons *across* samples, such contradictions in motivational states have been indicated *within* samples. Raymond et al. (2003) reported that one third of their participants described their thoughts to be intrusive and that 87 % attempted to resist such urges; supporting the compulsivity-based conceptualization. However, mean scores on the impulsivity subscale of the Minnesota Personality Questionnaire (Tellegen, 1992) were actually

indicative of higher levels of impulsivity when compared to normative samples.

Further support for the interrelationship between compulsivity and impulsivity has been demonstrated in other behavioral disorders. In a recent review, Grant and Potenza (2006) described several conditions, traditionally considered impulsive (i.e., pathological gambling, trichotillomania, kleptomania) and demonstrated that features associated with compulsivity were evident at varying points in the behavioral progression. Similarly, Matsunaga et al. (2005) investigated the existence of impulsive features among 153 Japanese adult patients diagnosed with OCD. Results indicated that a significant proportion of the sample (29 %) presented with impulsive traits in addition to compulsive ones. These results suggest that both impulsive and compulsive traits can be evident among individuals with hypersexuality and that a model focused predominantly on just one type of motivational drive is insufficient.

Clearly, an adequate conceptualization of hypersexual disorder must allow for the inclusion of both impulsive and/or compulsive features. The obsessive-compulsive and impulse-control disorder models negate the inclusion of diverse motivational states guiding behavior. Interestingly, substance addiction models have incorporated impulsivity and compulsivity as essential constructs, which interact with one another typically in a sequential fashion. Koob (2006), in his model of drug addiction, described addictive behavior as a progressive state from impulsivity (i.e., using the substance for pleasure) to compulsivity (i.e., using the substance to escape from negative emotional states). Additionally, Goodman (1993) stated that the function of excessive sexual behavior was both to produce pleasure and provide escape from pain, which, again, highlighted the divergent motivations underlying excessive sexual behavior.

Despite the potential utility of the addiction model as a conceptual model for hypersexuality, several problems remain, including, for example, the widespread and ambiguous use of the term "addiction" (see Kingston & Firestone, 2008 for a more detailed and critical review of the sexual addiction model). In addition, the progression from impulsivity to compulsivity, as described in some addiction models, may be evident among individuals exhibiting hypersexual disorder. Alternatively, there is also the possibility that the progression is reversed; that is, individuals may engage in sexual behaviors to regulate negative mood and then, due to principles of reinforcement, engage in such activities to increase pleasure and positive mood states.

Given the problematic application of current conceptual models to the heterogeneous presentation of hypersexuality, a consistent diagnostic and conceptual framework is needed. Kafka (2007, 2010) has proposed an alternative model of hypersexual disorder that is focused on culturally normative sexual outlets. This model of hypersexual disorder is based on current nosological nomenclature and includes criteria that are supported by previous theoretical and empirical research.

Table 1 DSM-5 proposed criteria[a] for hypersexual disorder

A. Over a period of at least 6 months, recurrent and intense sexual fantasies, sexual urges, and sexual behavior in association with four or more of the following five criteria:
A.1 Excessive time is consumed by sexual fantasies and urges, and by planning for and engaging in sexual behavior.
A.2 Repetitively engaging in these sexual fantasies, urges, and behavior in response to dysphoric mood states (e.g., anxiety, depression, boredom, and irritability).
A.3 Repetitively engaging in sexual fantasies, urges, and behavior in response to stressful life events.
A.4 Repetitive but unsuccessful efforts to control or significantly reduce these sexual fantasies, urges, and behavior.
A.5 Repetitively engaging in sexual behavior while disregarding the risk for physical or emotional harm to self or others.
B. There is clinically significant personal distress or impairment in social, occupational, or other important areas of functioning associated with the frequency and intensity of these sexual fantasies, urges, and behavior.
C. These sexual fantasies, urges, and behaviors are not due to direct physiological effects of exogenous substances (e.g., drugs of abuse or medications), a co-occurring general medical condition, or to manic episodes.
D. The person is at least 18 years of age.
Specify if masturbation, pornography, sexual behavior with consenting adults, cybersex, telephone sex, and strip clubs Source: http://www.dsm5.org

DSM-5 Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition

[a]DSM proposed criteria were rejected and will not appear in the upcoming DSM5 text

An operational and criterion-based definition of hypersexual disorder has been proposed (Kafka, 2010) that includes four criteria (see Table 1). These criteria include non-paraphilic recurrent and intense sexual fantasies, urges, and behaviors that result in adverse consequences and clinically significant distress or impairment in important areas of functioning. These symptoms must persist for at least 6 months and are independent of drug use, a general medical condition, or a manic episode. Following the diagnosis, an evaluator would specify the type of normative sexual behavior (e.g., masturbation, use of pornography, sexual behavior with consenting adults, etc.). Kafka as well as others (Briken, Habermann, Berner, & Hill, 2007; Kingston, 2009; Kingston & Firestone, 2008) have highlighted the importance of comorbidity, particularly between hypersexual disorder and the paraphilias.

One of the central advantages of Kafka's model of hypersexual disorder is that it is not entirely bound to current explanatory theories with predetermined etiological mechanisms underlying the behavior (i.e., models based on addiction, compulsivity, and impulsivity). However, these criteria

are somewhat biased toward features of compulsivity. Nevertheless, Kafka's model encourages evaluators to assess for a diversity of motivational mechanisms and other features important for the development of effective interventions.

Another advantage is the implication for nosological assessment. Currently, the DSM-5 does not include a formal diagnosis of hypersexual disorder and attempts at providing an operational definition were rejected.

Despite some recent evidence showing hypersexual disorder to have good reliability and validity (Reid et al., 2012), several researchers have expressed caution about defining this construct as a disorder in current nosology (Winters, 2010; Winters, Christoff, & Gorzalka, 2010). Winters and colleagues correctly identified that there is a significant lack of independent empirical evidence supporting the inclusion of this disorder in current nosology. Additionally, as discussed previously, the pathophysiology of the syndrome is unclear, and the fact that several of the proposed sub-criteria indicated earlier emphasize the compulsive aspects of the behavior may be inappropriate for many individuals.

Winters (2010) has also noted that the distinction between volitional impairment and sexual desire/drive is not entirely clear, and recent data have shown that behaviors associated with hypersexual disorder (e.g., protracted promiscuity) may simply be reflecting elevated levels of sexual drive (Winters et al., 2010). The fact that hypersexual disorder may simply reflect high sexual drive, without an orthogonal construct related to sexual dyscontrol, is inconsistent with previous conceptual models and is problematic for the inclusion of the putative syndrome in current nosology. Of note, hypersexual disorder was ultimately rejected for inclusion in the DSM5 and will not appear anywhere in the upcoming text (www.dsm5.org).

Psychological Tests, Questionnaires, and Inventories

Valid methods of assessing hypersexual disorder are needed in order to further our understanding of this syndrome. Importantly, the veracity of self-reported symptoms will likely depend on the context of the assessment. Non-forensic evaluators will encounter individuals who are relatively concerned about their excessive sexual thoughts or behaviors and, as such, may be motivated to disclose relevant aspects of their sexual behaviors. However, there is some evidence showing that questions related to sexuality and sexual dysfunction result in reduced disclosure among non-forensic populations (Meston, Heiman, Trapnell, & Paulhus, 1998). In contrast, forensic evaluators assess individuals who are, more often than not, reluctant to disclose at least some aspects of their sexual behaviors (Mills & Kroner, 2005). There are a variety of self-report and psychological inventories designed specifically to assess recurrent and intense sexual fantasies and behaviors, particularly for the paraphilias [e.g., the Sex Inventory; (Thorne, 1966), the Aggressive Sexual Behavior Inventory (Mosher & Anderson, 1986), the Coercive Sexual Fantasies Questionnaire (Greendlinger & Byrne, 1987), and the Clarke Sex History Questionnaire (Langevin, Handy, Paitich, & Russon, 1985)]. Several of these instruments (e.g., the Clarke Sex History Questionnaire) contain validity scales that detect impression management.

Unfortunately, far less attention has been directed toward psychological inventories for hypersexual disorder. Table 2 lists some of the more common screening tools and inventories that may be potentially useful in the assessment of normophilic hypersexual disorder. Among these instruments, the Sexual Addiction Screening Test (SAST), the Sexual Compulsivity Scale (SCS), and the Compulsive Sexual Behavior Inventory (CSBI) have received a fair amount of empirical attention. Unfortunately, these scales are generally transparent and, thus, are vulnerable to self-reporting biases. Many evaluators and researchers have utilized measures of social desirability (e.g., *The Balanced Inventory of Desirable Responding*; Paulhus, 1984) as a control variable. However, recent meta-analyses have indicated that social desirability may be an important aspect of personality (Li & Bagger, 2006), which has led some (see Mills & Kroner, 2006) to suggest that partialling out social desirable responding may distort the true relationship between the independent variable and the outcome measure.

The Sexual Addiction Screening Test (SAST; Carnes, 1991) is likely the most widely used screening tool to assess the presence of hypersexual disorder. The measure can be scored continuously or dichotomously. Weiss (2004) indicated that a score of 14 or greater is characteristics of sexual addiction, whereas others (e.g., Carnes, 1989; Marshall, Marshall, Moulden, & Serran, 2008) have stated that a score of 13 accurately reflects hypersexuality, given the significant association with self-reported sexual addiction. Initial psychometric evaluations on the SAST produced good internal consistency (alpha = .85 to .95) and discriminant validity (Carnes, 1989). A recent investigation has shown that the SAST measures a single underlying construct with good reliability and validity (Nelson & Oehlert, 2008); these results have been used with sexual offending populations (Marshall et al., 2008).

The Sexual Compulsivity Scale (SCS) (Kalichman et al., 1994) is a 10-item Likert-type self-report measure. Respondents are asked to endorse the extent to which they agree with a series of statements reflecting hypersexuality and preoccupation with sexual behaviors. Specific items were derived from a self-help guide for problematic sexual behaviors (e.g., my sexual appetite has gotten in the way of my relationships). The SCS scale has demonstrated good internal consistency (alpha = .84 to .89) and construct validity

Table 2 Some potentially useful measures in the assessment of hypersexual disorder

Test (source)	Description
Compulsive Sexual Behavior Inventory (Coleman, Miner, Ohlerking, & Raymond, 2001)	The CSBI is a 28-item self-report measure of hypersexual disorder that includes items related to historical experiences of abuse, volitional impairment, and using sex to cope with negative emotional states.
Garos Sexual Behavior Index (Garos & Stock, 1998)	The GSBI is a 72-item Likert-type self-report measure that assesses the cognitive, affective, and behavioral dimensions of hypersexual disorder. The measure includes four subscales: discordance, sexual obsession, values, and sexual adequacy.
Hypersexual Behavior Inventory (Reid & Garos, 2007)	The HBI is a 19-item self-report measure that examines the use of sex to cope with emotional distress, volitional impairment, and associated negative consequences resulting from sexual behavior.
Internet Sex Screening Test (Delmonico, 1999)	The ISST has undergone several revisions and now includes 117 items with eight subscales (e.g., online and offline sexual compulsivity). Items were adapted from the SAST.
MIDSA (Knight & Cerce, 1999)	The MIDSA is a computerized self-report inventory that includes over 4,000 items resulting in 55 scales, including 3 sexualization scales: Sexual Compulsivity (9 items related to an inability to control sexual urges); Sexual Preoccupation (7 items measuring how often a person thinks about sex); and Hypersexuality (5 items measuring sexual drive).
Sexual Addiction Screening Test (Carnes, 1991)	The SAST is a 25-item self-report measure that requires individuals to respond, in a yes/no fashion, as to whether a statement is characteristic of them. Scores of at least 13 have been suggested to reflect hypersexual disorder.
Sexual Compulsivity Scale (Kalichman & Rompa, 1995)	The SCS is a 10-item Likert-type self-report measure. Participants are asked to endorse the extent to which they agree to a series of statements reflecting hypersexuality and preoccupation with sexual behavior.
Sexual Dependency Inventory-Revised (Carnes & Delmonico, 1996)	The SDI-R includes 179 items in which individuals rate the frequency and power of the statement in their fantasy or actual life. A series of factor analyses produced 10 subscales based on distinct categories of hypersexual disorder (e.g., anonymous sex, fantasy sex, seductive role-playing).
Sexual Inhibition/Sexual Excitation Scales (Janssen, Vorst, Finn, & Bancroft, 2002)	The SIS and SES scales are based on the dual-control model of male sexual response which reflects individual differences in propensities for sexual excitation and sexual inhibition. Questions reflect situations that are either sexually exciting or threatening, and individuals describe their typical sexual response. Factor analyses identified a single excitation factor and two inhibition factors based on threat of performance and threat of performance consequences.
Sexual Outlet Inventory (Kafka, 1991)	The SOI is a clinician administered scale that includes 10 items measuring the frequency of sexual fantasies, urges, and behaviors, and is based on the construct of total sexual outlet.
Sexual Sensation Seeking Scale (Kalichman et al., 1994)	The SSS scale is an 11-item likert-type self-report measure. Respondents indicate the extent to which each statement is characteristic of them.

MIDSA The Multidimensional Inventory of Development, Sex, and Aggression

(Kalichman & Rompa, 2001) and has been used widely for assessing sexual risk-taking among individuals with HIV.

The Compulsive Sexual Behavior Inventory (CSBI) (Coleman et al., 2001) is a 28-item self-report measure of hypersexual disorder that includes items related to historical experiences of abuse, volitional impairment, and using sex to cope with negative emotional states. The initial validation study (Coleman et al., 2001) was conducted with 1,026 Latino men who had reported having had sexual contact with other men. Results of the initial validation study suggested a two-factor structure: behavioral dyscontrol and interpersonal violence. The measure also demonstrated good reliability and validity in the developmental sample as well as in two more recent investigations (Lee, Ritchey, Forbey, & Gaither, 2009; Miner, Coleman, Center, Ross, & Rosser, 2007).

The Hypersexual Behavior Inventory-19 (HBI-19) (Reid & Garos, 2007) is a three-factor, 19-item, self-report measure that assesses features of hypersexuality according to the proposed criteria for hypersexual disorder reported earlier. Items are rated along a 5-point Likert-type scale, yielding a total score ranging from 19 to 95. A score of 53 or higher is considered to be clinically significant. The HBI demonstrated convergent validity with other measures of hypersexuality and related constructs. Internal consistency was high in the initial validation sample ($\alpha = .89$ to .95) and in a subsequent field trial ($\alpha = .96$) (Reid et al., 2012).

In addition to the inventories listed above, there are several screening measures which have been developed specifically for online problematic sexual behavior, although most lack validation (e.g., Young, 2006). One exception is the Internet Sex Screening Test (Delmonico, 1999), which has undergone several revisions and now contains 117 items with eight subscales highlighting varying facets of online sexual behavior. One subtest relates to online sexual compulsivity and

examines indicators of hypersexual disorder (e.g., repeated efforts to stop the sexual behavior), whereas another subtest pertains to offline sexual compulsivity, which utilizes items adapted from the SAST. There is limited information regarding the psychometric properties of the most recent version of the Internet Sex Screening Test, but earlier versions have shown low to moderate internal consistency (alpha's = .51 to .86) (Delmonico & Griffen, 2008).

Hypersexual Disorder Among Sexual Offending Populations

Prevalence

There are few empirical investigations examining the prevalence of hypersexual disorder among sexual offenders. Initially, Carnes (1989) suggested that approximately 50 % of sexual offenders would exhibit hypersexual features, although he provided no empirical data supporting these figures. Subsequent studies, however, have supported Carnes' claims of elevated rates of hypersexual disorder or features among samples of sexual offenders. For example, Blanchard (1990) administered self-report measures to offenders and, along with detailed file review, found that 55 % of his sample of sexual offenders ($n = 107$) met criteria for sexual addiction, although his criteria were not clear and the reliability of his diagnosis was not reported.

More recently, Marshall and colleagues (Marshall et al., 2008, 2009, 2009; Marshall & Marshall, 2006) have examined the prevalence of hypersexual disorder in samples of incarcerated sexual offenders, and they have compared these rates with socio-economically matched community controls. Hypersexual disorder was determined using a clinical cutoff score on the SAST (Carnes, 1989). Results were generally consistent with data reported by Carnes and Blanchard, such that approximately 44 % of sexual offenders were considered to be hypersexual, whereas only 18 % of the socio-economically matched community controls met the criterion.

Several more recent studies employing strict, objective criteria have reported lower rates of hypersexuality among sexual offending populations than the rates reported earlier. Kingston and Bradford (2013) examined the behavioral criterion of hypersexual disorder (i.e., self-reported Total Sexual Outlet) among 553 adult male sexual offenders. Approximately 12 % of the sample, based on their self-report, met the clinical cutoff for problematic hypersexuality (Total Sexual Outlet ≥ 7). Briken (2012) examined a representative sample of 244 adult male sexual offenders with child victims and reported that only 9 % met the diagnostic criteria for Hypersexual Disorder, as defined using the proposed DSM-5 criteria (www.dsm5.org).

Hypersexual Disorder and Sexual Aggression

Features of hypersexual disorder (e.g., sexual self-regulation problems, the drive for impersonal sex, and compulsive masturbation) are essential components among several multifactorial theories and developmental models of sexually coercive behavior (Malamuth, 2003; Ward, Polaschek, & Beech, 2006). The confluence model (Malamuth, 2003), for example, was constructed from research demonstrating that sexual aggressors possess several key characteristics that are present both developmentally and at the time of aggression. These characteristics have been empirically reduced into two main clusters of characteristics or paths labeled hostile masculinity and impersonal sex. Of relevance to this review, the impersonal sex path is characterized by a noncommittal, game-playing orientation toward sexual activity and reflects individual differences in the willingness to engage in such acts without closeness or commitment (Malamuth, 2003). Knight and Sims-Knight (2003, 2004) have also emphasized the role of hypersexuality in adult and juvenile sexual offenders, although emphasis is placed on sexual drive, sexual preoccupation, and sexual deviance rather than promiscuity and a preference for impersonal sex, as these former variables differentiated sexually coercive and noncoercive males.

A number of investigations utilizing self-report among college males have shown that sexually coercive males report higher levels of sexual behaviors and fantasies, including number of sexual partners, when compared to noncoercive males (Abbey, McAuslan, & Ross, 1998; Malamuth, 2003; Malamuth, Linz, Heavey, Barnes, & Acker, 1995). With regard to forensic samples, Gebhard, Gagnon, Pomeroy, and Christenson (1965) found that sexual offenders as a group were categorized by more extensive sexual experiences, such as number of sexual partners (compared to non-offending men). Similarly, Knight and Sims-Knight (2003, 2004) have reported that sexual drive and sexual preoccupation discriminated sexually coercive males from noncoercive males and that such features of hypersexuality were correlated with pornography use, offense planning, and self-reported hostility toward women (Knight, 1999; Knight & Sims-Knight, 2004). More recently, Lussier, Leclerc, Cale, and Proulx (2007) examined the developmental antecedents to sexual offending in 553 adult male sexual offenders and found elements of impersonal sex, sexual compulsivity, and sexual preoccupation (e.g., all identified features associated with hypersexuality) to be important predictors of sexual coercion.

Hanson and Harris (2000) identified sexual preoccupation (generally defined as recurrent sexual thoughts and/or behaviors directed toward numerous casual or impersonal sexual encounters) as one of the most important dynamic risk factors for sexual offending. This finding was subsequently

replicated by Hanson, Harris, Scott, and Helmus (2007). In one of the most recent and comprehensive meta-analyses of adult male sexual offenders, Hanson and Morton-Bourgon (2005) again found that sexual preoccupation was significantly associated with sexual recidivism (d=.39) and any violent recidivism (d=.28). Most recently, Kingston and Bradford (2013) found that the behavioral criterion of hypersexual disorder was significantly associated with sexual recidivism (ROC=.65; 95 % CI=.58 to .71) and violent (including sexual) recidivism (ROC=.67; 95 % CI=.61 to .72). Given the relatively consistent relationship between sexual preoccupation and sexual aggression, it is not surprising that elements of hypersexuality have been included as risk indicators in commonly used personality and actuarial measures for sexual offenders (Hanson & Harris, 2000; Hare, 1991; Prentky, Harris, Frizzel, & Righthand, 2000).

Treatment of Hypersexual Disorder

Hypersexual behaviors can manifest as repetitive sexual fantasies, urges, and behaviors that are directed toward culturally sanctioned sexual activities (e.g., masturbation, sex with several consenting adults over time) or fantasies or behaviors that are defined as paraphilic, that is, directed toward nonhuman objects, the suffering or humiliation of oneself or one's partner, or children/nonconsenting partners (Kingston et al., 2007, 2010; Kingston & Yates, 2008). Treating sexual preoccupation involving paraphilic sexual outlets has been widely discussed in the literature (e.g., Laws & O'Donohue, 2008). Unfortunately, far less attention has been directed toward treating excessive sexual behaviors that are culturally normative in both forensic and non-forensic populations. The aforementioned theoretical conceptualizations of hypersexual disorder have been used in developing specific interventions and overarching treatment models, which included pharmacological treatment, supportive group psychotherapies, and more structured cognitive-behavioral therapies (Kafka, 2007).

Pharmacological Treatment

The association between neurophysiological systems and sexual dysregulation, as emphasized in the two neurobiological models reviewed earlier, has been used to support a pharmacological approach to treating hypersexual disorder. Unfortunately, few well-controlled studies have been conducted evaluating pharmacological interventions for the treatment of hypersexual disorder.

Although several studies have investigated the utility of psychotropic interventions with the paraphilias (e.g., Bradford, 2000), far less attention has been directed toward non-paraphilic sexual behaviors. However, there have been case reports (e.g., Grant & Won-Kim, 2001) and some small, open-label trials supporting the utility of Selective Serotonin Reuptake Inhibitors (SSRIs) (Guay, 2009; Kafka, 2007). Kafka (1991, 2007) reported results from open-label trials of sertraline or fluoxetine in very small samples (n=10–12). Improved symptoms of hypersexuality, including total sexual outlet, were evident, and individuals were generally able to maintain conventional sexual interests and behaviors. In addition to the SSRIs, several other pharmacological agents have been identified as possible treatment options for hypersexual disorder, all of which have been reported in case reports or case series. Recently, Guay (2009), in his review of the pharmacological interventions for paraphilic and non-paraphilic sexual behaviors, found that most interventions targeted either serotonin or testosterone. However, several reports were identified that described the use of mood stabilizers, neuroleptics, opioid antagonists, anticonvulsants/anxiolytics, and antiandrogens in the treatment of non-paraphilic hypersexual disorder. Guay identified various methodological limitations in these studies, including sampling biases and insufficient sample sizes.

Psychological Treatment

Various psychotherapeutic approaches have been used for the treatment of hypersexual disorder, although there are very limited data addressing efficacy of any particular treatment approach. Psychological treatment is typically provided in a residential treatment setting that includes both individual and group therapy modalities. Therapeutic programs are relatively integrative, without strict adherence to any one particular theoretical orientation, and, as such, elements of cognitive-behavioral therapy, relapse prevention techniques, experiential therapy, and support groups based on the 12-step recovery model are often utilized.

Psychological interventions typically include psychoeducation that is provided in the early phases of treatment and provides the individual with information regarding hypersexuality, healthy sexuality, and relationship functioning (Edwards & Colmean, 2004). Treatment programs based on cognitive-behavioral theory emphasize the role of and interrelationships between cognition, affect, and behavior. As such, the identification and modification of cognitive distortions that support and rationalize hypersexual behavior is crucial, and underlying core beliefs about the self and others (e.g., defectiveness/shame) are modified. Relapse prevention strategies are also used, which help the individual to recognize and anticipate high-risk situations associated with previous hypersexual behaviors and to implement effective coping strategies and problem-solving techniques.

In addition to the specific interventions that are used in both individualized and group formats, most treatment programs encourage enrollment in self-help support groups. Carnes (1989) has been one of the predominant advocates for a group psychotherapy model based on the 12-step approach for substance-based addictions.

12-step programs are nonsectarian spiritual programs emphasizing the role of a higher spiritual being and the acknowledged loss of personal control over the addictive substance (or behavior). While such programs designed for hypersexual disorder closely adhere to the principles outlined for substance-based addictions, there is one fundamental difference with regard to the degree of abstinence, such that abstinence is not a stated goal of the program, although celibacy contracts are often recommended while an individual addresses initial treatment targets (Carnes, 1989).

As indicated earlier, there are few well-designed outcome studies regarding treatment efficacy for hypersexual disorder. Quadland (1985) conducted one of the earlier outcome investigations of an outpatient psychotherapeutic group of 30 gay or bisexual men exhibiting features characteristic of protracted "promiscuity." The average course of therapy was 20 weeks, and interventions focused on developing insight and changing problematic sexual behaviors. Results indicated self-reported reductions in the number of different sexual partners, the percent of "one-night stands," and the percent who engaged in sex in public settings.

Wan, Finlayson, and Rowles (2000) reported treatment outcomes for 59 men and women who participated in a 28-day residential treatment program for hypersexuality. Most participants were treated between 1995 and 1998, and follow-up data were gathered via a structured telephone interview. Treatment consisted of psychoeducation, group psychotherapy, and 12-step support meetings. Results indicated that 71 % of individuals subsequently self-reported engaging in at least some of their sexual behaviors that were previously described as problematic.

Klontz, Garos, and Klontz (2005) reported treatment outcome data for 38 male and female self-reported "sexual addicts" who attended a residential treatment program. Treatment was described as an integrated experiential and cognitive-behavioral approach and primarily involved 32 h of intensive psychotherapy, along with additional time devoted to psychoeducation and mindfulness training. A variety of more specific interventions were also noted, including psychodrama, role-playing exercises, as well as art and music therapy. Treatment efficacy was assessed using the Global Measure of Symptom Severity (Garos & Stock, 1998) and the Brief Symptom Inventory (Derogatis, 1993). Results indicated a significant self-reported decrease in psychological distress, sexual obsessions, sexual preoccupation, and difficulty controlling sexual impulses. These changes were stable at the 6-month follow-up period.

Finally, there have been some theoretical concerns identified with twelve-step programs, and several researchers have criticized the utility of the 12-step approach for both substance-based addictions and other "behavioral" addictions. In particular, Coleman (1990) and Keane (2004) have suggested that problems identified within the 12-step treatment approach for hypersexual disorder are indicative of the inappropriate adaptation of the addiction model to out-of-control sexual behavior. With regard to the adapted 12-step approach for sexual behaviors, one predominant concern pertained to the utilization of celibacy contracts in the initial phases of treatment. In addition to being viewed as restrictive and moralistic, the focus on abstinence has been considered problematic and not consistent with positive approaches to healthy sexuality. More specifically, requiring individuals to refrain from sexual activity may reinforce negative and maladaptive attitudes toward sexuality (e.g., sex is inherently bad).

Another predominant concern with the 12-step approach pertains to the notion of rejecting personal control. This perspective is diametrically opposed to empirically validated cognitive-behavioral treatment, in general, and specific models of rehabilitation, in particular. It is important to note, however, that existing investigations have found support groups to be effective for substance dependence (e.g., Ståhlbrandt, Johnsson, & Berglund, 2007) and hypersexuality (e.g., Carnes, 1991). Unfortunately, serious methodological concerns, such as biased samples, have been identified in such studies (Kafka, 2007). Additional concerns evident in the outcome literature include the use of self-report measures, the lack of standardized assessment tools of symptomatology, the relatively short follow-up periods, as well as the lack of control groups.

Psychological treatment of hypersexual disorder should emphasize individualized case conceptualization, which is conducted in collaboration with the individual, reflecting therapeutic changes as they occur. Case conceptualization explores important developmental processes associated with hypersexuality, in addition to identifying affective, behavioral, cognitive, and contextual factors that culminate in unwanted sexual behavior. This process highlights important targets for treatment, such as core beliefs surrounding shame and guilt, emotional and sexual self-regulation problems, insecure attachment formation, previous trauma, and couple/family dysfunction.

Case conceptualization should also focus on the underlying motivational mechanisms that drive sexual behavior. In this review, the importance of differentiating compulsivity and impulsivity among individuals exhibiting hypersexual disorder has been emphasized, which underscores several implications for treatment. As indicated earlier, relapse prevention techniques are useful in identifying high-risk situations and developing comprehensive coping plans.

However, such techniques may be more suitable for individuals with demonstrable skills deficits with behavioral regulation (i.e., compulsive behavior), whereas individuals guided by sensation-seeking and/or behaviors that are ego-syntonic may benefit more from interventions that target underlying core schema and effective emotion management, rather than specific skill deficits.

In addition, impulsivity is a trait associated with decreased treatment efficacy, which is most likely due to the difficulty in motivating such individuals to stop pleasurable activity (Moeller & Dougherty, 2002; Oldham, Hollander, & Skodol, 1996). Maccallum, Blaszczynski, Ladouceur, and Nower (2007) provided support for the negative association between impulsivity and treatment success in an examination of 60 pathological gamblers attending treatment. Results indicated that lower levels of impulsivity were associated with better treatment response in addition to a nonsignificant trend toward treatment completion when compared to individuals with higher levels of impulsivity. As such, individuals with impulsive sexual behaviors would benefit substantially from intensive motivational interviewing techniques in order to facilitate both treatment completion and successful treatment outcomes, whereas individuals guided by compulsivity may benefit less from this approach.

Conclusions and Future Directions

Problematic and excessive sexual behavior has been variously defined throughout the literature (Kingston & Firestone, 2008). Despite such descriptive diversity, hypersexual disorder has been characterized by volitional impairment over excessive sexual fantasies, urges, and/or behaviors, which are accompanied by adverse consequences and/or personal distress. It has been predominantly studied in noncriminal populations, although the relevance to forensic samples has been emphasized (Kingston, 2009; Kingston & Bradford, 2013; Marshall & Marshall, 2006).

Unfortunately, definitions of hypersexuality have been unsystematically applied without any concrete understanding of the underlying theoretical tenets of the putative conceptual model (Kingston & Firestone, 2008; Winters, 2010). Classification systems are intended to elucidate etiological mechanisms and symptom profile and facilitate effective treatment. Unfortunately, several contradictory explanatory models have been utilized to explain hypersexuality, and clinicians and researchers have typically adopted one descriptive model that is unidimensional (i.e., focused on a particular motivational mechanism underlying the behavior) and have applied it to all individuals presenting with such behavior. This approach clearly contrasts with recent data indicating a more complex relationship among compulsive and impulsive traits.

In this chapter, I have supported an atheoretical and criterion-based perspective for hypersexual disorder (APA, 2010; Kafka, 2010), as it allows for the assessment of varied motivational drive states important for the design and implementation of effective treatment. Kafka has provided criteria for individuals exhibiting disinhibited sexual behavior with accompanying distress surrounding culturally normative sexual outlets, although such criteria are biased toward features of compulsivity. In addition, some researchers (e.g., Winters, 2010) have suggested that incorporating Kafka's criteria in current nosology may be premature, as the pathophysiology of the putative syndrome is not entirely clear.

In addition to the problems with conceptualization and diagnosis, there has been limited progress made with regard to the assessment and treatment of hypersexual disorder. The review provided herein indicated the predominant assessment measures that have at least some empirical support for assessing hypersexual disorder; although, future research is needed with regard to validating these measures across samples, particularly among cybersex users and sexually aggressive populations.

Finally, various pharmacological and psychotherapeutic approaches have been applied to the treatment of hypersexual disorder, although there are virtually no well-controlled studies addressing efficacy of any particular treatment approach. There is some evidence that SSRIs are associated with reduced symptoms of hypersexuality, including total sexual outlet, without associated reductions in conventional sexual interests and behaviors. Additionally, several outcome studies (e.g., Klontz et al., 2005) have identified the utility of residential treatment programs that utilize an integrative treatment approach. Unfortunately, these studies have suffered from several methodological limitations, such as lack of control groups and the use of self-report inventories and measures that have not been validated.

In this review, I have emphasized the importance of a comprehensive and individualized case conceptualization that explores important developmental processes associated with hypersexuality, as well as associated affective, behavioral, cognitive, and contextual factors related to the behavior. An individualized case conceptualization will also identify client-specific relevant treatment targets, such as core beliefs or schema, self-regulation problems, insecure attachment, and previous trauma. Importantly, a functional assessment of whether the sexual behavior is guided by impulsivity or compulsivity informs whether interventions should involve motivational enhancement or the recognition of high-risk situations and the facilitation of skill development.

Unfortunately, there are few well-designed outcome studies regarding the treatment of hypersexual disorder and, as such, it is unclear as to the most appropriate therapeutic modality. However, current evidence in related areas suggests

that cognitive-behavioral approaches may be useful (Kingston & Firestone, 2008). Given the importance of self-regulatory failure and the heterogeneity of the motivational mechanisms underlying the behavior, treatment approaches that are flexible and account for impulsive and/or compulsive processes are likely to be more successful than rigid/manualized-based treatment programs.

The evidence reviewed above justifies a refinement in the classification of hypersexuality for future editions of the DSM. Specifically, individuals who experience disinhibited sexual urges, fantasies, and/or behaviors involving culturally normative aspects of sexual expression should be accounted for in future nosological systems, and the evidence supports an atheoretical and criterion-based approach to conceptualization and diagnosis (Kafka, 2010). Given that accurate conceptualization and adequate diagnosis of psychological disorders informs effective treatment, a consistent approach to classification will promote future research into effective assessment and treatment of individuals presenting with hypersexual disorder.

Personality and Sexual Offending; Non-Sexual Motivators and Disinhibition in Context

Harry M. Hoberman

Sexual behavior, including sexual offending, occurs as the result of various factors. As Meston and Buss (2007) demonstrated, the reasons that persons engage in typical sexual behaviors are multiple and complex. While physical factors (e.g., pleasure, physical desirability) and emotional factors (e.g., love, expression) are related to sexual behavior, so are factors involving goal attainment (e.g., revenge) and insecurity (self-esteem "boost"). Tackett and Krueger (2011) noted that there are multiple pathways to aggressive and violent outcomes including high motivation (e.g., aggression and/or generally unconstrained impulses). Personality characteristics and related aspects of psychological functioning (including motivations and emotions) and disinhibition or "disconstraint" (deficits or limitations in self-control, including those of executive functioning and self-regulation) are of critical importance in the understanding of the nature of sexual offending. Both theoretical and empirical perspectives direct that sexual offenses result from the occurrence of and interactions among multiple sexual and/or other personality characteristics interacting across situations and time. Sexual offenses are most typically the end result of several different types of risk factors and processes. It might be expected that all sex offenses are exclusively the product of atypical or deviant sexual interests, hypersexuality (heightened sexual arousal levels), and/or sexual preoccupation. However, the available empirical data indicate that sexual factors are not always present or determinant of sexual offending (although these findings are potentially limited by research-related assessment issues relative to the self-report or other measurements and determinations of characteristic or episodic sexual interest and arousal levels). Deviant sexual interests, hypersexuality, and/or sexual preoccupation do show moderate correlations (and generally have the relative highest strength of association) with future acts of sexual offending. However, on their own at least as currently measured, they contribute a smaller amount of the variance in sexual reoffending than is commonly believed. In contrast, nonsexual characteristics, predominantly personality and related conditions, also show moderate correlations with future acts of sexual offending, and numerous theorists have suggested that sexual offending may be primarily or exclusively the result of nonsexual risk factors. Thus, various measures of antisocial personality and criminal history show relative similar association to sexual domains with sexual offense recidivism. In addition, research on the explanations provided by sexual offenders themselves shows that while sexual gratification is a key factor identified as related to sexual offending, nonsexual factors are also seen as central. Thus, beyond explicitly sexual motivations, Mann and Hollin (2007) found that child molesters most frequently explained their offending by way of desire to alleviate a negative emotional state or a wish to experience intimacy, while rapists attributed their offending months frequently to grievance and/or impulsivity. Of note, approximately 1/3 of rapists and 1/4 of child molesters did not or could not give any explanation for their offending. Of course, combinations of sexual and personality (and related) predispositions can also result in the particularly increased risk of sexual offending (e.g., Rice & Harris, 1997; Harris et al., 2003, Serin, Mailloux, & Malcolm, 2001; Hildebrand, de Ruiter, & de Vogel, 2004; Hawes, Boccaccini, & Murrie, 2012). Consequently, it appears that persons who commit sexual offenses are a heterogeneous group and that, in certain cases, nonsexual risk factors may predominate in the etiology of specific incidents of sexual offending or sexual offending by particular offenders as well as act in cumulatively with sexual risk factors relative to other incidents. If sexual elements are not always predominant for perpetrators

in such situations, for a significant set of sexual offenses and select recidivistic sexual offenders, persisting personal characteristics, related processes, and dispositions must likely be centrally or even primarily involved in the enactment of sexual offenses. That is, in many cases, apparently nonsexual predispositions may be sufficient and, in other cases, necessary for sexual offending to occur. In addition, a more limited manner, situational factors might also play an important role in a specific sexual offense. Alternately, there appear to be a large group of persons characterized by deviant sexual interests and sexual preoccupations that do not act on their atypical interests and arousal [e.g., per the DSM-5 (APA, 2013), persons with paraphilias but not paraphilic disorders]. For such persons, the relative presence of personality and related factors would appear to be highly significant in reducing their likelihood of acting on their atypical sexual interests and/or preoccupation (e.g., by the inhibition of such behavior).

Like other specific actions, criminal behaviors, particularly violent criminal behaviors such as sexual offending, most commonly have multiple determinants; multiple factors converge and interact with one another in various ways as well as situational factors resulting in a particular attempt or enactment of a sexual offense. To the degree that there are regularities or reoccurrences in criminal acts such as repeat or intermittent sexual offending, that phenomenon provides an indication that individuals possess relatively uniform or characteristic predispositions or propensities to commit such crimes. Relative to such tendencies, Elwood (2009) noted the most useful definition of the term "predispose" is that the association between the variable of interest is one that is statistically associated with an increased likelihood of future sexual offending. Most generally, a predisposition is simply a tendency to act in a particular or expected way or susceptibility toward particular behavior or actions and may exist more or less uniform ally across time and particular contexts. Thus, while the known commission of a specific criminal or sexual offending act may reflect an increased or primary role of situational or circumstantial factors (e.g., acute intoxication, antisocial associates), repeated criminal or sexual offending suggests that something more than just situational factors are at play. In addition, the specificity and continuity of types of particular violent behaviors, such as sexual offending (both in the context of other antisocial behavior and as a more unique and specialized form of repeated criminal offending), indicate that there are more than simply situational factors involved. Rather, that continuity or recurring violent and/or sexual behavior highlights the likelihood of more enduring and persistent characteristics of an individual over time. Enduring predispositions of persons are generally thought of as related to their "personality" (and associated conditions) and, in the case of illegal sexual behavior, persistent or recurring sexual offense-related characteristics. Thus, in addition to sexual interests and varied sexual motivational factors, both personality and related dimensions of a person are appropriately viewed, both conceptually and empirically, as factors that can and do predispose individuals to commit criminal sexual offenses.

Both theory and research have identified the central role that varying aspects of personality and related conditions play in sexual offending as well as both criminal and violent offending (Eysenck, 1964; Gottfredson & Hirschi, 1990). Nestor (2002) identified that personality dimensions and/or motivational elements (e.g., self-control, hostility) were strongly associated with general criminal behavior and violence toward others. Theorists have also identified and demonstrated that personality factors are central to sexual offending as a specific form of criminal and violent behavior (e.g., Groth, Longo, & McFadin, 1982; Finkelhor, 1984; Knight & Prentky, 1990; Marshall & Barbaree, 1990; Hall & Hirschman, 1992; Ward & Beech, 2006; Ward, Polaschek, & Beech, 2006; Beech & Ward, 2004). Individual studies and various meta-analyses of risk factors or criminogenic needs have identified sets of personality and related psychosocial characteristics as primary dimensions of sexual offending and sexual offense recidivism in particular (e.g., Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004; Mann, Hanson, & Thornton, 2010). Theories and available body of research identify several domains of psychologically meaningful predisposing conditions to sexual offending that are largely personality based: affective dispositions (e.g., anger, hostility, diminished empathy), general problem-solving and self-regulation (or executive functioning) issues (impulsivity, failure to learn from consequences, resistance to rules and norms), distinctive attitudes about society and potential victims (entitlement, emotional congruence toward women), and issues related to social relationships (lack of intimacy, recurrent conflict). Each of these empirically identified elements would be encompassed by personality, particularly aspects related to motivations, emotions, and self-regulation/self-control. In various combinations, these and other personality and related characteristics appear to coalesce into various forms of interacting psychological characteristics, which in turn predispose individuals to commit sexual offenses against youth and adults in specific immediate and recurrent social contexts. Predominantly, nonsexual personality and related conditions disorders related to sexual offending can be viewed as relating to the specific and cumulative effects of essentially dysfunctional or prepotent nonsexual *motivators* (including sensation-/thrill-seeking/risk-taking/novelty-seeking, anger/hostility, narcissism and entitlement, activating sexual offense-supportive attitudes, dominance/control (sadism), and desire for social belonging/nurturance) and varied and interacting factors of disinhibition, including failures of self-regulation and executive functioning. In addition, both other mental disorders (e.g., alcohol and drug use and ADHD) and select situational contexts also constitute potential nonsexual factors related to sexual offending. Despite the increasing

identified importance of nonsexual predisposing conditions to sexual offending, they have received remarkably little attention beyond that identification. Further, the field of personality and related predisposing conditions has changed dramatically over the past 20 years with important implications toward understanding the nature of nonsexual predisposing factors toward sexual offending. The purpose of this chapter is to review current perspectives on personality and related conditions and then to discuss their implications for sexual offending.

Toward A Contemporary Understanding of Personality and Related Conditions

Key Personality and Related Constructs in Relation to Sexual Offending

Personality, motivation, and self-control (inclusive of executive functioning and self-regulation) are all "fuzzy" concepts, each of whose boundaries and content are not fixed and precise. Moreover, each of these constructs overlaps, although both motivation and self-control (executive functioning and self-regulation) would all appear to be subsumed under the construct of personality. Costa and Widiger (2002) wrote: "Personality traits are often defined as enduring dimensions of individual differences in tendencies to show consistent patterns of thoughts, feelings, and actions" (p. 5). Others include attitudes and motivation as primary components of personality. The contemporary understanding of personality and its related conditions includes a number of perspectives that offer an updated and altered view of the nature, determinants, and organization of personality. More broadly and conceptually, personality has been understood as including regularities in or relatively enduring motivations; characteristic emotional orientations; mental representations (e.g., schemas) of self, others, and the "world"; interpersonal interaction sequences (e.g., social scripts); expectancies, goals, and motivation; regularities of appraisals and encoding of other persons and situations; self-regulation, executive functioning, and coping in reaction to stressors and distress; and strategies, competencies, and tactics in goal-directed action (e.g., Smith & MacKenzie, 2006). Relative to appreciating the role of nonsexual characteristics related to criminal sexual behavior, these perspectives are important in capturing the manner in which personality and related conditions function as key determinants in the occurrence of sexual offending. Current understanding of the interrelationship between personality, motivation, and self-regulation/self-control (executive functioning) offers valuable ways of considering relevant nonsexual factors in sexual offending. Other recent theoretical and empirical developments demonstrate that personality and related conditions are relatively consistent across similar situations and that individual differences in an individual's personality are best understood in characteristic behavioral signatures involving relatively consistent predispositions interacting with particular environmental characteristics. The core dimensional nature of personality has become clarified as a result of research, and the significant heritability of personality and related conditions has been demonstrated. In addition, it is now widely appreciated that personality has significant "unconscious" aspects and involves "dual" coexisting systems, both reflective and "hot" components. Both theory and scientific research have accrued that provide several frameworks for identifying those nonsexual personality and related conditions that appear important in the enactment of sexual offending. In turn, perspectives provide the framework for a discussion of personality and related conditions that interact with one another, as well as sexual factors, in the onset and maintenance of sexual offending.

Definitions and Aspects of Personality and Related Conditions

Personality Personality, although a term commonly used in varied communications, is actually quite a complex phenomena, one with many definitions and less than uniform agreement as to its nature. There is a common, everyday recognition that people manifest relatively uniform characteristics that allow them to be viewed as relatively constant, consistent, and unique (as a "particular" or "specific" person) and that persons have a relatively unique and consistent "identity" from the perspective of particular others and in common situations. From this more common perspective, personality is a global evaluation of a person's distinguishing attributes or characteristics of their inner experience and behavior; it can be viewed as an assessment of their individual distinctiveness or so-called individual differences. Personality refers to some consistency of predisposing elements for similar inner experiences and behavior over time that distinguishes persons from one another and is generally used to refer to those patterns of characteristic motivations, cognition content and processes, emotions or affective states, and behaviors that distinguish one person from another (systematic "distinctive" characteristics). At the same time, despite the perception that persons display relatively consistent features which distinguish them, there is also a secondary recognition that a person's experiences and behavior can be at least somewhat inconsistent to different degrees across situations and that there is some variation (and sometimes even complexity) to "who people are," temporally and situationally. Thus, personality can also be viewed as a "fuzzy" or multidimensional construct, a meaningful concept but one in which the content or boundaries vary—perhaps even considerably—according to context

or internal/external conditions and are not completely fixed; it has multiple meanings or manifestations which are clarified by elaboration and specification, particularly relative to context. Thus, within the personality literature, there is extensive discussion of "traits" [constructs of enduring characteristics as continuous dimensions (content and processes)] for which individual differences may be viewed and understood quantitatively in terms of the degree to which that characteristic applies to a particular individual (e.g., their degree of anger or concern for others) as well as a literature that identifies variation in personal characteristics across variations in internal and external factors, albeit still with consistency across those specific variations.

Motivation and Emotions Motivation and emotion are related constructs in that each is an affective and valenced (e.g., positive or negative toned) phenomena of psychological arousal that typically result in behavior; absent motivation or affect, it seems likely that no behavior will ensue. Both motivation and emotion are central dimensions of individual differences in personality, and each involves arousal as in physiological and/or psychological state of reaction to internal and external stimuli. They also exist in relation to one another, where the experience of or enacted motivation can elicit emotions and emotions can also serve as motivations. Emotions are most often considered the affective aspect of consciousness, the subjective experiences or reactions to events that occur in daily life, filtered by cognitions and accompanied by physiological changes. Motivation is considered to refer to the "impetus" or "movement" for action, for behavior; it is a process or experience of affective arousal that directs and impels a person toward particular "goals." Motivation is the "why" related to people's behavior and reflects internal states that "seek" external goals via behavioral enactment and that arise internally or are elicited or aggravated by environmental factors; these internal and external stimuli are seen as having the potential for two functions: informational and arousing or goal identification. Per Schultheiss, Strasser, Rosch, Kordik, and Graham (2012), "The term motivation characterizes an *affectively charged state* that energizes and directs action aimed at the attainment of a reward or avoidance of a punishment" (p. 650, emphasis added). Such stimuli initiate motivational and affective processes and are encoded and typically "matched" to memories based on previous learning. Common dimensions of motivation include activation (the sensitivity to and responsiveness of a range of stimulation to initiate arousal), persistence (continued effort toward a goal, often despite obstacles), and intensity (the vigor or strength over time) demonstrated in the pursuit of particular goals. Emotions are not typically associated with specific goals but may come to be stimuli for goals or experienced responses to goal-directed action. Hofmann and Kotabe (2012) distinguished between motivation and desire. They identified "desire" as an *affectively (emotionally) charged* motivation toward a certain object, person, or activity that is associated with pleasure or relief from displeasure. Desire refers to wanting to have or do something that instigates behavior. Desires are distinguished from general motivational states in that they are "about" *specific* objects or people and arise from the interplay of external stimuli, the individual's general motivational states, and a particular person's learning history. Motivations can and commonly do evolve or consolidate into dispositional states, where a specific individual is characterized by relatively persisting motivational factors and desires.

Corr, DeYoung, and McNaughton (2013) identify that most important classes of motivational stimuli can be grouped into "rewards" and "punishments" (or stimuli/behaviors desired and those avoided due to anticipated or associated fear), but point out that the *omission* of a perceived loss of an anticipated or expected "reward" is also experienced as punishment, a "frustrative non-reward." Per Corr et al., multiple motivational systems control both approach and avoidance behavior. Approach behavior includes *appetitive motivation* related to behavior directed toward goals that are usually associated with positive hedonic processes, while avoidance is related to *Aversive motivation* which involves escaping from some hedonically unpleasant condition (e.g., a reaction to a feared stimuli). Loewenstein (1996), in examining the discrepancies between actual behavior and perceived self-interest, emphasized the distinction between "visceral factors," which include motivational drive states including sexual desire and varied emotions, largely with hedonic qualities for the individual. He identified that the visceral factors had two implications:

> First, immediately experienced visceral factors have a disproportionate effect on behavior and trend to 'crowd' out virtually all goals other than that of mitigating the visceral factor. Second, people underweight, or even ignore, visceral factors that they will experience in the future, have experience in the past, or that are experienced by other people. (p. 272)

He noted that visceral factors, at higher levels of intensity, "can be so powerful as to virtually preclude decision making" (p. 273). More specifically, he argued that as visceral motivating factors increase in intensity, they overly focus attention and motivation on more proximal object goals and related "consumption," leading to suboptimal patterns of behavior and self-destructive behavior. Thus, he noted, "intense visceral factors tend to narrow one's focus inwardly"—to heighten self-centeredness and undermine concern for others. Put another way, visceral motivation impels individuals to myopically fixate on satisfying their immediate urges. Further, he noted that as time passes, persons tend to forget the degree of influence that such visceral motivations previously had on their own past behavior; consequently, most typically, past behavior that occurred under the influence of visceral factors will be increasingly forgotten.

Corr et al. (2013) noted that investigators such as Berridge (e.g., Berridge, Robinson, & Aldridge, 2009; Kringelbach & Berridge, 2012) have identified at least two major reward or motivational systems, one *incentive*-based ("wanting") and one *hedonic*-based ("liking"), each controlled by different brain sites. The incentive reward system involves motivation to seek reward (e.g., as iron toward a magnet) by commanding attention and enacting "approach"; an internal or external sensory experience causes some object or experience to be sought out. "Wanting" can range from particularly directional and "target-focused" to a broader projected range of more general rewarding stimuli. In contrast, the hedonic reward system is related to the "pleasure" or satisfaction (positive affect) experienced following attainment or contact with a reward/goal (which they note, as reinforcement, is relatively likely to produce enhanced motivation to subsequently approach similar "rewards"). These two reward systems constitute what is referred to as the pleasure system; further, it is noted that activation of the pleasure system aids in forming a cognitive representation of the rewarding stimulus in memory, which then renders that stimulus more likely to trigger later, repeated approach behaviors. This may represent a third aspect of motivation (learning), namely, the development of associations, representations, and anticipatory beliefs about future rewards. [In addition, subjective pleasure is but one element of reward, and "rewards" may influence behavior even in the absence of conscious awareness of them.]

However, dysfunctions of these motivational systems can occur. While wanting and enjoying typically go together, they may not always do so; typically, people want what they like and like what they want. In addition, sensitization occurs relative to motivated behavior, an *increase* in responsiveness to a stimulus (goal) or greater generalization to related (conditioned) stimuli. Within the context of sexual offending, motivation can be viewed as potentially expanding factors that create the intention or desire to enact what constitutes a sexual offense; in addition, related facilitatory factors increase the likelihood of committing a sexual offense, given the presence of relevant dispositions. In certain instances or for particular periods of varying time, habituation can also occur after repeated exposure to a specific stimulus, leading to at least temporarily decreased shifts in pursuit of particular stimuli but often associated with later renewed increase in reinforcement and more intensive pursuit of a goal. However, Kringelbach and Berridge noted that the incentive salience or "wanting" might become pathologically amplified so that the actual potency of liking or pleasure may actually decrease. Following the repeated gratification of goal seeking in behavior or imagination, an individual may become hyperresponsive and goal-cues become hyper-salient; this is referred to incentive sensitization or increased "wanting." Such cues and associations may be difficult to ignore, and motivational *toxicity* can arise where a motivation or drive effectively takes "control" of an individual's goal-directed behavior, relative to the expense of other aspects of their life (e.g., Esch & Stefano, 2004). Motivational "toxicity" occurs when an individual experiences a diminished or loss of behavioral control when presented with stimuli that have come to represent something desired and previously liked (something highly rewarding). Similar to drug addiction, such motivational toxicity is characterized by overvaluing certain stimuli or goals, reduced sensitivity to other potential rewards, and impaired inhibitory controls (sometimes in the context of dispositional impaired inhibitory controls) along the lines of heightened wanting. Such sensitized cue-triggered "wanting" or "overvaluing" a goal (despite the waning of the hedonic component) can persist for years after someone has stopped acting on the "liking" component of motivation and may account for the tendency of persons with dysfunctional motivational goals to relapse after quitting, sometimes even after many years of abstinence (e.g., Robinson & Berridge, 1993). Alternately, per Berridge et al. (2009), it may simply become easier to activate certain motivations and desires because of multiple brain pathways (expanded stimuli) that become responsive to expanded stimuli but harder to generate pleasure. Incentive sensitization produces a bias of attentional processing toward reward-associated stimuli; it also produces pathological motivation for the stimuli itself (compulsive "wanting"). Similar to addiction, based on more simple conditioning or learning, incentive sensitization can come to differ from more cognitive desires and lead to what might be referred to as "irrational" wanting, a "want" for something that is not cognitively or consciously desired (e.g., due to liking) caused by excessive incentive salience. Similar to substance abuse, this type of wanting or "incentive sensitization" may explain some portion of both the persisting and episodic activation and enactment of sexual offending.

Another aspect of motivation relates to individual's conscious perception of the degree to which their behavior is motivated. Relative to addiction, for example, Badger et al. (2007) found that people underestimate the influence of motivational states they are not currently experiencing. Thus, individuals typically cannot appreciate the intensity of impulses, desires, or temptations when they are not currently experiencing it. In addition, an inability to appreciate the subsequence motivational power of particular motivational factors likely contributes to initial decisions to pursue potentially unhealthy desires.

Emotions as affects are both similar to and different from motivation. Like motivation, emotions appear to be largely characterized by hedonic or valenced experience resulting from "events"; they can be responses to other internal experiences but are more often considered to be elicited in response to perceptions with varied degrees of consciousness of external events. Emotions, like motivations, are likely the product of multiple biological and experiential factors as well as personal values and goals. Thus, emotions are subjective

heightened sensations, typically but not always conscious; they are an affective experience that is characterized by physiological changes triggered by attention or pre-attentive processes and then typically "defined" or "filtered" by cognitive process or more enduring cognitive content. Thus, both motivations and emotions appear to be largely affected by cognitive appraisal; often out of immediate awareness, individuals experience sensations, but those interpretations, "labels," and meaning depend on cognitive processing in relation to the perceived environment. In turn, emotions affect both cognitive content and processing; it is widely believed that the brain systems that mediate emotions and cognitions overlap. In contrast to motivation, emotions are more reactive but less specific and less tied to explicit goal associations or directions. To a large degree by situation, emotions may be considered the subjective experience of being motivated. Like motivation, Bradley (2000) characterized emotions as having two primary dimensions: hedonic valences (varying in polarity from positive to negative) and degree of activation, arousal, or intensity. Emotions, as a subjective experience of states of recognized motivation, can and do impel a person to act in some particular way (e.g., to approach or avoid). In addition, emotions can also be thought of dispositions, similar to character traits, where an individual is predisposed to particular affects relative to other persons and thus characterized by predominant affective experiences and manifestations. Emotions and motivation appear to reflect a circularity or interaction; emotions can elicit motivation, and motivation is often associated with emotional experiences. Motivation is considered a state that produces behavior specifically oriented to propel a person toward one or more goals that have hedonic value, while more commonly emotions reflect an individual's status relative to such goals. Nonetheless, emotions and motivational states can act synergistically, creating more potent behavior fueled both by specific wanting and by anticipation of hedonic satisfaction.

"Impulses," "urges," or "desires" may best be viewed as either motivational or emotional manifestations relative to something specific at a particular time due to an interaction between constitutional, cognitive, and situational factors. They involve a push (an impulsion or impetus) or a pull (prompting, elicitation, or provocation) from some desired and/or present stimuli or imagined/perceptual stimuli. "Impulses," "urges," or "desires" typically involve varying degrees of arousal or intensity based on both a person's underlying predispositions and contextual factors and tend to be specifically directed. They tend to be immediate in a temporal and a "spatial" sense (directed toward short-term gratification) and possesses a strong incentive valued based on a hedonic (and wanting) reaction to a "tempting stimulus." Impulses, as a manifestation of motivation or emotion, typically represent a prepotent inclination to perform a certain behavior, typically an urge to approach or act on the underlying state(s). Hofmann et al. (2009a) noted that following impulses "seems to be the simplest and most natural thing in the world," but "most unconstrained impulsive behaviors interfere with the attainment of long-term goals or create conflict with others at some point." Hofmann and Kotabe (2012) make a distinction as well between desires/urges and "temptations," with the latter indicating that someone has a desire to engage in some behavior but also has some awareness that other factors present reasons not to act on the desire. Hofmann and Van Dillen (2012) note that a desire turns into a temptation (and thus enters the realm of self-control) only when or if the behavioral target conflicts with a person's values or self-regulatory goals. However, perhaps more important, they note that as individuals as ruminate about their desires and temptations, "they may generate more supporting cognitions that license and justify indulgence" (p. 319). Thus, cognitive awareness of desire or temptations can lead to an increase in impetus for actions.

Self-Control, Self-Regulation, and Executive Functioning As common definitions of personality include most relatively unique and enduring aspects of an individual's functioning, it is reasonable to consider individual differences in a person's "management" of motivation and emotions subsumed by personality. This overall process of management might most appropriately be labeled as self-control, where goal-directed behavior is "constrained" and modulated for optimal personal gain. Both personality theory and research demonstrate that a key developmental process is that shared social values, personal standards, and progressively longer-term goals typically become increasingly salient for individuals related to their experience of and expression of motivations and emotions. That is, particularly in a social world, many or most immediate manifestations of potentiated motivation and emotion become less acceptable or adaptive in the contexts of social norms and rules and in the individual's pursuit of valued longer-term goals. Several overlapping constructs refer to the elements of personality that represent the mechanisms by which impulses/urges/desires/temptations (stemming from motivational and emotional states) are managed, regulated, or controlled, typically in relation to maintaining some baseline level of functioning or of pursuit of more distal but highly valued alternative "goals." Numerous writers have suggested that self-control is the balance of attention to and consideration of "top-down" (goal driven) and "bottom-up" (stimulus driven) in particular contexts. In most respects, self-control is generally synonymous with "inhibition," defined as the conscious or unconscious restraining, constraint, or suppression of impulse-generated behavior. Thus, self-control exists as the opposite of "disinhibition," when disinhibition is understood as a condition or process in which an individual manifests

absent or reduced capacity to or in intention to manage pressing motivators (e.g., urges, temptations, emotions) in a situation and, as a consequence, acts on a desire or state of arousal in a relatively unmodulated manner. Biologically, self-control appears to be generally distinct from much of what is implied by "impulsivity" (Hofmann et al., 2009a, b; Reynolds, Ortegren, Richards, & Wit, 2006). Self-control represents constraint, relative inhibition or modulation of reactive emotional states and elicited and impelled motivational states (particularly prepotent or heightened dispositional characteristics) as manifested in particular impulses; more specifically, it refers to the effortful control and potential altering of motivations/emotions, thoughts, and behaviors "in the service of" personal and social goals or values. Available research indicates that individuals differ in their dispositional (generally enduring) ability to exert self-control (trait self-control) and also in their current, momentarily available resources for exerting self-control (state self-control); dispositional self-management can be affected by various internal factors such as distress, depletion, or situational demands. In terms of trait self-control, some individuals demonstrate a strong ability to self-regulate consistently from early childhood through adulthood, whereas others are consistently less successful at self-regulating. Generally, self-regulation is viewed as highly adaptive; Metcalfe and Mischel (2004) and Mischel (1999) spoke to the presence of self-regulatory features of persons that exist to manage (or not) less substantive impulses and feelings pressing for release so that less immediate and long-term goals can be obtained. Data clearly supports that self-control is highly adaptive: Tangney, Baumeister, and Boone (2004) found that persons with high scores on self-control were better off than those with low self-control on virtually all indices of effective adult functioning.

Self-regulation is a term often used as synonymous with self-control. However, within the psychological research literature, self-regulation most commonly refers to the more conscious resolution of conflict between immediate goals or desires and more long-term, socially, or personally valued goals. Baumeister (1998) indicated that self-regulation refers to the self-monitoring and managing one's self by altering its own responses or inner "states" (e.g., motivational or emotional) typically to delay gratification of overriding a particular state-based response to or behavior and replacing it with a more desired response related to "higher" or more long-term goals. As such, it is for the most part a more conscious top-down process, requiring awareness of the conflict of an inner state, the potential immediate response, and potential longer-term goals. Self-regulation requires such capacities as self-awareness (self-directed attention), planning (considering, organizing, and selecting among goals and strategies for actions), and the ability to delay gratification of urges, temptations, or surges of affect. Hofman et al. (2012a) suggested that, in a broad sense, successful self-regulation entails *social and personal standards*, sufficient *motivation to resolve discrepancies* between standards and actual states, and *sufficient capacity to achieve these thing*s in light of obstacles and temptations along the way. As standards, recognition of conflicts within the "self" and the capacities to address such conflicts self-control (or self-regulation) is the ability or capacity to "manage" the potentially conflicting experiences or expressions of one's feelings, motivations, and behaviors in order to obtain some more distal "reward" (or desired goals) and to avoid punishment. In various writings (e.g., Baumeister & Heatherton, 1996; Muraven & Baumeister, 2000), Baumeister has suggested that "strength model" or ego depletion models were most appropriate for self-regulation of such impulses. By this, he identified that a person's capacity for self-regulation appears to be a limited, finite constitutional resource, albeit potentially renewable over time and, to some extent, of being capable of being increased or decreased as a function of relative practice. In reviewing the literature on self-regulation, the ego depletion model of self-regulation has achieved wide acceptance, both theoretically and empirically. Baumeister and Heatherton (1996) indicated that given individual differences, some persons will demonstrate broad deficits in self-regulation in managing desires or other states; others will only show self-regulatory failure under specific situations (e.g., under stress, when overwhelmed by many simultaneous demands for self-control) and that self-regulation can be strengthened and facilitated by regular use and practice. However, Baumeister and colleagues argued that self-control "strength" is expended in the process of self-regulation; without replenishment of that strength, select persons may become acutely and chronically deficient in self-regulation and thus even more vulnerable to diminished expectancies of control or enhanced perception of "temptation" or competing motivational factors. However, while both persons high and low in self-control are subject to depletion in self-control, persons high in trait or dispositional self-control remain more capable of extended management than do persons with low trait self-control.

Executive functions (EF) are typically referenced in a neuropsychological context and have been described in a number of ways. Like personality, EF is also considered a "fuzzy," multifaceted construct that typically references a set of higher-order neurocognitive processes (e.g., metacognition: the cognition of conditions involved with monitoring and control of cognition) that allow persons to make choices and to engage in purposeful, goal-directed, and future-oriented behavior; EF is sometimes viewed as encompassing self-regulation (e.g., Barkley, 1997) or as providing the cognitive-affective structures and processes that provide both the bottom-up and top-down basis of self-control (e.g., Hofmann et al., 2012). As a cognitive "meta-process" or metacognition, Friedman et al. (2008) suggested that "inhibition" was the construct most closely related to a common or overall EF

factor, particularly in relation to real-world problems. Barkley (2012a, b) identified EFs as specific types of self-regulation or self-directed actions that people use to manage themselves effectively in order to sustain their actions (and problem-solving) toward their goals and the future. The elements of EF "permeate[s] psychology even when the construct itself is not invoked. In fact, self-regulation, self-control, emotion regulation, delay of gratification, attentional control, self-monitoring and response modulation, to name a few, all rely on some aspects of EF" (Suchy, 2009, p. 11). Similarly, EF has been defined as a collection of varying abilities that involve regulatory control over thought and behavior in the service of goal-directed or intentional activity, problem-solving, and adjustment of behavior to meet situational demands, particularly contextually appropriate behavior, and to inhibit unsuccessful, inappropriate, or impulsive behaviors (e.g., De Brito & Hodgins, 2009b). Barkley (2012b) noted that when experts in EF were asked to generate terms that would be considered, they came up with a total of 33; the greatest agreement was for the following six: (1) self-regulation, (2) sequencing of behavior, (3) flexibility or shifting of behavior, (4) response inhibition, (5) planning or strategy evaluation, and (6) organization of behavior. EF appears particularly important in a person's management of novel, nonroutine, and/or unstructured situations, managing overlearned patterns of experience (thought, feeling, and behavior) and seems essential to avoiding or inhibiting strong responses that are inappropriate to context or other parameters. Per Suchy (2009), EF can be viewed as both an evolutionary and learned adaptation that frees a person

> …from innate, hardwired drives and reflexes, as well as from over-practiced, over-learned and prepotent response…[EF] allows us the latitude of considering options and selecting a specific response to any given stimulus s based on situational contexts, previously acquired knowledge, and long-term goals. (p. 106)

He noted that EF is particularly effortful process that remains "dormant" for much of a person's everyday life and only comes on line when a person perceives a novel and/or complex situation that precludes an automatic, routine response. Further, Eslinger (1996) suggested that EF was most importantly a "social executor" and that social disabilities arising from EF impairment were the most distinctive aspect of EF.[1] There is considerable agreement that EF is best understood as a multidimensional, meta-cognitive process, where the "whole" is greater than the specific components identified in experimental and clinical assessment, many of which appear to overlap and interact with each other.

From a developmental perspective, so-called effortful control is regarded as a primary temperamental dimension and may properly be regarded as a dimension of personality, characterized by individual differences in its elements (e.g., Rothbart, 2007). As an early manifestation of a critical personality disposition, effortful control includes the focusing and shifting of attention, inhibitory control, perceptual sensitivity, and a higher threshold for pleasure. This factor reflects the degree to which a child can focus attention, is not easily distracted, can restrain a dominant response in order to execute a nondominant (as opposed to a prepotent) response, and to employ delay of gratification and planning. Developmentally, Rothbart (2007) has suggested that effortful control is based on and dependent on the particular development of "executive" attention skills in the early years. In turn, such attentional skills allow greater self-monitoring and, thus, the potential for control over reactive tendencies. Bridgett, Oddi, Laake, Murdock, and Bachmann (2013) demonstrated that generally EF and effortful control overlap, particularly with regard to self-monitoring and working memory, but *not* with inhibition (e.g., similar to Reynolds et al., 2006); compromised EF, specifically in combination with deficient inhibition (e.g., disinhibition), was uniquely associated with increased tendency to enact negative affectivity. Conversely, trait negative affect-mediated—undermined—EF and effortful control. Thus, developmentally as well as biologically, the dispositions for self-control and for impulsivity appear to be independent; their relative presence can conflict or potentiate prepotent motivations.

Barkley (2012b) proposed that the six core domains of EF include:

1. Attention and self-awareness (the ability to focus attention on one's self) as the starting point or pinnacle EF.
2. Executive inhibition (or cognitive inhibition) provides the ability to separate external stimuli from a response, inhibit or use self-restraint from immediate reaction, or enact a prepotent or more "automatic" motor response to allow a more "considered" response.
3. *Nonverbal* working memory involves the use of self-related multisensory mental representation (particularly imagery). This capacity allows seeing potential behavior in one's mind. This allows behavioral reenactments or rehearsal in memory related to hindsight and foresight (e.g., over time) and permits imagining a hypothetical future from an experienced past.
4. Verbal working memory refers to the "mind's voice," "self-talk," or private speech as a means of self-guidance. It involves providing self-direction and/or questioning oneself in a novel situation and permits the discussion of conflicts between longer-term self-interests and short-term self-interests.
5. Appraisal of motivation and emotion rooted in self-awareness. This allows for self-control (modulation) of feelings and urges that arise in the context of internal and external stimulation and provides a potential "metric" for

[1] Unfortunately, as Barkley (2012b) has noted, the measurement tasks typically utilized to assess EF (e.g., neuropsychological instruments) lack ecological validity for many issues, creating potential issues for generalization to real-life unstructured, novel situations. Nonetheless, the presence of deficits in EF in controlled evaluation sessions clearly suggests the probability of such deficits in novel, "real-world" settings.

"calculating" costs and benefits of possible courses of action (goals and means of attaining goals).
6. Problem-solving involves analyzing the features of one's environment and one's past behavior to develop plans for goal-directed action, then weighing pros and cons, and then making choices. Manipulate information into novel combinations to overcome obstacles and achieve weighed goals.

Moffitt (1990) effectively likened the day-to-day operations of the frontal lobes as the site and/or mechanisms of EF, stating:

> The normal functions of the frontal lobes of the brain include *sustaining attention and concentration*, abstract reasoning and concept formation, goal formulation, *anticipation and planning*, programming and initiation of purposive sequences of motor behavior, effective
> *self-monitoring of behavior* and self-awareness, and *inhibition of unsuccessful, inappropriate,*
> *or impulsive behaviors*, with adaptive shifting to alternative behaviors. These functions are
> commonly referred to as "executive functions," and they hold consequent implications for
> social judgment, *self-control*, responsiveness to punishment, and ethical behavior. (p. 115; emphasis added)

Thus, per Moffitt and others (e.g., Beaver et al., 2007), both executive functions and self-control are focused on the importance of regulating impulsive tendencies and the ability to control emotions and sustain attention, the salience of mental capabilities and cognitive functioning to anticipate and forecast behavioral consequences, and the ability to modulate tempers and to inhibit inappropriate conduct and are strongly related to aberrant, delinquent, and violent behaviors.

Impulsivity and Disinhibition Relative to Personality Conversationally, self-control is often conceptualized as particularly directed at the management of impulsivity, where impulsivity represents the opposite of self-control. However, increasingly, impulsivity is viewed as a multidimensional construct. First, it clearly involves both trait (dispositional) and state elements but also consists of varied subcomponents depending on context and measurement (e.g., Cross et al., 2011; Derefinko, DeWall, Metz, Walsh, & Lynam, 2011). Generally, impulsivity is viewed as the tendency (force, urge) to act on motivated desire/temptation or emotions with no or diminished consideration of consequences (particularly more distal or negative ones), often leading to inappropriate or even risky behavior that is inappropriate to a situation and/or leads to undesirable consequences. Others view impulsivity more simply as a rapid, unplanned reactions to stimuli without adequate processing of relevant information ("impulsive" decision-making); from a psychiatric perspective, Moeller et al. (2001) defined impulsivity as "…a predisposition toward rapid unplanned reaction to internal or external stimuli without regard to the negative consequences of these reactions to the impulsive individual or other others" (p. 1784).[2] Whiteside and Lynam (2001) used factor analysis of well-identified personality factors and found four distinct personality facets associated with impulsive-like behavior including sensation-seeking, urgency, (lack of) premeditation, and (lack of) perseverance (persistence). These traits were utilized to create the UPPS Impulsive Behavior Scale. Urgency is the tendency to act rashly; negative urgency involves reacting when experiencing negative affect (e.g., when distressed), while positive urgency involves reacting when experiencing positive affect. Sensation-seeking was the tendency to seek out novel and excitement. Lack of planning is the tendency not to think ahead before acting, while lack of persistence is the inability to sustain attention and motivation in pursuit of a more distal goal. Miller, Flory, Lynam, and Leukefeld (2003) validated these four dimensions of impulsivity. Smith et al. (2007) utilized factor analysis and found that lack of planning and lack persistence appeared to be two facets of a larger factor. Miller et al. found that lack of premeditation (deficient ability to consider possible consequences of one's behavior before acting) and sensation-seeking were the most consistent dimensions of impulsivity in predicting externalizing behavior. Leshem and Glicksohn (2007) also found that trait impulsivity was to a large degree related to heightened "venturesomness" or sensation-seeking. Sensation-seeking appeared to relate to the frequency of engaging in such behavior, while urgency as a dispositional element appeared to relate to a range of problem behaviors. Smith et al. indicated that rash action when distressed was distracting from negative affect and might lead to behavior that is pleasurable and leads to an immediate decrease in distress (negative reinforcement). From this perspective, without the experience of immediate punishing consequences, opportunities are missed to learn more effective self-management responses. Tuttle et al. distinguished the *capacity* for self-control from a *desire/interest* to exercise such control, inserting a volitional component (e.g., a motivation or intent to apply self-control); persons differ both in their "self-management skills" and the value they attach to utilizing those skills, perhaps relative to particular motivations and contexts. Impulsivity appears to be characterized by individual differences in a value or goal-related dimension (is it necessary or of importance to an individual

[2] In distinction, compulsivity refers to repetitive behaviors that are performed according to certain rules or in a stereotypical fashion and if resisted lead to negative affect. Impulsivity is more associated with pleasure seeking. Compulsivity is a tendency to repeat the same, seemingly purposeless acts, which are sometimes associated with undesirable consequences. Both impulsivity and compulsivity can be viewed as volitional impairment, with compulsivity more apparently driven by cognitive factors. Sexual behavior can be a product of compulsivity, but sexual offenses are more likely to be impulsive in nature.

to exercise self-regulation of one or more particular impulses?) as well as by the relative strength (dispositional or situational), to enact constraint in the presence of impelled or elicited states. What can be seen in the various definitions of impulsivity is that, for most writers, the construct consists of impulsivity which is composed of two components: motivators or behaviorally activating factors (sensation-seeking, urgency) and deficits in inhibition. Inhibition refers to the process of overriding urgent impulses or desires by the "stopping" or "slowing" of some psychological phenomena (with or without conscious intention) either temporarily, intermittently, or permanently. This second component of so-called impulsivity may be best referred to as disinhibition, reflecting limitations in EF, self-regulation, and other aspects of self-control (a lack of various inhibiting or modulating factors including planning, premeditation, and persistence toward more distal goals).

In short, among the more critical aspect of personality and related behaviors are motivation and self-control (as including both executive functioning and self-regulation). On all levels of understanding (e.g., biological, developmental, and psychological), these are each overlapping, related and interacting constructs. It is clear that dysfunctions in motivation and self-control all likely play key roles in sexual offending, including those instances where nonsexual predisposing factors appear to predominate or function as primary risk factors in sexual offending.

Relevant Perspectives on Personality

Personality as Dimensional

A primary development in the understanding of personality is the growing acceptance of theory based on increasing and relatively consistent research regarding the central or primary dimensions of personality. Dimensional structural models of personality reflect theoretical and empirical efforts to identify the "essential" or "primary" domains of personality on which people differ both in type and degree. Structural-dimensional models of personality are hierarchical with a greater number of personality "facets" subsumed under limited number of superordinate personality factors. A number of dimensional models of personality have been proposed, all of which have a significant amount of overlap (Eysenck, 1967; Leary, 1957; Gray, 1994; Cloninger, 1987, 1979; Zuckerman, Kuhlman, Thornquist, & Kiers; 1991; Tellegen & Waller, 1992; and the Five-Factor Model (FFM) developed by McCrae & Costa, 2003, 2004). In particular, the FFM has become the most generally accepted model of general personality structure and provides a basis for understanding personality disorders (or sets of maladaptive persons laity characteristics) as abnormal variants of normal personality dimensions (see also Markon, Krueger, & Watson, 2005). From the perspective of the FFM, a review of the literature would indicate that a number of personality dimensions have been implicated in criminal, violent, and sexual offending including antagonism and negative emotionality (anger, hostility, distress), sensation-seeking and risk-taking, a lack of premeditation or thoughtfulness (deficient ability to consider possible consequences of one's behavior before acting), low conscientiousness and constraint, and a general (historical) impulsiveness.

Personality and Related Conditions as "Dual Systems"

Motivational and emotional aspects of personality are manifested in the context of self-regulation/self-control; they are the "yin" and "yang" of much human behavior such that this duality is a key aspect to personality (e.g., as a "dual system" of motivational forces in the context of varying degrees of regulation/constraint). However, both motivational and emotional conditions vary as psychological phenomena; some are more "visceral," "incendiary," and "tempting" than others, with the "hotter" incentives eliciting more potent motivation than the "cooler" incentives in individuals. While satiation can occur, as does self-control depletion, most appetitive or consummatory urges increase again over time, particularly to the degree that they have resulted in previous positive reinforcement (either behaviorally or via covert reinforcement through imaginal processes). In certain instances, even "sated" persons may respond with approach behavior toward someone or something that has particularly high incentive value; novel, dispositionally exciting stimuli appear particularly potent. [In contrast, most long-term, distal goals acquire motivational power only over time and through socialization.]

Among others, Metcalfe and Mischel (1999), Hoffman et al. (2009), and Kahneman (2011) have proposed the conceptualization of a dual processing framework, involving "hot" and "cool" dimensions. The "hot system" of processing experiences appears to be a "bottom-up" system developmentally specialized for quick emotional processing and response on the basis of unconditioned or conditional trigger features, a "go" system as in a basic fight or flight process. The hot system provides the basis for dealing with relatively automatic responses to both appetitive and fear-producing stimuli. Thus, rapid automatic triggering, conditioned responding, inflexibility, stereotypic and affective primacy characterize "hot" systems. In contrast, the "cool cognitive system" is a "top-down" one, specialized for more complex, longer-term goals and representation and thought, a "know"

system. The cool system provides the mechanism for a more integrated, personal identity, such that simple to complex knowledge about sensations and emotions, thoughts, actions, and contexts are organized into a personal and "world" narrative that is typically coherent and capable of deferring automatic reactions to appetitive and threat stimuli toward more long-term goals for self or society. Metcalfe and Mischel suggest that when the "hot system" is dominant (when the cool system is inadequately developed, temporarily or chronically dysfunctional, or an individual does not "activate" their available control strategies), the simple exposure of a salient "hot stimulus" will typically elicit the automatic relevant and/or prepotent response. Under such conditions, person's cognitive processing of powerful, visceral motivators is often fast, automatic, largely unconscious, and, depending on context, potentially costly in terms of competing goals.

Barkley (2012b) too noted the importance of essential "adaptive" self-management or self-regulation "in the face of strong temptations and immediate 'hot' situational triggers that elicit impulsive, automatic responses that threaten the individual's pursuit of more important distal goals…" (p. 17). Barkley noted that motivations for pleasure (and for avoiding pain) and the emotions that accompany everyday and stressful experiences serve as the "hot" domain of EF providing the "why" or basis for behavior. [To be contrasted with the "cool" domain of EF (such as working memory, planning, problem-solving, and foresight) which may provide the basis for the "how, when, where" of behavior.] Another dimension to EF is evidence that they may operate differently in different contexts relative to the degree of affective or motivational valence perceived in contexts or situations. A notion of "cool" EFs refers to "to-down" processes that are purely cognitive in nature and elicited in neutral settings; working memory, sustained attention, set-shifting, and certain types of response inhibitions are considered to be cool EFs. For example, the inattentiveness associated with ADHD likely reflects cool EF deficits. In contrast, "hot" EFs are viewed as cognitive processes that have an affective, motivational, or incentive component and involve more affective decision-making such as appraising the significance of a stimulus, a state of heightened arousal (motivational significance) or behavioral choices related to a desired stimulus or elevated arousal. Disinhibition is likely to be a function of deficits in either or both cool or hot EF.

Relative to criminal, violent, and sexual offending, it seems likely that "hot" systems of both motivation and control are relatively potentiated for individual perpetrators; more predisposing conditions for sexual offending are relatively simple, prepotent, and automatic, while "cool" systems are either underdeveloped or ignored generally and/or in specific situations of particular affective valence.

Personality and Related Conditions Have Significant "Unconsciou" (or Out of Awareness) Elements

In psychological science, there is increased awareness of the significance of *unconscious* processing of internal and external stimuli; in fact, it appears that a considerable amount of psychological experience (motivation/affect, thoughts) occurs outside of personal awareness. As Nisbett and Wilson (1977) suggested in their seminal article, most or many persons are neither aware of nor can accurately report on the true causes of their behavior. Cognitive unconsciousness refers to the findings that much of what the mind "does" occurs outside of consciousness, for example, leading to relatively automatic behaviors. A key distinction of personality, particularly relative to motivations as internal states, is that between explicit (conscious) and implicit (unconscious) motivations; as Westen (2006) has noted, a large body of research indicates that motivation falls into both categories and may have different antecedents. Bargh and Morsella (2008) noted, "…the past 25 years have produced a stream of surprising findings regarding complex judgmental and behavioral phenomena that operate outside [personal] awareness" (p. 75). Westen (1999) has pointed to the activation of unconscious beliefs, fantasies, networks of association, and experiences that are unconscious but can substantially influence conscious thought and behavior, remaining relatively inert until activated by internal or external stimuli. He noted that considerable motivational and affective processing, including sexual arousal, occurs outside of personal awareness. Bargh and Morsella (2008) confirmed that unconscious "simulation" of a desired or wanted course of action can be learned without actually performing such actions via observation, modeling, narratives, and so on (and thus without initial risk or other consequences). They also pointed out that such unconscious fantasies and urges may *also* come to be experienced as explicit, conscious ones and that unconscious and conscious fantasies can serve as convergent stimulation for potential, future action. Bargh and Morsella also pointed out that unconscious motivations, like thought processes, become automatized particularly through high reinforcement in particular situations. Schultheiss et al. (2012) noted that implicit motivation is generally biologically based motivation related to the attainment of pleasurable and rewarding goal states and which typically influences behavior "non-consciously;" such implicit motivation directs behavior toward incentives and away from disincentives without requiring conscious awareness. In fact, research suggests that people who are *less perceptive* of their visceral reactions appear to exhibit stronger affective responses to evocative stimuli (e.g., Larsen, 2000).

Persistent and Situationally Expressed Personality and Other Characteristics

Regarding personality, there is a recognition that people respond similarly and somewhat consistently to similar situations or conditions but not the same at every time and/or situation; the intuitive notion is that personality is probabilistic. Thus, personality is most commonly conceptualized as those *relatively stable characteristics* of a person that make their behavior relatively predictable similar across time and situations, the common ways that persons adapt to the situations that they encounter in their lives. Such traits represent relatively enduring dispositions or vulnerabilities that are relatively distal to particular acts (e.g., Ward & Hudson, 1998).

Mischel (1968) was perhaps the first personality theorist to argue emphatically for the position that then personality and related behavior were too cross-situationally variable. He claimed that the view that personality traits as inherently uniform dispositions was unacceptable and that perceived consistency might reside in the consistency of situations that persons were exposed too. He described the "personality paradox," referring to the attempts to reconcile the "invariance and stability of personality with the equally compelling empirical evidence of the variability of the person's behavior across diverse situations…" (p. 1). Over time, via theory and research, a rapprochement or integration has been achieved in terms of reconciling the overall stability of personality dimensions and the manner or degree to which situations elicit sometimes different but relatively consistent responses. Buss (1979) pointed out that while the effect of personality is dependent on situations (and vice versa), biologically based personality predispositions act to create greater consistency in finding certain situations, so that individuals affect their exposure to situations by their "inclinations" to behave similarly across situations. Currently, psychological science recognizes that a significant degree of consistency in personality is best understood as patterns of behavioral response to variation in specific types of situations, with the recognition that individuals may behave "non-prototypically" as a function of distinct or unexpected properties of the environment or situation exerting influence on existing predisposing personality and EF factors. Individual differences in particular dispositions moderate a person's responses in particular situations or classes of situations; proximal situational factors are events that may elicit more transitory "states" that are manifestations of less apparent or unconscious individual predispositions or vulnerabilities and lead to particular behaviors under particular environmental influences.

In recent writings, Mischel and Schoda (1995, 1998, 2004) noted that when aggregating an individual's behavior on a given dimension over many different situations to estimate "true" characteristics of the individual, data shows that specific persons can differ significantly on certain dimensions given the particular characteristics of situations and still show stable overall individual differences. He has argued that individual differences would be expressed less in varied cross-situational behavior and more in distinctive (but still relatively stable) patterns of "if, then situation behavior relations," what he describes as contextualized, psychologically meaningful *personality signatures* (e.g., "he does A when X, but B when Y"). Such *if, then* patterns or *personality signatures* (or behavioral scripts) would be likely to become activated in relation to the perception of specific situations; those scripts would be similar across perceived similarities in particular situations but might vary when situations were perceived as different. Similarly, motivations/emotions and self-regulation/control are also contextual phenomena. Schultheiss et al. (2012) pointed out that goal-directed behavior is a joint product of the individual's internal need (e.g., sexual arousal or control) and situational incentives (sexual- or dominance-related cues) that allow the expression of this need, stating "A specific episode of motivated behavior is set in motion by the interplay of an internal need and the presence of suitable external incentive cues and persists until the individual reaches the desired reward" (p. 651). Internal states, such as deprivation or satiation, will affect the sensitivity to external cues, intensity, duration, and expression of appetitive behavior. The density, novelty, vividness, and other aspects of environmental cues may also affect both drivers and regulators of behavior, both on conscious and unconscious levels.

Similarly, to the contextual basis of other personality characteristics, the role or meaning of EF will vary across individuals and contexts. Individuals with more limited EF or less practiced EF are likely to find themselves in positions of increased stress exposure, to show increased stress reactivity and development of problematic coping strategies that in turn have greater potential to be stress generating. EF influences self-regulation in interpersonal contexts and thus enhances some individuals' vulnerability to interpersonal conflict or degrades social support. A person with well-developed reasoning and problem-solving skills faced with a particular situation may rely on minimal EF "skills," while possible effective adaptation to the same situation may require a person with less developed skills or cognitive limitations to rely more highly on EF "skills" or face adaptive "failure." Thus, the particular person's history and status of EF characteristics affect their reliance on more effortful and extensive use of EF skills. Further, common or routine situations may not typically demand much in the way of EF skills, while a novel or complex situation may identify that EF skills are insufficient and/or poorly practiced and lead to functional impairment or distress; as Suchy (2009) put it, "The better practiced the skills, the less reflective of EF they actually are" (p. 111; emphasis in original).

Personality and Self-Control (Including Self-regulation and EF) Are Significantly Genetically Determined

Over the past 30 years, an abundance of research has accrued demonstrating the heritability of most characteristics of human behavior, including personality. Livesley (Livesley, Jang, Jackson, & Vernon, 1993, 2006; Livesley & Jang, 2008) has noted that behavioral genetic research provides convincing evidence of extensive genetic influences on individual differences in normal and disordered personality. Heritability is typically estimated in the 40–60 % range, and environmental influences are largely confined to non-shared effects (unique experiences of the individual relative to siblings). Per Livesley, "heritability does not differ significantly across traits and heritability estimates are not appreciably influenced by method of measurement" (pp. 42–43). He further showed that there was extremely high congruence between genetic and phenotypic factor structures including the domains of emotional dysregulation, antisocial, and inhibition. Livesley suggested that the research indicated a few general genetic factors account for observed trait covariation, mostly via extensive pleiotropic effects (e.g., a single genetic entity influencing several distinct phenotypes or behavioral expressions). That is, a particular individual may manifest several different mental disorders because of a single genetic contribution, or a small set of shared genetic contributions, thus leading to the common phenomenon of psychiatric comorbidities. Livesley also noted that environmental influences on personality traits, while similar in magnitude to genetic influences, most probably act to consolidate the pleiotropic effects. Thus, genetic factors interact, most typically in an exacerbating or aggravating way, with environmental factors. That is, heritable personality dimensions are not completely independent and are more commonly compounded or exaggerated by varied environmental effects.

Factor analysis of studies of comorbid mental disorders have repeatedly revealed two broad dimensions accounting for systematic covariance among disorders (e.g., Krueger, 1999; Krueger et al., 2001). The first dimension is an internalizing factor (representing fear, anxiety, and mood disorders). The second dimension is an externalizing factor representing traits and characteristics associated with antisocial personality and substance abuse disorders. As a result of these and other behavioral genetic studies, these externalizing psychopathological conditions appear to have strong biological, genetic links to one another; strong evidence exists of a common externalizing liability for a "family" of antisocial and related disorders of dysregulation. Relative to externalizing proneness, two subdomains have been identified as particularly relevant: *disinhibition* (including traits such as impulsivity, sensation-seeking, and unconventionality) and a subtype of *negative affectivity* (anger, suspiciousness, and aggression as distinguished from depression and anxiety). Krueger and colleagues have termed this collection of antisocial personality characteristics and disorders, substance abuse/dependence, and attention-deficit hyperactivity disorder (ADHD) as "externalizing spectrum disorders" (ESD) which later work found was a continuous genetic liability (e.g., Markon & Krueger, 2005). In their review of a number of recent twin studies, Krueger et al. (2002) reported very high heritability (80 %) of externalizing proneness (e.g., disinhibition) as accounting for the shared variance among antisocial and substance abuse disorders; Egan (2011) found similar results. Kendler, Aggen, and Patrick (2012) identified that from a genetic perspective, two dimensions of genetic risk reflecting aggressive disregard and disinhibition influence the dispositions related to antisocial behavior/personality. Similarly, dimensions of Fearless-Dominance and Impulsive-Antisociality showed genetic covariation with externalizing psychopathology (Blonigen, Hicks, Krueger, Patrick, & Iacono, 2005). Other research also demonstrates that impulsivity (disinhibition) appears highly heritable; genetic factors account for between 44 and 56 % of variation in low self-control. Niv et al. (2012) demonstrated the heritability and longitudinal stability of impulsive tendencies across adolescence, with additional genetic and environmental effects also coming into play at later ages. Utilizing a longitudinal study of youth, Beaver, Wright, DeLisi, and Vaughan (2008) identified that genetic factors accounted for between 52 and 64 % of the variance in self-control, that self-control was relatively stable and was determined almost exclusively by genetic factors. Relatedly, Barnes and Boutwell (2012) found that genetic factors accounted for 97 % of the stability in offending behavior over a 13-year span from adolescence to adulthood. In other words, when antisocial conditions are extreme and stable, genes are disproportionately responsible. Boutwell and Beaver (2010) showed that once genetic factors in self-control were statistically controlled, the effects of parental socialization were minimal, with the exception of associative mating. Livesley et al. (1993) found that narcissism (most specifically the vulnerable narcissistic dimension) had a particular high heritability; other dimensions of personality that had heritability coefficients greater than 0.5 were callousness, oppositionality, and social avoidance. Torgersen et al. (2000) determined that the heritability for ASPD, BPD, and NPD were approximately .70 and the effects of shared/familial environmental effect was zero. Similarly, Trull and Durrett (2005) also found that when symptoms of all the personality disorders were factor-analyzed, a unidimensional factor reflecting dissociality/psychopathy emerged. Egan (2011) reported an effect size of .5 for heritability of criminal offending, *independent* of the presence of a personality disorder. Nestor (2002) noted that

commonly SAB are also accompanied by distinct comorbid conditions, specifically Cluster B disorders (particularly ASPD), in part due to shared genetic liability. Hodgins (2007) noted several studies indicating that callous-unemotional traits in youth as well as psychopathic traits in adults showed high heritability. Multiple studies have also found a very strong heritable component to EF (e.g., Rothbart, 2007; Bell & Deater-Deckard, 2007; Coolidge, DenBoer, & Segal, 2004; Friedman et al., 2008). Per Friedman et al. (2008), central executive functions are correlated because they are influenced by a *highly* heritable (99 %) common factor that goes beyond general intelligence or perceptual speed; Young et al. (2009) reported similar findings. This combination of general and specific genetic influences places executive functions among the most heritable psychological traits. Similarly, low self-control has been demonstrated to have a significant genetic or heritability effect; Bezdjian et al. (2011) referenced studies showing that even after controlling for multiple demographic and environmental factors, heritability accounted for over 50 % of the variance in self-control. Conversely, Young et al. (2009) reported behavioral disinhibition (e.g., deficits in self-control) as having a highly heritable genetic liability of .82 and concluding that collective results provide compelling evidence that the etiology of behavioral disinhibition is primarily genetic and that the primary mechanisms of action were deficits in cognitive response inhibition.

In addition to a pure strong genetic diathesis, developmental and situational contexts determine the degree to which such a genetic liability is expressed. Particular genetic influences (e.g., impulsivity, hyperactivity, lower intelligence) increase the odds of exposure to particular (non-shared) environments or situations and lead to aggravation (and sometimes mitigation) of a particular dimension of personality. Thus, children high in impulsivity and disinhibition are often born to a parent with similar difficulties or who for other reasons are not effective at encouraging the development of self-control or prosocial attitudes; there is "goodness of fit" for preservation and exacerbation of those characteristics but poor fit for effective modification of them (e.g., Lykken, 1995). At the same time, Buker (2011) reviewed research indicating that most parenting measures showed small effects once measures of EF were covaried and that psychopathological personality features captured a significant amount of variance in self-control. Krueger et al. (2002) pointed to the likely development and expression of a self-reinforcing cycle, where impulsivity and antisocial behavior (substance use) leads to increases in disinhibition/novelty-seeking and continued antisocial behavior and substance use. Further, genetic or evolutionary perspectives suggest that persons who are "competitively disadvantaged" in terms of obtaining resources through socially acceptable means (e.g., agreeableness and higher intelligence) and are characterized by high degree of impulsivity and sensation-seeking may be more likely to engage in antisocial behavior as a means of obtaining those resources. While heritability is a prominent factor in personality and related conditions, it is important to appreciate that a key aspect of the power of such biological determinants bias may be understood to lie primarily in their ability to limit or restrain the acquisition of alternative personality dimensions rather than to simply determine a particular one.

In summary, there are several key aspects of personality, self-control, and EF that are important to consider in understanding their nature and expression. First, all three domains are dimensional in nature, and persons vary in the degree to which a particular characteristics is generally present. Second, personality and related conditions apparently function in line with a "dual system." There are aspects of motivation and emotions that are particular "hot," visceral, and prepotent and lend themselves to more rapid, automatic, and largely subconscious processing. In addition, expression toward proximal goals occurs or does not in the relative absence or presence of "cool," largely cognitive processes involving attention-demanding, analysis, and conscious effort relative to the pursuit of less immediate goals. Third, much of motivation, emotion, cognitive content, and processing (including self-regulation and EF) occurs largely out of individual awareness/attention or is "unconscious." Fourth, the expression of personality and related conditions is contextual; specific aspects of those conditions will only be apparent in particular contexts and at particular times; thus, particular behaviors (e.g., select sexual behaviors) will only occur with the juxtaposition of a set of circumstances involving stimuli of various specificity, unique personal states, and relatively permissive environments. Fifth and finally, personality and related conditions have clearly been demonstrated to be largely genetic and heritable in their etiology and self-enhancing in their effects on varied environments. Thus, there may be relatively little malleability for much of what personality and related conditions contribute to sexual offending.

Personality and Related "Disorders"

Even with the acknowledged influence of situational context, personality traits are still commonly viewed as enduring patterns of perceiving, relating to, and thinking about oneself and one's environment across a range of social and personal contexts. There is increasing scientific consensus that the structure and elements of normal and "abnormal" personality are essentially the same; thus, there is a bipolarity of maladaptive-adaptive personality characteristics. Pathological or abnormal personality dimensions are understood as typically more extreme (e.g., more intense, more frequent, longer duration, and typically negatively valenced) and functionally maladaptive (e.g., resulting in one or more areas of impairment) variations on continuums of a "primary" personality dimensions.

Thus, a "personality disorder" has come to be viewed as a collection of a multiple intense, persistent, or pervasive personality dimensions (or traits) that lead to personal distress and/or functional impairment in major life domains (including harm to others). Since 1980, per DSM-III, the DSM-IVs, and the current version of the DSM-5, a personality disorder has been defined as an enduring pattern of inner experience and behaviors that deviates markedly from the cultural norms or expectations, is pervasive and inflexible, has an early onset (e.g., in adolescence or early adulthood), is stable over time, and leads to impairment. The enduring pattern of inner experience and behaviors must be manifest in two or more of the following areas: cognition (ways of perceiving and interpreting self, other people, and events), affectivity (range, intensity lability, and appropriateness of emotional response), interpersonal functioning, and impulse control. Individuals with personality disorders are typically unable to respond flexibly or adaptively to the changes in the hands of life. Rather they create and exacerbate stress by provoking aversive reactions in others; by failing to make optimal social, occupational, or other life decisions; and by creating situations that are problematic and pathogenic. Of great significance, per DSM-5, "the characteristics that define a personality disorder may not be considered problematic by the individual (i.e., the traits are ego-syntonic)."

The DSM-IVs (and the recent DSM-5) enumerated 10 specific personality disorder categories. Various issues have been raised about the particular categories of personality disorder associated with the DSM-IV, recent DSM-5, and ICD. As Trull (2005) noted: "Most would agree that ten official personality disorders presented in the DSM-IV-TR do not represent all forms of personality pathology that the clinician is likely to encounter and to treat…" (p. 172). Widiger and Trull (2005) pointed out that the current and proposed criteria sets for DSM personality disorders were overly restrictive. Widiger and Simonsen (2005) identified a number of additional issues regarding the current categorical system of classification of personality disorders: excessive comorbidity (many patients meet diagnostic criteria for more than one personality disorder), inadequate coverage of personality pathology (as many as 60 % of patients seeking treatment manifest maladaptive personality presentations that do not fit well under current DSM personality disorder categories), and limited scientific basis exists for the specific boundaries or trait thresholds for specific personality disorder diagnostic categories. In a meta-analysis, Verheul and Widiger (2004) found that the relative prevalence of PD NOS ranged from 21 to 49 %, and in nonstructured interview studies, it was the most commonly used personality disorder diagnosis. Similarly, the National Epidemiological Survey on Alcohol and Related Conditions (NESARC) initially examined the co-occurrence of most the ten DSM-IV-TR personality disorders in the US population, using face-to-face interviews covering this set of seven disorders in 2001–2002 ($N = 43{,}093$; e.g.,Grant et al., 2004). The initial analysis of the NESARC study found that all of these personality disorders were related or overlapped with one another (Grant, Stinson, Dawson, Chou, & Ruan, 2005); in particular, personality disorders within DSM-IV personality disorder clusters (groupings of personality that were believed to have descriptive similarities) were particularly correlated or comorbid within three clusters. Not surprisingly, personality disorder not otherwise specified (PDNOS) was the most commonly assigned personality disorder diagnosis.

Of particular importance, the DSM-5 (APA, 2013) recognized the various problems related to a categorical system of classification of mental disorder and, in particular, personality disorders. They noted that a categorical approach did not capture the significant clinical reality of overlapping or shared symptoms across more narrow diagnostic categories and the heterogeneity of conditions captured within specified categories. As a result of this recognition, while maintaining a categorical approach to classifying personality disorders, the DSM-5 also provided an alternative DSM-5 model for personality disorders where personality disorders are characterized by two primary dimensions: (1) impairments in personality function (self and/or interpersonal) and (2) one or more pathological personality traits. While recognizing the validity and the significance of a dimensional approach to organizing and classifying mental disorders, including personality disorders, the DSM-5 elected to maintain a categorical classification of personality disorders as a "bridge" from past to updated diagnostic practices. Select professionals continue to advocate for the categorical model of DSM personality disorders (e.g., Zimmerman, 2011). Further, in a more recent and methodologically more sophisticated study of NESARC data, Harford et al. (2013) indicated that the DSM-IV diagnostic criteria provided a good fit for an underlying latent dimension for each personality disorder.

In addition to the disorders in the DSMs, psychopathy (PP) has come to be viewed as a particular personality construct [historically evaluated with the Psychopathy Checklist-Revised (PCL-R; Hare, 1991; 2003a)] that both dimensionally and categorically has demonstrated strong relationships with criminal and violent behavior (e.g., Hemphill et al., 1981a, 1981b). Psychopathy or psychopathic traits appear to reflect a blend of egocentrism or narcissism, sensation-seeking, and callousness leading to irresponsible, antisocial behavior; it represents a blend of so-called Cluster B personality disorders (the "erratic, unstable" cluster), and it identifies a particular subgroup of persons with increased proneness to criminal, violent, and sexual offending. Much of the current understanding of psychopathy, as collections of maladaptive traits and, more extremely, as a personality disorder, has been based on research utilizing the PCL-R. Hare's research (1991, 2003b) found that the measured construct of psychopathy was composed of two primary "factors." Factor 1 One (F1) reflected a more narcissistic or "callous aggressive" variant of personality,

consisting of traits such as self-centeredness, egocentric, callous, and/or the remorseless use of others. Factor 2 Two (F2) was shown to be related to a social deviance or chronically and unstable and antisocial lifestyle, including early onset of antisocial behavior, more diverse criminal behavior, and a low tolerance for frustration. In 2003 (a), Hare identified that each factor was compromised of two facets: interpersonal and affective facets comprised the interpersonal/affective factor, while impulsive lifestyle and antisocial behavior comprised the social deviance factor. Dimensionally, Hare and Neumann (2008) reviewed the results of various analyses of approximately 7,000 varied offenders and forensic patients, while Neumann and Hare (2008) replicated the four-factor structure in a randomly selected community sample as well as identified a "superordinate" factor of psychopathy. Neumann, Hare, and Newman (2007) also demonstrated that the four dimensions/facets of psychopathy are so significantly interrelated that when structural equation modeling was applied across diverse samples of over 7000 individuals, results showed that the four first-order facets could be explained by a single superordinate cohesive "super factor."

Other research efforts have also attempted to identify the critical elements of psychopath or a psychopathic personality. Alternately, Cooke and Michie (2001) argued for a three-factor model, based on the notion that an antisocial or criminal factor is a concomitant or consequential to "true" psychopathic traits and not a core factor of the theorized construct of psychopathy. The three factors that they identified were *arrogant and deceitful interpersonal style*, *deficient affective experience*, and *impulsive and irresponsible behavioral style*. Hall, Benning, and Patrick (2004) and then Patrick, Fowles, and Krueger (2009) found similar three-factor models; Patrick et al. identified a triarchic model emphasizing three-dimensional constructs: *meanness*, *boldness*, and *disinhibition*. Sellbom and Phillips (2013) showed that these three dimensions captured a substantial amount of variance in self-report measures of psychopathy.

Lilienfeld has examined self-reported psychopathic characteristics in predominantly community samples. His research (e.g., Lilienfeld & Fowler, 2006) has identified eight replicable factors associated with these perspectives on psychopathy (fearlessness, cold-heartedness, Machiavellian egocentricity, social potency, impulsive nonconformity, carefree non-planfulness, stress immunity, and blame externalization). Utilizing self-report instruments, other investigators have reported the identification of two common primary dimensions of self-reported psychopathic traits: fearless dominance and impulsive antisociality (e.g., Benning, Patrick, Hicks, Blonigen, & Krueger, 2003; Witt, Donnellan, Blonigen, Krueger, & Conger, 2009). As Hare and Neumann (2007) pointed out, the interpersonal/affective and the social deviance factors of the PCL-R appear to match the "fearless dominance and "impulsive antisociality" factors identified via personality self-report.

Given the available theory and science, it seems clear that the nature of psychopathy is complex and multifaceted. The best evidence is that psychopathic conditions are heterogeneous as Lykken (1995) and others have suggested and that subtypes of psychopathic individuals exist defined by relative emphasis on different dimensions identified by different investigations and investigators. In reviewing this available work, it seems clear that there is a significant degree of overlap and consistency across the different research efforts and models for subtypes of psychopathy. Skeem et al. (2003, 2007) has advocated that it makes considerable sense to conceptualize that there are variants of psychopathy or psychopathic personalities. More specifically, Skeem et al. (2007) have suggested that relative to primary psychopaths, secondary psychopaths had greater trait anxiety, fewer psychopathic traits, and comparable levels of antisocial behavior. Of note, Ross, Benning, and Adams (2007) showed that symptoms of deficient EF were "endemic" to secondary psychopathy but not primary psychopathy. Hicks, Markon, Patrick, Krueger, and Newman (2004) identified two subtypes of psychopathic individuals: *Emotionally stable* psychopaths were marked by low trait anxiety, positive emotionality, and more goal-directed behavior (e.g., primary psychopaths), whereas *aggressive* psychopaths were marked by high negative emotionality, high disinhibition, and social affiliation (e.g., secondary psychopaths); Poythress et al. (2010) found similar groups. Across validation variables, secondary psychopaths manifested more borderline personality features, poorer interpersonal functioning (e.g., irritability, withdrawal, poor assertiveness), more symptoms of major mental disorder, and significantly poorer clinical functioning than primary psychopaths. In contrast, lower anxiety and greater assertiveness/dominance characterized the primary psychopaths. These results were similar to those of Blackburn (2009), who found four profile classes: *primary psychopaths* (impulsive, aggressive, hostile, extraverted, self-confident, low to average anxiety), *secondary psychopaths* (hostile, impulsive, aggressive, socially anxious, introverted, moody, lower self-esteem), *controlled psychopaths* (defensive, controlled, sociable, very low anxiety, and high self-esteem), and inhibited *psychopaths* (shy, withdrawn, controlled, moderately anxious, low self-esteem); these last two classes are considered more "well-socialized" psychopathic individuals. More recently, Eaton et al. (2011) showed that BPD was effectively an externalizing disorder with an additional component of distress; thus, some persons with BPD appear likely to be best understood as secondary psychopaths (e.g., emotionally reactive and dysregulated).

Paulhus and Williams (2002) initially identified a "dark triad" of psychopathy, narcissism (dominance, grandiosity, and superiority), and Machiavellianism (interpersonal strategies that advocate self-interest, deception, and manipulation); they identified each element of the dark triad as associated with antisocial behavior. From the five-factor model, persons

are disagreeable, extraverted, open, and have high self-esteem along with low levels of neuroticism and conscientiousness score high on the dark triad; they extract what they want from their environment via an exploitive approach (e.g., Jonason et al. 2010). In another study, Jonason and Trost (2010) found that both psychopathy and Machiavellianism were correlated with low self-control, a tendency to discount future consequences, and high rates of attention-deficit disorder. They stated: "These systems are likely to leave the person with a fast life strategy to feel as though they just cannot control themselves, although it is unlikely they want to" (p. 614). Persons possessing elevated levels of the characteristics that make up the dark triad are likely to be selfish, possess a grandiose sense of importance, and feel an increased sense of entitlement. Further, these individuals are often preoccupied with dominance and power and will use aggressive tactics such as manipulation and exploitation to get whatever it is that they feel that they deserve. Johnson and Tost (2010) provided evidence that "the short-term exploitive strategy that characterize the dark triad is supported by a system of limited self-control, a tendency to discount future consequences, and attention deficit symptoms" (p. 614). "They noted that these systems "are likely to leave a person feeling as though they just cannot control themselves, although it is unlikely they want to" (p. 614). Thus, those individuals with significant elements of the dark triad are particularly prone to antisocial behavior. More recently, Buckels et al. (2013) suggested adding sadism to compose a Dark Tetrad of personality. They discussed "everyday sadism" as a callous tendency to enjoy the suffering of others, which is associated with antisocial outcomes. They found "Only sadists increased the intensity of their attack once they realized that the innocent person would not fight back. Sadists were also the only dark personalities willing to work (i.e., expend time and energy) to hurt an innocent person. Together, these results suggest that sadists possess an intrinsic appetitive motivation to inflict suffering on innocent others—a motivation that is absent in other dark personalities. Inflicting suffering on the weak is so rewarding for sadists that they will aggress even at a personal cost" (p. 9).

Personality-Related Conditions: Criminal, Violent, and Sexual Offending

Personality Traits and Disorders

The role of disorders of maladaptive personality traits and related conditions has long been recognized as prominent factors in criminal behavior (e.g., law-violating acts) and violence toward self and others. In particular, personality and related factors appear important given the delimited group of individuals who persist or repeat violent behavior. First, most "antisocial individuals" do not become involved in the criminal justice system; only 50 % of individuals in the USA diagnosed with antisocial personality disorder (ASPD) have an official record (history) of some criminal offending (e.g., Robins & Regier, 1991). In contrast, essentially, it is only a relatively small group of individuals who engage in repeated criminal behavior and an even smaller group who engage in repeated violent behavior over time. In prominent studies, typically 5–6 % of criminal offenders were found to be responsible for 50 % of recorded crimes (e.g., Farrington, Ohlin, & Wilson, 1986). Approximately only 23 % (Coid, Yang, Roberts et al., 2006) to 33 % (De Brito & Hodgins, 2009a) of persons with ASPD are characterized by repeated acts of violence. Black (2011) found that while only 35 % of recently incarcerated inmates met the criteria for ASPD in a US sample, those with ASPD showed a greater frequency of three or more criminal convictions and prior mental health treatment. It is notable that approximately 70 % of persons with ASPD who were violent had engaged in instrumental—as opposed to reactive—aggression; that is, their aggression had some degree of premeditation as opposed to being a result of simply a situational provocation (DeBrito & Hodgins, 2009a).

Related to the finding that it is a relatively small group of persons who perpetrate the majority of any violent behavior, the extant empirical literature clearly supports a finding that there is a subgroup of *persistent* antisocial offenders. Moffit's (1993) life-course-persistent antisocial behavior group were persons who engaged in repeated or episodic antisocial behaviors after adolescence and constituted a unique group of persons; they persisted in and fail to desist from violence and crime. Generally, it appears that those who show earlier onset of antisocial behavior commit the majority of crimes and are more likely to continue to do so throughout their lives. As a group, they appeared to be one with a strong genetic diathesis toward antisocial behavior. Cross-sectional studies suggest the prevalence of antisocial behavior as expressed in the community peaks between 35 and 40, suggesting the possibility of remission for some antisocial individuals. However, the few longitudinal studies available indicate substantial variation in the persistence of antisocial behavior, particularly violent behavior. In a 30-year follow-up of antisocial personality disordered individuals, Guze (1976) found that 72 % of incarcerated male felons were still classified as meeting the criteria for ASPD by interview at follow-up. Robins et al. (1966) found that while 12 % had remitted, 27 % had improved but not remitted and fully 60 % of persons previously diagnosed with ASPD were unimproved. Black, Baumgard, and Bell (1995) in a long-term follow-up of males with ASPD showed while antisocial men had reduced their impulsive behavior and to some extent their criminality, they continued to have antisocial and/or impulsive issues leading to significant interpersonal and other problems throughout their lives. Several smaller studies have showed that while a minority of persons with ASPD were either

"remitted" or "improved," a significant proportion of persons remained criminally active throughout follow-up periods (e.g., Black et al., 1995). McLean and Beak (2012) identified several factors associated with a persistent violent offending career: an offending career that begins before the age of 14 (early onset) and previous violent crimes. A longer criminal career was also associated with a greater frequency of violent offending. DeLisi and Vaughan (2007) demonstrated that "career" criminals had significantly lower levels of self-control. They found that those who scored just one standard deviation above the mean on a measure of self-control had five times the odds of manifesting career criminality and that low self-control distinguished career criminals with ROCs between 74 and 87 %. It is notable that Moffit (1993) identified persistent offenders as most likely to be individuals with significant inherited cognitive and emotional difficulties that later interacted with varied criminogenic situations; thus, persistent antisocial behavior appears to have a considerably stronger degree of heritability than that which is time-delimited and typically has a much earlier age of onset. In summary, a relatively small portion of persons with ASPD are detected by the criminal justice system, violent behavior distinguishes a select group of persons with ASPD, and only a more select group of offenders persist in violent criminal behavior over time.

Eysenck (1977) theorized that low arousal capability and low boredom (leading to a need for excitement) in the relative absence of conditioning for rule adherence by parents and schools were critical in the causation of crime. In A General Theory of Crime, Gottfredson and Hirschi (1990) argued that the central underlying criminal propensity is low self-control or difficulty delaying short-term gain, reward, or pleasure at the expense of longer-term interests. Persons with deficient self-control or a greater degree of disinhibition tend to forego consideration of the long-term costs associated with engaging in antisocial and/or deviant acts, provided an opportunity to offend is present. Per Gottfredson and Hirschi, "people who lack self-control will tend to be impulsive, physical (as opposed to be mental) risk-taking, short-sighted, and nonverbal, and they will tend therefore to engage in criminal and analogous acts" (p. 90). Per Buker's (2011) summary of Gottfredson and Hirschi's theory, crimes (a) are stimulating, dangerous, or thrilling; (b) require little skill or planning; (c) result in pain to or discomfort of a victim; (d) provide immediate, easy, and simple satisfaction of desires; and (3) supply few or insufficient long-term benefits. Persons with low self-control were predisposed to criminal activity due to their impulsivity, risk-seeking, "bad" temper, and preference for goals/tasks that do not require persistence, low cognitive and academic skills, self-centered nature, low empathy and short time horizons. In a modification to his earlier self-control theory, Hirschi (2004) suggested that the *prevalence* and *salience* of varying social bonds are likely to be considered as "costs" of offending at the time of offending and that both short- and long-term implications for social bonds may exert an effect on the degree of self-control. Given difficulties in delaying gratification, offending behaviors took place in the relative absence of concern over possible future negative consequences. Pratt and Cullen (2000) conducted a meta-analysis of self-control theory using 21 studies and found effect sizes from of .47–.58, indicating a moderate consistent effect of self-control and general criminal behavior. Specifically, they showed that approximately 73 % of offenders were characterized by low self-control relative to 50 % of non-offenders, indicating self-control deficit. DeLisi and Vaughan (2007) showed that persons scoring just one standard deviation below the mean on a self-control measure were well identified as career criminals; low self-control was by far the best predictor of chronic criminality.

Alternately, following Zukerman (1994), Burt and Simons (2013) suggested that thrill-seeking or risk-taking represents an independent personality predisposition that is equally prominent relative to self-control in criminal behavior; individual differences exist relative to the degree of "pleasure" or reward that (versus "pain") they anticipate receiving from risky acts (e.g., Lykken, 1995). Such preference for risk is viewed as a distinctive motivating factor unrelated to the ability or intent to consider the consequences of one's behavior; the intense reward effects of risk acts can outweigh the consideration of potential negative consequences for persons high on thrill-seeking. Thus, risky or thrilling behavior can involve a substantial amount of planning and fantasy (as opposed to being simply impulsive or a result of low self-control). A related issue is that persons may be characterized by individual differences in their threshold for and breadth of thrill-seeking stimuli, with some manifesting broader and others more narrow pleasure preferences. Particular personality disorders, as specified categories of particular combinations of personality traits, have been implicated in general criminal offending.

Krueger et al. (1994) showed that specific personality dimensions or traits were linked to criminal behavior. Specifically, they found that negative emotionality (e.g., higher stress reactivity, anger, grievance, adversarial interactions) and low constraint (impulsive, danger seeking, rejecting of conventional values) were related to antisocial behavior, as well as social alienation, lack of social closeness, and risk-taking. They also found that particularly antisocial individuals (e.g., those who engaged in a wide variety of criminal acts) exhibited personality profiles that were characterized by particularly strong rejection of rational values, thrill-seeking, impulsivity, aggressive behavior, lack of sociability, and feelings of alienation. Tackett and Krueger (2011) identified several factors related to the ESD; two included impulsive irresponsibility and callous aggression. Krueger (2006) pointed out that negative emotionality paired with high levels

of disinhibition lead to more general externalizing behavior, while substance use and antisocial behavior problems were both related to an unconstrained, impulsive personality style. In a later study of the self-report approximately 1800 adult (including both correctional and community samples), Krueger et al. (2007a) created a hierarchical, quantitative model of the externalizing spectrum disorders (ESD), including ASPD. The following are among the 23 facets identified: aggression (relational aggression, physical aggression, and destructive aggression); excitement-seeking and boredom proneness; problematic impulsivity, impatient urgency, and planful control; rebelliousness (rule violations/disobedience); irresponsibility and dependability; honesty; fraud; criminal theft; empathy; blame externalization; alienation (from others); and various substance use dimensions (alcohol use, alcohol problem, marijuana use, marijuana problem, drug use, drug problems). In a more recent research, Carragher et al. (2013) demonstrated that attention-deficit hyperactivity disorder (ADHD) was a component of the larger continuous and dimensional liability to externalizing disorders in adulthood including ASPD and alcohol/substance use disorders. In addition, Eaton et al. (2011) showed that BPD was related to ESD liability as well as a particular sensitivity to an aspect of internalizing disorders, namely, distress.

Violence (the use of physical force to harm or injure someone) or aggression (violent behavior motivated by negative affect such as anger), which includes many sexual offenses, is a particular set of criminal acts. Most persons who commit criminal acts do not engage in violent behavior. Violent behavior is typically dichotomized as instrumental violence (goal-directed and/or at least somewhat anticipated or planned violence that occurs in an attempt to obtain a goal or goals, including simply "harming" another) and reactive violence (violence that occurs in response to provocation and arousal of hostility, which is often expressive violence ventilating anger or similar affective states) (e.g., Cornell et al., 1996). In addition, there are mixed forms of violence, for example, when an instrumental act encounters resistance experiences as provocation.[3] Megargee (e.g., 1976, 2011) offered a framework for conceptualizing "the algebra of aggression" or violence toward others; it suggests factors that determine whether or not a person performs a given aggressive act against a specific target at a particular point in time.

> …In this often unconscious bargaining process or 'response competition', the behavior that offers the most satisfactions at the least cost will … [occur]. The 'reaction potential, or net strength of an aggressive response, is determined by balancing the factors promoting each response against those deterring it. (p. 5)

[3]Cornell et al. (1996) developed a coding scheme that included planning, goal-directedness, provocation, arousal, severity of violence, relationship to victim, intoxication, and psychosis.

Megargee identified three primary factors related to "fostering" aggressive behavior. *Intrinsic instigation to aggression* is the conscious or unconscious drive to attack, injure, or harm someone or to damage something (such factors were seen as anger, hostility, rage, or hatred: angry aggression). *Extrinsic instigation leads to instrumental aggression* in which aggression is used as means of achieving ends other than simply injuring the target; extrinsic goals include dominance power, self-esteem, and acquisition or the accomplishment of personal objectives. Finally, the third personal factor that increases the relative potential of aggressive responses is *habit strength*, the extent to which aggressive acts have been reinforced in the past via pleasure or satisfaction. For Megargee, the stronger the habit strength for particular aggressive acts, the more likely that similar acts will be enacted again in the future. In addition, Megargee noted that both additional personal and situational factors, particularly "internal inhibitions" and "pragmatic concerns," could deter aggression. Conversely, a lack of such inhibitions (e.g., a lack of empathy, objectification, and so on) and/or an insensitivity or indifference to pragmatic concerns (such as negative consequences or low probability of achieving the goals of violent behavior) can further facilitate or foster aggressive or violent responses. Megargee emphasizes that the potential for violence is multifactorial and complex, that violent offenders are likely to be heterogeneous, and that violent acts will occur variably or episodically as function of relative variability in factors "fostering" or "inhibiting" aggression, habit strength, and situational factors.

Litwack and Schlesinger (1987) noted that repetitive violence was "more likely to stem from relatively enduring personality traits" (p. 211) than from momentary crises and other events, thus indicating the relative significance of maladaptive personality and likely personality disorders. Nestor (2002) examined the relationship between personality dimensions and violent behavior and identified four as fundamental to that relationship: impulse control, affect regulation, threatened egotism or narcissism, and paranoid cognitive personality style. In a systematic review, Yu, Geddes, and Fazel (2012) reported that there was a substantially increased probability of a violent outcome for persons characterized by any personality disorder in the general population as well as for the subset of known offenders. Meta-regression indicated that the risk of offending was increased among persons with antisocial personality disorder (odds ratio of 12.8), particularly for such persons who were already identified as offenders (e.g., had a history of antisocial and violent behavior). Of such persons, 666 % were criminal recidivists. [Of note, Yu et al. found that young age was not a risk factor for violence among samples of individuals with personality disorders.] Widiger and Trull (1994) noted that violent behavior is a "defining feature" for both antisocial personality disorder and borderline personality disorder

(while noting that antagonistic, hostile traits are evidence in eight of the ten DSM personality disorders). Generally, ASPD increased the relative risk of being convicted of a violent crime by a factor of 7 for males; inmates with ASPD generally showed significantly higher scores for violent offenses than those without antisocial personality disorder (DeBrito & Hodgins, 2009a). Maladaptive Personality disorders identified as early as in adolescence (including narcissistic, paranoid, and passive-aggressive traits) were independently associated with risk for violent acts both during adolescence and eagerly adulthood (Johnson et al., 2000). Widiger and Trull suggested that a diagnosis of either antisocial personality disorder (ASPD) or borderline personality disorder (BPD) is a significant risk factor for violent, aggressive behavior, particularly in persons with a prior history of such behavior. Similarly, Blackburn and Coid (1999) have also noted that the more "psychopathic" subgroup of persons with ASPD were responsible for a disproportionate amount of both detected and undetected violence. In addition to ASPD, various studies have shown that borderline personality disorder (BPD) is associated with violent behavior (e.g., Black, Gunter, Allen et al., 2007; Newhill, Eack, & Mulvey, 2009). Howard (2009) showed that persons who met criteria for either (or both) ASPD or BPD were characterized by high levels of impulsive sensation-seeking and aggression hostility, indicating a tendency to act out when in a state of heightened affect (including both positive and negative emotional/motivational states). That is, in addition to anger, experiencing increased positive affect leads to a strong desire to maximize a state of excitement or thrill-seeking anger (affectively positive affect) via acting out; the process of acting out on such motivation (e.g., via violent behavior) is reinforcing itself, in addition to the outcome. Narcissistic personality disorder (NPD) is also strongly related to criminality in general and violence in particular (e.g., Johnson et al., 2000; Esbec and Echeburua, 2010). Esbec and Echeburua identified: "Narcissism is a frequent trait in all types of violence subjects, especially antisocials and psychopaths, who usually give preference to their desires over the needs and rights of the others…" (p. 256). Thus, most existing research identifies dual dimensions as related to violent behavior, one a sensation-/thrill-/risk-seeking dimension that presses for action against others and the other reflecting deficiencies in self-regulation, involving a lack of consideration of consequences for self/other and related deficits in the management of impulses or urges for action.

Per meta-analyses of the PCL-R and its relationship to criminal recidivism, results have demonstrated that the PCL-R was consistently among the best predictors of recidivism, whether utilized as a continuous or categorical measure (Hemphill, Hare, & Wong, 1998; Hemphill, Templeman, Wong, & Hare, 1998). In fact, surprisingly, *survival analyses for "medium" and "high" PCL-R groups were not clearly differentiated from one another; both of these groups showed similar recidivism rates and patterns*. More recently, Leistico et al. (2008) conducted a meta-analysis involving 95 studies involving almost 16,0000 institutionalized or incarcerated persons. They found that higher PCL total, Factor 1 and Factor 2 were each moderately associated with increased antisocial behavior. Rice and Harris (1997) showed that sexual recidivism rates for sex offenders were substantially higher among identified psychopaths. They found that violent recidivism rates for five years after release were 85 % for persons classified as psychopaths by record review (e.g., cutoff score of 25) based upon survival analysis; this rate was approximately 50 % above that of non-psychopaths. The PCL-R score was typically the strongest (or one of the strongest predictors) of violent and sexual recidivism (e.g., Hare, 2003b; Hanson & Morton-Bourgon, 2004).

In addition, it is important to emphasize that while a large number of persons commit an act of violence and other criminal acts, essentially, only a relatively small group of individuals engage in repeated criminal behavior and an even smaller group engage in repeated violent behavior over time. In prominent studies, typically 5–6 % of criminal offenders were found to be responsible for 50 % of recorded crimes (e.g., Farrington et al., 1986). Utilizing a national representative sample, Vaughan et al. (2011) found that while 66 % of NESARC sample showed little involvement in criminal behavior, there was a low substance use/high antisocial behavior group (21 %) and a high substance use/moderate antisocial behavior group (8 %). As previous researchers had shown, only 5.3 % of the sample was identified as a "severe" group, characterized by pathological involvement in more varied and/or more intensive forms of antisocial/externalizing behaviors and extensive psychiatric disturbance. O'Driscoll et al. (2012) showed that released prisoners with a personality disorder (the majority "mixed" or meeting criteria for more than one personality disorder) showed a 26 % increase in the risk of criminal reoffending over a 5-year follow-up; Grann, Danesh, and Fazel (2008) reported similar findings. More specifically, only 20 % (Coid et al., 2006) to 33 % (DeBrito & Hodgins, 2009a) of persons with antisocial personality disorder are characterized by repeated acts of violence. Approximately just 50 % of individuals diagnosed with ASPD have an official record (history) of some criminal offending (e.g., Robins et al., 1991); most persons with ASPD are not detected for criminal or violent offending. Black (2010) found that while only 35 % of recently incarcerated inmates met criteria for ASPD in a US sample, those with ASPD showed a greater frequency of three or more criminal convictions and prior mental health treatment. Similarly, it is notable that approximately 70 % of persons with ASPD had engaged in instrumental—as opposed to reactive—aggression; that is, their aggression had some

degree of premeditation as opposed to being a result of a situational provocation (De Brito & Hodgins, 2009a).

Related to the finding that it is a relatively small group of persons who perpetrate the majority of violent behavior, the extant empirical literature clearly supports a finding that there is a subgroup of *persistent* antisocial offenders. Moffit's (1993) life-course-persistent antisocial behavior group appeared to be one with a strong genetic diathesis toward antisocial behavior. That group of persons who engage in repeated or episodic antisocial behaviors after adolescence constituted a unique group of persons with a history of such behaviors; they persist and fail to desist. Generally, it appears that those who show earlier onset of antisocial behavior commit the majority of crimes and are more likely to continue to do so throughout their lives. Cross-sectional studies suggest the prevalence of antisocial behavior as expressed in the community peaks between 35 and 40, suggesting the possibility of remission. However, the few longitudinal studies available indicate substantial stability in the persistence of antisocial behavior, particularly violent behavior. Vaske, Ward, Boisvert, and Wright (2012) examined the stability of risk-seeking from adolescence to emerging adulthood and found that individuals who scored medium and high on risk-taking displayed absolute stability across time; this suggests that high levels of personality deficits are problematic across important segments of the life course. In a 30-year follow-up of antisocial personality disordered individuals, Guze (1976) found that 72 % of incarcerated male felons were still classified as "antisocial" by interview at follow-up. Robins et al. (1966) found that while 12 % had remitted, 27 % had improved but not remitted and fully 60 % of persons previously diagnosed with ASPD were unimproved. Black et al. (1995) in a long-term follow-up of males with ASPD showed that while antisocial men had reduced their impulsive behavior and to some extent their criminality, they continued to have antisocial and/or impulsive issues leading to significant interpersonal and other problems throughout their lives; while a minority of psychopaths and persons with ASPD were either "remitted" or "improved," a significant proportion of persons remained criminally active throughout follow-up periods (Black et al., 1995). Hare (2003a) noted that only cross-sectional data existed and that dimensional scores of psychopathic traits were only weakly related to age (albeit somewhat differently for ratings based on interview + file versus just file review). Hare also pointed out that older psychopaths spent significantly less time in the community than did non-psychopaths of similar: "Clearly, older psychopaths had far less opportunity to offend (less time at risk) than did nonpsychopaths…the criminal (and violent) propensities of the aging psychopath may have been greatly underestimated" (p. 62). Moffit (1993) identified persistent offenders as particularly early-onset offenders, with most likely to be individuals with significant inherited cognitive and emotional difficulties that later interacted with varied criminogenic situations; thus, persistent antisocial behavior appears to have a considerably stronger degree of heritability (and which leads to criminogenic environments and experiences) than that which is time-delimited. DeLisi and Vaughan (2007) showed that lower levels of self-control were uniquely related to career criminals. In summary, violent behavior distinguishes a select group of persons with ASPD, and only a more select group persists in violent criminal behavior over time.

Executive Functioning

Deficits in EF have been implicated in criminal, violent, and sexual offending. De Brito and Hodgins (2009b) provided a review of executive functioning in persistently violent offenders and noted a strong relationship to increased violence as a result of interactions between deficits in EF and impulsivity. Theoretically, the role of EF is a key element to particular theories of sexual offending, particularly the self-regulation theory.

Banich (2009) stated:

> The very nature of executive function makes it difficult to measure in the clinic or the laboratory; it involves an individual guiding his or her behavior, especially in novel, unstructured, and non routine situations that require some degree of judgment. (p. 89)

Consequently, clinical and experimental measures of EF likely provide relatively general proxies for EF deficits in actual life situations. Morgan and Lilienfeld (2000) conducted a meta-analysis of ASPD and performance on six reasonably well-validated measures of EF. Thirty-nine studies yielding a total of 4,589 participants were included in the analysis. Overall, antisocial groups performed .62 standard deviations worse on EF tests than comparison groups; this effect size is in the medium to large range. They noted that significant variation within this effect size estimate was found, some of which was accounted for by differences in the operationalization of antisocial conditions and measures of EF. Morgan and Lilienfeld concluded that evidence for the *specificity* of EF deficits relative to deficits on other neuropsychological tasks was inconsistent. Ogilvie, Stewart, Chan, and Schum (2011) found results similar to those of Morgan and Lilienfeld's (2000) original meta-analysis; their updated meta-analytic results confirmed that there is a robust and statistically significant association between ASB and EF impairments. An average weighted grand mean effect size of 0.47 standard deviations difference between antisocial and comparison groups was found across the studies. This effect size was in the medium range, compared to the medium to large 0.62 average weighted mean effect size produced by Morgan and Lilienfeld. This difference in grand mean effect size magnitude is likely a reflection of the heterogeneity of effect sizes observed in the current and earlier meta-analysis.

Larger differences in EF performance were observed in studies involving participants from correctional settings and with comorbid ADHD. Effect sizes for EF impairment were moderated by ASB categorization. Effect sizes for EF measures were found to be largest for the operationalization of physical aggression ($d=0.67$), criminality ($d=0.56$), and psychopathy ($d=0.49$). Measures of "hot" components of EF (those involved in affective decision-making and delay of gratification) were found to have a moderate-large effect size (relative to "cool" components of EF, which showed smaller EFs). De Brito, Viding, Kumari, Blackwood, and Hodgins (2013) showed that violent offenders with and without psychopathy showed similar impairments in verbal work memory and adaptive decision-making: "They failed to learn from punishment cues, to change their behaviour in the face of changing contingencies, and made poorer quality decisions despite longer periods of deliberation." The performance of both groups of offenders did not differ on what were deemed measures of "cool" and "hot" EF. In their review, Paschall and Fishbone (2002) concluded that a large body research from diverse files suggest that impaired EF plays an important role in aggression and violent behavior. However, they also make an extremely important point, namely, that "subclinical impairment" in EF (while less observable or diagnosable) is likely associated with a significant amount of such violence.

Rather than regard ASB as specific to EF impairments, a more accurate view may be that ASB is associated with a broader syndrome of more generalized neurocognitive impairments that include EF impairment as well as other deficits in self-control. Deficits in the initial stage of EF—attention—have been implicated as a key factor in psychopathy. Newman in various publications (e.g., Vitale & Newman, 2009, 2013; Baskin-Sommers, Wallace, MacCoon, Curtin, & Newman, 2010; Zeier & Newman, 2013) has studied and delineated the relationship of attentional deficits as the critical component for response modulation as a key component of psychopathy. Their response modulation hypothesis holds that abnormalities in selective attention undermine the ability of psychopathic individuals to consider contextual information that modulates prosocial and/or more distal goal-directed behavior. Newman and his colleagues have focused on the role of attentional deployment as the critical pathway associated with psychopathic traits. Attentional deployment involves directing one's attention toward or away from an emotional or otherwise arousing situation. Per Newman's work, psychopathic individuals are not affected by peripheral or contextual information that is incongruent with their primary focus of attention. Rather, they are characterized by an attentional "bottleneck" that interferes with simultaneous processing of multiple channels of information so they are not able to rely on previous experience or other concurrent experiences to influence goal-directed behavior in the face of a prepotent goal. Consequently, they appear oblivious to internal and external stimuli that cause less psychopathic individuals to cognitively "stop" to evaluate their behavior. Such impaired response modulation results in better "task performance" relative to enactment of prepotent motivational or affective states for psychopathic individuals (they cannot or do not pay attention to distracters), but create problems when such information is central for effective self-regulation toward longer-term goals. A related more general finding per Gable and Harmon-Jones (2008) is that high-intensity approach motivation reduces global attentional focus (relative to low-approach-motivated positive affect). Reward incentives are also known to promote greater goal persistence. Thus, attentional deficits which lead to impulsive, immediate, and self-gratifying behavior relative to "hot" stimulation are key components relative to disinhibited and unconstrained behavior such as sexual offending. Compared to non-offenders, De Brito et al. (2013) found that violent offenders with ASPD (both with and without psychopathy) showed similar impairments in verbal working memory and adaptive decision-making. They failed to learn from punishment cues, to change their behavior in the fact of changing contingencies, and made poorer quality decisions despite longer periods of deliberation. Of note, both of the offender groups were comparable on measures of "cool" and "hot" executive function.

Equivalent findings regarding EF have been found for sexual offenders as well. Joyal et al. (2014) examined 23 neuropsychological studies reporting data on 1,756 sexual offenders via meta-analysis. As expected, a highly significant, broad, and heterogeneous overall effect size was found; sexual offenders generally differed across tasks to assess EF. However, taking subgroups of participants and specific cognitive measures into account significantly improved homogeneity. Sex offenders against children tended to obtain lower scores than did sex offenders against adults on higher-order executive functions, whereas sex offenders against adults tended to obtain results similar to those of nonsex offenders, with lower scores in verbal fluency and inhibition. Similarly, Langevin and Curnoe (2007) suggested that various conditions related to EF as measured by neuropsychological tests are common among sexual offenders. Fabian (2010) concluded that the research was unclear and inconsistent regarding the prevalence of neuropathology among sexual offenders relative to sexual violence; his review identified many potential neuropathological domains which might be related to problems in self-control among sexual offenders. Reid et al. (2010) found a correlation of .37 between global indices of executive functioning and hypersexuality, suggesting a moderate relationship between those two domains. While Hare and Neumann (2008) reported that a large literature demonstrates that there is, at most, only a weak association between psychopathy

and intellectual ability, Egan (2011) reported a robust and unambiguous relationship between lower intellectual functioning and criminal behavior, with little difference between those offenders detected and those not detected. He pointed to an association between lower intelligence, decreased economic independence and resources, and a greater sensitivity to "small personal losses, whether material or personal," that lead to higher frequency of humiliation, anger, and hostility. An interesting distinction arises regarding EF and "hot" and "cool" internal experiences. On the one hand, for select individuals, it seems clear that to the degree that an individual possess EF, those processes can be undermined and overwhelmed by "hot" processes, leading to significant disinhibition. On the other hand, for select sexual offenders, the "cool" processes of EF appear to be employed (e.g., focused, sustained attention, problem-solving, and organization/coordination of actions) in enacting sexual offenses in such a manner as to minimize the likelihood of detection.

Generally, problem-focused coping (PS) reflects EF-related strategies in the face of provocation and arousal, particularly in the identification of problems and appropriate skills to manage the source of those reactions. Both coping and PS involved perceiving, defining, and appraising problematic acute or recurring situations or "a life episode" (e.g., cognitive reappraisal) in ways that they can be confronted and managed; they also involve various specific strategies or tactics to both address one's experience and situation. A common notion of issues in problem-solving involves (a) deficits in problem recognition, (b) a lack of consequential (means-end) thinking (e.g., failing to think through potential consequences of actions, particularly longer-term results), and (c) difficulties generating a range of reasonable options. McMurran (2009) has identified PS as significant factor in violent behavior generally, while Serran and Marshall (2006) suggested that dysfunctional coping is associated with sexual offending. Similarly, Slab and Guerra (1988) found that criminal offenders, including sexual offenders, showed a variety of deficiencies in problem-solving, including (a) problem definition and failure to seek relevant information, (b) enacting hostile goals, and (c) generating relatively few alternative coping or PS solutions. Hanson et al. (2007) found that deficient problem-solving, including sexual coping, showed a significant linear relationship to sexual offender recidivism. Nezu, Nezu, Dudek, Peacock, and Stoll (2005) found that social problem-solving deficits were associated with sexual aggression and sexual deviance in a sample of child molesters.

Given the strong evidence found in studies of genetic liability to externalizing disorders, including substance use disorders and ADHD, it should not be surprising that such conditions have also been demonstrated to have some particular association with criminal, violent, and sexual offending.

Alcohol/Substance Use Disorders

Substance abuse disorders (SAD) also show strong associations with criminal and violent behavior, including sexual offenses. At least one-half of all violent crimes involve alcohol consumption by the perpetrator, the victim, or both (Collins & Messerschmidt, 1993). Per DOJ review by Cannon and Carmon (2006), studies overwhelmingly indicate a strong link between the consumption of alcohol and violent acts. Between 27 and 47 % of all homicides and acts of purposeful injury have been found to involve the use of alcohol by the perpetrator. Alcohol consumption is not only linked to acts of violence but to the escalation of violence and the resulting severity of injuries. US crime reports indicate that approximately six in ten incidents of alcohol-related violence resulted in injury to the victim. Alcohol use increased the frequency with which threats of violence escalated to actual assaults, with a higher percentage of assailants who had been drinking committing a physical attack resulting in injury than did the nondrinkers. Per DOJ review by Cannon and Carmon (2006), almost one in four victims of violent crime report that the perpetrator had been drinking prior to committing the violence. O'Driscoll et al. (2012) showed that released prisoners with substance use disorders showed a 33 % increase in the risk of criminal reoffending over a 5-year follow-up.

As noted, Krueger et al. (2007a) have demonstrated that alcohol and drug use/dependence are part of a genetically linked spectrum of externalizing disorders along with ASPD; thus, there is strong biologically mediated comorbidity between those conditions. From a personality perspective, Hopwood et al. (2011) noted negative affect and disinhibition represent risk factors for increased substance abuse; further, alcohol use is associated with increased impulsivity and disinhibition, while other substance abuse is associated with greater disinhibition. Dick et al. (2010) reported that alcohol consumption increases impulsive acts, particularly via increases in perceived urgency and sensation-seeking. Other researchers have found that the dimension of sensation-seeking was associated with increased impulsive behaviors among alcoholics (Lejoyeux et al., 1998). Godlaski and Giancola (2009) found that irritability successfully mediated the relation between EF and intoxicated aggression for males. Nonspecific or nonsexual affective (e.g., anger, fear) or motivational arousal can "transfer" to and heighten sexual arousal given a sexualized context; thus anger, particularly when accompanied by alcohol intoxication or disinhibition, can relatively easily become additionally experienced as sexual arousal in the presence of sexualized cues or context.

In addition, substance abuse also affects EF and self-regulation. In his early review, Giancola (2000) stated, "In summary, the framework postulates that when executive

functioning is impaired, there is a resultant lack of cognitive control (i.e., inhibition) over behavior as a result of an inability to pay attention to and appraise situational cues, take another's perspective, consider the consequences of one's behavior, and defuse a hostile situation. Given this reduction in behavioral inhibition, hostile cognitions and negative affective states are more likely to manifest as overt violence" (p. 589). Giancola concluded that executive functioning mediates the alcohol-aggression relation in that acute alcohol intoxication disrupts executive functioning, which then heightens the probability of aggression. In addition, he found that executive functioning moderates the alcohol-aggression relation in that acute alcohol consumption is more likely to facilitate aggressive behavior in persons low, rather than high, in executive functioning. In line with the notion that EF is best viewed as a meta-cognitive or overriding construct, Giancola, Godlaski, and Roth (2012) found that the best predictor of intoxicated aggression was a "Behavioral Regulation Index," comprising component processes such as self-monitoring, inhibition, emotional control, and flexible thinking. Hofmann and Frieze (2008) found that implicit attitudes affected alcohol consumption and increased the behavioral impact of impulsivity by disrupting cognitive restraint standards. In fact, Wolfe and Higgins (2008) showed that actual low self-control has a separate additive effect on (low) perceived behavioral control relative to alcohol consumption; lower levels of inhibitive factors and less belief those factors affect control of behavior each can lead to increased that alcohol use. Further, alcohol consumption may begin under some degree of self-awareness and self-control, over time additional consumption may act to further decrease both perceived and actual self-control. As Abbey (2011) summarized, alcohol consumption biologically impacts a number of cognitive functions including basic reasoning, planning, and judgment while impeding response inhibition relative to the suppression of a compelling predominant response (e.g., a strong motivation). When intoxicated, persons focus on salient, superficial cues, including motivations and affects, rather than distal or subtle cues. Consequently, feelings of anger, sexual arousal, entitlement, frustration, etc. may be considerably more salient or potentiated than "morality," empathy for a potential victim, or anxiety or concern for future consequences. As noted by Giancola (2004), meta-analytic studies indicate that alcohol has a medium effect size on aggression, but he suggested that key moderating factors are at work. He found that dispositional low EF was related to increased aggression in males after alcohol consumption and that alcohol also exerts its effect by disrupting EF. In addition, alcohol consumption likely leads to a decrease in perceived or experienced anxiety or fear of negative consequences. Psychologically, learned alcohol-related expectancies can also play a role in increased social violence. Walters (2002) found that reactive criminal behavior was more strongly associated with substance abuse, with criminal thinking mediating the relationship between such abuse and criminal behavior. He suggested that substance abuse might affect EF and magnify the impulsive and irresponsible features (e.g., cognitive indolence or critical reasoning about potential consequences of behavior) that underlie more reactive criminal behavior.

Anecdotally, the use of alcohol or alcohol or drug abuse/dependence is frequently implicated as a factor in sexual offending. Meta-analytic research has failed to identify such a psychiatric condition of the perpetrator as a predictor of sexual offense recidivism (e.g., Hanson & Bussière, 1996, 1998, Hanson & Bussiere, 1998); however, this finding was likely affected by various forms of dissimulation. A considerable research literature has accumulated which strongly links substance use, particularly alcohol use, to sexual offending. Looman and Abracen (2011) reported that incarcerated sexual offenders reported significantly high histories of alcohol abuse; they also reported that such a history added incrementally to the prediction of risk for future sexual offenses, as did Långström et al. (2004). In a recent review, Kraanen and Emmelkamp (2011) concluded "about half of the sexual offenders had a history of substance abuse, that about a quarter to half of the sexual offenders had a history alcohol misuse or alcohol-related disorders, and that about one fifth to a quarter of the sexual offender s had a history of drug misuse or drug related disorder" (p. 486). Of note, they found more sexual offenders than nonsexual violent offenders abused alcohol.

As with other types of criminal and violent offending, reports of substance abuse among sexual offenders appears common. Felson, Burchfield, and Teasdale (2007) reported that in 36 % of incidents of sexual assault, the perpetrator had been using alcohol. Similarly, Cannon and Carmon (2006) found that over one-third of victims of rapes or sexual assaults report that the offender was drinking at the time of the act. Kraanen and Emmelkamp, in their review, concluded that sexual offenders are often intoxicated when committing sexual offenses, most commonly by alcohol. Alcohol and drug use appears to function primarily as an aggravating predisposing factor to sexual offending. Seto and Barbaree (1995) proposed that alcohol abuse was related to increased likelihood of sexual offense by way of increasing or magnifying disinhibition. However, in addition, such use, primarily in excess (e.g., intoxication), can also serve as a primary mechanism of sexual assault. Alcohol and drug use, as noted previously, share the externalizing spectrum with antisocial behavior in adulthood.

Perpetrators of sexual assault typically have strong beliefs about alcohol's effects on their sex drive and a female's sexual interest. Abbey, McAuslan, Zawacki, Clinton, and Buck (2001) identified that men who believe they are drinking

alcohol experience more sexual arousal than do men who do not believe they are drinking (regardless of whether they actually consumed alcohol). In addition, they noted that alcohol enhanced expectancies of generally disinhibited, aggressive, and sexual behavior. Alcohol use appears to also influence an offender's perception of situations, such that their view of circumstances seems more permissible for a sexual assault. More specifically, Abbey (2011) found that alcohol use supports the perception of cues that a female is interested in being sexual and the ignoring of disconfirming cues; further, to the extent that sexual overtures by a male who has consumed alcohol are perceived as rejection is also supported as a basis for sexual assault. Given the alcohol-related expectancies, Abbey also noted that some offenders might use alcohol use to provide justification for initiating a sexual assault. More generally, consuming alcohol can provide expectancies for lowered concern re "normal rules," the interpretation of "ambiguous" behavior on a target or companion, as well as misperceptions about the behavior or intent of others. Most specifically, Parkhill, Abbey, and Jacques-Tiura (2009) found that:

Heavy drinking men may be so focused on their own sexual arousal and feelings of entitlement that they:

> miss or ignore messages intended to convey the woman's lack of interest…Alcohol administration studies demonstrate that intoxicated men are more aggressive than sober men, particularly when they feel provoked… Intoxicated perpetrators may view any form of consensual sexual activity as permission to engage in intercourse, thus feeling wronged and provoked when a woman stops their sexual advances. (p. 4)

Relative to sexual offending, Prentky and Knight (1991) interpreted their multivariate research results as showing that alcohol as a factor in sexual offending served primarily as a disinhibitor of "lifestyle impulsivity," consistent with other studies that have found that premorbid personality traits were more important in predicting aggressive, violent behavior during altered states than the substance itself. Similarly, Abbey (2011) noted that more intoxicated perpetrators are less likely to report planning an assault in advance. A positive linear relationship exists between the amount of alcohol consumption and the greater degree of aggression in a sexual assault. (Since a large consumption of alcohol is also likely to interfere with the erectile or ejaculatory response of a male, the inability to maintain an erection or to ejaculate may further contribute to the experience of frustration and the degree of violence expressed in a sexual assault.) However, at very high levels of blood alcohol consumption, assault severity appears to decline due to more significant physical and even cognitive impairment.

Abbey (2011) points to studies that show key interactions between alcohol use and personality predisposition: persons high on measures of irritability, low on empathy, and who have more general antisocial personality characteristics are particularly aggressive when intoxicated. She found that both perpetrators who acknowledged coercion or who used a victim's impairment were both characterized by more endorsed greater acceptance of casual sex and lower empathy and reported a more extensive history of antisocial behaviors. Thus, the cumulative literature indicates an interactive, synergistic relationship between alcohol and drug abuse/dependence and sexual violence. Thus, alcohol and/or substance abuse/dependence may be most likely to function in a facilitative role for sexual offending, interacting with a variety of other personality and related conditions. Anger may accentuate entitlement, exacerbate generalized hostility or anger toward women, lessen inhibitions toward sexual behavior with persons for whom an individual has a dispositional low level of sexual interest in, and/or affect expectancies. Persons elevated on varied predisposing personality and related factors linked to sexual violence are more likely to abuse alcohol and other drugs, which, in turn, amplifies their likelihood of sexual violence; (like pornography) alcohol's effects are greatest for persons characterized by other predisposing characteristics toward aggression and sexual assault.

Like other personality-related conditions, it is key to recognize that alcohol and other substance use is strongly influenced by implicit, automatic or "out of awareness" aspects of psychological processes. Implicit attitudes, attentional bias, implicit arousal and memory associations have all been directly implicated as key factors in alcohol and substance use. Rooke et al. (2008), in a meta-analysis of approximately 20,000 participants, found a medium effect size for implicit psychological factors indicating a reliable association between such factors and substance use.

However, alcohol and/or substance abuse/dependence may also be viewed as a primary condition predisposing individuals toward sexual offending as well, particularly given the perception of an opportunity for victimization and/or permissive circumstances. That is, persons with some minimal number or accumulation of other predisposing conditions appear to commit sexual offenses as a result of episodes of intoxication or "elevated" states secondary to drug use; it seems possible that some persons may experience repeated episodes of substance abuse which lead to repeated acts of sexual assault. Per Felson and Staff (2010) sexual offenders are more likely to be intoxicated while committing their offenses than other criminal offenders; studies suggest that approximately 2/3 of sexual offenders were intoxicated when they committed their crimes (with a higher rate among those who targeted adults compared to those who battered children) (e.g., Peugh & Belenko, 2001). In addition, when sexual offenders were intoxicated, evidence indicates that the particular sexual offense was more likely to include physical injury, sexual penetration, and threats to harm or kill the victim (e.g., Parkhill et al., 2009).

Attention-Deficit Hyperactivity Disorder

In most incidents of sexual offending, attention-deficit hyperactivity disorder (ADHD) is likely to be an insufficient condition to provide a primary or exclusive basis for sexual offending. However, given the information described above, it seems clear that ADHD (via its component elements) is likely a powerful facilitating or aggravating condition related to sexual offending. ADHD is a particularly prevalent condition, with a pronounced effect on EF and thus undercuts both self-regulation and more global self-control (e.g., Buker, 2011). Barkley (2012a) identified the six dimensions of EF as the fundamental deficits that accompany and effectively define presentations of ADHD. Thus, he elaborated on the maladaptive aspects of ADHD-related deficits in EF: impairment in self-monitoring; lack of inhibition or restraint in behavior and inability to subordinate immediate interests or urges; deficiency in hindsight and foresight; disrupted self-talk and self-guidance; overdependence on external, immediate consequences related to motivation and affect; and lack or diminished capacity for problem-solving. Others have identified issues in boredom susceptibility, failure to attend to consequences and rules, and varied forms of impulsivity as central components of this condition; those specific components have been identified as personality-related motivators and dishinibitors, respectively. Egan reported that ADHD also interacted with lower IQ to increase the relationship with antisocial behavior. Third, by interfering with sustained attention, ADHD in select individuals appears to potentiate urgency, a lack of early response inhibition, and subsequently compromise the ability to premeditate and persist in appropriate problem-solving strategies. Chamorro et al. (2012) found impulsivity to be strongly associated with ADHD in the general population. Willcutt, Doyle, Nigg, Faraone, and Pennington (2005) conducted a meta-analysis of 63 studies involving EF assessment in over 3700 persons with ADHD. They found that persons with ADHD exhibited significant impairment on all EF tasks, with strongest effects on measures of response inhibition, vigilance, working memory, and planning. Such differences were not explained by differences in intelligence, academic achievement, or symptoms of other disorders. They concluded that ADHD is associated with significant weaknesses in several key EF domains, laying the foundation for compromised self-control and self-regulation. ADHD has been demonstrated to be related to specific personality dimensions, specifically low conscientiousness and low agreeableness (e.g., Nigg et al., 2002). Retz and Rosler (2009) noted a strong association between the condition and reactive aggression both during childhood and into adulthood. Certainly, impairing symptoms of ADHD may persist into adulthood in as many as 65 % of cases (Faraone et al., 2006). In fact, Dalsgarrd et al. (2013) showed that approximately 50 % (47 %) of children with ADHD with conduct problems and 26 % of those without conduct problems had criminal convictions in adulthood; they were 12 times more likely than peers to have violent convictions as adults.

Numerous studies have demonstrated that ADHD appears to be comorbid and predisposing conditions for personality disorders associated to sexual offending. Miller, Nigg, and Faraone (2007) showed that the presence of ADHD in adults (particularly those subtypes of ADHD that involved hyperactive/impulsivity or combined subtype, most especially the latter) was associated with increased rates of personality disorders, including Cluster B personality disorders and avoidant personality disorder. In addition, the joint presence of ADHD was an incremental predictor of increased impairment when present with a personality disorder. In a prospective follow-up study, Miller et al. (2008) found that persons diagnosed with childhood ADHD were at increased risk for personality disorders in late adolescence, specifically borderline (OR = 13.2), antisocial (OR = 3.0), avoidant (OR = 9.8), and narcissistic (OR = 8.7) personality disorders. Those with persistent ADHD were at higher risk for antisocial (OR = 5.3) and paranoid (OR = 8.5) personality disorders when compared to those in whom ADHD remitted, but not the other personality disorders. Cumyn et al. (2009) showed that males with combined ADHD type were more likely to be characterized by ASPD, BPD, and NPD as adults, as well as other comorbid psychiatric conditions. Similarly, as per Bernardi et al. (2012), ADHD was associated independently of the effects of other psychiatric comorbidity with increased risk of narcissistic, histrionic, borderline, antisocial, and schizotypal personality disorders. They also showed that a lifetime history of ADHD was also associated with increased risk of engaging in behaviors reflecting lack of planning and deficient inhibitory control (as well as with high rates of adverse events, lower perceived social support, and higher perceived stress). Again, ADHD is associated with the development of high rates of ASPD in adulthood, including in persons who did not receive a diagnosis of conduct disorder prior to maturity (Retz & Rosler, 2009). Langevin and Curnoe (2011) found that ADHD was a particularly good predictor of criminal recidivism and showed a strong association with psychopathy scores; the primacy of heightened impulsivity appeared particularly important. [Of noted, several studies have found that of persons with diagnosed paraphilic disorders, as many as half may have a history of ADHD (e.g., Kafka and Hennen, 2002; Kafka & Prentky, 1998).] Buker (2011) identified several studies that ADHD acts a significant factor affecting an individual's level of self-control (e.g., disinhibition) independent of other social factors. Thus, on its own and by its strong association with personality disorders, ADHD is associated with strong motivators and elements of disinhibition.

Hypersexuality

Hypersexuality should also be considered as an additional personality-related condition potentially related to increased sexual offending as a particular form of interpersonal violence. Hypersexuality is increasingly used in reference to a putative mental disorder; thus, ICID-10 included both a category for excessive sexual drive (e.g., satyriasis for males) and one for excessive masturbation. However, more generally, hypersexuality refers to the individual differences in the relatively elevated experience of sexual thoughts, fantasies, urges, and/or activities (sexual preoccupation and/or high sex drive). Laumann, Gagnon, Michael, and Michaels (1994) reported that approximately 54 % of men think about sex every day or several times a day and 43 % do so a few times per month or a few times per week. Prior to the increased access to sexualized material via the Internet, that study also showed less than 2 % of males ages 18–59 masturbated daily and just more than 1 % masturbated more than once per day. More recently, Kafka (1997) suggested that excessive sexual preoccupation might be viewed as persons who spend over one hour per day involved in sexual thoughts, fantasies, urges, planning, or other sexual-related behavior. While specific causes are unclear, hypersexuality is found in neurodegenerative conditions and more acute neurological conditions. Thus, there can be significant individual differences in solitary sexual behavior, indicating the likelihood of differing predispositions to sexualized experience. Such individual differences could include lower thresholds for sexualized stimulation, a broader set of stimuli for sexualized stimulation, greater excitation (response) for sexualized stimulation, and decreased latency for decreased sexual arousal (e.g., remaining in a state of such arousal for more lengthy periods). Hypersexuality is implicated in various theoretical models for sexual offending and in multiple research studies as risk factors and/or as dynamic or criminogenic needs for sexual reoffending (often identified as sexual preoccupation and/or sex as coping). Hypersexuality provides for specific elevations in or enhanced propensity for generalized sexual arousal and behavior that acts as an additional prepotent motivator towards an increased probability of sexual offending.

In addition, cognitive factors such as attribution also appear to play a role in the experience of hypersexuality. Thus, several studies have demonstrated that social context and personal beliefs can affect more generalized arousal (e.g., from fear or anxiety) so that misattribution leads to the experience of sexualized arousal (e.g., Dutton & Aron, 1974; Loftis & Ross, 1974). Arousal has also been identified as a key factor in attention and memory so that persons in a state of heightened sexual arousal attend more to their set of sexual "cues" and demonstrate facilitated retrieval of sexualized memories. In addition, heightened sexual arousal can affect the effectiveness of various forms of self-regulation when such arousal is "nonoptimal" and compromises cognitive and behavioral performance of self-control mechanisms. Moreover, Malamuth, Check, and Briere (1986) demonstrated that aggression per se was particularly sexually arousing for a subgroup of males, specifically for those whom aggression itself was especially arousing (while for most males, exposure to aggression had an inhibiting effect on sexual arousal). Ross (2012) demonstrated that self-control moderated the association between sexual desire and various high-risk sexual behaviors; the relationship between sexual desire and high-risk sexual behaviors was stronger when self-control was low than when self-control was high. Reid et al. (2010) found a correlation of .37 between global indices of executive functioning and hypersexuality, suggesting a moderate relationship between those two domains. In short, individual differences in hypersexuality appear to function both as a nonspecific amplifier of motivation and emotion and/or as specific amplifier of generalized motivational and emotional arousal in a sexualized direction. Baughman, Jonason, Veselka, and Vernon (2014) showed that psychopathic traits were most correlated with overall sex drive (as well as with a wider range of sexual fantasies themes) relative to other dimensions of the dark triad. Similarly, Williams, Cooper, Howell, Yuille, and Paulhus (2009) showed that the greater the degree of self-reported psychopathic traits, the more likely the persons were to report acting out deviant sexual fantasies in behavior (including pornography use).

Collectively, the available scientific information regarding personality and related risk factors and/or predisposing conditions for sexual offending is quite convergent and largely supports earlier and current theoretical models of sexual offending against both children and adults. Further, it should be noted that most of this information is based on self-report of identified sexual offenders. Thus, it is likely to be colored by the ego-syntonic nature of problematic personality characteristics and related dimensions such as EF, the common "self-enhancing" aspect to personal evaluation, the degree of lack of awareness of maladaptive intrapsychic/interpersonal characteristics and related dimensions, and the conscious denial or minimization of recognized negative personality and interpersonal characteristics and related dimensions. Similarly, Suchy (2009) pointed out that many traditional neuropsychological measures of EF rely on practiced skills and practiced abilities (which vary across individuals) and artificial tasks lacking in personal meaning and other dimensions for subjects. Consequently, such measures lack ecological validity in that they do not present novel, complex situations to individuals related to real-life situations involving "hot" or personal issues. Thus, the currently available empirical literature regarding nonsexual risk factors for sexual offending probably represents a limited set of the factors actually related to such offending and potentially distorting the identification and degree of the dimensions of those factors (e.g., intensity, frequency, generalization, duration) as well.

Personality and Related Conditions and Sexual Offending: Implications from Theory and Research

Sexual offending is typically an antisocial and/or criminal behavior as it involves violating the rights of others. Further, most criminal sexual offenses are violent offenses or acts of violence, involving contact or the threat of contact with other persons. Violent offending is often dichotomized as reactive or instrumental; in the former, such offending is viewed as provoked, mediated by negative affect and enacted impulsively, while in the latter, the offending is viewed as planned/premeditated and implemented in a more detached, less emotional fashion (albeit still mediated by arousal/temptation motivational factors). In considering victim-focused sexual offending, while some such offending also appears to fall within each category, a large body of sexual offending also seems to be of a more hybrid form of violent offending. That is, much sexual offending begins with some form of erotic, even romanticized fantasizing (a crude form of planning and/or premeditating) that may be generalized (e.g., from unspecified memories, images, stories, or pictures of children or females) or specific to one or more particular potential victims. Further, while some sexual offending is particularly "opportunistic" and reactive to either the opportunity and/or particulars of an available victim (in the context of distal and/or proximal motivational factors), other incidents of sexual offending involve more focused grooming or planning to secure the opportunity to sexually offend against relatively specific victims (e.g., a particular victim or one of a set of victims likely to be available at a time and place). When an appropriate victim (relative to motivational factors and personal history) and a perceived permissive situation or setting occur or present itself, an act of sexual offending can be enacted. In such ways, these sexual offenses seem to be characterized by both elements of some degree of conscious or unconscious premeditation and reactivity (impulsivity). Alternately, a sexual offense could begin with an encounter with an appropriate (e.g., emotionally appealing or sexually arousing victim) and a perceived permissive situation or setting, provoking or eliciting a positive emotional or motivational response, which interacts with state variables (e.g., intoxication, pre-existing emotional and/or sexual arousal), leading to a sexual offense (which may serve as the basis for erotic/romanticized fantasizing and reinforcement via subsequent sexual arousal and/or orgasm).

Theoretically Based Factors in Sexual Offending

While atypical or deviant sexual interests and individual differences in sexual arousal and preoccupation have always been accorded a prominent place in the etiology of sexual offending, nonsexual factors have also long been identified as playing a significant role in sexual offenses. Groth (1979) and Finkelhor (1984) both proposed that underlying motivations for sexual offending were not necessarily exclusively sexual in nature but rather may reflect *nonsexual* "needs" and unresolved life issues. In the evolution of theoretical models of sexual offending, there are strong commonalities among them as to the relevant dimensions of those theories (e.g., Finkelhor, 1984; Marshall & Barbaree, 1990; Hall & Hirschman, 1992; Ward & Hudson, 1998; Ward & Siegert, 2002; Beech & Ward, 2004). In addition to a primary sexual factor [deviant sexual arousal/fantasies and sexual preoccupation (dysregulated and misdirected sexuality)], the following three "nonsexual" areas have consistently been identified as particularly significant in the etiology and maintenance of sexual offending:

- Self-regulation, including issues related to self-interest/entitlement and negative affect
- Distorted attitudes permissive of sexual offending specifically and antisocial acts in general
- Deficits in social intimacy and social competence (social conflict/isolation)

Each of these models validated a perspective that sexual and/or personality dimensions impelling certain urges and/or behaviors that conflicted with and overcame potential internal inhibitions related to self-regulation in the context of situational factors (e.g., "permissive" circumstances for sexual offending, acute dysregulation, strategies for overcoming victim resistance). In addition, these models also highlighted the cumulative effect of multiple sexual and nonsexual factors; that is, some number and degree of sexual factors can interact with some number and degree of nonsexual factors and those various combinations would lead to sexual offending.

Ward and Beech (Ward & Beech, 2003; Beech & Ward, 2004) offered a unique perspective on notion of static/dynamic distinctions of etiological factors but one that paralleled the evolving view of personality and related conditions. They suggested that states (dynamic variables) and traits (static variables) were each aspects of the same underlying construct; for any temporarily manifest state, there would be a corresponding underlying trait or predisposing condition. Per their view, so-called "static" risk factors are significant because they serve as markers of the expression of dynamic risk factors. For example, what has atypically been labeled as a "static" risk factor (e.g., history of criminal behavior) can be an indicator of underlying antisocial or psychopathic predisposing characteristics as psychologically meaningful causal factors. Similarly, deviant sexual preferences (a trait factor) lead to sexual arousal (a state factor) in particular situations. Thus, per Beech and Ward, so-called dynamic risk factors are best understood as ongoing or current expressions (states) of more long-term or enduring underlying predispositions. Beech and Ward argue that every sexual offense involves

some degree of each of the four domains noted above but that different sexual offenses will have at their center a particular set of primary dysfunctional factors, which may vary across specific sexual offenses. Beyond sexual self-regulation, each of the other domains or vulnerabilities to sexual offending involve particular personality dispositions such as motivations/emotions and/or self-control/executive functions that compromise emotional and behavioral expression, attitudes toward types of persons, and social interactions/relationships. In addition to a smaller group of offenders characterized by avoidance and general distress, Ward et al. also pointed to much larger subgroups of "approach" sexual offenders whose sexual offending is associated with positive affect and motivation as well as premeditation.

Specific Research into Risk Factors/ Criminogenic Factors in Sexual Reoffending

A sizeable body of research has been conducted in attempts to identify specific risk factors or predisposing conditions empirically related to sexual offending in general. Most of this work has been organized and presented in the form of a series of meta-analyses by Hanson and various colleagues (e.g., Hanson & Bussière, 1996, 1998, Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004, 2005; Mann et al., 2010). One significant set of variables included various dimensions of sexual *deviance and preoccupation:* any deviant sexual interest, sexual interest in children, multiple paraphilias, sexual preference for rape, sexual preoccupation, prior sex offenses, and early onset of sexual offending. Another primary set of variables identified as predisposing to sexual reoffending fell under the category of antisocial orientation. This cluster of risk factors/predisposing conditions included a measure of psychopathy; antisocial personality disorder; any personality disorder; general criminal and violent history, including such behavior during youth; hostility toward women; "Machiavellianism"; callous/lack of concern for others; self-regulation issues (including impulsivity/recklessness); deficits in problem-solving; offense-supportive attitudes; grievance/hostility; noncompliance with conditional release; and substance abuse. Further, another set of risk factors/predisposing conditions concerned social relations including failure to establish or maintain intimate relationships or conflict in such relationships and negative social influences (criminal families and associates). Of note, Eher et al. (2003) found that personality disorders were common among paraphilic sexual offenders; they were even more common among apparently non-paraphilic sexual offenders. In particular, so-called non-paraphilic sexual offenders were more likely to be characterized by Cluster B and avoidant personality disorders, although narcissistic personality disorder was found commonly among sexualized rapists. In addition, various cognitive factors largely related to self-regulation and goal achievement also influenced rates of sexual offending. Cantor et al. (2004) found lower IQ scores among sexual offenders relative to other criminal offenders, particularly for offenders against young children and for child molesters with hands-on offenses. Langevin and Curnoe (2007) found that, like other criminal and violent offenders, sexual offenders showed significantly lower education attainment, greater failed grades, more frequent placement in special education classes, and higher incidences of school dropouts than community controls.

Several investigators have attempted to delineate the multivariate pathways to sexual offending against both children and adults. Again, notably, these efforts have consistently identified nonsexual factors as playing central roles. In their most recent typology of child molesters, Daversa and Knight (2007) found that aspects child molesters as a group exceeded non-offenders in terms of their psychopathic traits/externalizing behavior, indicating that some portion of child molesters are characterized by a significant amount of externalizing behavior. Additional pathways included dimensions of inadequacy, negative affect, and low social competence. Relative to rapists, Knight (1999) suggested that in addition to sexual *deviance/promiscuity*, the other primary pathway involved *negative (hyper)masculinity* (including hostility toward women, gratification from dominance, and hypersensitive and generally hostile orientation). In his most current model of sexual offending, Knight (2010) postulated several key dimensions related to sexual offending: *hypersexuality*, *impulsivity* (opportunity), and *callous-unemotional/violent* (expressive aggression). In addition, other studies have also identified that generalized hypersexuality should be noted to be a non-paraphilic sexual dimension related to sexual offending as well. Malamuth (e.g., Malamuth, Linz, Heavey, Barnes, & Acker, 1995; Malamuth, 2003) has postulated the confluence model of sexual aggression against adult females. In addition to a sexual group of risk factors (e.g., *sexual promiscuity/impersonal sex, both related to notions of hypersexuality*) which in part reflected that status and self-esteem are achieved by sexual "conquest." *Hostile masculinity* was the second constellation of risk factors for sexual offending including callous, manipulative attitudes toward women; grandiose, narcissistic personality characteristics; hostility toward women; and dominance as a motive for sex (e.g., increasing sexual arousal). The hostile masculinity path was found to be rooted in a proneness to *general* hostility (a combination of impulsiveness and irritability) which leads to *attitudes accepting of violence against women* and, in turn, narcissism, (specific) hostility to women, and (sexual) dominance (particularly in the personality context of low empathy and nurturance). Further, hostile masculinity was also viewed as containing other interrelated components related to a propensity for sexual offending: an insecure, defensive, hypersensitive, suspicious, and hostile orientation (particularly toward women) leading to social isolation as well as related

gratification from controlling or dominating women. Disinhibition occurs primarily as a result of the confluence of such hostility dimensions overriding whatever existing levels of empathic responses and other inhibitory mechanisms. Malamuth has described the confluence model as an integrative and interactional one, in that sexual assaults result only when there is a "confluence" or co-occurrence of major constellations of personal attributes (which each include various subcomponents of motivational/affective and attitudinal predispositions). There is clearly substantial convergence between Knight's and Malamuth's models of sexual violence; each model emphasizes several similar nonsexual personality dimensions: dispositional anger/general hostility, negative attitudes toward women, narcissistic personality characteristics including entitlement, callousness/low empathy, impulsivity, and dominance.

Another consideration related to risk factors and/or predisposing conditions for sexual offending is an earlier belief that a strong or distinctive presence of one of several conditions might be sufficient to explain sexual offending. However, both empirically and theoretically, it seems clear that any meaningful theory or empirical description of sexual offending would most likely involve cumulative probability of multiple interacting primary and secondary (or specific and general) risk factors or conditions converging in particular situations or contexts. Thus, risk of sexual offending likely increases: (1) simply as the number of risk domains or predisposing conditions increases and/or (2) certain risk domains interact (e.g., act synergistically so that their combination is actually greater than a simple additive impact). Such is the case for the presence of deviant sexual interests and relative dimensions of psychopathy (e.g., Hawes et al., 2013) and in the research on the confluence model by Malamuth and his colleagues.

A Dimensional Perspective on Personality and Related Conditions Related to Sexual Offending

Given the previous discussion, it seems clear that personality and related predisposing characteristics should clearly be viewed as playing a role in sexual offending. Following various models of self-control and self-regulation, a primary personality element is a general awareness or what could be termed psychological mindedness, even to a crude degree, referencing an individual's awareness of their past disposition and present internal states. Thus, a critical, initial issue in the self-control process is the individual's self-monitoring of their "experiences" (e.g., Carver & Scheier, 1981). People also differ in the degree to which perception of relevant internal and external stimuli is conscious or unconscious; they are more or less attentive or aware of their own visceral reactions or events/features of their environments that cue or trigger personal responding. Individual differences also exist in person's perception of and sensitivity to internal experiences (including thoughts/fantasies/plans) so that their conscious thresholds are different and they "feel" such experiences with differing degrees of intensity or urgency. Desire or temptation varies for individuals in strength, duration, and frequency. It is notable that in everyday life, sexual arousal and the desire for sexual behavior is typically experienced particularly intensely, much more so than desire for tobacco or alcohol despite their stereotype as "addictions" (e.g., Hofman et al., 2012b). Persons also differ in their ability and need to cognitively appraise those experiences in an accurate manner, whether it is recognizing arousal as sexual or nonsexual (e.g., anger).

Individuals differ in their ability to organize their capacities and experiences to direct their behavior toward desired goals (rewards, reinforcements) and away from threatening circumstances. From a self-regulatory perspective, most persons are characterized by various values, standards, and principles that are associated with short- and long-term goals. In addition, a conscious or unconscious conflict can arise between urges or desire for approach behavior that can create a conflict between what an individual wants to do and what one believes they should do (realized or experience to different degrees). The experience of such conflicts typically triggers more active self-control attempts. Relative to their awareness of motivational and emotional states, some persons will feel impelled to gauge those particular states against personal/social standards or general life goals. Others will feel no or less intense conflict regarding the balance of motivators relative to consequences or long-term goals. Individual differences exist in the degree to which individuals experience such conflict as well as to the nature (variety and significance) of and commitment to those personal standards, values, and life goals. Clearly, some persons lack prosocial goals or values or they "discount" the potential for the degree of consequences of behavioral enactment or overvalue a more immediate gratification over other perceived (e.g., negative and/or long-term consequences).

For some people, self-regulation entails a preventive element; utilizing foresight and awareness of past motivated behavior, they can and do anticipate the problematic consequences of acting on motivators and engage in preventive self-control to minimize the potential elicitation and/or intensity of particular motivations or emotions. Alternatively, an individual's appraisal of the relative consequences or risk in the attempt to enact some motivation may be relatively deficient, compromised, or absent. Avoidance motivation can also play a role; to the degree that an individual experiences anxiety relative to particular consequences, motivated inhibition can also occur. To the degree that there is recognized

conflict between the impetus of motivations or emotions, there may be attempts to reconcile those; attempts may be made to manage the press/pull of motivations/emotions to delay or prevent their expression because of a potential cost in terms of other, more significant consequences. This is sometimes referred to as resistance to temptations; of note, resistance to desire for sexual behavior is among the highest of such urges. Hofmann and Kotabe (2012) identify the significance of a potential formation of an "intent" (or motivation) to resist a particular desire rather than simply enacting it; person's trait and state self-control repertoires may or may not include the conscious identification or expression of an intent not to act on a desire or may entertain ambivalence about possible enactment.

Persons are characterized by individual differences in their incentive or capacity (intent, energy, and/or skills) to manage such conflicts between motivators/emotions and values/consequences: they differ in their intent to adhere to values and standards and awareness/knowledge of varied strategies, and they differ in their ability or "energy" to enact strategies and/or to problem-solve when selected strategies appear to be initially unsuccessful, raising the "question" of alternative strategies. Ultimately, self-regulation comes down to suppression or prevention of behavioral enactment. However, as noted, self-regulation appears to function as a "strength" or "(moral) muscle" model and consumes limited psychological resources and becomes diminished from relative exertion. When a person's self-regulation capacity is limited or becomes further depleted, the individual will become less effective at other self-regulatory tasks. Thus, persons repeatedly challenged with sexual and nonsexual motivators, as well as other self-control situations, will episodically or chronically exist in a state of depleted self-regulation. However, with regular "practice," the capacity for self-regulation (like a muscle) increases in strength. Thus, those who fail to implement self-regulation fail to develop increased capacity for such self-control. At the same time, a consequence of some repeated attempts self-regulation (e.g., attempts at cognitive suppression of a representation or desire) can ultimately lead to diminished self-regulation and, subsequently, to the ultimate "appearance" or experience of such mental/emotional representations or desires.

Obviously, this is a dynamic process that occurs "in real time." It is influenced by differing phenomena. Motivators vary in intensity over time and situations. Self-control clearly has various state aspects as well, and motivation can affect relative depletion in self-regulation. DeYoung (2010) notes that even when persons consider a desired behavior over time, a combination of affective and environment cues can affect enactment and the reaction to either performing or not performing the behavior. As noted, self-regulation is "energy" and resource dependent, and recent efforts at self-regulation deplete available self-control capacities. Additional state conditions, particularly negative affect or mood-altering substances, affect self-regulation and EF; it impacts on the perceived significance of reconciling conflicts between values and "experienced needs". Most particularly, Inzlicht, Schmeichel, and Macrae (2014) argued that depletion leads most people to shift from "have to" goals to "want to" goals; depletion in existing capacities for self-regulation potentiates motivation for personally rewarding hedonistic activities (and the accompanying positive emotions). As they note, "Depletion however, is not simply less motivation overall. Rather, it is produced by lower motivation to engage in 'have-to' tasks and higher motivation to engage in 'want-to' tasks. Depletion stokes desire" (p. 131).

Situational factors can also impinge on self-regulation and problem-solving; both strong negative affect and alcohol can potentiate the behavioral impact of impulsive determinants on eating behavior while disrupting the behavioral impact of reflective determinants. Hofmann and Kotabe (2012) state, "Arguably the two most powerful preventive self-controls strategies can be found in situational and stimulus control, the avoidance of tempting situations or the removal of tempting stimuli from one' immediate environment" (p. 716). They note that research indicates that persons high in dispositional or trait self-control make more use of such preventive self-control in attempting to address their desires. However, regarding sexual offending, crudely, self-control can fail either because the impulses, desires, or temptations related to one or more motivators (individually or collectively) are too "strong" or "intense" or too many to restrain/inhibit/constrain or because capacities for self-control are too limited or too weak. In addition, from a more dynamic perspective, lower self-control (trait or dispositional) likely provides for the experience of increased strength of sexual and nonsexual impulses. Low self-control has been shown to be associated with poor dispositional and episodic sexual restraint in everyday life. Research by and review by Gailliot and Baumeister (2007) showed that individuals with low self-control were more likely to fail at stifling motivational (including sexual) thoughts, inhibiting their expressed willingness to engage in inappropriate sexual behavior. In addition, they obtained some evidence that the effects of diminished self-control were strongest among those with the strongest sexual desires.

How best to categorize the various predisposing nonsexual conditions that are most strongly related to sexual offending? The DSMs would suggest that maladaptive personality characteristics can be grouped into four categories: cognition (ways of perceiving and interpreting self, other people, and events), affectivity (motivation, range, intensity lability, and appropriateness of emotional response), interpersonal functioning, and impulse control. However, these domains clearly overlap and appear largely interrelated: cognitions influence affect, affect and cognition influence impulse control; and

interpersonal relations impact affect, cognitions, and impulse control. Similarly, from a more conceptual perspective, the constructs of motivation, executive functioning, and self-control/self-regulation also implicitly or explicitly overlap and/or interact with the construct of personality. Given such categorical and theoretical overlap, identified predisposing factors cannot be neatly separated into precise categories of cognition, affect, and interpersonal and/or impulse control. In addition, maladaptive behavior is larger than just that with implications for interpersonal functioning but relates to problematic functioning in other areas of life such as work (e.g., irresponsibility) and self-care (e.g., suicidal behavior). Consequently, while one can attempt to sort personality dispositions into the four categories of the DSM, the outcome of that endeavor would be quite artificial. In considering nonsexual predisposing conditions, it appears clear that those nonsexual dispositions likely involve varied and interacting combinations of conditions of personality, motivation, executive functioning, and self-regulation/self-control or as overlapping/interacting cognitions, affect, impulsivity, and interpersonal relations. Further, given the nature of "behavioral signatures," it is of value to acknowledge "facilitating" and specific situational or state factors that may relate to sexual offending.

Nonetheless, it makes sense to attempt to specify the central varied personality and related dimensions that appear to be theoretically and/or empirically linked to increased predisposition to sexual offending. An empirical basis for such personality and related dimensions exists: analyses of FFM dimensions related to antisocial behavior, analyses of externalizing spectrum behaviors, and the meta-analyses of risk factors for sexual offense recidivism of personality-based dimensions all inform what the nature of nonsexual personality and related dimensions might be. A simplistic framework for understanding human behavior would suggest that human activity could be reduced to a balance of desire or urges for rewarding experiences and/or fears of danger to self or punishment. Ultimately, all sexual offenses involve approach motivation of some sort in the presence of some deficient or lack of self-control or self-regulating elements, even for those sexual offenders characterized by ambivalence or "avoidance" pathways. Thus, there are nonsexual "motivators" that impel or urge a person to act in a particular manner and other nonsexual factors that represent deficiencies or failure to constrain or inhibit such behavior ("elements of disinhibition"). While some nonsexual personal predisposing factors might be strong enough to determine a sexual offense on their own, it seems more likely that various sets of such factors act in an additive/cumulative and even synergistic fashion, combining and augmenting one another in different ways across different situations to also converge in a resulting sexual offense. What seems most useful is to simply identify and consider particular personal dimensions (each of which could be considered aspects of motivation, executive functioning, and/or self-regulation/self-control) as motivators or elements of disinhibition and consider their potential and/or likely relationship to personality constellations in relation to incidents of and persisting sexual offending. It should be noted that this is not intended to be a comprehensive or exhaustive list but rather a suggestion of factors for which there is significant theoretical, explanatory, and/or empirical support. Finally, following (Mischel and Shoda 1995, 1998; Mischel, 2004) and related theories, situational, contextual, or triggering factors clearly exist which elicit and amplify to varying degrees personality "motivators" and/or augment or intensify personal dispositions (or both) and provide opportunities for the more pronounced manifestation of both sets of factors. Thus, following the notion of a behavioral signature, the identification of particular predispositions for particular action without specification of context obviously limits the explanatory value of the identified characteristics.

Several things are useful to consider relative to nonsexual factors related to sexual offending. First, the enactment of sexual behavior is clearly not an "automatic" phenomenon; the frequency of sexual dysfunction is so common that it has been identified as a significant public health problem (e.g., Lauman, Paik, & Rosen, 1999; Derogatis & Burnett, 2008). There is a high prevalence of sexual dysfunctions among men who indicate an interest in and desire for sexual behavior; various things commonly interfere with both sexual interest and sexual performance. In general, from both a biological perspective and an experiential one, numerous "threats" exist to "normative" sexual arousal or functioning. For sexual behavior to be enacted, both varying degrees of excitation/arousal t and relatively low levels of inhibitory mechanisms must be present. Obviously, the frequency of commercial advertisements for products related to increasing sexual interest and capacity (performance) provides some metric of the difficulty of initiating and enacting sexual behavior among the general population of males. Thus, the enactment of sexual behavior, including sexual assault, must overcome a variety of factors that commonly and/or frequently impede sexual desire and impair sexual functioning. Second, in light of potential nonsexual predispositions for sexual offending, one must consider why persons experiencing or manifesting such predispositions elect to "express" or "manifest" those issues (individually or collectively) end up enacting a sexual as opposed to some other violent behavior. Can nonsexual personal factors lead to a sexual offense in the absence of *any* specific or general sexual interest or motivation? That is, what type or degree of nonsexual personal dispositions leads someone who has no or little sexual interest in children or in adults in general to enact sexual offenses involving such victims, particularly ones involving force, distress from the victims, and likely leading to negative consequences for a perpetrator? Little information, theoretical or empirical, exists to explain why nonsexual-specific

motivators and elements of disinhibition on their own, given particular contexts, result in uniquely sexual forms of violent offending.

Currently, the available research would direct that nonsexual personality and related conditions do act as significant predisposing factors for sexual offending (either on their own or certainly in combination with sexual predisposing factors). As Meston and Buss (2007) pointed out, the primary reasons persons engage in sexual behavior involve physical, goal attainment, insecurity, and emotional factors. Similar to Malamuth's confluence model, the general literature suggests that violent behavior generally and sexual offending specifically is characterized by a multidimensional and cumulative nature. There are personal and related conditions which are potentially more specific to sexual offending which are subsumed to some degree by more general domains that are related to antisocial and violent behavior generally. Marshall and Barbaree (1990) emphasized that sexual offenders frequently met a number of psychological needs via sexual offending, theorizing "…the task for human males is to *acquire inhibitory control* over a biologically endowed *propensity for self-interest associated with a tendency to fuse sex and aggression*" (p.257, emphasis added). Hall and Hirschman (1992) proposed that the probability of sexual offending was crudely a function of the perceived benefits of sexual aggression (e.g., sexual gratification or pleasure) outweighing estimated threats to the perpetrator or to a victim; this was termed the threshold gradient.

Clearly, there appear to be two key dimensions, which can exist to varying degrees, with differing frequency and across greater or fewer situations for specific individuals. First, there appear to be primary motivational states and needs (experiential, affective, and attitudinal conditions) that, when activated, function as "pushes" or elicited "pulls" and thus serve as predisposing psychologically meaningful risk factors for sexual offending. Secondly and conversely, the presence of degrees of "disinhibition," some set of varied deficits in "constraint"—absence or degrees of lack of capacity or affinity for self-control, self-regulation, or inhibition (inhibitory deficits)—appears sufficient to allow sexual offending to occur even under conditions of minimal primary sexual and nonsexual motivational dispositions or states. In addition, there appear to be an additional set of contexts or facilitating conditions that might be unlikely to lead to sexual offending on their own but can greatly enhance the likelihood of one or both primary motivational factors leading to a sexual offense (e.g., alcohol/substance use, ADHD, lack of environmental restraints). Given the interrelationship of motivation and emotions, cognitions, interpersonal elements, and self-control of impulses (via, in part, executive functioning and/or self-regulation), it is somewhat artificial to "divide" or identify specific characteristics as if they were divorced from other, related dimensions. That is, most nonsexual predisposing conditions to sexual violence involve admixtures of multiple personality elements (Fig. 1).

Primary Motivational Dispositions, Affective and Attitudinal Conditions ("Motivators")

Motivation is a key aspect of human personality and functioning. Appetitive motivation represents urges that drive individuals toward desired and/or pleasurable events (or, rooted in anger, to relieve unpleasurable or distressing experiences); such motivation catches and directs attention, determining the direction, preoccupation, and persistence of behavior in the world. [Sexual arousal and gratification per se would appear to be the primary exemplar of that.] As noted, appeti-

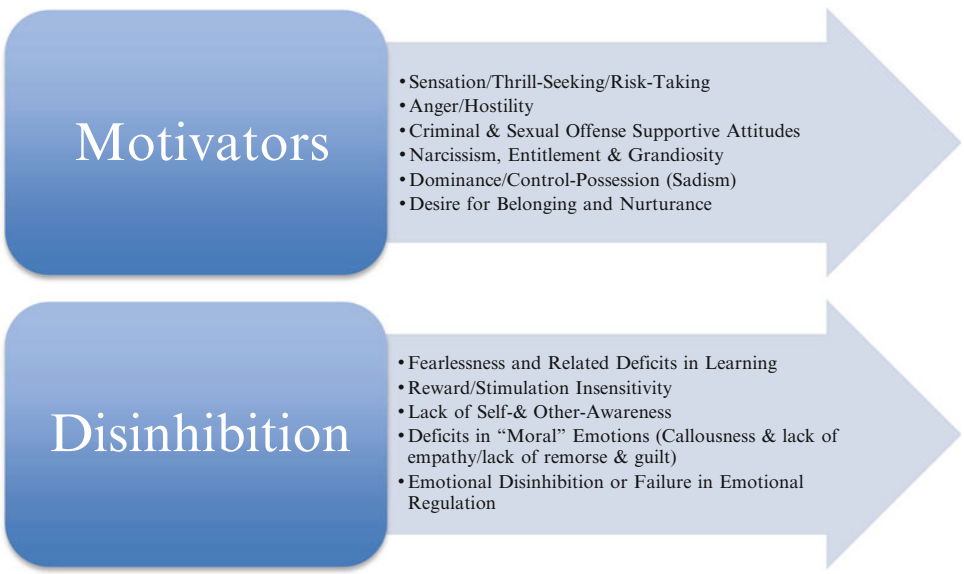

Fig. 1 Motivators and dimensions of disinhibition

tive motivations involve two dimensions. *Wanting* or desire refers to the motivational or incentive salience that makes the reward desirable; wanting transforms a reinforcer from a sensory representation into a desired reward capable of capturing attention, motivating behavior but which can eventually become unlinked from the hedonic element of liking. Somewhat in contrast, *liking* refers to the pleasurable, hedonic feelings experienced when a desired reward has been procured via behavior or imagination (Zhang et al., 2009). Significant individual differences exist relative to motivational conditions in terms of both wanting and liking. Persons are characterized by the variety of motivations that they experience as well as differences in the number of triggers/eliciting elements and degree of sensitivity (and responsivity) to internal and external cues (thresholds) leading to the initial intensity and duration of the motivational force; they also differ in the degree to which a gratification or satisfaction of motivation is rewarding and, subsequently, changes their expectancy for similar experiences in the future.

Motivation is typically perceived and "interpreted" when it has a conscious impact to cause a person to initiate approach behavior and is appraised or interpreted after enactment. Walters (2009) has argued for the primacy of "criminal thinking" in the enactment of criminal behavior; per his definition, such thinking is cognition designed to initiate and/or maintain the habitual violation of rules and laws. In particular, his model and data suggest that various "thinking styles" either potentiate or facilitate positive reinforcement before and after motivated antisocial behavior occurs. Criminal thinking has this affect by virtue of its influence on thinking styles, (criminal) values, attributions, self-efficacy for crime, outcome expectancies for crime, and criminal goals. An important distinction to keep in mind is that motivation is not always about what is perceived as "positive" affect per se; approach motivation also occurs when persons act on anger to inflict pain or harm on some, offending others, and/or in an effort to remove a violation of what "ought to be" (e.g., Carver & Harmon-Jones, 2009). In this vein, anger functions as motivation to restore some desired state. In a similar vein, attitudes about the nature of the world as it is and as it "should be" can also serve as approach motivations.

As indicated, among other dimensions, a sexual offense can result from a motivational impetus (a push/pull for reward or pleasure) or a motivational avoidance of some unpleasant, aversive state, attitudes related to privileging one's own desires or urges or defined by negative affectivity (particularly directed toward others). Such factors necessarily have to be ones that strongly impel or push a person to interact with another person via sexual behavior but in the service of a nonsexual motivation. Hofman et al. (2012a) reported that more enduring, high desire strength of appetitive motivators should increase the probability of behavior enactment, as should novel or dispositionally "exciting" stimuli. A number of factors [some of which might be likely to occur in individuals with particular life histories (e.g., of adversity)] would appear to possess sufficient "power," provide such a "push" or "urge," or be susceptible to a "pull" from relevant environmental stimuli. In addition to the individual differences noted above, the experience of one or more motivations is experienced contextually relative to the degree of presence and "strength" of one or more elements of disinhibition. Therefore, the relative lack of or deficiencies of inhibitors can further potentiate the more immediate or persistent pursuit of rewarding and/or pleasurable motivations and undermine the potential for delays in seeking gratification relative to longer-term goals.

In the context of Meston and Buss's (2007) research, factors that appear to possess a sufficient degree of motivational for persons to engage in sexual behavior include pleasure, stress reduction, experience-seeking, revenge, social status, utilitarian, self-esteem "boost" (under insecurity), and expressive communication (under emotional). An attempt to integrate the general psychological concepts and findings with the theoretical and empirical perspectives on sexual offending suggests that a number of motivators can be identified which singly or in combination appear sufficient to provide the basis for specific acts or episodes of sexual offending.

Sensation-Seeking/Thrill-Seeking/Risk-Taking

Again it is useful to note that numerous researchers have argued for a distinction between this condition and general impulsiveness (e.g., Cross et al., 2011; Derefinko et al., 2011; Burt & Simons, 2013). Zuckerman (1979) defined sensation-seeking as the need for varied, novel sensations and experiences and the willingness to take physical and social risk to obtain such experiences. A disposition for hedonistic sensation- or thrill-seeking (sometimes referred to as affective impulsivity) provides a personality-based motivation for risky, stimulating, and exciting behavior, which could include sexual behavior and particularly sexual behavior that would be regarded as novel, illegal, or immoral. Particular individuals experience the process of taking risks as highly pleasurable or rewarding, whether planned or not; a related dimension would be a lower threshold for the rewarding aspects of sensation-seeking and excitement. In addition, criminal behavior, including violent and sexual offending, provides an opportunity both for risk and potential immediate, albeit short-term reward; thus, such risky behaviors are more rewarding and motivating to high "thrill-seekers." From the perspective of the FFM and the UPPS, Miller et al. (2003) showed that sensation-seeking was one of the two most consistent of the four dimensions of "impulsivity" in predicting crime and violence. Joliffe and

Farrington (2009) showed that historical "high daring and risk-taking" were shown to be more related to later violence relative to other dimensions related to impulsiveness. Relative to self-reported impulsivity, Kirby and Finch (2010) identified thrill- and risk-seeking, impatiently pleasure seeking, and "happy-go-lucky" as key dispositional dimensions. As noted, Miller et al. (2003) found sensation-seeking was one of the most consistent dimensions in predicting externalizing behavior in general. Quay (1995) spoke a "need" to create excitement, adventure, and thrill-seeking behavior; Blackburn (2006) noted that evidence favoring an association between heightened stimulation-seeking and psychopathy has been consistent. Krueger et al. (2007a) identified excitement-seeking as a key facet of the ESD, sensation-seeking is strongly associated with externalizing behavior (e.g., Miller et al., 2003), and boldness was identified as a key dimension of psychopathy by Patrick et al. (2009). In addition, the intensity of high-approach-motivated positive affect reduces attentional focus and degrades EF. In addition as Burt and Simons (2013) point out, thrill or sensation-seeking likely is associated with some degree of offending versatility, such that repetition breeds habituation, while novel stimulation or situations may lead to new victims and/or types of offending behavior.

Hoyle, Fejfar, and Miller (2000) conducted a meta-analysis of personality and sexual behavior that determined that sensation-seeking was the strongest trait-level predictor of risky sexual behavior. Birthrong and Latzman (2014) found that positive urgency was uniquely associated with risk sexual behaviors. Porter et al. (2001; 2010) characterized a subset of sexual offenders whose primary motivation for sexual offending was thrill-seeking (particularly in the context of heightened boredom or low autonomic arousal and a select/generalized lack of empathy); that is, they have a propensity for exciting and risk situations that involve novelty and excitement, including the arousal that can precede and accompany violent behavior.

Anger/Hostility

A common emotional response to frustration, hurt, disappointment, and real or imagined threats is anger and its more generalized form, hostility. As a negative emotion, anger has both episodic and dispositional elements; certain types of situations commonly elicit displeasure ranging from irritation to rage, and individual differences exist in the frequency, pervasiveness, and intensity of angry feelings. Anger appears to be elicited by perceptions of threat or damage, including threats or "damage" to self-esteem; it is a common response to frustration, when some desired or potentially rewarding goal is thwarted, for example, by another person. Per Carver and Harmon-Jones (2004), "Anger often promotes an effort to remove the violation of what 'ought' to be, an effort to change the behavior of other" (p. 184). As a reactive response to internal or external stimulation, anger has been identified as falling into the category of approach motivation toward a – specific or generalized "offending" other, others, or life situation (e.g., Carver & Hampton-Jones, 2009). Anger and hostility are activating experiences such that angry/hostile persons are motivated to behave toward a perceived or displaced source relative to elicitation of their negative emotional experience; anger provides a "confidence" to act against a "perceived" threat. Hostility, as generalized anger, represents a heightened baseline in which provocation may be more minimal in terms of elicited reactive behavior; there appears to be a paranoid, suspicious, or distrusting basis to hostility. The experience of anger appears to be disinhibiting by increasing generalized arousal (transferable to sexual arousal) as well as by providing increased permission to act and by desensitizing an individual to both the immediate situation and future-like situations; it also primes cognitive schema or "scripts" related to anger-based aggression. That is, angry states lead to a tendency to appraise subsequent events in a manner consistent with earlier threat appraisals; thus, more frequent anger (e.g., from frustration) may lead to more pervasive and dispositional (intentional) anger and/or hostility. By facilitating attention to future-provoking events, the salience of such events may evolve. The relative intensity of anger/hostility can lead to increased self-absorption, narrowing the angry persons' cognitive processing and heightening the salience of more immediate (angry) goals. In addition, the generalized physiological arousal associated with anger states, like other arousals, can easily be displaced onto other targets or activities. Finally, intense anger, like other intense affective states, can act to compromise attentional focus to other aspects of EF.

Walters (1995) found that "willful hostility" was one of the two key dimensions of criminal thinking, while Miller et al. (2004) showed that the FFM dimension antagonism was associated with risky sexual behaviors. As noted, Knight and Prentky (1990) theorized that both generalized anger and more vindictive (retributory) anger were associated with rape. Hanson and Harris (2001) showed that negative affect, particularly anger, increased prior to sexual reoffending. In addition, Yates et al. (1983) found that anger induction led to greater disinhibition of sexual arousal to rape depictions; other research supports the notion that any form of generalized arousal can "inflame" or infuse sexual arousal and motivation.

Hostility can be viewed as the dispositional or "trait" form of anger. It is sometimes distinguished from anger as involving a persisting negative cognitive perception/evaluation of other persons or situations (a hostile attributional bias); intense or repeated anger can lead to more enduring attributions of blame or responsibility for real or imagined frustrations or "injury."

This can be viewed as "grievance thinking" per Thornton (2010), where persons feel easily wronged, suspicious of others, tend to ruminate angrily when feels wronged, and has difficulty accepting another's point of view. From the FFM perspective, hostility is viewed as persistent or frequent anger or irritability (often in response to perceived slights by others) or as mean or vengeful behavior. Persistent and enduring generalized hostility can lead to motivation to "punish" others based on the perception that "the world" or some specific subset of persons (e.g., females) have done them wrong or that children are "available" as potential vulnerable, attainable victims.

Significant levels of distrust and suspicions of others (e.g., a generalized paranoia) often characterize criminal and violent offenders. A common cognitive distortion is the fundamental attribution error, which involves blaming others for one's failures or misfortunes. However, as De Brito and Hodgins (2009b) point out, given the frequent early experiences of being raised in antisocial and/or abusive, neglectful homes, the subjective experience of persons with personality disorders (particularly ASPD) that the world is unfriendly and dangerous may not be "wholly irrational" (145). This characteristic reflects a dispositional orientation that affects perspective-taking (misperceiving the actions and motivations of others) and expectancies of negative experiences with other people. The two most recent meta-analyses have identified "grievance thinking" as risk factor, where an individual perceives that others are responsible for their problems.

Criminal and Sexual Offense-Supportive Attitudes

Attitudes are typically understood as persisting personal beliefs or evaluations of people, things, or events with value (positive-negative, conflicted) attached to them; they are a sense of how things should be and are potentially motivational in that regard. Attitudes are thus understood as admixtures of thoughts and feelings that operate both explicitly (consciously) and implicitly (out of awareness). Critically, attitudes provide significant filters on perception and other aspects of information processing. Antisocial attitudes have been found to be among the most potent of criminogenic needs among criminal offenders generally (e.g., Andrews & Bonta, 2006). Walters (2009) has argued for the primacy of "criminal thinking" in the enactment of criminal behavior; per his definition, such thinking is cognition designed to initiate and/or maintain the habitual violation of rules and laws.

Attitudes about one's self and nature of the world as well as specifically about females and children would provide motivation toward engaging in sexual behavior with such individuals. Regarding persons who sexually offend against children, Ward and Keenan (1999) identified several implicit theories or cognitive distortions that supported such offending: that children are sexual objects, that sexual activity with children does not cause harm (and may be beneficial), that children benefit from sexual contact and are compliant in sexual offending, and that in a dangerous world (e.g., rejecting), children are more likely to accept an offender and provide him acceptance and affection would all provide specific predisposing factors toward sexual offending. In addition, Ward and Keenan identified that entitlement and that sexual behavior is uncontrollable are related to sexual offending against children; these appear to be more general attitudes that could apply to such offending. In terms of persons who sexually offend against adolescents and older persons, Mann and Hollin (2007) identified five potential schemas related to rapists of adolescents and older persons. Four appear to be more general violent-supportive attitudes: need for control over others, entitlement, grievance (leading to retaliation), and the view of self as victim. In contrast, one proposed schema seems specifically related to sexual assault of females, namely, disrespect for (certain) women. This last cognition is one of the "bundle" of beliefs and attitudes subsumed by the Malamuth (confluence) factor of hostile masculinity as a primary factor in sexual assaults of female victims; other studies have also found a relationship between a hostile or mistrusting attitude toward women (e.g., viewing women as both malicious and untrustworthy in their relationships with males) and sexual recidivism. Polaschek and Ward (2002) proposed and tested five implicit theories relative to rapists. Several appear to be specific to sexual assaults against females: women are sex objects (constantly sexually receptive), women are dangerous (out to harm men), and male sex drive is uncontrollable. Two of the five appear to be more general but were related to rape behavior: entitlement (meeting one's needs on demand, specifically the right to have sex whether a victim was consenting or not) and dangerous world (in general, people are viewed as dangerous, a more generally paranoid view of others). There is obvious convergence of the rape-supportive attitudes found by the different investigators as well as in relation to sexual offending against children; both sets of attitudes include a primacy on egocentrism, a view of the world as negative/hostile, and views of both women and children as sexualized or sex objects.

In contrast to attitudes that motivate specific sexual offending behaviors, additionally, a number of writers have written regarding that distorted attitudes supportive of sexual offending may be invoked to serve as justification and reinforcement for sexual offending subsequent to an offense: minimizing the nature (e.g., force) and consequences of the offense (e.g., harm to the victim), blaming others and situations

for an assault, and/or making attributions that they themselves lack the capacity to control their motivations. Leeuven et al. (2013) showed that several models of self-serving cognitions [(primary: self-centered) and secondary (minimizing, blaming others, and assuming the worst)] are related to antisocial behavior (albeit via callous-emotional traits).

Recently, Helmus, Hanson, Babchishin, and Mann (2012) conducted a meta-analysis of attitudes supportive of sexual offending. They noted that many of the attitudes that potentially contribute to sexual offending are present in the general population, including rape attitudes and the sexualization of children, suggesting some general sociocultural "support." Their results demonstrated a consistent relationship of such beliefs to sexual reoffending, particularly when particular attitudes were matched to the type of offender (e.g., generally, specific beliefs were associated with sexual offending against youth or against adults); it was noted that measured attitudes were better predictors of sexual offense recidivism for child molesters than for rapists. Helmus et al. also pointed out that attitudes supportive of sexual offending were also related to other constructs and/or factors previously related to sexual offending (e.g., they overlap and/or co-occur).

Narcissism, Entitlement, and Grandiosity

Narcissism has unfortunately been misunderstood in the construction of the related personality disorder in the DSMs (e.g., Miller, Widiger, & Campbell, 2010). Conceptually, healthy narcissism relates to generally realistic self-awareness, self-appraisal, and regulated affect relative to self-evaluation; self-esteem is largely accurate and proportional to one's achievements in important life areas. In contrast, pathological narcissism (abnormal narcissism) is understood as expressed or manifest excessive self-regard in response to perceived or experienced deficits regarding one's self. Pathological narcissism is compensatory and defensive, thus, the terms "threatened egotism" and "narcissistic injury," when an individual's veil of manifested grandiosity is threatened or exposed by life events. Typically, the narcissistic individual's exaggerated sense of self (relative to his/her life circumstances) is rooted in self-devaluation, inadequacy, and shame. Such pathological narcissism is associated with a sense of invulnerability, such that social norms/rules do not apply to him, impaired capacity for empathy, and genuine commitment to others.[4] Such persons may engage in "grandiose" fantasies about others that prop up or reassure their fragile or low self-esteem but are indifferent to or unaware of the experience of others who may be the object of desire. As Logan noted, narcissism is typically accompanied by other core dimensions such as hypersensitivity, low frustration tolerance, strong aggression, entitlement, and problems with regulation of negative emotions; in addition, manipulation, deception, and control of others "serve" narcissism or grandiosity in those who feel essentially inadequate and lacking. Meloy (2003) noted that a psychopathic individual's apparent grandiosity is a function of the disparity between his view of himself and the facts of his life and then is further maintained (reinforced) through violence and the control and behavioral devaluation of others. Vaughan, DeLisi, Beaver, Wright, and Howard (2007) showed narcissism demonstrated significant overlap with measures of self-control, concluding that "…self-control is likely subsumed by narcissism" (p. 816).

Numerous authorities have linked narcissism to entitlement (e.g., APA, 2013; Walters, 2009; Patrick et al., 2009) and to aggression and violence. Miller et al. (2010), having reviewed the available literature on narcissism, found a strong association between greater narcissism and various forms of aggression, in both provoked and non-provoked circumstances; they also found that narcissism was associated with a callous lack of concern for the feelings and needs of others. For these and related reasons, narcissism has a particularly negative impact on interpersonal relationships over time. Campbell, Bonacci, Shelton, Exline, and Bushman (2004) showed that psychological entitlement had a pervasive impact on social behavior (including aggression and exploitative relationships) and was stable over time. Narcissism is associated with a wide range of externalizing spectrum behaviors including alcohol abuse and antisocial behavior via enhanced appetitive and/or reward-seeking disposition (e.g., Miller et al., 2010). Baumeister et al. (1996) also suggested that "higher" self-esteem and/or grandiosity/narcissism had a "dark side" that served to potentiate violence potential. Specifically, they identified that a considerable degree of violence is a result of "threatened egotism," where relatively favorable views of oneself (albeit not necessarily "true" ones) are disputed or devalued by persons or circumstances. Such "threatened egotism" relative to a fragile or threatened self-concept leads to an externalization of hurt/anger toward another as a means for compensating for the psychological threat. Thus, violence was viewed as often not in proportion to actual abilities or qualities that encounter an "ego threat." Baumeister et al. stated:

> Preliminary evidence portrays rapists as having firm beliefs in male superiority and often elaborate beliefs in their own individual superiority, all of which is contrary to the low self-esteem view. Some observations support the view that ego threats figure prominently in the events leading up to rape. In many cases, however, the victim was not the source of the ego threat. (p. 18)

In addition, evidence suggested that perceived higher self-regard was a correlate of aggression so that the experience and expression of anger among narcissistic individuals

[4] Some writers have distinguished between the truly grandiose narcissist and the "vulnerable" narcissists.

increased as their self-reported self-esteem increased. Later, Baumeister et al. (2002) found that narcissism might be a key factor in attitudes and behavior related to the deprivation of sexual options (e.g., rejection, indifference); such circumstances might be moderated by narcissism to lead to sexual offending, and they identified this phenomenon as rape as a form of narcissistic reactance. However, other research has shown that narcissistic characteristics are related to proactive aggression in the absence of ego threat. A common link has been observed between entitlement and a sexually supportive attitude such that persons feel that sexual arousal "entitles" a person to act to gratify that arousal. In turn, this links entitlement to exploitation of an "available" victim for motivated gratification. Miller et al. (2004) showed that the FFM dimension low agreeableness (egocentric) was associated with risky sexual behaviors. Utilizing a domain-specific measure of sexual narcissism, Widman and McNulty (2010) showed that higher scores on the measure were associated with specific types of sexual aggression and the likelihood of future sexual aggression. Eher, Rettenberger, Matthes, and Schilling (2010) found that narcissistic personality traits offered incremental predictive power above static risk factors for sexual reoffending. As noted, Esbec and Echeburua (2010) and Dunsieth et al. (2004) identified that narcissism/entitlement as a trait or a disorder is associated with violence and sexual offending.

Entitlement refers to the characteristic belief that a person should receive special treatment or that others will/should automatically comply with his or her expectations. Walters (2009) identified entitlement as a key facet of criminal thinking, the belief that for personal gain/reward, one is entitled to violate the rights of other and the rules of society. Such deficits in learning from experience or consequential learning, allow individuals to act on immediate urges or motivation for pleasure without evaluating or considering the implications of their actions for themselves or for others. Entitlement often accompanies narcissism but also exists independently, often as a result of experiences of deprivation or devaluation. Other persons are typically objectified and viewed as means to gratify oneself. Such egocentrism often involves self-gratification through the emotional and physical use of others. According to Meloy (2003):

> For some offenders, this is a function of narcissism or grandiosity while for other it is a more hostile entitlement in the sense that they believe that because of their own life history they are 'owed' what they want from select others… .(p. 2)

Thus, such individuals believe that they are entitled to obtain sexual gratification from others due to their own past experiences of mistreatment. Hanson et al. (1994) found that sexual offenders were characterized by specific sexual entitlement whereby an individual believes or acts as if he is permitted to or it is his right to engage in sexual behavior with whomever he wants. Relatedly, they may believe that they should have sex whenever they "need" it and/or that others should oblige a man's sexual needs. Typically, they view other persons as objects for sexual gratification and, for a variety of reasons, experience themselves as "entitled" to use those victims for their own sexual gratification.

Blame externalization can be understood as a manifestation of a narcissistic or entitled orientation toward the world as well as a violence-supportive attitude or a manifestation of chronic anger/hostility; "good events" are attributed to oneself, while "bad events" are attributed to others and used to justify past or further violent offending.

Dominance/Control Possession (Sadism)

A press or need (motivation) for dominance (control/possession or esteem) via sexual offending may be rooted in frustration/anger or anxiety about anticipated or real rejections of potential sexual partners or even more general circumstances. Often related to a narcissistic orientation toward the world, persons must control others to feel as if the world is predictable. Hedonic dominance involves obtaining pleasure to influence or control others and a rearward in use of seduction or charm to achieve one's ends. Affectively, dispositional fearlessness (e.g., boldness or fearless dominance) is related to persistence in maladaptive behavior, including behavior that is harmful to others and that was or is rewarding even when potential consequences for "punishment" increase or become more probable. In addition, dominance motivation may be triggered or heightened by experiences of external "rule imposition" or social consequences, leading to a motivation to violate such rules or potential sanctions. Grieger, Hosser, and Schmidt (2012) found dominance (forceful, striving for goals) was associated with violent recidivism. Fearless dominance was strongly associated with sensation-seeking. Krueger et al. (2007a) identified rebelliousness as a key facet of ES. Walters (2009) identified power orientation as a key facet of criminal thinking, referring to a desire for personal power and control over others. Tracy and Robins (2003) suggested that individuals protect themselves against feelings of inferiority and shame by externalizing blame for their failures, which leads to feelings of hostility and anger toward other people. Donellan et al. (2005) found a robust relation between low self-esteem and externalizing problems across methods, nationalities, and age groups. In addition, they showed that the effect of self-esteem on aggression was independent of narcissism. It has been hypothesized that persons with low self-esteem turn to aggression as an alternative source of potential esteem or, similarly, that individuals with low self-esteem actively dominate or aggress on others in an attempt to raise their self-esteem.

Dominance via sexual behavior of adults or children can more generally provide a sense of esteem, control, or retaliation that can be rewarding, particularly for individuals who feel inadequate. Groth (1979) in describing the power rapist

suggested, "Sexuality becomes a means of compensating for underlying feelings of inadequacy and serves to express issues mastery, strength, control, authority, identify and capability. His aim is to capture and control his victim" (p. 25). He also suggested that coerced sexuality could be a means of affirming masculinity or more generally personhood. "Fearless dominance" has been identified as a key trait in studies of self-reported psychopathy and related to narcissism and low behavioral inhibition (such as low fear or distress; Witt et al., 2009).

A related dimension to be considered along with the motivation for dominance and control is sadism; in addition, sadism also appears to have roots in motivating aspects of anger and hostility. Generally, sadism goes beyond the mere expression of just dominance/control and anger or hostility to the experience of pleasure from both "seizing" control and associated gratification from imposed humiliation or the callous feeling of "power" over another to the pleasure derived from observing or inflicting pain, discomfort, or devaluation on another. While some sadistic individuals obtain pleasure in the actual enactment of pain and suffering upon others, sadism does not always involve the use of physical aggression or violence; sadistic individuals also express angry or hostile behaviors not just for a perceived sense of retaliation but to experience the pleasure of humiliating others and achieving a sense of power and control over them. Kirsch and Becker (2007) also suggested that deficits in emotion recognition and emotional experience are characteristic of both persons elevated in psychopathy and sadism. In addition, Buckels et al. (2013) identified that "everyday" or subclinical sadistic persons were particularly inclined to "work for" the opportunity to hurt an innocent person. Mokros, Osterheider, Hucker, and Nitschke (2011) showed that affective deficits in combination with behavioral disinhibition (associated with psychopathy) were precursors for sexually sadistic conduct. Similarly, Woodworth et al. (2013) found that sexual offenders who were high in psychopathy were significantly more likely to be characterized by a sadistic paraphilia. Thus, sadism appears to be multifactorial but "intercorrelated" with other personality dimensions, involving, for example, differing degrees of approach motivation for dominance/control and anger/hostility.

Desire for Belonging and Nurturance

Aspects of belonging and social relatedness (e.g., emotional loneliness, fears of intimacy) have been identified by several authors as presumably related to sexual offending (e.g., Bumby & Hansen, 1997; Marshall, 1989). This has been based on observations that sexual offenders appear to have difficulty developing and maintaining "intimate" relationships with age-appropriate adults. In turn, this "difficulty" has been focused on theorized distal attachment deficits and proximal limitations in social competence. However, as Ward et al. (2006) pointed out, a "theoretically persuasive" explanation of the relationship between such interpersonal deficits and sexual offending has been lacking. Yet it seems clear that both primary and secondary predisposing conditions related to sexual offending exist. Krueger et al. (2007a) identified alienation as a key facet of ES. Empirically, various measures of lacking emotional intimate or conflicted relationships with adults have been identified as a risk factor for sexual offending (e.g., Hanson & Bussiere, 1998; Hanson & Morton-Bourgon, 2004; Mann et al., 2010).

Murray (1938) identified the human "need" for affiliation, to be close and loyal to another person, pleasing them, and winning their friendship and attention; Maslow (1954) too identified belonging as a key in the hierarchy of human psychogenic needs. From a somewhat different perspective, Bowlby (1969) spoke of the power of early attachments to form templates for relationship patterns. From these early perspectives, it was posited that most individuals are powerfully motivated for acceptance, approval and a sense of belonging to one or more people. Cloninger (1987, Cloninger, Svrakic, & Przybeck, 1993) discussed "reward dependence" as a key dimension of personality, where, in part, persons who were high on this biological/temperamental dimension were often particularly high in their need for social approval and were socially dependent. In the absence of genuine approval and acceptance, he suggested that persons high in reward dependence would substitute other potentially hedonic experiences, including sexual behavior and substance use. More recently, Baumeister and Leary (1995) identified the need to belong as a fundamental human motivation; they defined this need for belonging as a need for frequent, non-aversive interactions (free from conflict and low in negative affect accompanied by a perception that the interpersonal relationship or bond has some stability and a positive affective component) within an ongoing relational bond. They viewed persons as driven or motivated to establish and sustain a sense of belonging, with some level of intimacy and shared experiences. Baumeister and Leary noted that social attachments can vary greatly in their depth, so that even minimal contact can create a sense or perception of attachment and belonging as well as the perception or feeling of being cared for or comforted by the notion that one is "accepted," "approved," and "connected" to another. Consequently, obtaining or perceiving that one belongs to another/others is reinforcing. Belongingness typically generates positive affect; the absence or end of belongingness is associated with negative affect, including both depression and anxiety. Thus, individuals who lack the personality characteristics that typically lead to affiliation and belonging (e.g., social anxiety, rejection sensitivity) may experience heightened loneliness; their motivations to affiliate are fueled by both the secondary pain of being isolated and disconnected and the primary motivation to experience a sense of belonging.

Further, the motivation for belonging can become conflicted and, over time, ebbs and flows of expectancies for positive experiences and perceptions of negative experiences leading to expectancies and experiences of interpersonal instability (e.g., idealization and devaluation). In addition, as actual and imagined experiences of social rejection, alienation, and detachment occur, the motivation to belong may also change over time, sometimes being ignored and at other times being potentiated and activated. In short, various aspects related to the motivation for belongingness can serve as a predisposing dimension to sexual offending, particularly when that impetus or desire has been frustrated acutely or chronically. For persons who have experience or perceived chronic social rejection or even a lack of acceptance, they may experience extended periods of alienation and/or adopt a manner of social detachment or isolation. However, like other motivational factors, the desire or urge to belong likely persists.

It appears that select sexual offenders seek out interactions with adults, adolescents, and children out of a desire to belong. Unable or limited for various reasons to develop or maintain satisfying relationships with age-appropriate peers, they seek to find a sense of belonging with age-inappropriate persons or through a variety of inappropriate means. To the extent, an individual perceives or desires to belong to an inappropriate or disinterested partner, and they may engage in sexual or sexualized behavior as a means of experiencing a "positive" interaction (from the perspective of the offender) that they believe may have or will have relative stability. In the case of certain sexual assaults, sexual behavior can be viewed as a crude attempt to establish a connection and potential relationship with another person (a victim albeit) or as a means of shared experience or acceptance.

Even a cursory review of the identified set of likely motivators would suggest that there will be a high degree to likely overlap among persons who are prone to violence and sexual offending specifically. Theoretically, all involve admixtures of cognitions, motivation (arousal to goal-directed behavior), and accompanying affects, and as such, combinations of those psychological elements would likely be juxtaposed and additive in leading to behavioral enactments. As noted previously and per other available research, there appears to be significant validation of the varying degrees of intercorrelation among such dimensions.

Primary Deficits in Self-Control Related to Sexual Offending: "Disinhibition"

With varying degrees of consciousness, virtually all persons are motivated to pursue appetitive motivations, both everyday temptations (e.g., a particular food, nicotine, caffeine, etc.) and those urges with potentially more significant, longer-term implications (achievement, risk-taking, retaliation). It also seems clear that dispositionally, developmentally, and/or by situations, individual differences exist among persons in the intent and capacity to delay an immediate approach for gratification of motivation/emotion via self-regulation or self-control. Per Baumeister (1998), under-regulation as a failure of self-management occurs when "willpower" or self-control is inadequate (in terms of the range and "strength" of self-regulation mechanisms) to override unwanted thoughts, emotions, or motivations (impulses). However, self-regulation failure is not an unusual event; it is a core feature of many significant "everyday" personal problems: overeating, nicotine or alcohol use, and/or the expression of anger. Certain conditions and issues appear to readily undermine such self-control by way of failures to transcend temptation/urges, negative moods, and resource/skill deficits. In daily life, as Heatherton and Wagner (2011) noted, the most common circumstances under which self-regulation appears to fail in everyday life are when people experience temptations or urges as relatively overwhelming or when controls are impaired or deficient. Desires and urges of some strength are part of everyday life; per Hofman et al. (2012b), people feel some desire about half the time they are awake, and half of these desires were viewed as conflicting with other goals, values, or motivations. Unresisted urges lead to behavioral enactment; just less than half of these urges were "resisted." However, notably, personal resistance or self-management dramatically lowered enactment of urges. The strongest urges were more difficult to resist and more likely to be enacted than the weaker ones but with resistance/management, "indicating that not only did people often resist so-called inevitable desires, but they were surprisingly successful when they did" (p. 1330). Thus, regarding more significant issues, involving high potency gratifications of liking and/or wanting, many people appear capable of managing both frequently and repeatedly to transcend or resolve conflicts between potent motivators and potential consequences of acting upon those motivators. Thus, most people do not commit criminal behaviors in terms of seeking gratifications from the possessions or bodies of others or in seeking harm of others. Plainly, in everyday life, despite the potency of potential sexual gratification or personal satisfaction from enacting sexual behavior, generally, an overwhelming number of persons are relatively successful at resisting sexual urges that might cause a variety of problematic consequences. Thus, for most people, the potential nature of resistance or conflict about acting on sexual desires is quite well managed, regulated, and controlled. Yet clearly, like other criminal and violent behavior, some persons are either more responsive to both sexual and nonsexual motivators or experience significant and sometimes repeated deficits in managing those experiences of impulse and desire. These represent far more serious failures of self-control, both in terms of the

consequences to victims and the potential implications for the perpetrators.

Consequently, in addition to the potency and interaction of motivators, a variety of issues related to the absence of or relative deficiencies in EF, personality, and self-control could be understood as factors of *disinhibition*. Relative to antisocial behavior, including violent and sexual behavior, it represents the degree and factors by which prosocial behavior is less likely to arise. Disinhibition appears to reflect the relative absence of constraining and/or prosocial elements of EF, personality, and self-regulation (e.g., absent or diminished inhibitions); they represent primary deficits in cognitive (information processing) and personality dimensions (deficits and dysfunctions in emotional experiencing) that underlie and interact to create problems in EF and self-control related to aspects of social attachment. The occurrence of disinhibition should be understood as a potential function of multiple cognitive and affective factors both sequentially and simultaneously that lead to enactment of behaviors that have undesirable consequences for an individual and/or others. Conceptually and empirically, these factors seem likely to be correlated and interrelated so that it is likely that they occur more commonly together than in isolation. Research would suggest that increased sensitivity to and reactivity to novelty and intensity (or "degree of arousal") to internal or external stimuli would create particular predisposition for disinhibition. A combination of and/or even just some increase in factors of disinhibition would appear sufficient to allow sexual offending to occur even under conditions of relatively minimal primary sexual and nonsexual motivational dispositions or states, particularly in select situational contexts. Yet without some press of motivators (either sexual or nonsexual), dimensions of disinhibition would probably not be sufficient on its own to lead to violence or sexual offending. However, when motivators are activated and impelling behavior, disinhibition represents a relative lack of modulation of the push of primary motivators.

Disinhibition is related to but different from impulsivity per se. Impulsivity per available research reflects the juxtaposition or interaction of motivators and deficits in inhibition. Burt and Simons (2013) demonstrated that thrill-seeking was distinct from self-control as a factor in risky and criminal behavior. A consistent finding identifies that particular individuals are characterized by a heightened "general" and "behavioral" of "lifestyle" impulsivity and show marked relatively persistent and/or pervasive immediate action in the face of prepotent or dominant motivators that appear to offer immediate rewards or emotional gratification. As the UPPS model suggests, general impulsivity consists of both motivating elements [urgency (positive and negative), sensation-seeking] and disinhibition, namely, the absence of inhibiting influences (premeditation and perseverance/persistence). Persons high on individual difference in impulsivity are predisposed to act on the spur of the moment in response to relatively strong or immediate potentially rewarding situations (or affective experiences) without consideration for potential outcomes. Generalized impulsivity is associated with a lack of concern for or perseverance in self-management, lack of long-term goals, and irresponsibility; such persons are characterized by acting upon immediate needs and feelings. As a result, generally impulsive individual fails to follow through on (1) existing commitments to provide for others or to honor normative obligations (social roles or responsibilities) or (2) anticipated obligations to one's own best longer-term interest (rules/social expectations). So-called lifestyle impulsivity also has the effect of increasing access to situations involving other similar individuals and, as a result, access to vulnerable potential victims, both adults and children. In particular, generalized impulsivity leads to failing to avoid situations that entail greater opportunities and potential for enacting sexual gratification and offending. Persons high in generalized impulsivity generally and repeatedly fail to engage in "preventative" interventions relative to the implications of desired motivators.

Joliffe and Farrington (2009) showed that approximately 75 % of violent offenders were characterized by "historical" impulsiveness, significantly more than nonviolent offenders. As noted previously, Whiteside and Lynam (2001) identified that "impulsivity" (per the FFM dimensions) had three subscales in addition to sensation-seeking: urgency, a lack of premeditation, and a lack of perseverance (effortful control); Miller et al. (2003) showed that simple urgency and a lack of premeditation (deficient ability to consider possible consequences of one's behavior before acting) were the strongest predictors of aggression. Relative to self-reported impulsivity, lack of preparation, carelessness, and impetuousness were identified as key dimensions (Kirby & Finch, 2010). Walters (1995) found that one of the two key dimensions of criminal thinking was simply a lack of thoughtfulness (e.g., a lack of attention to one's experience/psychological mindedness). Generalized impulsivity is often accompanied by a clear lack of planning and greater intoxication (Reidy, Shelly-Tremblay, & Lilienfeld, 2011). In addition, other research has demonstrated that persons experiencing strong "positive" emotions (e.g., increased sexual arousal) are also characterized by increased impulsivity, particularly the dimension of urgency (e.g., Muhatdie et al., 2013). Johnson et al. (2013) also showed increased emotional-reactive impulsivity was associated with both externalizing and internalizing symptoms and that non-emotion-relevant impulsivity was associated with alcohol problems. In a large representative sample, Chamorro et al. (2012) found a simple measure of impulsivity was associated with a set of behaviors that could be dangerous to others. Individuals higher in impulsivity were more likely to engage in behaviors reflecting behavior disinhibition, attentional deficits, and lack of planning including starting fights, perpetrating domestic violence, and trying to hurt others. Notably, the

most common behavior associated with impulsivity was "engaging in quick sexual relationship without thinking about the consequences" (p. 6) which was three times greater in impulsive versus non-impulsive persons. Similarly, Hoyle et al. (2000) conducted a meta-analysis of personality and sexual behavior that determined that impulsivity was the second strongest trait-level predictor of risky sexual behavior. Cyders and Coskunpinar (2011) showed that urgency is a significant predictor of risky behavior, independent of frequency/intensity of emotions; in addition, urgency predicted above and beyond the additive and interactive effects of lack of premeditation and frequency/intensity of emotions. DeLisi and Vaughan (2007) found that career criminals have significantly lower levels of self-control. Derefinko et al. (2012) showed that (in addition to sensation-seeking) a lack of premeditation was particularly important in predicting general violence. Grieger et al. (2012) found that overall deficits in self-control were more strongly associated with violence as opposed to criminal recidivism; sexual offenders were distinguished from other criminal offenders by low scores on all forms of self-control and in particular effortful control. Love (2006) reported that their analyses found "illicit sexual behaviors are positively correlated with criminal behaviors providing support for Self-Control Theory. Furthermore, the analyses of this data support that low self-control is a predictor of illicit sexual behaviors and crime" (p. 505).

No comprehensive or coherent model of disinhibition appears to exist, but varied lines of research provide frameworks for obtaining an increased appreciation of the numerous factors or dimensions that likely contribute to varying degrees of disinhibition or failure to desist in undesirable behavior. Factors of "disinhibitions" are one or more structural psychological elements and/or dispositional processes or states that result in an individual having absent or, more typically, reduced capability to recognize and manage urges, desires, temptations, and impulses (or diminished application of those capabilities). As motivators and emotions occur on both conscious and unconscious levels, so can such deficits of self-regulation/self-control (via environmental or physiological elicitation).

Bottom-Up and Top-Down Processes in Disinhibition: Deficits in Executive Functioning and Self-Control Related to Sexual Offending

Currently, there are two primary perspectives that provide a partial theoretical framework for considering key elements of disinhibition. Barkley's (2012a) proposed core domains of EF provide the "scaffolding" of the largely cognitive elements that create the potential for self-control and, in their relative or complete absence, degrees of disinhibition. Some degree of self-consciousness or awareness of and attention to one's self-experience is the starting point of EF; this would range from virtually no self-consciousness of one's "person" or "experience" to higher degrees of psychological mindedness. Only with such awareness or attentional capacity (e.g., of urges related to motivators or emotions) can there be some degree of cognitive or "executive" inhibition that allows an individual to "pause" a reflexive, automatic, or immediate, often prepotent, reaction to internal and external stimulation; such acute inhibition of an immediate response creates the opportunity for some consideration of responding. Nonverbal working memory (WM #1) allows recollection of past (learned) experiences as multisensory mental representations (particularly visual imagery) for hindsight; it also creates the capacity to "view" potential behavior in one's mind for foresight in imagining the hypothetical future based on an experienced past. Per Barkley, EF via self-awareness and nonverbal working memory also includes the opportunity for "appraisal" of motivations and emotions and potential conflict among them; such a process allows for modulation of arousal and related experiences. Motivational and affective appraisal can serve as a "metric" for considering costs and benefits of possible courses of action relative to several potential goals (e.g., distal for proximal). Problem-solving involves analyzing one's experiences and features of one's environment in the context of one's past behavior and current goals to develop plans for a particular goal-directed action, by weighing pros and cons, anticipating potential obstacles and then making choices regarding weighed goals and behavioral enactments. Generally, problem-focused coping (PS) reflect EF-related strategies in the face of provocation and arousal, particularly in the identification of problems and appropriate skills to manage the source of those reactions. PS involves perceiving, defining, and appraising problematic, acute, or recurring situations or "a life episode" (e.g., cognitive reappraisal) in ways that they can be confronted and managed; they also involve decision-making regarding the various specific strategies or tactics to both address one's arousal experience as well as the situation. Identified issues in problem-solving involves (a) deficits in problem recognition, (b) a lack of consequential (means-end) thinking (e.g., failing to think through potential consequences of actions, particularly longer-term results), and (c) difficulties generating a range of reasonable options. Finally, to the extent that it is present, verbal working memory (WM #2) as "self-talk" or private speech can serve as a means to question oneself in an unfamiliar or challenging situation, "mental discussion" of conflicts between short- and long-term interests, and of self-guidance through behavioral enactment. Of note, the execution of working memory, arousal appraisal, and problem-solving each requires the ability to focus and sustain attention of multiple psychological elements.

Clearly, Barkley's model provides a largely cognitive, information-processing approach to EF. However, it provides a

means of highlight potential deficits that will affect the experience and potential control of motivators. Persons who lack self-awareness are persons who would be dramatically influenced by automatic, prepotent motivations and emotions and would act relatively immediately to gratify such urges and impulses; there would be no pause or possibility of premeditation; they would lack "executive attention." Individuals with deficits in nonverbal working memory, while perhaps capable of being aware of motivations and emotions, would manifest difficulty in recognizing and interpreting (making sense) of arousal experiences; effectively they would not benefit from past experiences, they would have difficulty picturing the future after a behavior (and potential consequences), and they may not be particularly capable of learning from such experiences (relative to storing them in longer-term memory). Verbal working memory deficits would limit both premeditation of conflicts between arousal experiences and differing aspects of self-guidance that might slow behavioral enactment of urges and impulses. Deficits in nonverbal and verbal memory would also limit one's capacity to "process" arousal experiences and limit or prevent any "cost-benefit" analysis of conflicting interests and motivators, let alone to modulate the initial experience and related arousal created by conflicting interests and motivators. A lack of or compromised ability to modulate arousal experiences would also allow impulses and urges to manifest in behavioral enactment in a relatively "pure" form with no dampening of intensity or duration.

Disinhibition From a Self-Regulation Perspective

From a "self-regulation" perspective, Hofmann and Kotabe (2012) proposed what can be referred to as preventive-interventive model of self-regulation (PIMSR) which identifies several basic conceptual components to be considered; the interventive elements relate to steps that lead up to the successful or unsuccessful use of "willpower" in the "heat of the moment," while the preventive elements relate to the use of "anticipatory strategies" to enhance self-control. From their perspective, Hofmann and Kotabe suggest that self-control can only occur when a given "desire" or motivator turns into a *temptation*, defined as degree to which the behavior impelled by the desire would be "at odds" with a person's value system and (self-regulatory) goal standards; thus, self-control is only initiated by some experienced conflict between a desire for or to do something and potential consequences of related actions. Hofmann and Kotabe invoke constructs of motivational control and "volition;" (they consider that the former relates to the formation of some intention to resist a desire via self-control and the latter refers to the capacity to control and persistence of efforts to control. In addition, Hofmann and Kotabe also identify "opportunity constraints" as external factors outside of a person's immediate control which "substantially constrain the range of available options for action" at a given time, including resource, physical, and social barriers—even in the presence of strong internal desires—situational conditions must be available for desire enactment (if those conditions are not present, it leads to "fortuitous" self-control). Weak or nonexistent opportunity constraints will allow for behavioral enactment of desires and temptations, while strong opportunity constrains will prevent such enactments.

According to the PIMSC, some individuals will temporarily (in the presence of a singular or multiple "hot" states) or consistently (dispositionally) lack awareness of a conflict between a desire and their own or social values and simply enact the desire, opportunity permitting. In other cases, they note that persons may lack "some of the standards a given culture deems essential and binding for everyone." Since there is no internal conflict, they suggest that persons are characterized by some significant lack of values and there can be no motivated or intentional self-control.

Thus, per Hofmann and Kotabe, self-regulation is about resolving the conflict between desire and one's internal standards, and they identify two primary possibilities of interventive self-regulation as to why self-management may fail. First, motivational self-regulation failure concerns when a person is tempted (e.g., experiences both a desire and conflict about enacting the desire) but then fails to translate such a conflict into a concrete intention to resist a problematic desire; they give up before the "battle" even starts. Second, volitional self-regulation failure occurs when a person is tempted and forms a concrete intention to resist that desire and struggles to exert the "effortful willpower" and skills to self-regulate their conflicted state. [In addition to interventive self-regulation, Hofmann and Kotabe also discuss what can be termed preventive self-regulation, regarding tactics that people employ in anticipation of temptation to improve the probability of adhering to their goals and values.]

Both Barkley's model and PIMSC offer useful perspectives, respectively, on the structural psychological elements of effective processing one's own experience in environments of stimulation and the selection and the struggle between value- and standard-based struggles to balance desires with other goals, presumably those more distal and socially validated. Issues related to each of these models clearly have significant bearing on potentiating elements of disinhibition. The presence of elements of EF would appear largely necessary elements for self-control. However, Barkley's model provides insufficient detail to explain why individuals who experience one or more motivators that impel them toward violence generally and sexual offending more specifically behaviorally enact those motivators; there is a lack of specification as to how the elements of EF occur to lead to disinhibition. Similarly, PIMSC provides a useful heuristic for considering

those persons who possess select "higher" psychological characteristics that would lead to "temptation"—the experienced conflict between immediate desires and other personal goals—and the capacity and intent to muster "willpower" to manage those conflicts. However, it is suggested that many sexual offenders, particularly those who are repeat sexual offenders, do not experience significant cognitive-affective conflict (or self-regulatory "temptation") about acting on their sexual or nonsexual motivators when opportunity constraints are absent. That is, it is suggested that sexual offending for most perpetrators rarely results from a "reasoned" process where there is any extended consideration or "weighing" of the potential consequences of sexual acting out as opposed to restraining one's sexual or nonsexual motivators. Consequently, neither set of constructs is sufficient for comprehensively understanding the nature of disinhibition. What follows is an attempt to offer additional perspectives on select dimensions of disinhibition that would appear to play a prominent role in deficits in constraining sexual offending behavior.

In reviewing the extensive available literature regarding EF, personality, and self-regulation/self-control and the much smaller literature specifically concerning disinhibition, it seems clear that multiple, somewhat overlapping, and likely interacting factors are related to the phenomena of disinhibition. If self-control refers to a person's ability or motivation to delay typically more immediate gratification by modulating internal states and behavioral responding, then disinhibition as deficits in inhibition must involve a lack of ability or motivation to recognize the need to delay such gratification or to regulate internal states and behavioral responding. Key elements of disinhibition relating to response inhibition appear to include deficits in attention (initial focus sustained attention) and working memory leading to cognitive impulsivity, self-monitoring, self-focused attention, and/or degrees of self-awareness; deficits in fearfulness and/or social anxiety that create deficits in learning from experience (represented in working and long-term memory); deficits in emotional regulation and coping with arousal experiences; deficits in moral emotions; deficits in recognizing and appreciating values and standards regarding others; deficits in planful or effortful control or "premeditation"; deficits in "willpower" for self-regulation in balancing short- and long-term goals; and a lack of preventative interventions.

Dimensions of Disinhibition: Other Cognitive, Affective, and Social Factors Related to Sexual Offending

Fearlessness and Related Deficits in Learning

Herpertz and Sass (2000) reviewed various studies of the affective domain associated with psychopathy and antisocial behavior and concluded that various emotional "deficiencies" may predispose individuals to violence. Socialization is commonly and simplistically conceptualized as a process through which regular rewards and punishments (aversive conditioning) lead a person to learn rules and values of his family and of the society at large which are internalized as memories. From this perspective, personal values or "conscience" is a conditioned reflex (e.g., Eysenck, 1964), where anxiety induced by punishment for a behavior becomes associated with that behavior. In particular, psychosocial maturation is often construed as a process of learning the value of delaying an immediate reward or gratification for a more substantive reward after some time delay. To the degree an individual possess such information, it may become rewarding and self-motivating to fulfill those rules and values. Some individuals may not be so socialized; others appear to have deficits in "response modulation," specifically an inability to learn from experience and to modify behavior in response to some aversive or punishing consequence.

Fearlessness refers to the absence of normative feeling of distress, apprehension, or alarm caused by potential threat (fear) such as punishment and, as a result, leads to behaviors that have the potential to have negative consequences for the individual which in others would normatively lead to fear. The idea that psychopaths are low in trait fear (persistent and pervasive experience of state fear across situations) or are fearless (e.g., impoverished in condition ability) was first suggested by a study in which Lykken (1957) used the concepts of low fear arousal and conditioned fear to account for the poor performance of psychopaths in classical conditioning and in passive avoidance learning paradigms. In short, poor or absent conditioning results in a failure to appreciate and learn harmful or undesirable consequences of one's behavior and thus results in deficient avoidance behavior and increased approach behavior. An absence of normative fear, particularly related to likely aversive consequences, is associated with engagement in risky behaviors. As noted previously, the apparent fearlessness of some antisocial individuals is, in fact, related to an inability or lack of capacity to process emotion-related cues, particularly punishment, once they have established an initial attentional focus on a particular goal or "reward." As Newman, Curtin, Bertsch, and Baskin-Sommers (2010) suggest, in such cases, an "attentional bottleneck" occurs that prevents potentially salient-inhibiting emotions to enter awareness. Newman et al. (2013) demonstrated that low trait anxiety and trait fearlessness were comprehensively accounted for by the existing PCL-R items and related to all four facets of the PCL-R as well as a superordinate PCL-R factor. A lack of fearlessness or other deficits related to response modulation may commonly lead to a perseverative pattern of seeking more frequently rewarding experiences that provide more immediate gratification. Alternately, the deficit in response modulation may be related to a cognitive impairment (e.g., working memory) that minimizes or negates the memory of the negative effects or consequences of previous—even punished—maladaptive behavior (e.g., Campbell, 2003).

Reward/Stimulation Insensitivity

A related construct refers to the degree to which individual differences potentiate stimulating and rewarding experiences. Herpertz and Sass (2000) identified "emotional deficiency" as closely related with a general underarousal and viewed this attenuated level of autonomic reactivity as linked to pathological fearlessness and a lack of "harm avoidance." Persons with low physiological arousal are viewed as potentiated for seeking stimulation, either through increased motivation via novelty, exciting ("sensational") experiences, or more strongly motivating experiences. Thus, per Cloninger's personality model (e.g., Cloninger, 1987; Cloninger et al., 1993), persons low in reward dependence may find conventional social-sanctioned sources of reward unfulfilling relative to satisfaction and pleasure. In addition, such individuals may also be characterized by hypoarousal, relatively indifferent to negative consequences (e.g., potential punishment, stressors) and less able to experience strong feelings evoked by consequences; they are thus less likely to be conscientious or to learn constraint, self-regulation, or self-control. Shirtcliff et al. (2009) noted that callousness, particularly a related to hypoarousal, was a "two-edged sword," where such persons may be less responsive to social distress and be less responsive to the warmth and other rewards of social interaction and affiliation.

Lack of Self- and Other-Awareness

Self-awareness is the process and state of a motivation and/or ability to understand one's own experience of psychological states (affects, beliefs, motivators, intents, desires, knowledge, and so on). Self-awareness and self-monitoring function as integrated, iterative processes. From the perspective of intellectual functioning, Demetriou and Kazi (2006) state, "These processes enable the person to capitalize on his or her thinking activity by forming increasingly more accurate maps of mental activity and problem-solving processes so as to be able to direct decision-making regarding problem solving as efficiently as possible…Self-awareness is an integral part of DEF [directive-executive function], because the very process of setting mental goals, planning their attainment, monitoring action vis-a-vis both the goals and the plans, and regulating real or mental action requires a system that can remember and review and therefore know itself. Therefore, conscious awareness and all ensuing functions, such as a self-concept (that is, awareness of one's own mental characteristics, functions, and mental states) and a theory of mind (that is, awareness of others' mental functions and states) are part of the very construction of the system" (p. 314). Demetriou and Kazi showed that self-awareness is, in fact, a central element of general intellectual development and functioning, on par with working memory and processing speed. Further, as they point out, self-awareness provides the foundation for theory of mind (TOM) as the ability to understand that others experience psychological states that may be similar and different from one's own. Similarly, Cacioppo et al. (1996) demonstrated that individual differences exist in the degree to which persons are interested or motivated to engage in cognitive activity, distinguishing between cognitive "misers" and "cognizers" (e.g., low versus high intrinsic motivation to engage in mental processing). Deficits in self-awareness are twofold, at minimum. First, deficits in self-awareness are associated with compromised intellectual functioning and attendant higher-order cognitive processes, including reasoning and problem-solving. In addition, from an interpersonal perspective, deficits in self-awareness—"mind-blindness"—necessarily limit the capacity for TOM and compromise the potential for understanding the feelings or intentions of others, for example. Consequently, persons a self-awareness deficit and resultant TOM deficit would be limited in perceiving things from any other perspective than their own; it provides the basis for egocentrism and for failure to appreciate the inappropriate nature of their behavior. Individuals who experience self-awareness deficit and resultant TOM deficit have difficulty determining the intentions of others, lack understanding of how their behavior affects others, and have a difficult time with social reciprocity.

Deficits in "Moral" Emotions (Callousness and Lack of Empathy/Lack of Remorse and Guilt)

In the modified form of the self-control theory of crime, Hirschi (2004) highlighted the significance of the presence of short- and long-term social bonds as particularly influential factors in self-control and constraint. Conversely, various forms of emotional "detachment" from others, particularly related to the so-called moral emotions of empathy, guilt, and shame/remorse, are centrally implicated in disinhibition of antisocial behavior. Both cognitive and affective elements have the potential to underlie deficits in the experience of and intentions based on moral emotions, thus persons may be unable or unwilling to act based on feelings for others, such as those associated with antisocial behaviors. Moral emotions require moral standards—some internalization of moral norms and conventions. In particular, moral standards are those that involve prohibitions against behaviors likely to have negative consequence for the well-being of others. Moral emotions provide a motivational force to "do good" and avoid doing "bad." It is useful to note that there is strong consensus from childhood through adulthood as to the difference between "transgressions of convention" and "moral transgressions." Huebner (2010) identified that the latter are

relatively universally perceived as more wrong, more punishable, independent of authority, and universally applicable. He demonstrated that for seven of eight types of hypothesized moral transgression (physical assault, vehicular assault, sexual assault, assault by a child, inducing illness, recklessly endangering the lives of others, and violating another person's property), subjects rated each scenario as strongly and clearly immoral by virtue of being more wrong, more punishable, having more normative force independent of simple authority, and more universally applicable. Empathy is conceived as an affective response to another person's experience, where an individual can "represent" the internal mental state of another (e.g., perspective-taking) and experience some emotional response congruent with the other's emotional state. Consequently, empathy is contingent on some degree of TOM (in turn contingent on self-awareness).

Relative to such standards, guilt is typically viewed as a more "private" negative emotional reaction (bad "feelings") arising from self-generated feelings to violating socially accepted rules or expected conduct and particularly negative consequences (e.g., harm) done to others as a result of one's behavior. Remorse involves feeling distress, typically guilt or regret, about past rule-violating behaviors. Thus, remorse or guilt refers to a relatively private emotional experience related to one's own negative evaluation of a specific behavior either in the present or past. In contrast, shame is viewed as arising from negative feelings related to public exposure and perceived social disapproval for one's behavior. However, both affects are necessarily tied to recognizing and appreciating moral norms or right and wrong. Callousness or unemotionality (or lack of empathy) refers to an inability or unwillingness (disinterest) to experience emotions, particularly empathy for others as well as guilt or shame; it can be an acquired or heritable (physiological) condition. Callousness is also manifest in a failure to respond to the distress cues of others. Thus, these conditions refer to being unaware of or indifferent (uncaring/unfeeling) regarding the thoughts or feelings of others and deficits in experiencing guilt or shame (a lack of indifference to violating one's own values or those of a social group); rather, such individuals are typically more concerned about the consequences of their behavior on themselves not others. [At the same time, some callous individuals appear capable of understanding enough about others that they are capable of engaging in effective manipulation of them.] These three characteristics are ones that strongly associate with each other; effectively, Blair (1995) referred to them as the "moral emotions" related to transgressions against the rights and welfare of others. These conditions are each one's that can involve perception, attitudes, and deficits in perspective-taking or emotional reciprocity. One key element of callousness is the perception or experience that other persons are objects. Keysers and Gazzola (2014) emphasize an important point, namely, the need to distinguish between the capacity and the propensity for empathy (and other moral emotions) along the lines of the distinction between motor capacity versus motor performance. Citing evidence that more empathic individuals are only moderately more likely to help others and that individual differences in empathy are relatively stable across the lifespan, they note that individual differences in attention and motivation "could thus turn the know of empathy up and down, creating individual differences in how strongly propensity and ability dissociate" (p. 165). They suggest that being sensitive to others can be viewed as "costly," leading to a motivation against acting empathically.

A key element of disinhibition for criminal, violent, and sexual offending are deficits in the identification of moral norms, the experience of "moral emotions," and the propensity to act on norms and emotions; such deficits can operate on automatic, unconscious level or affect more conscious decision-making. Per Patrick et al.'s conceptualization of psychopathy, a callous, coldhearted disposition is viewed and expressed as "meanness" (e.g., Patrick et al., 2009). Persons who lack guilt or remorse do not feel concerned and/or responsible for the consequences of their own behavior; in particular, they do not experience negative affect (e.g., "feel badly") in response to the results of their own behavior upon others (e.g., particularly to other's apparent distress, pain, or injury). More generally, lack of remorse or guilt exists in reference to consequences of most rule- or law-breaking. While some may have deficits in capacity, others lack the propensity to act with sensitivity to and concern for others. As noted, Leeuven et al. (2013) showed that several types of self-serving cognitions [(primary, self-centered) (secondary, minimizing; blaming others and assuming the worst)] appear to be a function of callous-emotional traits and mediate the initiation and maintenance of antisocial behavior.

Antisocial, narcissistic, and psychopathic individuals are commonly viewed by others as manifesting an absence of or deficiency in such feelings that is ego-syntonic. In contrast, they are typically more concerned with the negative effects of antisocial events such as sexual offending upon themselves. There is a consensus that lack or incapacity for empathy or some selective empathy (e.g., a "suspension" of concern for another in a particular situation or one's own victims) is the proposed mechanism for such affect and attitudes; that is, some persons cannot or do not feel others' emotions, while others may be deficient in understanding others' emotions or both. Joliffe and Farrington (2004) utilized a meta-analysis, and their results suggested negative relation between empathy and increased offending; they also found that controlling for intelligence or socioeconomic status eliminated this relationship. After committing violent acts such as sexual offending, certain persons do not identify experiencing remorse or guilt, and, in turn, such predispositions are not surprisingly associated with more persistent

violent behavior. Offenders often proffer verbal expressions of remorse after admissions of sexual offending, but the genuineness of such expressions is questionable, at least in many cases particularly repeat offenders. It has been suggested that select sexual offenders lack the capacity for empathy for most specifically for their victims. Marshall, Marshall, Serran, and O'Brien (2009) have suggested that most sexual offenders do not indicate a lack of empathy toward persons in general but do fail to display or experience empathy toward their specific victims or class of victims. Some empathy deficits may be defensive and mutable, serving as "self-protection" for experiencing emotional distress (e.g., against guilt or shame relative to sexual offending), while others are more pervasive and dispositional.

Callous disregard for the rights and feelings of others is a key hallmark of many antisocial individuals; the characteristic appears to be highly heritable (e.g., De Brito & Hodgins, 2009a). In a meta-analysis, Miller and Eisenberg (1988) showed that aggression and antisocial behavior were inversely related to empathy. In the DSM-5, the "moral emotions" are potential specifiers for conduct disorder in youth and highly predictive of more persistent antisocial and violent behavior. Blair (1995, 2009) reviewed research that indicated persons with greater degrees of psychopathy evidence selective impairments in emotional recognition of others, particularly of manifest fear and unhappiness (as opposed to happiness); thus, some more psychopathic individuals may possess some sense of self-awareness but lack capacity for awareness of distress emotionality in others. While showing that psychopathic individuals manifested deficits in emotional processing and in distinguishing conventional from moral transgressions, Cima, Tonnaer, and Hauser (2010) found evidence that, in a laboratory situation utilizing moral dilemmas, such individuals understood the distinction between right and wrong but did not care about that knowledge or consequences that ensue from morally inappropriate behavior. *Among others*, Keysers and Gazzola (2014) *point out that some apparently psychopathic individuals posses some capacity for empathy that they display in manipulating and "seducing" potential victims but little propensity to allow that empathy to prevent them from victimizing others for personal gain or reward*. Be it genetically and/or environmentally determined (or both), persons with distinctive callousness lack many of the conventional constraints on general antisocial behaviors and interpersonal violence in particular.

Along these lines, Keenan and Ward (2003) have suggested that persons at risk for sexual offending may be characterized by general or particular deficits in theory of mind such that they are unable or deficient in understanding that other people are also characterized by beliefs, emotions, motivations, and values. Alternately, entitlement suggests that other persons' psychological experiences are simply irrelevant given one's own desires or motivations. Referencing deficits in theory of mind, Keenan and Ward (2000) questioned whether certain sexual offenders cannot or do not appreciate that other persons have "minds" (e.g., act on the basis of mental states such as motivation/desired, emotions, and beliefs) and are impaired in their ability to infer other's mental and emotional states. If one does not appreciate that another has their own "mind," they may act as if others are simply objects or simply not grasp that others may view/experience events (e.g., shared events) different from oneself. As Meloy (2003) has noted, more psychopathic individuals display "part-object relations." Noting "The psychopath does not conceive of others as whole, real, and meaningful…" (p. 2). In addition, sexual offenders marked by callousness often "body part" others or over-focus on particular aspects of physical appearance that have emotional or sexual salience for them. Per Meloy, "The extreme of callousness is sadism, wherein indifference toward others has become pleasure at their suffering, submission, and loss of control. Given the degree to which psychopaths attempt to dominate their objects, rather than affectionately relate to them, it is not surprising that there is a strong and positive relationship between sadism and psychopathy" (p. 2).

Emotional Disinhibition or Failure in Emotional Regulation

In contrast to experiential deficits in emotional experiences, more intense affective and other arousal experiences are implicated as motivators in violent and sexual offending. Deficits in the process of modulating desires and strong feelings lead to an increased probability that such arousal experiences will be behaviorally enacted; consequently, such an inability to moderate affects and motivational desires is a key element in disinhibition. In addition, some persons are characterized by a dispositional variance toward unstable emotional experiences and mood (e.g., emotional lability) such that emotions are easily aroused (low sensitivity), manifest in relatively extreme experiences (intensity) to events and circumstances, and persist longer than for most individuals. Emotional regulation refers to the processes related to identification, monitoring, evaluating, and modifying emotional reactions so that they are prosocial or not unsociable; deficits in this domain would include faulty monitoring (recognition and tracking) of one's experiential and arousal states, personal appraisal, or interpretations of what one is experiencing (valence, meaning, attribution) and the range and skill an individual possesses to modulate or change the intensity or frequency of emotional and motivational experiences. Thus, individuals who are emotionally dysregulated typically experience arousal experiences more intensely than others, have difficulties identifying such

experiences based on both personal and situation qualities (e.g., biased toward perceiving more negative information), and do less to modulate (e.g., suppress) the behavioral expression of their feelings.

Emotional regulation is considered a central mechanism for everyday functioning as well as coping with more stressful experiences. Thus, Lazarus and Folkman (1984) distinguished between emotion-focused coping aimed at reducing or managing the emotional experience associated or cued by an internal or external stimulus (distinguished from problem-focused coping which is aimed a problem-solving or doing something to later the source of the problem). Emotion-focused coping involves distracting oneself, ventilating to others, ignoring the situation, or expecting something worse to happen. Similarly, Carver, Scheier, and Weintraub (1989) also identify a range of coping strategies, including acceptance of one's state, suppression of competing activities, behavioral and mental disengagement from "distractions," and denial; all of these strategies might be employed to facilitate motivated action toward a sexual offense. Persons with deficits in emotional regulation attempt few or none of such things or do them incompletely; maladaptive externalized coping involves the tendency to respond in a reckless, impulsive manner when faced with intense or overwhelming upset or distress. Deficits in emotional regulation begin at the attentional level, in terms of initial self-awareness of one's experience and secondarily self-monitoring the dynamics of that experience. Failure of initial response inhibition will likely lead to reactive behavior derived, unmodulated, from the arousal experiences. Avoidance or crude suppression (denial) of the arousal experience typically does not modulate the arousal itself, requires significant psychological resources, and may actually increase or potentiate less conscious behavioral responses. In particular, as a result of compromised psychological resources, arousal suppression reduces the ability of individuals to maintain focused attention on potentially more relevant social interaction and related cues. Distorted or inappropriate cognitive appraisals are associated with arousal-based behavioral enactment. Per this model, a hostile attribution bias (HAB) is the interpretation, in response to ambiguous or accidental circumstances, that another has provoked a person with hostile intent, potentiating an aggressive response (Dodge & Frame, 1982); this is similar to so-called grievance thinking. Folkman and Lazarus (1988) point out that "confrontive coping" with the source or target of negative affect invariably leads to negative consequences. In particular, behavioral expression of arousal states can be quite directly harmful to others and, additionally, compromise potential social support. Further, following Hofmann and Kotabe's notion of preventive intervention, emotional dysregulation would include repeated failures to avoid situations likely to elicit or be perceived as eliciting provocation.

Yet another form of deficient emotional regulation concerns so-called cognitive deconstruction (Baumeister, 1990) defined as an attempt to escape distressing feelings, including ones that may carry some threat of social exclusion or retaliation. Such a process can be understood as a psychological effort to confine awareness to the immediate present as opposed to making inferences or self-attributions about particular behaviors mainly in a cross-temporal sense. Current experiences are "detached" from hindsight or foresight ("self-meaning") to reduce or eliminate the potential for social disapproval and rejection and/or related negative affect.

Howard (2009) suggested that violence could be said to represent the extreme interpersonal manifestation of dysregulated affect (and related motivation). Similarly, Grieger et al. (2012) found that a primary aspect of deficits in self-control associated with violent recidivism was problematic emotional regulation (stress sensitivity and reactivity, compromised ability to modulate the relative intensity of strong hedonic or negative affective experiences, inability to delay the press of arousal, leading to aggressiveness). As noted, various theorists have identified dysregulated negative active as related to sexual offending. **S**exualized coping is defined as the use of sexual behavior, including sexual violence, to manage negative emotions and stressful life events (e.g., Cortoni & Marshall, 2001); it is hypothesized that persons who engage in sexualized coping show increased sexual activity [by themselves (masturbation or viewing erotic materials as a means of inducing arousal) or acting out with or toward others as a means of relief or distraction)] during periods of stress or "dysfunction." Serran and Marshall (2006) reported that sexual offenders are more likely to use other forms of emotion-focused coping (including increased deviant sexual fantasies, expressions of anger, or loneliness) and/or avoidance-focused coping (e.g., pursuing sexual behavior, substance use, or generalized aggressive behavior). In fact, sexual offenders often report increased deviant sexual fantasies and masturbation during periods of stress (McKibben et al., 1994). A link between negative emotion and sex is common among those who engage in high-risk sexual behavior (Bancroft et al., 2003, 2004) as it is among child molesters (Whitaker et al., 2008). Serran and Marshall indicate that certain sexual offenders are much less likely to engage in task-focused coping or PS as a direct means of addressing the provoking experience or stressor.

Relative to the role of emotional dysregulation as a component process of disinhibition is the notion of reconstrual. Such a reappraisal can fundamentally alter the memory of an experience such that any residual emotional element is suppressed or eliminated. Thus, any or some residual affect which might affect future behavior becomes disconnected or attenuated from memory and interferes with consequential learning.

General Emotional Deficiencies

General deficits (as opposed to excesses) related to emotional experience can serve as potent factors in disinhibition. The research literature offers several perspectives on the types of broad deficits in emotional experience that can lead to increased potency of motivators. Similar to reward insensitivity, hypoarousal (low state of arousal) is viewed as cognitively compromising (result in an inability or limitations) in sustaining attention on predictable and/or mundane activities; affectively, it can also be experienced as such an aversive state that it leads to stimulation-seeking or novelty (thus potentiating the value of action on strong arousal states (reinforcing) and leading to action behavior simply as a means of creating stimulation). Hypoarousal is associated with diminished stress sensitivity as well behavioral overactivity, causing such individuals to be less responsive to and likely to elicit positive consequences of social affiliation leading to social rejection and isolation.

Another aspect of emotional deficiency is proneness to boredom. The term boredom is used to refer to a wide range of experiences. Boredom can refer to an aversive subjective state of dissatisfaction attributed to an environment that is experienced as inadequately stimulating; boredom proneness appears to be dispositional condition of individual differences. Persons vary in their experience of environmental monotony and constraint, leading to a difficulty in sustaining attention. Boredom proneness is related to inattention to both external and internal stimulation. Persons also differ in their need for variety and change in their environment and their ability to generate sufficient stimulation for themselves. In part, this can be thought of as habituation. Consequently, boredom proneness can be a predisposing condition based on a failure or deficit in regulating attention in a directed or focused way, particularly to obtain stimulation in an environment or at a time that there is a perceived or experienced loss of interest or stimulation. Further, boredom is also a contextual phenomenon; for a number of people, socioeconomic and other conditions may preclude more socially acceptable forms of thrill-seeking while increasing monotony or sameness of everyday life. Thus, boredom proneness may interact with sensation-seeking by potentiating the motivation for increased frequency of or more intense stimulation (particularly hedonic or positive-valenced stimulation); increased experience of boredom leads to various negative affective states including hostility, anger, and loneliness. As such boredom has been linked to various problem behaviors, particularly externalizing behaviors (e.g., antisocial and substance use/abuse). Quay (1965) proposed that a distinctive feature of psychopathic behavior was the lack of tolerance for sameness, thus predisposing them to seek or create "excitement" or heightened pleasurable sensations. Susceptibility to even minimal sensation-seeking might be particularly true for persons characterized by chronic, generalized low (hypo) arousal or susceptibility to boredom. Such thrill-seeking to generate some arousal via norm violation might be stimulating enough on its own, regardless of the reinforcement that might occur as result of sexual gratification. Krueger et al. (2007a) identified boredom proneness as a key facet of the ES. Raine (2002) pointed out that boredom proneness may be complementary to sensation-seeking in that low levels of arousal predisposes to antisocial behavior both because of its association with fearlessness and its "encouragement" for thrill-seeking; Raine also suggested that such factors may act synergistically. [In addition, repetition and expansion of sensation-seeking behavior over varying periods of time might reflect a likely increase in type, frequency, or variety of a particular behavior because someone prone to boredom (e.g., potentially hypoaroused) would habituate even more quickly than others might to a particular (sexual) stimuli.]

A construct related to boredom proneness as well as callousness, lack of empathy, and lack of guilt/remorse is anhedonia, typically defined as the inability to experience pleasure from activities or experiences usually found enjoyable. Individuals with these personality characteristics are also noted to display particular difficulty in both recognizing and describing their feelings more generally. Alexithymia is considered both a personality disposition and a personality disorder trait of emotional dysregulation, such as found in persons with schizoid personality disorder. Alexithymia is typically viewed as composed of three factors: difficulty identifying one's own feelings, difficulty describing one's feelings to others, and "externally oriented thinking" (a tendency to approach decisions and problem-solving with "logic" as opposed to emotion). From the perspective of motivation, a lack of "anxiety" and other deficits in avoidance motivational processes may also be implicated in alexithymia (as well as callousness and a lack of remorse). Anhedonic persons, similar to persons easily or temperamentally bored, may be motivated to seek out relatively intense experiences that are expected to be arousing as a means of self-stimulation. Grabe, Spitzer, and Freeberger (2004) found that alexithymia was associated with a range of psychiatric disorders, particularly depressive disorders. Alexithymia resembles or would appear similar to persons characterized by the affective components of Factor 1 on the PCL-R; consequently, an inability to understand one's own emotions and those of others might constitute a disinhibitor. Kirsch and Becker (2007) suggested that the emotion recognition and emotional experience deficits found among psychopaths, and perhaps present in sexual sadists, may lead to deficits in their ability to empathize with others, in turn resulting in an increased likelihood for perpetrating instrumental violence.

Amoral Attitudes or Deficits in Common Moral Standards/Judgment or Personal Values

A premise of self-regulation as a top-down element of self-regulation is that persons possess defined personal values and goals, which at times may conflict with immediate desires. However, it is unclear that all individuals are characterized by either self-awareness or personal identities that incorporate "higher" values and goals and don't live much of their daily lives at a level of more immediate impulses and have little concern for how they are viewed by others. Rather, disadvantaged, socially alienated individuals—typically those with "low-embodied capital" (e.g., attributes associated with social success, Bock, 2002)—may be largely reactive to their limited, prepotent internal experiences and their surrounding environment. Thus, persons, including offenders, vary significantly in their psychological mindedness, including the depth and "presence" of higher-order conceptualization and "intellectual" discourse.

Morality refers to what is considered right or wrong by most people—e.g., a common or shared perspective on acceptable behavior. Deficits in moral beliefs and feelings and/or motivation for moral behavior have all been implicated in criminal, violent, and sexual offending. Beliefs are ideas that persons hold as true, and they can be held with varying degrees of certainty; typically, they are derived from what others say, perceived cultural and social norms, or what other people do or say. To the degree that certain beliefs about what is important to a person come to be seen as "true," they become personal values; persons vary as to their perception of importance and commitment to those values. By definition, values are more abstract principles that are hypothesized to guide persons' lives. Many values are viewed as instrumental ones because it is the means of acquiring something else of value (anticipated consequences). Attitudes are the mental dispositions or cognitive content that people develop regarding others and the current circumstances that typically "inform" behavioral enactments, either on an automatic or more conscious decision-making process. A body of research indicates that persons primarily form their attitudes from underlying values and beliefs. However, factors which may not have been internalized as beliefs and values can still influence a person's attitude at the point of decision-making. Typical social influences relative to values include the desire to please, political correctness, convenience, peer pressure, and psychological stressors.

Behavior that violates what are regarded as sociocultural moral guidelines is a fundamental feature of antisocial disorders and almost defines criminal behavior. Moral judgments are viewed as involving both cognitive ("reasoning") and affective components. Per Raine and Yang (2006), "Negative moral emotions likely evolved to counteract the breaking of social conventions. Moral feelings of indignation, disdain, disgust and contempt can give rise to the stronger emotions of outrage and vengeance that then give rise to ostracization of the cheat from the social group, injury or even death. At this level, morality is largely emotion-driven, relatively automatic, and has little or no higher cognitive control component in early hominids. As hominid society became more complex, higher-order cognitive processes likely became increasingly important for both dealing with more complex moral dilemmas, and for regulating the expression of moral emotions" (p. 208). Raine and Yang continued, "While some evidence exists for a difference in level of moral reasoning in delinquent, criminal and psychopathic groups… antisocial behavior could cause differences in moral thinking, rather than vice versa. That is, living an antisocial way of life may change moral thinking to justify the individual's repeated antisocial actions and reduce cognitive dissonance" (p. 209).

Some research shows that "…psychopaths show excellent (not poor) moral reasoning ability when discussing hypothetical situations—their real failure comes in applying their excellent moral conceptual formulations to guiding their own behavior" (Raine & Yang (2006); p. 209). Thus, it may be for some group of antisocial individuals that while formally "knowing" what moral and conventional standards, they do not appreciate the emotional attachment or basis for other person's adherence to those standards; that is, they are cognitively capable of distinguishing right from wrong, but they lack the capacity of the feeling of what is moral. Further, this lack of appreciation for general and/or specific moral and social transgressions and/or an endorsement of more deviant values and goals in social situations (e.g., viewing aggression and dominance as a more acceptable means for obtaining goals) leads to more disinhibited behavior. Alternately, a lack of self-awareness or critical insight, or the presence of ambivalence or uncertainty about sociocultural values, can lead to a less reasoned attitude to choices and consequences and ultimately to undesirable behavior.

Multiple Interactions and Reinforcement Among Personality and Related Conditions in Sexual Offending

It should be apparent that psychological functioning particularly in the management and "mismanagement" of behavior is clearly multidimensional and overlapping in nature. Clearly, the "emotional" and "cognitive" dispositions of self-control (e.g., attention, working memory, etc.) co-occur and interact in a dynamic fashion. Motivators also co-occur and interact with other motivators, likely potentiating the "energy" with which behavior is directed or driven. Even more strongly, dimensions of disinhibition also interact with other elements of disinhibition, potentiating the deficiencies in constraint and management of reactive and "goal"-directed, motivated

behavior. Motivators also interact with elements of disinhibition, likely in various ways and to various degrees. Both the available theoretical models and empirical data direct that individual nonsexual as well as sexual motivators on their own can lead to sexual offending. However, multiple motivators—both nonsexual and sexual—at varying intensities (including lower levels of arousal or activation) could also act cumulatively and/or interactively to cause the enactment of a sexual offense. It is difficult to conceptualize any one or an accumulation of the factors of disinhibition as responsible for a sexual offense without some internal arousal or impetus, either a sexual or nonsexual motivator or emotional experience. However, in the presence of one or motivators, at varying intensities, aspects of disinhibition could also act cumulatively and/or interactively to cause the enactment of a sexual offense. Megargee's (2011) notion of habit strength and like concepts—the number or density of motivators and elements of disinhibition, as well as their intensity—likely function in an interactive and exacerbating manner. Just as with risk factors generally, it makes sense that various personality and related dispositions affect each other differentially, so that some may significantly potentiate one another's power in leading to the enactment of sexual offending, while others might serve to modulate the impetus to sexually offend. Thus, Krueger et al. (1994) showed that anger in combination with low constraint was the most consistent set of predictors of persisting antisocial behavior. They also found that, in combination, alienation, lack of social closeness, and risk-taking were associated with increased antisocial behavior. Patrick et al.'s (2009) construct of "meanness" involves egocentricity, fearlessness, as well as deficits in guilt/empathy or unemotionality, leading to the exploitation of others. Self-regulation has been found to buffer against "risky" behavior but only among those low in sensation-seeking. Kirsch and Becker (2007) and Mokros et al. (2011) found thought affective deficits and "behavioral disinhibition" both have an effect on sexually sadistic behavior. Both the dark triad and Dark Tetrad involve interactions between multiple factors leading to sadistic behavior. In a study of particularly "high-risk" sexual offenders in Canada, Woodworth et al. (2014) demonstrated that offenders scoring high in psychopath were significantly more likely to have a sadistic paraphilia than those with low or moderate levels of psychopathy.

Further, it is useful to consider the role of personality and related conditions after sexual offending. For many or most sexual offenders, both theory and evidence are that such offending is rewarding or positively reinforcing. After criminal events take place, such as sexual offending, additional personality and related dispositions are activated that relate to the relative reinforcement of the event(s). In addition, particular cognitive styles of an engrained nature contribute to the maintenance of sexual offending as a form of antisocial behavior. Krueger et al. (2007a) called attention to externalization of blame as a key element of the ES spectrum. More broadly, Walters (2009) identifies the following aspects of criminal thinking as among those functioning to maintain the propensity for future antisocial behavior: mollification (externalizing the blame for any negative consequences of a criminal act) and super-optimism (unrealistic beliefs that one can escape from the nature negative consequences of a criminal act or lifestyle).

Making Sense of Nonsexual Personality and Related Conditions as Factors in Sexual Offending

Personality and related conditions appear to play several roles in the development and maintenance of sexual offending in the manner of a hierarchical system. Several of these factors may play relatively primary motivational or situational roles in sexual offending (e.g., when it appears that sexual factors play little or no significant role); they are directly related to sexual offending as sufficient conditions for the enactment of a sexual offense. Moreover, personality and related conditions as one of two sets of primary pathways to sexual offending clearly act in a potentiated manner when the other primary pathways (deviant sexual interests, sexual preoccupation) are present. The most well-documented example of that is the so-called dynamic duo of sexual offending where the presence of the both sexual and personality risk factors significantly increase the risk of future sexual offending (e.g., Hawes et al., 2012). Similarly, personality and related conditions may also function as "secondary" risk factors that act in combination (additive and/or interactional) with the presence of either or both primary factors in the enactment of sexual offense. Thus, they magnify the likelihood that predisposing deviant sexual interests and sexual preoccupations on the one hand and primary nonsexual motivational/situational risk factor lead to sexual offending. Further, it seems likely, given existing research that such secondary risk factors frequently act in an additive and/or interactive manner in potentiating and enhancing other predisposing sexual and nonsexual psychosocial risk factors. Thus, sensation-seeking is potentiated by both boredom and disinhibition (e.g., Zuckerman, 1979). In addition, it seems increasingly clear that personality and related conditions may act as or more potently on the level of implicit cognition and affective dimensions, Thus, a significant subset of sexual offense predisposing factors most likely function largely automatically and out of conscious awareness and are not necessarily accessible to rational-analysis or intentional control. Finally, both primary and secondary risk factors, acting alone or in combination, act in a circular manner regarding the actual enactment of a sexual offense, such that their predisposing qualities of such characteristics likely or potentially

become greater over time via simply the rewarding or positive reinforcement aspect of obtaining the goal of a sexual offense. Thus, "positive feedback" increases the "habit strength" of one or more personality and related conditions as key factors in the occurrence of sexual offending.

Situational Opportunities and Constraints

As noted earlier, personality patterns demonstrate relative consistency by context or situation; however, without an appropriate or permissive context, those manifestations may not occur. Relative to intermittent, violent behavior, including sexual offending, some manifestations of personality involving "hot" motivators will only emerge as behavioral enactments at particular times and in particular contexts. Such contexts may be perceived or actual opportunities that allow for a behavioral enactment. For example, while persons might be similar or differ in their general levels of aggression, the key issue is that individuals would nevertheless differ predictably and clearly in the types (and number) of situations in which they committed acts of aggression. That is, even globally similar "aggressive" individuals would "vary in the their pattern of where [aggression] is displayed" (Mischel, 2004; p. 6); he noted that some persons will be highly aggressive with individuals over whom they perceive themselves as having power over (e.g., perceived vulnerable females and children) but might be exceptionally friendly and compliant with those who they perceive as being "in control" of them (policemen, correctional personnel). Such "signatures" of personality were, in fact, revealed in a large observational study of behavior, especially social behavior, across multiple repeated situations over time (Mischel & Shoda, 1995). Qualities of environmental conditions also exert an eliciting or provocation effect on aggressive predispositions and individuals' differ in their susceptibility to potentially stimulating situations; greater aggressive responses are found for persons high in trait anger, generalized hostility, narcissism, and impulsivity (e.g., Bettencourt, Talley, Benjamin, & Valentine, 2006). Similarly, some persons are more sensitized to a greater number of situations so that similar personality dimensions will be displayed more frequently, with greater intensity and more consistently than others. Conversely, some personality dimensions and related behavior will require some very specific situational or contextual cues in order for them to be instigated and displayed. Mischel (2004) utilized the term "personality types" to define people who shared common characteristics in processing certain situational features: "The types are defined in terms of characteristic social cognitive and affective processing dynamics that generate characteristic *if…then…*patterns of thought, feeling and behavior visible in distinctive types of situations" (p. 14). Similarly, in their discussion of self-regulation, Hofman and Kotabe (2012) noted that "opportunity constraints" were powerful situational determinants of the "appearance" of self-regulation; environments that do not permit access to desire gratification provide powerful "preventive interventions," often absolute preventive interventions. As per Fujita (2011), "Research has repeatedly show that when people are able to anticipate potential self-control failures, the prospectively restrict the future availability of an opportunity to indulge in temptations…the first step to self-control is to avoid having the opportunity to indulge in immediately available temptations" (p. 355). He pointed out that "Indeed, research has demonstrated that those with a history of better self-control are more likely to capitalize on opportunities to engage in prospective self control…" (p. 359) often to the point where what was effortful control becomes automatic and less dependent on conscious monitoring. Thus, it is notable that Edens, Kelley, Lilienfeld, Skeem, and Douglas (2014) found that no symptoms of ASPD, including a lack of remorse, or that diagnosis predicted institutional misconduct. For most persons with ASPD, they do not commit aggressive or other antisocial acts while in prison or they escape detection; nonetheless, their antisocial behavior decreases in a more monitored and controlled environment.

For sexual offenders, it is clear that a significant group of such offenders attempt or commit sexual offenses at a rate greater than the general population as well as the general population of criminals. However, they do not commit sexual offenses "all the time" or even necessarily frequently (although for certain offenders, that may be the case). Yet, *at certain times*, perhaps when particularly predisposed (for some by particular "hot" impulses and others by some greater number of motivators in combination with dimensions of disinhibition), when presented with particular situations (or if able to create particular contexts) involving personally "appropriate victims" and "perceived permissive circumstances," some sexual offenders show much more characteristic (and/or repetitive) patterns of sexual offending. A smaller group appears to act simply on the basis of subjective, perceived opportunity, and of that group, a subset demonstrates more varied types and targets of sexual offending, as differing sexual and nonsexual motivators are in play within particular, diverse contexts. Individual differences (in general predisposing personality characteristics, a larger set of potentiated motivational or emotional states, more varied and extensive deficits in self-control, self-regulation, or executive functioning) differ among sexual offenders and may be more or less "active" at different times, intensities, and levels of awareness. Clearly, despite the experience of similar or even exaggerated motivational states via general arousal or mental self-stimulation

(perhaps even intensified by situational deprivation), virtually no sexual assaults of females or children occur while identified sexual offenders are incarcerated or detained; neither the situational factors of appropriate victims and/or permissive circumstances exist and so behavioral enactments do not occur. Consequently, varied combinations of predisposing personality and related conditions and the particular nature of situations (or perceived situations) that an individual finds himself in (or creates for himself) will determine the expression or manifestation of those traits or predisposing characteristics as sexual offenses. Thus, the presence of increased influence of motivators and elements of disinhibition, in conjunction with particular situational elements, plays a critical role in the likelihood of many sexual offenders to reoffend.

Aggregating Nonsexual Dimensions of Personality in Relationship to Sexual Offending

From a consideration of personality and related conditions, numerous personality and related variables are identified by theory, empirical study, or both as related to future sexual offending. In examining this set of factors, namely, those including motivators, disinhibition (or lack of self-control), it seems clear that they are predominantly elements of or related characteristics of various personality disorders, executive functioning, or alcohol use disorders. The primary categories of PDs that contain personality-based predisposing characteristics for sexual offending are the set of so-called Cluster B disorders (per the DSMs). Smaller secondary categories of personality disorders related to sexual offending are those involving issues in social bonding, social skills/immaturity, and social anxiety, particularly, avoidant personality disorder.

Clearly, ASPD by means of its subsidiary traits appears to be the principal personality disorder related to sexual offending. Its manifest components include primary motivational elements (irritability or aggressiveness) and multiple elements of disinhibition (indifference/disregard for rules, impulsivity, reckless disregard for safety of others, and lack of remorse). In addition, to those particular antisocial elements identified in the DSMs are related characteristics that empirical research has demonstrated accompany antisocial characteristics (or are consequences of the previously mentioned ones) such as deceitfulness and irresponsibility.[5] Relative to the dimensional construction of ASPD in DSM-5, components include several primary motivational elements (egocentrism, goals for personal gain or pleasure, hostility, risk-taking, irritability, or aggressiveness) and aspects of disinhibition (callousness, impulsivity, reckless disregard for safety of others, and lack of remorse).

In addition, BPD also includes potential primary motivational elements (inappropriate, intense anger; unstable interpersonal relationships (social bonds), including idealization of potential "partners;" chronic feelings of emptiness; identity disturbance) as well as multiple elements of disinhibition [impulsivity and affective instability/reactivity (dysregulated affect)]. Relative to the dimensional construction of BPD in DSM-5, components also include potential primary motivational elements (chronic feelings of emptiness, hostility, risk-taking) as well as multiple elements of disinhibition (impulsivity, emotional instability, compromised empathy, unstable relationships). In addition, a number of studies have demonstrated significant comorbidity in diagnoses of ASPD and BPD. Zanarini et al. (1998) found that males who met criteria for BPD were significantly more likely than female borderlines to meet DSM-III-R criteria for paranoid, passive-aggressive, narcissistic, sadistic, and antisocial personality disorders relative to persons with other personality disorders. Black, Gunter, Loveless, Allen, and Sieleni (2010) found that in a random sample of newly incarcerated offenders, those who met the criteria for ASPD showed higher rates of BPD, ADHD, and SUA. Grant et al. (2008) showed a strong relationship between BPF and NPD and substantial disability. Berger et al. (1999) found the criteria for the former sadistic personality disorder overlapped with both ASPD (42 %) and BPD (32 %) and suggested that sexually sadistic behavior might be an important sub-dimension of such Cluster B disorders.

Per the categorical approach in DSM-5, NPD too includes primary motivational elements (grandiosity and self-importance, particularly in reaction to experienced inadequacy, entitlement, and arrogant, haughty attitudes) and elements of disinhibition (lacking empathy, interpersonally exploitative, need for others for self-esteem or inflated self-esteem, grandiosity leading to entitlement, and attention-seeking). Relative to the dimensional construction of NPD in DSM-5, components also include potential primary motivational elements (entitlement/grandiosity/egocentrism, excessive attention-seeking, fluctuating self-appraisal, sensitivity to approval from others, superficial or limited intimacy) and

[5]It should be noted that Markon and Krueger (2005) also found that conduct disorder and antisocial personality disorder were not related in the manner generally believed; conduct disorder did not appear to be a necessary prerequisite for adult antisocial behavior disorders. Other investigators have made similar findings, although the presence of conduct disorder may identify a particularly persistent form of ASPD. However, per Robins (1978) and Moffitt (1993), early-onset antisocial behavior was a "sturdy" predictor of persistent antisocial behavior over time.

elements of disinhibition (impaired or absent empathy, inability for intimacy). Again, available research indicates the significant comorbidity in diagnoses of ASPD, BPD, and NPD as well as substance abuse (Stinson et al., 2008). Cox, Clara, Worobec, and Grant (2012) recently found that via factor analysis of NESARC, data identified a three-factor cluster model, supporting the DSM grouping of theoretically related personality disorders. Similarly, Warren and Burnette (2012) found that the primary factor associated with criminal offending was composed of predominantly antisocial personality traits as well as select traits associated with BPD and NPD. Indirectly, these results highlight the continued usefulness of psychopathy. As a construct, psychopathy as a collection of maladaptive personality traits and antisocial behaviors (in particular as measured by the PCL-R) obviously offers a particularly useful approach to aggregating many of the key elements of personality and other predisposing elements related to violent and sexual offending. Relative to the PCL-R, motivators include grandiose sense of self-worth, need for simulation/proneness to boredom, and (what is termed) poor behavioral controls. Elements of disinhibition include impulsiveness; lack of remorse or guilt; callous/lack of empathy; shallow affect; failure to accept responsibility for own actions; lack of realistic, long-term goals; and irresponsibility. Woodworth et al. (2013) found that a substantially greater portion of (four times) sexual offender who scored high on the PCL-R reported engaging in sexually violent fantasies (relative to those low on the measure).

In addition, avoidant personality disorder (APD or key traits associated with that disorder) also represents a condition that likely predisposes select individuals to sexual offending, both for rape but particularly for child-focused sexual offending. APD also includes potential primary motivational elements (low self-esteem, anxiety about "acceptance" in relationships, reluctance to take risks in interactions with peers); thus, persons with APD may be characterized by powerful motivations for belonging, acceptance, approval, and nurturance, leading them to seek and even force social contact with minors in efforts to "achieve" perceptions of those experiences. Relative to the dimensional construction of APD in DSM-5, components also include potential primary motivational elements [low self-esteem, reluctance to take perceived risks (such as social behavior with appropriate peers, frustration from anticipated or real social rejection, and limited or nonexistent intimacy] as well as – disinhibitors (anhedonia, social or emotional detachment).

It is also worth considering that the predominant DSM personality disorders model as consisting of "categorical" conditions (requiring a minimum number of specific maladaptive personality traits to be present) reflect the notion that a minimum additive effect exists. As with other phenomena, studies indicate the most valid way to view the significance of personality and other related condition is in a dimensional, additive model so that both the total number of and severity of characteristics present are predictive of increased criminality, violence, and sexual offending. Thus, Skilling, Harris, Rice, and Quinsey (2002) found that the severity of life-course-persistent antisocial conditions (both ASPD and psychopathy) as measured by the number and strength of symptoms/characteristics was strongly associated with future violence. Assessed dimensionally, both ASPD and psychopathy were highly correlated ($r = .85$).

In considering the role of the DSM-defined personality disorders, it is clear that the particular definitions of these disorders fail to acknowledge, let along privilege, what are key aspects of personality that are likely related to sexual offending, such as reward/novelty-seeking, dominance, generalized hostility, social inadequacy, and social isolation.

Comorbidity of Personality and Related Predisposing Conditions: Implications for Sexual Offending

Various motivators and elements of disinhibition appear likely to interact to increase the predisposition to sexual offending. Similarly, select traits associated with one or more personality disorders, deficits in executive functioning, and substance abuse/dependence are also likely to interact or converge to aggravate the likelihood of sexual offending. Tyrer and Mulder (2006) demonstrated that the "complexity" and severity of a personality disorder (the former defined in terms of meeting criteria for more than one personality disorder and the latter in terms of the possibility of severe disruption to both individual and to many in society) were robust predictors of more negative outcome. Empirically, the *combination* of or comorbidity of so-called Cluster B personality disorders and their subsidiary (and overlapping) traits show a particularly strong relationship to criminal and violent behavior; in particular, persons with traits of both ASPD and BPD and/or narcissistic or paranoid traits showed particularly high levels of such antisocial behavior. Black et al. (2010) reported that as many as 50 % and 75 % of those meeting criteria for ASPD meet the criteria for alcohol dependence or drug abuse. Blackburn and Coid (1999) used cluster analysis to identify six diagnostic patterns among personality disorder among violent offenders; three of those groups (antisocial-narcissistic, paranoid-antisocial, borderline-antisocial-passive-aggressive) had more extensive criminal histories, were more likely to be identified as psychopaths, and more lifetime history of substance abuse. Both Blackburn and Coid (1999) and Egan (2009) identified

that persons with antisocial, narcissistic, borderline, and paranoid personality disorders were more likely to be arrested (due in part to high levels of angry hostility, excitement-seeking, and impulsiveness) and that violent offending among those with such diagnosed personality disorders was more strongly associated by their comorbid traits than by one particular category of personality disorder. Howard, Mccarthy, Huband, and Duggan (2013) showed that patients with antisocial/borderline comorbidity took significantly less time to reoffend compared with those without such comorbidity; in addition, Factor 2 of the PCL-R also strongly predicted a more rapid reoffense.

Further, as noted, substance use disorders, particularly recurrent alcohol use, have been implicated as a significant factor in violent and criminal offending; while situational alcohol consumption *independently* contributes to increased rates of violent behavior, it is also genetically associated with externalizing personality disorder traits and likely interacts with other dispositional features to aggravate the risk of violence. In substance-abusing populations, the co-occurrence of substance abuse and any personality disorder is particularly high, with a median prevalence of co-occurrence of 61 % identified in one review of 50 studies; the association is particularly strong between substance misuse and antisocial and/or borderline personality disorders; and illicit drug users show a higher co-prevalence rates personality disorder than problem drinkers (Verheul, Bartak, & Widiger, 2007). Fifty percent of males who demonstrated a life-course-persistent pattern of antisocial behavior were diagnosed as alcohol dependent at age 18 (e.g., Moffit et al., 1991). In the ECA study, Regier et al. (1990) showed that persons with ASPD were approximately 30 times more likely than non-antisocial individuals to have any type of substance use disorder, 21 times more likely to show alcohol abuse/dependence, and 13 times more likely to show substance abuse/dependence.

Nestor (2002) concluded that higher rates of violence were firmly established most prominently for individuals with Cluster B personality disorders in addition to substance abuse/dependence disorders (SAB); he noted that rates of violence are 12 to 16 times higher for individuals with SAB and Cluster B personality disorders. Further he noted that these conditions interacted so that persons with SAB and comorbid personality disorder were as high as 43 %. When characterized by comorbid substance dependence, 52 % of personality disordered individuals reported committing acts of violence (Coid et al., 2006). Similarly, Howard (2009) pointed out that persons with both ASPD and BPD with a history of drug and alcohol problems had significantly more violent convictions; they also showed significantly higher levels of anger and impulsivity (affective impulsivity). Stinson et al. (2008) found that substance use disorders, particularly drug abuse or dependence, were quite common in persons with narcissistic personality disorder (e.g., greater or equal to 50 %). Howard et al. (2013) showed that patients with antisocial/borderline comorbidity took significantly less time to reoffend if they were characterized by comorbid substance use. Utilizing exploratory factor analysis, Warren and Brunette (2012) found that the primary personality factors associated with future violence including predominantly traits of ASPD (violation of social norms, aggressiveness, deceitfulness, impulsivity, reckless disregard for the safety of others, and irresponsibility), BPD (impulsivity and anger), and NPD (exploitation).

As in criminal and general violent behavior, personality and related conditions particularly motivation/emotions and self-regulation/self-control acting as motivators and elements of disinhibition clearly play several roles in sexual offending. In some instances, such conditions serve as predisposing factors which singly or, more commonly, in various combinations provide the primary basis for enactment of sexual offenses. Such personality and related conditions consist of several components. First, as nonsexual appetitive or incentive or consummatory motivations, blends of cognitions, affects, and arousals/impulses provide pushes of varying intensities toward inappropriate sexual behavior. In addition, as noted previously, nonsexual arousal and motivations may become sexualized as well and lead to additional sexual arousal. Second, deficits or other limitations in self-regulation/self-control and/or executive functions represent failures of inhibition and constraint—elements of disinhibition—that to various degrees function singly or more commonly in varied combinations to allow appetitive motivations to emerge relatively unmodulated in a press for sexual and other psychologically meaningful gratifications. Further, both nonsexual appetitive motivations and deficits or failures in self-regulation may also combine with varied degrees of awareness of primary sexual appetitive motivation and generalized sexual preoccupation to result in attempts at varied sexual offenses. In fact, this seems like the most common set of states and traits involved in the enactment of sexual offenses. In addition, in limited cases, it appears that situational or contextual factors, particularly alcohol and/or drug intoxication (e.g., excessive use) and negative peer associations, can be sufficient to lead to the occurrence of a sexual offense.

Personality and related conditions are composed of multiple elements that are dimensional in nature. Research and theory has increasingly defined which dimensions of personality appear relatively universal and cohere to account for the most potential behavior. As dimensions, atypical or maladaptive effects can be created by extremes at each end of a continuum. Personality and related dimensions appear to be strongly influenced by factors of heritability as well as shaped by an interactive reciprocity where biologically based dispositions repeatedly interact negatively with particular environmental influences to amplify their dysfunctional potential relative to behavior conditional on situations;

thus, developmental environmental forces often exacerbate or aggravate problematic personality and related predispositions toward antisocial, violent, and sexually violent behavior. In particular, motivational domains and EF/SR domains each appear to be characterized by "cool" and "hot" elements or dimensions; more biologically elementary "hot" dispositions may function relatively autonomously of more "cool" systems optimized for affect/arousal neutral information-processing and behavioral regulation. Given such vulnerabilities, more automatic and reactive sexual offending might result, particularly for visceral motivational factors. In contrast, despite "hot" dispositions, "cool" systems (associated with better-managed inhibiting factors) may allow for more calculated and premeditated—instrumental and predatory—enactment of sexual offending; thus, intense motivation may be titrated to improve the likelihood of behavioral gratification and the minimization of undesired consequences. Further, persons with a greater frequency or intensity of "hot" affective-arousal factors appear to be characterized by lower degrees of self-control, a dynamic duo of disinhibition. While data suggests that personality and related dispositions are relatively enduring and consistent over time and situations (e.g., relatively characteristic), situational stimuli can exert a very powerful influence in eliciting such predispositions (both in evoking or provoking motivators or compromising deficits or limitations in EF/SR) and in further impacting one or more elements of disinhibition. Behavior resulting from personality and related dimensions thus are a function of the type, degree, and number of motivators and elements of disinhibition but also the degree to which a particular situation impacts on those particular dimensions and provides "permissive circumstances" (or a lack of "opportunity constraints") for related behavior to occur. Thus, one would expect to find the enactment of a particular type of sexual offense on occasions when sets of motivators and elements of disinhibition are present and activated *and* when the situation or context are both appropriately stimulating and permissive of the desired behavior. Absent appropriately stimulating and permissive environmental elements, particular types of sexual offending, are less likely to occur. At the same time, particularly heightened motivators, deficient mechanisms of self-control, and the relative "availability" of potential sexualized target individuals or activities might also lead to more diverse sexual offenses. Thus, given knowledge of particular characteristics of the contexts of one or more sexual offenses, one might be able to evaluate the relative but general strength of a set of dispositions (motivators and/or elements of disinhibition) toward sexual violence. However, without full or accurate knowledge of the specific characteristics of time and situation that one or more combination of predisposing conditions became manifest in particular acts of sexual offending, it is very likely that only a general picture of the nature of the predisposing conditions to such offending can be obtained.

Thus, nonsexual motivators and elements of disinhibition can be understood as enduring predispositions (e.g., trait-like) or vulnerabilities that also manifest contextually as well as more intense "state-like" phenomenon under particular types of environmental stimulation and circumstances. Each personality and related predisposition is characterized by individual differences in the nature and variety of conditions; the sensitivity, intensity, persistence, and frequency of such conditions; the nature and degree of their interactions (e.g., additive or interactive/synergistic); and the degree (magnitude) to which they are elicited or provoked by a range of situational factors. In certain instances, it may be that one identified predisposing personality and related factors might be sufficient on its own to lead to sexual offending, such as a particular intense motivator and/or a profound type and extreme degree of disinhibition (particularly at particular times and in specific situations). However, it appears most likely and most commonly that these factors act in combination and sometimes interactively or synergistically. That is, motivators and aspects of disinhibition exist and appear as part of a dynamic process. Consequently, one can conceptualize multiple pathways for a particular individual with a particular set of predisposing motivators and/or elements of disinhibition to enact a sexual offense; many different combinations of predisposing conditions given eliciting or provoking situations might lead to sexual offending. Varying combinations of personality-related motivators of differing degrees interplay with differing combinations of elements of disinhibition of varying degrees or intensity. Further, the added impetus or motivational power of sexual predisposing factors in addition to the presence of nonsexual predisposing conditions, including motivators and elements of disinhibition, would create particularly powerful forces that both press for and permit the enactment of sexual offending, given fluctuating or divergent situations. Finally, the degree of relative reward (reinforcement of one or multiple motivators) experienced in consummating a sexual offense would most likely dramatically increase the habit strength of the source motivations as well as further degrade the influence of elements of disinhibition. Thus, it is understandable that research efforts might best be able to only characterize the broad themes of nonsexual personality and related conditions as they relate to sexual offending. The reality of varying sensitivities to varying and multiple motivators and relative presence of multiple potential elements of disinhibition, all activated to varying degrees by varying situations and circumstances, would be quite difficult to capture in even sophisticated statistical analyses.

For some individuals with some of these predisposing conditions, developmental experiences likely further aggravate their genetic liabilities either in more or less enduring

ways by interfering with the acquisition of more normative means and levels of self-control and heightening key motivators of antisocial and violent behavior. In contrast, alternate developmental experiences likely mitigate their genetic liabilities either in more or less enduring ways by enhancing the acquisition of more normative means and levels of self-control (e.g., in part, via the acquisition of skills to manage both motivators and elements of disinhibition or through the development of particular values and self-schema that act as particular inhibitors). Thus, well-developed self-control mechanisms could potentially mitigate the effects of the presence of one or more appetitive-predisposing conditions at certain times and across situations. In contrast, the apparent interrelationships between elements of disinhibition might allow a more or even less powerful motivator (or convergence of less intense motivators) to be expressed with little or no modulation. It would seem clear various issues (e.g., acute or chronic stress, particularly vulnerability-reactive stress) might also interfere with or exacerbate such predisposing conditions for sexual offending. In sum, it seems clear that multiple personality and related conditions exist which potentiate and play key causal roles in sexual offending in perceived permissive contexts, either on their own or in the presence of general or specific heightened sexual arousal, interests, and/or urges.

Adolescents Who Have Engaged in Sexually Abusive Behavior: An Overview

William D. Murphy, I. Jacqueline Page, and Harry M. Hoberman

Over the last 20 years, there have been numerous advances in our understanding of adolescents who have engaged in sexually abusive behavior. The current chapter highlights research related to this population including prevalence, characteristics, etiology, and recidivism. In addition, assessment, treatment, and public policy issues will be addressed.

Definition and Prevalence

Adolescents who engage in sexually abusive behavior are generally youth between the ages of 13 and 17 who are involved in sexual behavior with youth significantly younger than themselves (usually defined as 4–5 years younger and generally under age 13) or who engage in sexual behavior with peers or adults against their will through the use of threats or physical force (Kemper & Kistner, 2010; Murphy, Haynes, & Page, 1992; Ryan, 1997). Some studies include 12 year olds or 18- to 19 year olds (Seto & Lalumière, 2010). However, youth below the age of 13 with problematic sexual behavior are typically referred to as children with sexual behavior problems. Children with sexual behavior problems differ considerably, including developmentally, from adolescents who have engaged in sexually abusive behaviors, and research specific to this population supports different approaches to assessment and treatment (e.g., Chaffin et al., 2008). In some jurisdictions and in some research studies, juvenile or adolescent sex offenders are those who have charges and/or adjudications for a statutorily defined sexual offense. However, we prefer a definition based on behavior as many juveniles may not be officially charged or adjudicated and a number may be identified by Social Services or Child Welfare systems rather than the Juvenile Justice system (Kjellgren, Wassberg, Carlberg, Långström, & Svedin, 2006; Prentky et al., 2010).

The actual incidence (the rate of new cases) or prevalence (the percentage in a population with the condition) of sexually abusive behavior by adolescents is difficult to determine. There are a number of estimates based on different data sources which include criminal justice reports, victim surveys, surveys of general nonclinical populations, and adult offender self-reports of age of onset. These sources do suggest that adolescents are responsible for a significant proportion of sexual offenses. In 2009, approximately 15,400 youth were seen in juvenile courts in the USA for a sexual offense (Puzzanchera & Kang, 2012). Data from the FBI's Unified Crime Report indicated that about 17 % of arrests for rape or other sexual offenses were of individuals under age 18 (Puzzanchera, Adams, & Kang, 2012). Finkelhor, Ormrod, and Chaffin (2009) analyzed data from the 2004 National Institutional Based Reporting System (NIBRS). The NIBRS is designed to replace the FBI crime reports; it provides more case detail and covers a wider number of criminal offenses. They found that 25.8 % of all sex offenses known to the police were perpetrated by persons under age 18 and 35.6 % of those sex offenses committed against juvenile victims were by youth under 18. It should be noted that the 2004 NIBRS did not have complete coverage of all jurisdictions in the United States and therefore cannot be considered a representative sample of police data.

Surveys of victims also find that a significant minority report that the offender was an adolescent. Analysis of data from the National Incident Study of Missing, Abducted, Runaway and Throw Away Children (NISMART-2) found that 25 % of the sexual victims indicated that the offender

was under 18 with only 30 % of these victims reporting the offense to the police (Finkelhor, Hammer, & Sedlak, 2008). The NISMART study is based on a national representative sample of children. Information on victimization was obtained through telephone interviews with caretakers of youth under age 17 and additional direct interviews with the youth themselves for children ages 10 to 17. It should be noted that in all the studies cited above, some of the youth identified as engaging in sexually abusive behavior were under 13. For example, in the Finkelhor et al. (2008) study, about one out of eight was under age 12.

There have also been attempts to determine the prevalence of sexual abuse among adolescents by studying nonclinical populations. One of the first studies was by Ageton (1983), in an analysis of youth from the National Youth Survey, a representative sample of over 1700 youth nationwide. Her findings indicated that 2.4 % of adolescents engaged in sexually assaultive behavior. Two additional studies (Borowsky, Hogan, & Ireland, 1997; Casey, Beadnell, & Lindhorst, 2009) studied sexual coercion in relatively large representative nonclinical samples. Borowsky et al. (1997) used data for 9th and 12th graders from the Minnesota Student Survey. This survey included over 71,000 students and they found a history of sexually coercive behavior in 4.8 % of male and 1.3 % of female adolescents. Similarly, Casey et al., in an analysis of the male participants in the National Longitudinal Study of Adolescent Health, found that 5.6 % of the respondents had engaged in sexually coercive behavior. It should be noted, however, that in both the Borowsky et al. study and the Casey et al. study, sexual coercion/aggression was defined by one question generally asking whether they had ever "forced anyone to engage in sexual activity." In addition, Casey et al. included the third wave of the national longitudinal study when the average age of subjects was approximately 22 years of age, so some coercive sexual behavior may have occurred after adolescence.

In a clinical sample of sexual offenders from the community, Abel and his colleagues (e.g., Abel & Rouleau, 1990) found that many of those individuals reported early onset of sexual offending and paraphilic behavior. For example, 50 % of those with voyeurism, frottage, exhibitionism, and nonincest pedophilia indicated an onset of those behaviors before age 18. It is not clear how well the population studied by Abel and colleagues represents the general adult sex offender population. These data were collected as part of a research study operating under a Federal Certificate of Confidentiality so no disclosures were reported to authorities. There have been no replications of this study under these conditions.

Collectively, the available research suggests that a significant number of sex offenses are committed by adolescents. Abel and colleagues' data would suggest that at least a significant minority of adult offenders may begin in adolescence. However, as we will see in later sections, most adolescents, once detected for a sexual offense, are not detected for future offenses. A challenge to the field is to be able to identify those at most risk so that interventions are targeted to those most in need of services.

Characteristics and Typologies

Early publications in the juvenile field suggested that juvenile sex offenders show similar characteristics to adult offenders (National Adolescent Perpetrator Network, 1993). It was speculated that issues such as deviant sexual arousal, cognitive distortions, lack of victim empathy, and social skills were important drivers of adolescent sex offending. Twenty years later it is clear that adolescents who engage in sexually abusive behaviors are a very heterogeneous group who vary on many characteristics (Dwyer & Letourneau, 2011). In addition, several factors thought to be relevant to adult offenders may occur much less frequently in adolescent offenders. The lack of consistent findings in attempts to define characteristics of adolescents who have engaged in sexually abusive behavior has resulted in attempts to develop classification systems to better understand the heterogeneity. There have been attempts to subdivide youth on such factors as the presence or absence of other delinquent behavior, the age of the victim, whether the offender has been victimized themselves as well as other classifications based on psychological profiles rather than offender or victim characteristics, and typologies based on offense trajectories.

Classification Based on the Presence of General Delinquency

A consistent finding in the literature is that adolescents who engage in sexually abusive behavior are characterized by high rates of engaging in nonsexual offending delinquent behavior (Seto & Lalumière, 2010) and have much higher recidivism rates for general delinquent offending than they do for sex offending (Caldwell, 2010). There have been multiple studies comparing adolescents who sexually offend to adolescents who have engaged in general delinquent behavior but not sexual offending. These studies have been summarized in a qualitative review by Van Wijk et al. (2006) and in a meta-analysis by Seto and Lalumière (2010). The Seto and Lalumière meta-analysis reviewed 59 studies comparing adolescent sex offenders (3,855) to adolescent nonsex offenders (13,393). Both the qualitative review and quantitative review indicated many similarities between the two groups; in general, there were more similarities than differences. However, Seto and Lalumière did find some significant differences with adolescents who had committed sexual offenses having greater exposure to pornography, more atypical sexual interest, more history of sexual abuse, and to a lesser degree, but still significant, more anxiety problems

and lower self-esteem than general delinquents. On the other hand, the general delinquent youth were characterized by a more extensive criminal history, associations with more antisocial peers, and more substance abuse issues.

Given the overlap between these groups, there have been attempts to classify adolescent offenders on the basis on the presence or absence of other delinquent behavior and/or other violent behavior (Aebi, Vogt, Plattner, Steinhausen, & Bessler, 2011; Butler & Seto, 2002; Wanklyn, Ward, Cormier, Day, & Newman, 2012; Way & Urbaniak, 2008). Butler and Seto (2002) compared a group of sex-only offenders and a sex-plus group that had both sexual and nonsexual offending with half in the sex-plus group having aggressive and non-aggressive offenses. These groups were also compared to two control groups: a group that engaged in non-aggressive, nonsexual offending and a second group that engaged in both non-aggressive and violent non-sex offending (and was termed a "versatile" group). The sex-only group had less childhood conduct problems, better current adjustment, more pro-social attitudes, and lower risk for future offending as measured by a youth version of the Level of Service Inventory (YO-LSI, Shields & Simourd, 1991). The sex-plus group was most similar to the versatile group. Way and Urbaniak (2008) also compared adolescents with and without other delinquent behaviors, but did not have a non-sex offending delinquent control group. Those adolescents with no delinquent history tended to have younger victims and more often sexually abused a relative (including siblings) than the group with both sexual and nonsexual offending. They also investigated a number of individual/family history factors such as drug and alcohol use and criminal history of the male and female caregivers. In general, the youth with both sexual and nonsexual offending had histories characterized by more childhood maltreatment, multiple maltreatments, indications of alcohol and drug use, prior mental health treatment, and prior out-of-home placements. It should be noted that the delinquent and nondelinquent groups did not differ significantly on history of being sexually abused. The female caregivers of the delinquent youth were more likely to have histories of alcohol and drug abuse and were more likely to have a past history of being arrested; there appeared to be no differences between the delinquent and nondelinquent youth in terms of male caregivers.

Aebi et al. (2011) also compared a sex offending group to a sex offending plus other offending group. The sex-plus group was slightly older, had more nonsexual violent recidivism, was more likely to use alcohol and drugs, and more likely to use verbal aggression. However, they did not find significant differences on a number of variables including sexual recidivism or victim characteristics such as sex of the victim, multiple victims, related victims, or unknown victims. They also did not differ on being a victim themselves.

Wanklyn et al. (2012) compared three groups that all had histories of nonviolent general offending. The groups differed on either the presence of sex offending or the presence of violent offending. They compared a sex offending group that had no violent offending apart from sex offending, a violent non-sex offending group who had no sex offending but had violent offenses, and a versatile violent offending group that had both sex offending and other violent offending. In univariate analyses, the versatile violent group had a greater history of sexual abuse, physical abuse and emotional abuse, criminal family members, overt antisocial behavior, family relationship problems, involvement with alternative care, and having an adolescent mother. The sex offender only group tended to be intermediate between the versatile group and the non-sex offending, nonviolent group.

Because of the differences in control groups and measurement procedures, it is difficult to draw firm conclusions from this set of studies. Those youth who engage in both sex offending and criminal delinquent behavior appear to have characteristics similar to delinquent youth. However, those who have both sex offending and violent offenses seem to represent a more severe group with significantly more behavior and family problems and a higher number of adverse childhood experiences.

Classification Based on Victim Characteristics

Research with adult sexual offenders has found consistent differences between those who sexually offend against children and those who sexually offend against adults. For example, those adults who target children are more likely to have been sexually abused themselves and to have more social deficits, while those who target adult women show more issues with anger and hostility and are more generally antisocial (Lee, Pattison, Jackson, & Ward, 2001; Olver & Wong, 2006). There have also been multiple studies in adolescent sexual offending examining those who abuse prepubescent children and those who abuse pubescent children (see Fanniff & Kolko, 2012 for a review). Hunter, Figueredo, Malamuth, and Becker (2004) used path analysis and contrasted adolescents who sexually offended against prepubescent children and those who targeted postpubescent females. They found those adolescents who targeted children had greater deficits in psychosocial functioning, used less aggression in sex offending, and were more likely to offend against relatives. Fanniff and Kolko (2012) conducted a qualitative review of studies comparing groups of sexually abusive youth with prepubescent children to those with peer or adult victims and found inconsistent findings across studies. Their conclusion was that the most consistent findings were that youth who offended against peers or adults were more likely to use force or aggression and were more likely to offend against strangers. Those adolescents who offended against child victims are more likely to offend against family members or acquaintances and were more likely to offend

against at least one male. In their own study of an outpatient sample, which was presumably a lower risk sample, Fanniff and Kolko (2012) found few differences based on the age of the victim. Inconsistencies in results across studies may be related to result of different populations (e.g., higher risk versus lower risk populations) and different measurement methods. There is at least some support for the conclusion that adolescents who sexually offend against peers may be more similar to general delinquent adolescents than those who molest children, with this latter group more characterized by social deficits [although this is not always found (e.g., Kempton & Forehand, 1992)].

Classifications Based on Sexual Victimization

A history of sexual victimization is a characteristic of some adolescents who engage in sexually abusive behavior that may also be a factor that impacts the difference found in the above-cited studies. Cooper, Murphy, and Haynes (1996) found that those adolescents who engaged in sexually abusive behavior who reported having been sexually abused tended to have an earlier onset of offending, more victims and more psychopathology and interpersonal problems. The groups did not differ on either general delinquency or family functioning. In a similar vein, Burton, Duty, and Leibowitz (2011) and Leibowitz, Burton, and Howard (2012) found that those youth who had been sexually abused had more severe and more recent behavioral difficulties including both sexual and nonsexual criminal behavior than the group who had not been victimized.

There is some evidence that those adolescent offenders who have been sexually abused, especially those who also target male victims, may show more age inappropriate sexual arousal patterns while undergoing physiological testing (Becker, Hunter, Stein, & Kaplan, 1989; Becker, Kaplan, & Tenke, 1992; Murphy, DiLillo, Haynes, & Steere, 2001), although this is not found in all studies (Hunter, Goodwin, & Becker, 1994). Studies have shown that when comparing adolescents who engage in sexually abusive behavior that report a history of sexual abuse to those who report no history of being sexually abused, those that report a history of sexual abuse are more likely to have male victims (Cooper et al., 1996; Worling, 1995). Consequently, in investigating such factors as delinquent vs. nondelinquent or child vs. peer victims it may be important when to control for victimization history.

Classification Based on Psychological Factors

In view of the studies above, it appears that classification systems based upon characteristics such as delinquent/nondelinquent, victim age and presence, or absence of sexual abuse may be somewhat overlapping. In fact, Aebi et al. (2011) presented data related to various classification schemes including classifying by age of victim, presence of delinquency, and group versus solo offenders. They found that the classification types were actually correlated with one another, leading them to suggest that a dimensional system of understanding heterogeneity of this population may be more valuable than classification by simply one characteristic of the offense or the offender. In a similar vein, Fanniff and Kolko (2012) suggested that classifications based on personality variables or meaningful psychological factors might be more relevant than classification systems based on factors related to the offense.

Four studies have used cluster analyses of various personality inventories to develop subgroups of youth (Oxnam & Vess, 2006; Richardson, Kelly, Graham, & Bhate, 2004; Smith, Monastersky, & Deisher, 1987; Worling, 2001). For example, Worling (2001), in a study of 112 adolescent males who had engaged in sexually abusive behavior, used cluster analyses to classify subjects using scores on the California Personality Inventory (CPI). He identified four personality-based subgroups: Antisocial/Impulsive, Unusual/Isolated, Over-controlled/Reserved, and Confident/Aggressive. Worling described two of the groups as being "healthier" (the over-controlled/reserved and the confident/aggressive) compared to the groups described as antisocial/impulsive or unusual/isolated. The Antisocial/Impulsive adolescent sexual offenders were the largest group (e.g., "almost half"). Subgroup membership was not related to the age of the victim or their gender, or the adolescents' history of sexual victimization. However, Worling observed statistically significant differences between these groups regarding history of physical abuse, parental marital status, residence of the offenders, and whether or not offenders received criminal charges for their index sexual assaults. The Antisocial/Impulsive adolescents were those most likely to have received criminal charges for their index sexual assaults; they had also experienced more abusive physical discipline from their parents. Recidivism was measured by criminal charges; the follow-up period ranged from 2 to 10 years. No differences were found for subsequent sexual offenses among the groups (mean = 11 %). Adolescents in the Antisocial/Impulsive (37 %) and Unusual/Isolated (47 %) were more likely to be charged with a subsequent violent (sexual or nonsexual) or nonviolent offense. Worling concluded that the four-group typology is suggestive of different pathways and treatment needs.

Worling's results are very similar to those of Smith et al. (1987) using the MMPI and those of Richardson et al. (2004) and Oxnam and Vess (2006) using the Millon Adolescent Clinical Inventory (MACI), although none of these studies reported recidivism data. In general, the clusters found in these studies using multidimensional psychological inventories appeared to identify three groups of adolescents who engage in sexually abusive behavior: a group high on

internalizing behaviors and/or significant mental health issues, one characterized by externalizing behaviors and one that appeared to not have significant psychopathology.

Classification Based on Developmental Pathways

Another approach to classifying adolescent offenders draws from the literature from developmental and life-course criminology (Farrington, 2003). This approach focusses not only on correlates of recidivism but in addition factors related to the initiation of offending and desistance from offending. Similar to Moffitt's (1993) conceptualization of life-course persistent delinquency and adolescent limited delinquency, Hunter (2006) proposes three developmental pathways for youth engaging in sexually abusive behavior based on his and colleagues' earlier empirical work. (e.g., Hunter, Figueredo, Malamuth, & Becker, 2003, 2004, Hunter et al., 2004). The "Life Course Persistent" group is "characterized by psychopathic traits, including superficial attachments to peers and family. They distrust others, aggressively seek dominance interpersonally, manifest hostility towards females, and predominantly assault pubescent and postpubescent females" (e.g., same age or older females). This group is more likely to engage in more general antisocial behavior than other groups, and sex offending is most likely part of a general antisocial lifestyle. The "Early Adolescent-Onset Paraphilic" group is thought to possibly represent early onset pedophilia; they are motivated largely by deviant sexual arousal/interests and target pre-pubescent children. This group is considered to have the highest risk of continued sexual offending. Lastly, "Adolescent-Onset, Non-Paraphilic" group is composed of youth believed to engage in transient sexual offending as a form of adolescent experimentation and/or in compensation for psychosocial deficits that impair healthy peer relationship development. From clinical experience, only a few youth seem to fit the Early Adolescent-Onset Paraphilic group which may partially explain the low detected sexual recidivism rates in adolescents who engage in sexually abusive behavior. The Life Course Persistent Group also may be the group that contributes significantly to the much higher general recidivism rate for adolescents who engage in sexually abusive behavior.

The above typology is primarily based on clinical observation, but Lussier, Van Den Berg, Bijleveld, and Hendriks (2012) provide partial support for this model. They studied offense trajectories of 448 Dutch juveniles convicted of a hands-on sex offense who were sent to a specialized institution for assessment. It should be noted that the group was considered a moderate- to high-risk group. They were followed for on average 14 years with the average age at time of assessment being 14.4 (SD = 1.8). They found two trajectories for sexual offending, an adolescent limited group and what they labeled a high-rate slow desister group. The high-rate slow desister group compromised 10.4 % of the sample and the adolescent limited group comprised 89.6 % of the group. The high rate slow desister group's offending peaked at around age 12 and went down at a very slow rate and did not match the rate of the adolescent limited group until they were around age 30. Fifty percent of the high-rate slow desister group offended in adolescence, 60 % in adulthood, and had on average 3.77 convictions for sexual offense. For the adolescent limited group, their offending peaked at age 14 and then rapidly declined. Thirty-five percent of this group reoffended in adolescence but only 2 % in adulthood. These groups did not differ in terms of age of victim. It should be remembered that this was a select group of youth who were considered to be moderate to high risk. If low risk groups were included, other trajectories may have been found that had low recidivism in adolescence and adulthood.

It was also found that even though the youth may have been in the adolescent limited group for sex offending that did not mean they were in an adolescent limited group for general criminal offending. While most of these subjects' sexual offending stopped in adolescence, many continued to engage in other criminal behavior into adulthood.

A study by Carpentier, Proulx, and Leclerc (2011) also looked at offense trajectories and characteristics of youth with different offense trajectories. The sample was 351 youth assessed in an outpatient psychiatric clinic and followed for an average of 8 years. Their classification included what they termed stable highs, who were charged with at least one sexual and/or violent offense after assessment; de-escalators who were charged with other offenses, none with which were sexual and/or violent; and desisters who were not charged with any new offenses. The stable highs were characterized by significant adverse childhood experience, family dysfunction, early signs of antisocial behavior, early onset of sex offending, and versatile criminal careers. There were few differences between de-escalators or desisters.

Summary

Given the apparent heterogeneity among adolescents who engage in sexually abusive behavior, there have been multiple attempts in the literature to try to find typologies or classification systems to produce more homogenous groups. The field in the future might be better served by moving away from typology approaches to systems that are related either to etiology, various possible pathways to offending, offense trajectories, or dimensions more relevant to treatment need such as the identification of psychologically meaningful risk factors for adolescents as have been identified for adult offenders (Mann, Hanson, & Thornton, 2010).

Etiology

There has been a recent emphasis in the field to recast sexual abuse as a public health problem (ATSA, 2011; Kaufman, Barber, Mosher, & Carter, 2002). Those working with sex offenders up until this time have tended to focus on tertiary prevention by treating those engaging in sexually abusive behavior. This knowledge of sexual offenders has also been used to inform primary or secondary prevention efforts. However, to truly adopt a public health approach, one needs to understand the cause of sexually abusive behavior in adolescents and be able to identify both risk factors and protective factors that can be targeted for intervention (Hammond, 2003). Unfortunately, the field of sexual offending is significantly lacking in the identification of etiological factors in the development or onset of sexually abusive behavior in either adolescents or adults. Studies that do exist are almost exclusively cross-sectional in nature. As compared to other areas of developmental psychopathology, the research on adolescents who engage in sexually abusive behavior lacks prospective longitudinal studies that assess relevant variables over time before the behavior of interest manifests itself and which distinguish such youth from others with different problems. In marked contrast, the availability of prospective, longitudinal studies has advanced the knowledge of risk and protective factors for general delinquency and general youth violence (Lösel & Farrington, 2012).

Another inherent difficulty in determining etiology is the aforementioned heterogeneity among adolescents who engage in sexually abusive behavior. Thus, adolescents who engage in sexually abusive behavior vary on numerous factors such as degree of nonsexual delinquency, age of victim (child versus peer/adult), presence or absence of personal sexual abuse trauma, and offense trajectories. In addition, the previous section on typologies suggests several subgroups of offenders or that youth who engage in sexually abusive behavior vary on at least several psychosocial dimensions. In general, it appears that there are groups most characterized by antisocial/impulsive traits, those characterized by social and relationship deficits, those that may have early onset paraphilias, and those that appeared to have very limited psychopathology. It is likely that these groups will differ in developmental pathways and risk and protective factors that should be targeted in prevention studies. Studies that tend to "lump" all adolescents engaging in sexually abusive behavior together are unlikely to be fruitful, and true comprehensive longitudinal research is required to understand the development of sexually abusive behavior among different subgroups of youth.

Studies Focusing on General Delinquency and Youth Violence

As noted, a consistent finding in the literature is that there is a good deal of overlap in characteristics between adolescents who engage in sexually abusive behavior and adolescents who engage in general delinquent behavior or general youth violence. In addition, there are fairly consistent findings that youth who engage in both sexually abusive behavior and general delinquent behavior differ from those who engage in only sexually abusive behavior. Therefore, it is instructive to consider the risk and protective factors identified for general delinquency and violence, but a review of this literature is beyond the scope of this chapter. Much of these data have been summarized by Lösel and Farrington (2012) and the outcomes of longitudinal studies have been summarized by Hall et al. (2012). This research has identified a number of promising factors that might be targeted in prevention efforts for general delinquency and violence. Factors include impulsivity, attention deficit disorder, lack of parental supervision, lack of bonding to school and poor achievement, lack of positive peer groups, deviant peer association, and belief systems that support antisocial and aggressive behavior. There also are environmental factors related to general criminal behavior (such as economically deprived neighborhoods and those with high crime rates) that speak to broader sociological contributors to criminal behavior in youth.

Nonclinical Samples

As noted, there have been studies of nonclinical samples that have examined factors that differentiate those youth engaging in sexually aggressive behavior and those who have not engaged in sexually abusive behaviors. However, such studies are somewhat limited in that the measurement of sexual aggression tends to be one or two broad questions, generally such as have you ever done something sexual against someone's will or have you ever forced someone to do something sexual? Also, these studies are probably most relevant for sexual aggression against peers.

One model that has influenced research both in studies of the general population and research with offenders is the confluence model developed by Neil Malamuth and colleagues (Malamuth, Linz, Heavey, Barnes, & Acker, 1995; Malamuth, Sockloskie, Koss, & Tanaka, 1991). This model was mainly developed on college student samples, but some of their sexually aggressive behavior that was the focus of study would likely have occurred in adolescence. This model posits that early adverse childhood experiences of physical and/or sexual abuse and exposure to family violence lead

to increased delinquency which is then linked to sexual aggression via two pathways. The hostile masculinity pathway is characterized by viewing relationships with females as adversarial and hostile; it may also include feelings of inadequacy which are masked by anger and the need to control (Malamuth et al., 1991). The second pathway was labeled sexual promiscuity (and in later studies identified as sexual promiscuity/impersonal sex) and is reflected by a high emphasis on sexual conquest (Malamuth et al., 1991; 1995). This model was generally replicated when an additional group of college students were followed up after 10 years. From an etiological standpoint, the confluence model suggests parental violence and child abuse as key causative factors, with general delinquency being an early step in the chain to sexually coercive behavior. It should be noted that many of the early precursors to sexual promiscuity and hostile masculinity were collected retrospectively and therefore can be biased by memory distortions. Malamuth's work has influenced studies of adult offenders and adolescent offenders.

The confluence model was used as a theoretical framework for the Casey et al. (2009) study which utilized data collected as part of the Longitudinal Study of Adolescent Health. As noted in the prevalence section, the Casey study used the third wave of this longitudinal study when the average age of subjects was 22; consequently, some of the coercive sexual behaviors may not have occurred during the subjects' adolescence. However, a positive aspect of the study was that some data were collected prospectively. Data regarding adolescent behavior were collected longitudinally, although data related to childhood reports of abuse were retrospective data. The results did provide support for the confluence model in this nonclinical population. They found that child sexual abuse was predictive of age at first sexual experience and number of sexual partners and age at first sexual experience was related to sexually coercive behavior reported when the sample was adults. In addition, child sexual abuse had a direct pathway to sexual coercive behavior. In this study, child physical abuse was found to be directly related to impersonal sexual beliefs, delinquent behavior, problems with alcohol, and co-occurrence of sex and drinking. However, only delinquent behavior had a direct impact on sexual coercive behavior.

The second study of a nonclinical population was the Borowsky et al. (1997) Minnesota student survey. Their results were also consistent with the confluence model. They found that sexual aggression was related to experiences of intra-family or extra-family sexual abuse, witnessing family violence, frequent use of illegal drugs, anabolic steroid use, daily alcohol use, gang memberships, high levels of suicide risk behavior, and excessive time spent "hanging out." They also found that emotional health and connection with friends, adults, and communities was a protective factor for male adolescents and academic achievement was a protective factor for female adolescents.

This data with nonclinical samples would suggest that at least for sexual coercive behavior with peers, targets for prevention programs would be early histories of abuse and that factors related to general delinquency would also be promising targets for the prevention of general sexual coercion. However, although some of the data in these studies could be considered longitudinal, much of it was retrospective and the types of sexual aggression being reported are probably less extreme than that seen in clinical populations. These studies also suggest that sexual abuse may have a direct effect on sexually abusive behavior and indirect effects on sexually aggressive behavior through the concept of sexual promiscuity/impersonal sex.

Studies of Adolescents Who Have Engaged in Sexually Abusive Behavior

There have been a series of studies by Knight and colleagues (Daversa & Knight, 2007; Johnson & Knight, 2000; Knight & Sims-Knight, 2004) and Hunter and colleagues (Hunter et al., 2003; Hunter, Figueredo, & Malamuth, 2010) that have investigated developmental pathways to adolescent sexual abusive behavior. These studies were retrospective, including reports of early childhood abuse and studied adolescents who had already engaged in sexually abusive behavior. These studies as a whole used path analytic and structural equation modeling approaches that at times produced rather complex models of potential risk factors that need replication. Some of these findings are highlighted below.

Daversa and Knight (2007) investigated developmental pathways to sexual coercion against children in a group of 329 adolescent offenders. It should be noted that this appeared to be a high risk group: the sample had an average age of first arrest of 9.55 years, an average of 3.43 arrests, only 7 % had not been in a juvenile detention facility, and they were sampled from inpatient treatment facilities. Variables in the study were derived from subscales of the Multidimensional Assessment of Sex and Aggression (MASA; Knight & Cerce, 1999). The relationship of sexual abuse, physical abuse, and emotional abuse was investigated both in terms of direct effect on choice of child victim and indirectly through the constructs of psychopathy, sexual inadequacy, sexual fantasy, and child fantasy specifically. They found four pathways to choice of child victim by adolescents who engaged in sexually abusive behavior. These were (Daversa & Knight, 2007; pg. 1323):

(a) From emotional abuse and physical abuse, through psychopathy and sexual fantasy, to child fantasy and child victim
(b) From emotional abuse and physical abuse, through sexual inadequacy, sexual fantasy, and child fantasy, to child victim

(c) From emotional abuse and physical abuse, through sexual inadequacy, to child fantasy and child victim
(d) From sexual abuse directly to child victim

To better understand the model, it is also important to understand how some of the constructs are defined. The concept of psychopathy was measured from subscales of the MASA tapping impulsivity, "gaming" and superficial charm, and pervasive anger, reflecting a general criminal or antisocial construct. Sexual inadequacy reflected erectile dysfunction, sexual anxiety, and female anxiety reflected more internalizing symptoms. The construct of sexual fantasy reflected sexual preoccupation, hypersexuality, and sexual compulsivity. This model is consistent with other formulations reflecting delinquent/criminal pathways, sexual pathways, and possibly those related to internalizing behavioral problems. In addition, this study included emotional abuse which seemed to be a stronger predictor of psychopathic traits than physical abuse.

Hunter et al. (2010) investigated developmental pathways to "social and sexual deviance" in a group of 256 youth with "hands-on" sexual offenses recruited from residential treatment programs in five states. They investigated the direct and indirect relationship of four exogenous variables, "extent of exposure to pornography prior to age 13, extent of exposure to male-mediated violence prior to age 13, extent of physical abuse by a father or step-father prior to age 13, and extent of sexual abuse by a male perpetrator prior to 13" (pg. 142) to nonsexual delinquency and number of male child victims. Intervening constructs were psychosocial deficits, psychopathic and antagonistic attitudes, hostile masculinity, and pedophilia measured by a self-report measure of sexual attraction. Exposure to pornography, physical abuse, and sexual abuse impacted psychosocial deficits, which in turn had direct effects on hostile masculinity, and psychopathic and antagonistic attitudes. In addition, psychopathic and antagonistic attitudes also showed a path to hostile masculinity. Hostile masculinity was related to pedophilia and predicted the total number of male victims. Sexual victimization had a direct pathway to total number of male victims but, in addition, had an indirect pathway through pedophilia.

Knight and Sims-Knight (2004) have also used similar measures to investigate pathways for severity of sexual coercion against peers and adults by adolescents who engaged in sexually abusive behavior. Similarly, they found pathways from sexual abuse and physical/verbal abuse to the extent of coercive behavior through antisocial behavior, callous unemotional traits, and sexual fantasy. It is of note that, unlike other studies looking at victim age, there was no direct pathway from sexual abuse to degree of sexual coercion. Thus, while a personal history of sexual victimization plays a role in the onset of sexual offending for some adolescents who engage in sexually abusive behavior, it is not a uniform or necessarily direct pathway.

One final study to note is by Johnson and Knight (2000), which found that alcohol abuse prior to age 13 also had both direct and indirect effects on degree of sexual coercion, which is consistent with the finding of Borowsky et al. (1997).

Summary

Integrating the studies reviewed related to typologies and studies related to etiologies, it appears that across these various studies early adverse child experiences have shown correlations both directly and indirectly to sexual coercion, degree of coercion, and age of victim choice. Such adverse childhood experiences seem to lead by various pathways to sexually abusive behavior that involve social competence, general antisocial behavior/attitudes, hostile masculinity, and sexualization. However, as noted, these data (even studies using sophisticated data analytic techniques) are correlational and the studies are cross-sectional. Secondly, negative sequela to childhood abuse are not specific to the onset of sexual offending and are implicated in the development of a number of psychiatric disorders (Burnam et al., 1988) as well as general youth violence and delinquency (Feiring, Miller-Johnson, & Cleland, 2007; Mass, Herrenhohl, & Sousa, 2008). It is not clear whether childhood maltreatment is a general risk factor for dysfunctional behavior in youth rather than one linked to specific disorders. Thirdly, not all youth who engage in sexually abusive behavior report a history of childhood abuse or victimization, with wide variations in reported rates depending on such factors as whether abuse is assessed pretreatment or posttreatment, whether the youth victimizes males or females (Worling, 1995), and whether the sample is from outpatient programs or residential programs (Zakireh, Ronis, & Knight, 2008). History of sexual abuse may be more relevant for those youth who offend against children than against adults (Jespersen, Lalumière, & Seto, 2009). In a longitudinal study of 224 males sexually abused as children followed into adulthood, only 11.6 % were identified as committing a later sexual offense using criminal justice records in the UK (Salter et al., 2003). In a 45-year follow-up study of 2,759 children sexually abused and a group not abused, Ogloff, Cutajar, Mann, and Mullen (2012) found that 0.1 % of the non-abused group later completed a sexual offense as compared to 1.1 % of the sexually abused children. Although, sexual abuse may be a risk factor for future sexual offending, these studies suggests that most males who are victims of sexual abuse are never identified as committing further sexual offenses. While some advances have been made in gaining perspective on potential

etiological factors and processes related to adolescents who engage in sexually abusive behavior, a large number of unanswered questions remain. Without prospective studies, many questions will probably remain unanswered.

Sexual Offense Recidivism Among Youth Who Have Sexually Offended

Recidivism refers to reoffending (or repeat offending) among persons who had previously been detected for an offense of interest, such as a sexual or violent offense. However, determining "true" recidivism rates for both adult and adolescent offenders is difficult for a number of reasons.

One significant factor is that sexual crimes are underreported. In a national probability sample of adult women, Hanson, Resnick, Saunders, Kilpatrick, and Best (1999) found that 437 reported a rape before age 12 and only 11.9 % of these were reported to the police. Truman and Planty (2012), in data from the National Crime Victimization Survey, which include individuals age 12 and above, found that 27 % of rapes, forcible rapes/sexual assaults, were reported to the police which was significantly lower than previous years where the rate reported to the police is generally around 50 %. Finkelhor et al. (2008), in data from the National Incident Study of Missing, Abducted and Runaway Children, found that only 30 % of sexual offenses against children were reported to the police. Even when reported to the police there may not be an arrest, as Finkelhor et al. (2009) found that for sexual offenses by juveniles reported to the police, 30 % led to an arrest.

In addition, there is evidence that one finds higher re-offense rates if law enforcement/criminal justice data are supplanted by other data sources, at least for adults. Marshall and Barbaree (1988) found that the rate of sex offenses by adult offenders increased by 2.4 times when less formal reports of sexual offending than those to law enforcement were included. Similarly, Marques, Day, Nelson, and West (1993) found that reviewing parole office records produced a 33 % increase in estimates of the number of serious crimes committed by sex offenders (e.g., crimes that were recorded and/or resulted in release violations but were not necessarily charged for more formal prosecution). Thus, a significant number of subsequent sexual offenses are managed as probation or parole violations and may not register as new, independent sexual crimes, at least for adults. In addition, research indicates that even when sex offenses are reported, particularly those involving children, less than 70 % of those offenses are processed through the legal system. Falshaw, Bates, Patel, Corbett, and Friendship (2005) found that collecting evidence of recidivism for offense-related sexual behavior from multiagency information increased the identification of any sex offense by fivefold relative to just a reconviction rate. The implication of this study was that convictions represent perhaps half of the sex offenses perpetrated by sex offenders. This type of data are limited for adolescents. Bremer (1992) reported that for 193 youth who completed a treatment program, 6 % were officially identified as recidivist, while 11 % self-reported reoffending.

Length of follow-up will also significantly impact observed re-offense rates, and many juvenile studies have shorter follow-ups than the 5 years generally considered a minimum follow-up period. For adult offenders, some have suggested that 20 year rates of reoffending are at least twice that of 5 year rates, although others have questioned this multiplier (Wollert & Cramer, 2012). It is clear that the longer the follow-up period, the higher the identified re-offense rate for adult offenders. Similarly, increased sexual offense recidivism has also been found for adolescent offenders when they are followed for longer periods of time (Gerhold, Browne, & Beckett, 2007). They looked at studies with 3-, 5-, or 7-year follow-up with the largest increase in recidivism rates found between studies with 3- or 5-year follow-up compared to the 7-year follow-up. However, across studies, only 236 subjects had at least 7 years of follow-up, and one of these was the Långström (2002) study which included exhibitionists, a group with high recidivism rates. Therefore, the increase may be somewhat related to type of subjects followed and not just the longer follow-up period.

Worling, Litteljohn, and Bookalam (2010) presented results of a long-term follow-up study (Mean follow-up 16 years; Range 12–20 years) of the Worling and Cruwen (2000) study (Mean follow-up of 6 years; Range 2–6 years). At the first follow-up, the recidivism rate of sex offense for the treatment group was 5 % and 18 % for the comparison group. At the longer term follow-up, the treatment group had a recidivism rate of 9 % versus 21 % for the comparison group. While approximately double, this is not as great an increase as is found in studies of adults.

There are also multiple of other factors that can impact reported rates (Gerhold et al., 2007). Studies use different definitions of recidivism: some use convictions, others use charges or arrests, and some use self-report. Most studies of adolescents who engage in sexually abusive behavior to date have included only treated subjects (Fortune & Lambie, 2006) and some have not controlled for time at risk (Hagan, Gust-Brey, Cho, & Dow, 2001). Some studies such as Långström (2002) included subjects aged 15–20 and not just adolescents.

Given these limitations, the most comprehensive review of recidivism rates is the meta-analysis by Caldwell (2010). He identified 61 data sets with a total of 9,726 juvenile offenders with a weighted mean follow-up of 58.4 months. He included only studies where the youth was under 18 at the time of the offense and excluded samples that were prescreened and selected because of severe mental illness or developmental

delays. Approximately half (e.g., 29) of these studies had been published in peer-reviewed journals while the remainder were unpublished papers, government reports, data sets, or unpublished dissertations. Recidivism was defined as arrests or convictions; the sexual re-offending rate was 7.32 % for approximately 5 years, but the general recidivism rate was 43.2 %. Sexual offense recidivism rates were higher during adolescent follow-up periods than during adult follow-up, despite the former studies characterized by time frames that were half of the latter studies.

It should be noted that there are more restricted meta-analyses that have found rates of sexual reoffending from 12 to 14 % among adolescents who have engaged in sexually abusive behavior. Reitzel and Carbonell (2006) looked at only studies that had a treatment and some type of comparison group, while Gerhold et al. (2007) and McCann and Lussier (2008) limited their meta-analysis to studies that were investigating risk factors for recidivism, therefore excluding many of the studies in the Caldwell (2010) meta-analysis. Similar comprehensive meta-analyses with adult sexual offenders find higher rates. For example, the Hanson and Bussière (1998) meta-analysis of primarily adult sexual reoffense (although three samples were adolescents and three samples were mixed) found a recidivism rate of 13 % over approximately 5 years of follow-up. Hanson and Morton-Bourgon (2009), in their meta-analysis of risk assessment instruments, found an average re-offense rate of 11.5 %; this study included 18 studies with adolescent samples. If one compares the results of the Caldwell meta-analysis to the adult meta-analysis, adolescents appear to have lower rates, although the more limited adolescent meta-analyses presented above indicate rates which are similar to those found in studies of adult sexual offenders. However, this difference may be less important than the fact that most adolescents are not detected for future sexual offense and that there is significant variability between studies, with some investigations showing relatively high rates.

There are two studies involving presumably high risk adolescents who had engaged in sexually abusive behavior; youth in these studies were those identified as possibly meeting statutory criteria for civil commitment but were not committed; Milloy (2006) studied 21 juvenile sex offenders in Washington and Hagan, Anderson, Caldwell, and Kemper (2010) studied 12 juveniles in Wisconsin. In the Milloy study, 33 % were subsequently convicted for a new felony sex offense and one for a misdemeanor. Hagan et al. (2010) reported a 42 % rate of sex offender recidivism during a 5-year follow-up. It is of note that these youth represent a small proportion of adolescent offenders, and in the Milloy (2006) study they represented only 1 % of juvenile sex offenders paroled over a 13-year period. These rates are similar to adult offenders referred for civil commitment, but not committed (Milloy, 2003). Other studies of "pre-selected" groups of adolescents who have engaged in sexually abusive behavior, such as those evaluated in secure residential forensic settings, appear to have high rates of sexual reoffending (Lussier et al., 2012). These variations in rates stress the importance of trying to identify the higher risk youth earlier in their criminal careers.

Editor's Comment: A reliance on Caldwell's (2010) meta-analysis for sexual offense recidivism of adolescents who sexually offend is problematic for a variety of methodological reasons. Meta-analysis of adult sexual offenders (e.g., Hanson & Bussière, 1998) relied primarily on sexual offense recidivism rates of sexual offenders who had not received treatment. However, not unexpectedly, most of the subjects covered in the Caldwell study was exposed to some form of sex offender treatment: 24 % in community programs, 21 % in residential programs, and 18 % in secure programs. Of note, the youth placed in secure settings demonstrated somewhat higher rates of sexual offense recidivism despite a follow-up period that was an average of 9 months less than the other two groups. In addition, in the Caldwell study as in most adult meta-analyses of sexual offense recidivism, methodological techniques such as survival analysis were not utilized and most, if not all, studies did not control for actual time in the community (Caldwell, personal communication). Survival analysis provides a control for sample censorship, particularly opportunity time to commit an offense; that is, as an example, time that persons are reincarcerated are controlled by subtracting that time from opportunity time to reoffend. Caldwell's study showed that 43 % of the total sample of adolescents who had sexually offended were rearrested or reconvicted for a nonsexual offense during their adolescence or early adulthood, suggesting that a significant number of the samples studied were potentially detained for some indefinite period of time and not available to commit a sexual offense during the study period. In studies of adult sexual offenders, where survival analysis is utilized, identified rates of sexual offense recidivism can be increased by a factor 1.5 (e.g., Prentky, Lee, Knight, & Cerce, 1997).

Assessment

Assessment plays a key role in the characterization and management of youth engaged in sexually abusive behavior. This section will review the purposes of the evaluation, appropriate and inappropriate uses, briefly review the content of evaluations, describe the use of the risk/need/responsivity principles to guide assessment, discuss research literature on factors related to risk/need, review specific risk instruments, and review more controversial issues such as physiological assessment of sexual arousal, viewing time, and polygraph.

Purpose of Evaluations

Assessments of youth engaged in sexually abusive behavior are designed to serve the following purposes, among others:

1. Identify factors that may be related to youth's individual risk.
2. Identify treatment needs or criminogenic needs that if addressed might reduce risk
3. Identify strengths or protective factors of the youth and family
4. Identify factors that may impact on the youth's response to treatment such as significant psychiatric disorders, intellectual disabilities, and learning disabilities.
5. Assist decision makers in terms of level of supervision, level of structure, and intensity of services needed.

Evaluations are not appropriate to determine guilt or innocence and cannot determine whether a youth fits the "profile" of a "sexual offender." As is clear, this group of youth who have engaged in sexually abusive behavior is clearly heterogeneous, and there is no one profile for youth who engage in sexually abusive behavior.

Clinical and Forensic Evaluations

Assessment of adolescents who have engaged in sexually abusive behavior can be viewed in two broad contexts, clinical and forensic. An evaluation is considered forensic in nature when it is a part of, or related to, proceedings within the legal system. Clinical evaluations provide information to assist professionals working with the youth and his/her family and are not a part of the legal decision process.

Not all adolescents who have engaged in sexually abusive behavior are prosecuted, and reasons for this vary across jurisdictions. In some instances, the youth is already involved in the state social services system due to his/her own history of abuse and neglect, and the system chooses to handle the situation without prosecution since the youth is already being overseen by the state system. Evaluations of youth who have not been prosecuted and evaluations that occur after adjudication and disposition and that have no legal implications can be considered clinical since these evaluations inform the treatment process rather than the legal process. Clinical evaluations provide information about risk, needs, and responsivity to assist those working with the youth and his/her family in developing management strategies and treatment goals and in treatment planning.

Juvenile courts have a rehabilitation focus rather than a punishment focus and are designed to be less adversarial than the adult criminal system. However, juveniles have similar protection and rights as adults do in the court proceedings (In re Gault. 387 U.S. 1, 1967). At times, the court utilizes evaluations to inform legal decisions and these evaluations are considered forensic in nature since they provide information that serves the legal system (Hoberman & Jackson, 2014, 2015). Forensic evaluations differ from "clinical" evaluations and are informed and guided by more traditional forensic concerns (e.g., Greenberg & Shuman, 1997; Heilbrun, 2003).

When forensic type evaluations are completed is an area of discussion and at times is controversial. General practice is for evaluations to occur post-adjudication and be utilized to help inform disposition. Pre-adjudication evaluations raise concerns regarding self-incrimination and that the evaluation could subtly impact the outcome of the adjudication phase of the legal proceedings. Concern about pre-adjudication evaluations being less reliable and valid has also been raised. This concern notes that the youth and family may be less forthcoming due to their concern that the evaluation may impact a finding of guilt within the court proceeding. However, there is little data to support this belief and youth and families do not "automatically" become more honest post-adjudication when there may still be significant concern that the evaluation may impact the youth's removal from the community and a possible placement in a residential or correctional facility.

While evaluations for youth involved in the juvenile justice system are best conducted post-adjudication, thereby avoiding any issues of self-incrimination, the reality is that there are situations or jurisdictions in which this may not occur. One of the situations involve potential plea-bargains as many judges and prosecutors are unwilling to consider a plea-bargain or include community-based treatment as a part of the plea-bargain without information about the youth's risk for future sexual offending. Another situation involves courts choosing to postpone taking official action on the criminal charge and instead monitoring the youth's progress in treatment and possibly dismissing the charge at a later date.

Each evaluator has to weigh the ethical issues related to pre-adjudication evaluations. At a minimum, it is recommended that there needs to be clear information that the youth did engage in the sexually abusive behavior. This information may be provided by: (1) a child protective services agency investigation's finding substantiating the abuse; (2) the youth admits to the abusive behavior; and/or (3) the behavior was observed by a reliable witness. In addition the youth, his/her guardian or custodian and his/her legal representation should understand the potential risk of a pre-adjudication evaluation and provide informed consent to the evaluation.

Overview of Assessment Process

This chapter is not intended to provide detailed clinical instructions for completing assessments of adolescents engaging in sexual behavior and such detailed assessments can be found in Prescott (2006) and O'Reilly and Carr

(2004). However, an overview of the assessment process is provided.

O'Reilly and Carr (2004) and Center for Sex Offender Management (CSOM, 2007) have identified factors related to a good assessment which are worth noting.

1. Assessments should be developmentally appropriate.
2. Assessment methods should have some research support.
3. Assessments should be approached as being collaborative and the youth and family should be treated with respect.
4. Evaluators should use multiple sources of information.
5. Evaluations should focus on both strengths and weaknesses.

Evaluations should at a minimum include detailed interviews with the youth and youth's caretakers; review of information regarding the sexually abusive behavior; collection and review of information from other sources such as social services, police, court, school, previous mental health records, past evaluations, and past treatment records.

Depending on the nature of the case, at times the use of more structured standard psychological tests and sex offender specific tests may be of assistance. For some youth, where there is suspicion of significant intellectual disabilities or learning disabilities, a more detailed psychological assessment may be warranted and for some youth with suspicion of more serious behavioral, psychological, or psychiatric difficulties, a standardized behavioral checklist and validated measures of psychopathology and personality may also be warranted.

At times specialized scales of sexually abusive behavior are also used with the most frequent being the adolescent version of the Multiphasic Sex Inventory (Nichols & Molinder Assessment, Inc.), the juvenile version of the Sexual Adjustment Inventory (Lindeman, 2005), and the Adolescent Cognition Scale (Hunter, Becker, Kaplan, & Goodwin, 1991). All of these have limited research support and Fanniff and Becker (2006) described the Adolescent Cognition Scale as less than adequate. Knight and his colleagues (Knight, Prentky, & Cerce, 1994) reported on the development of the Multidimensional Assessment of Sex and Aggression which has undergone revisions for adolescents (Knight & Cerce, 1999). It is now commercially available as the Multidimensional Inventory of Development of Sex and Aggression (www.MIDSA.com). Theoretically, it covers many of the areas that appear relevant to the risk and needs of adolescents who engage in sexually abusive behavior and is a promising instrument. There are also a number of physiological assessment procedures such as measurement of penile tumescence, viewing time, and polygraph that are more controversial when used with adolescents, and these will be reviewed in a separate section.

For the last 10 years, there has been increased adoption of the risk/need/responsivity (RNR) framework to guide both treatment and assessment of youth who engage in sexually abusive behavior (CSOM, 2007; Murphy, Page, & Ettelson, 2005; Prescott, 2006). In the risk/need/responsivity model, risk refers to factors within the youth or in the youth's environment that are associated with increased risk of delinquent and/or sexual reoffending. The risk principle states that the intensity and intervention and level of supervision should be based on the youth's level of risk. High risk youth should receive the most intense treatment and most intense supervision, while youth with lower risk should receive less intense intervention and less supervision. The need principle refers to factors that can be changed and if changed have the potential to reduce the risk for future delinquent and/or sexual offending behavior. The need principle states that the majority of treatment needs to focus on those needs that have been established to have a direct link to reoffending. The responsivity principle has two components: one related to treatment itself, which is sometimes referred to as general responsivity principle which suggests that effective methods should be used, and the second is sometimes referred to as specific responsivity, which suggests that one assesses and addresses those factors that can be related to the youth's ability to benefit from treatment. Common responsivity issues include, among others, intellectual level, learning disabilities, severe psychiatric disorder, gender, religious affiliation, and cultural/ethnic issues/variables.

It is recognized that youth who engage in sexually abusive behavior and their families may experience a variety of problems that may not be directly linked to their offending. Youth and their caretakers may have significant psychiatric disorders, past trauma, or substance abuse problems which also need to be assessed and addressed for the youth's and families' overall well-being. These issues need to be assessed and addressed in treatment in addition to factors related to their specific offenses and their risk of reoffending.

Assessing Risk and Need in Youth Who Have Engaged in Sexually Abusive Behavior

The application of the RNR principal to the assessment and intervention with youth who engage in sexually abusive behavior requires assessment methods to identify risk and needs. Given the high rates of general delinquency in the adolescent sex offender population, general risk/need assessments should be part of a comprehensive evaluation. There are assessment tools available to predict general delinquent recidivism and violent recidivism such as the Youth Level of Service/Case Management Inventory (Hoge & Andrews, 2009) and the Structured Assessment of Violence Risk in Youth (Borum, Bartel, & Forth, 2006). These have been proven to have moderate validity (Olver, Stockdale, & Wormith, 2009), and there is preliminary evidence that if

such tools are used to guide interventions, there is a reduction in general reoffending (Vieira, Skilling, & Peterson-Badali, 2009).

There is also a need for assessment tools that specifically assess risk and needs related to sexual reoffending. The state of risk assessment in juveniles is still in the early developmental phase as compared to research with adult offenders (Beech, Fisher, & Thornton, 2003; Hanson & Morton-Bourgon, 2004, 2005; Mann et al., 2010), and there is limited data on dynamic risk factors.

There have been quantitative reviews of risk factors related to sexual reoffending in adolescents (Worling & Långström, 2003, 2006; Gerhold et al., 2007) and one meta-analysis (McCann & Lussier, 2008). Although there are some inconsistencies across studies, there is some support that risk and need factors for this population are those that appear to be related to the concept of sexual deviation (such as male victims, stranger victims, child victims, and previous sexual offenses) and those related to anti-sociality. McCann and Lussier grouped risk factors into a sexual deviant domain and an anti-sociality domain and found that each domain was significantly related to sexual offense recidivism. However, the effect sizes were small (e.g., only 0.11 and 0.10, respectively). Some studies with adolescents also indicate that adverse childhood experiences may be linked to sexual recidivism. For example, Carpentier and Proulx (2011) found parental abandonment and sexual victimization related to sexual recidivism. Being a victim of sexual abuse, however, is not found to be risk factor in all studies (Worling & Långström, 2003).

As one can see, it is still not clearly established what the most promising variables are for predicting reoffending in juveniles. One significant methodological problem is the low base rate of reoffending over short follow-up periods, meaning that in most studies there are low numbers of sexual reoffenses. Other methodological issues include the definition and measurement of recidivism, length of follow-up, and whether the youth are followed only in adolescence, only for charges as an adult or followed in both adolescence and into adulthood.

There have been a number of risk assessment instruments developed for adolescents based on the rather limited empirical data available on risk factors for this group.

Risk Assessment Instruments

In times of limited resources, accurate risk assessment allows for a more judicious and appropriate allocation of resources so that interventions are provided to youth based on risk and criminogenic needs. Generally, that means providing more comprehensive and intensive interventions for those youth who post the most risk for future offending and not providing unnecessary intervention for youth who are identified as at lower risk and lower need.

Risk assessment tools or measures utilize different means of combining empirically or theoretically supported risk factors. For youth who commit sexual offenses, the development of empirically validated risk assessment instruments has lagged relative to such activity regarding adult sexual offenders. The literature on risk factors for adolescent sexual offending is more limited than that for adults (e.g., McCann & Lussier, 2008; Worling & Långström, 2006). Fewer risk assessment instruments have been developed and, on the level of individual studies, the empirical results have been viewed as less impressive than those that have been created and studied for older sexual offenders.

Generally, in the literature concerning risk assessment, two types of risk assessment instruments have been proposed and studied: actuarial risk assessment instruments and structured professional judgment. First, following directly from research that identified static or historical characteristics of sex offenders (particularly meta-analyses), risk assessment instruments were developed largely through a so-called "actuarial" methodology; these actuarial risk assessment instruments can be considered as attempts to develop adjusted base rates for groups of sex offenders with particular numbers and types of easily measured risk factors. Actuarial methods are typically ones that rely on objectively identified factors associated with an outcome of interest; an actuarial scale specifies *which factors* are selected for examination, and the relative *"weight"* that factor has as part of the assessment of some outcome. Actuarial scales are statistical means of selecting and combining easily obtained information and examining the degree to which those particular variables are associated with some future outcome (e.g., predictive accuracy). For adult sexual offenders, starting in the mid-1990s, several actuarial scales were developed that were repeatedly demonstrated to show moderate predictive accuracy of sex offender recidivism; these actuarial instruments provide estimates of the degree of risk (probability) of a future sex offense for sex offenders with particular numbers or degree of risk factors (Doren, 2002; Hanson & Bussière, 1998; Quinsey, Harris, Rice, Cormier, & McCleskey, 2005). Different instruments rely on different "outcomes" to measure sex offender recidivism, ranging from convictions to arrests; other instruments rely on broader outcomes in an effort to address the dramatic underreporting of sexual offending.

In contrast to actuarial methods, measures of Structured Professional (Clinical) Judgment represent an explicit attempt to incorporate both empirical findings and clinical experience in making determinations of relative risk for sexual reoffending. Measures of structured professional judgment require evaluators to: (1) systematically consider a specified list of potential risk factors and (2) using a detailed manual for additional structure to rate the degree to which each factor may be

present (e.g., typically assess the degree to which there is no, some, or good evidence for the presence of a characteristic). On the basis of the "intensity," number of or interaction among risk factors, the evaluator determines if the individual is low, medium, or high risk. In addition, risk level per structured professional judgment can also be a function of additional risk factors or information not explicitly considered by the individual items of a particular instrument.

For adolescents who have engaged in sexually abusive behavior, there are two instruments that are considered structured professional judgment instruments: the Estimate of Risk of Adolescent Sex Offender Recidivism (ERASOR; Worling, 2004) and the Juvenile Sex Offender Assessment Protocol-II (JSOAP-II; Prentky & Righthand, 2003). There is one adolescent specific instrument that would be considered an actuarial instrument, which is the Juvenile Sex Offense Recidivism Risk Assessment II (JSORRAT-II; Epperson, Ralston, Fowers, DeWitt, & Gore, 2006). Also, there are a number of studies (Viljoen, Mordell, & Beneteau, 2012) that have applied the STATIC-99 (Hanson & Thornton, 1999) to juvenile populations, but many of the studies using the STATIC-99 with adolescents have not been peer-reviewed or published. In addition, the developers of the Sex Offender Risk Appraisal Guide (SORAG) (Quinsey, Harris, Rice, & Cormier, 2006) have noted that the development and validation samples have included some adolescents, and therefore they view it as a possible measure for adolescent offenders, although to our knowledge it has not been tested in an adolescent only population. In this review, we will focus primarily on those scales developed by adolescents and used widely with adolescents in the United States and Canada.

In the Unites States (McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2010), in community programs and residential programs, the ERASOR is used in 53.1 % and 48.8 %, respectively, while the JSOAP-II is utilized in 61.1 % and 58.2 %, respectively, and the JSORRAT-II in 18.5 % and 18.1 %, respectively. Generally, almost all treatment programs in the USA report using at least one instrument (81.1 % of community programs and 76.5 % residential programs). In Canada, 60 % of programs for adolescents with sexually abusive behavior reportedly used the ERASOR, 26.7 % used the JSOAP-II, and 66.7 % used at least one of the instruments.

Actuarial Measures for Adolescent Sexual Offense Recidivism

The Juvenile Sex Offense Recidivism Risk Assessment Tool–II

The JSORRAT–II (Epperson et al., 2006) is currently the only *actuarial* tool designed for adolescents (ages 12–17) who have been detected for a sexual offense. Initially, it was developed on a sample of 636 youth adjudicated for a sexual offense in Utah between 1990 and 1992. The JSORRAT-II consists of 12 easily scored historical items including number of adjudications for sex offenses, prior sex offender treatment status, and any placement in special education. A manual specifies the criteria for rating these items. Initial reliability ratings for item agreement were quite high (ICC = 0.91). Although a summary of validity studies will be discussed in a separate section, some note will be made of the validation on the JSORRAT-II. Initially, the JSORRAT-II demonstrated very good predictive validity or accuracy (AUC = 0.89) in the Utah construction sample of an inclusive set of 636 juveniles (ages 11–17) adjudicated for a sexual offense in 1990–1992. However, in a cross-validation of 538 male juveniles (ages 11–17) adjudicated in Utah for a sexual offense in 1996–1997, the AUC was 0.65, showing more shrinkage than expected (Ralston & Epperson, 2007). The base rate for sex offense recidivism was 14 % in Utah. A subsequent cross-validation study in Iowa of a nearly exhaustive sample of 318 juveniles between 11 and 17 adjudicated for a sex offense also found an AUC of 0.65. However, the base rate in this sample was 7 % over a shorter follow-up period; in addition, JSOs in Iowa were also subject to registration and community notification. Preliminary findings suggested the measure was more effective in predicting recidivism which occurred during adolescence than adulthood. Although still a significant predictor, the shrinkage of the AUC in the second study suggested the need for cross-validation of instruments. Recently, Ralston, Epperson, and Edwards (2014) examined the predictive validity of the JSORRAT-II using an exhaustive sample of 11- to 17-year-old male juveniles who had committed a sexual offense between 2000 and 2006 in Iowa. Scoring reliability was quite high for total score. The validity of the measure in predicting sexual offender recidivism was 0.70; it did not predict nonsexual recidivism (e.g., general criminal recidivism). The instrument performed better for youth who were younger at the time of their index offense who had longer times at risk, although that result might be an artifact of shorter time at risk for youth who were older at the time of their most recent offense.

The JSORRAT–II has emerged as a promising option for professionals attempting to understand risk. Its items derive from careful data analysis and reflect findings from elsewhere in the research on youth who have sexually abused.

Structured Professional Judgment for Adolescent Sexual Recidivism

Juvenile Sex Offender Assessment Protocol–II

The Juvenile Sex Offender Assessment Protocol-II (JSOAP-II) "is a checklist whose purpose is to aid in the sys-

tematic review of risk factors that have been identified in the professional literature as being associated with sexual and criminal offending" (Prentky & Righthand, 2003). Originally, the scale consisted of 23 items that were rationally identified from the research literature on juvenile and other offenders. Later editions of the JSOAP-II were expanded to 26 and 28 items falling on four subscales: Sexual Drive/Sexual Preoccupation, Antisocial, Impulsive Behavior, Clinical Intervention, and Community Adjustment. The current version of the JSOAP-II, along with a scoring manual, is available from the website of the Center for Sex Offender Management at www.csom.org.

Prentky, Harris, Frizzell, and Righthand (2000) originally tested the first edition of the JSOAP on a sample of 96 male, inner-city adjudicated and non-adjudicated youth (ages 9–20), of whom 75 were followed up for 12 months. Internal consistency reliability ranged from 0.68 to 0.85 across the subscales. Later, a subsequent study examined a 26-item version of the JSOAP on 134 male sexual offenders (ages 7–20) from rural child welfare and correctional settings. This revised JSOAP showed similar internal consistency ratings to the original version (0.64–0.95) (Righthand et al., 2005). Factor analysis also identified a four-factor solution that was consistent with the four originally created scales, and the instrument was revised to the current 28-item scale.

Estimate of Risk of Adolescent Sex Offender Recidivism

The Estimate of Risk of Adolescent Sex Offender Recidivism (ERASOR 2.0) is "an empirically-guided checklist to assist clinicians to estimate short-term risk of a sexual reoffense for youth ages 12–18" (Worling, 2004, p. 1). Explicitly modeled on other structured professional judgment scales (particularly the Sexual Violence Risk-20 or SVR-20), the scale items consist of 16 dynamic and 9 static risk factors in five categories. The five categories are Sexual Interest, Attitudes and Behavior, Historical Sexual Assault, Psychosocial Functioning, and Family/Environmental Functioning and Treatment. Each of the 25 items is scored as absent, partially/possibly present, and present. As with other structured professional judgment instruments, the total score of the ERASOR can be used to make a determination of low, medium, or high risk.

Initially, Worling (2004) examined properties of the ERASOR with a sample of adjudicated male adolescents ($n=136$, ages 12–18) receiving treatment in community-based programs in Canada ($n=45$) or at a specialized residential treatment center in Minnesota (n–91). Initially, 28 trained masters or doctoral level professionals completed scale ratings after clinical assessments. Inter-rater reliability was acceptable for most scale items (average intra-class correlations coefficient was 0.60). Overall, inter-rater reliability for clinical risk estimates was excellent at 0.92. Internal consistency reliability for total score was 0.75.

Validity

Up until recently, there have been multiple individual studies of each of these instruments and if one read the existing individual studies, it would be difficult to draw firm conclusions due to their apparent variability in findings. However, a recent meta-analysis (Viljoen et al., 2012) of the JSOAP-II, ERASOR, JSORRAT-II, and STATIC-99 not only provides some clarity but also raises a number of questions. The authors were able to identify nine studies that assessed the relationship of scores of the JSOAP-II to sexual reoffending and seven to general reoffending. There were ten studies that investigated the relationship of the ERASOR to sexual reoffending and seven that looked at the relationship of the ERASOR to general offending. It should be noted that there were additional studies that looked at certain subscales for both the ERASOR and JSOAP-II. Viljoen and colleagues were able to identify seven studies of the JSORRAT-II and eight studies that looked at the total score of the STATIC-99 in adolescent populations. The AUCs for the four instruments were between 0.64 and 0.67 for sexual offending, and the JSOAP-II showed an AUC of 0.66 for predicting general reoffending while the ERASOR showed a 0.59 AUC for general reoffending. Data are not available from the JSORRAT-II or STATIC-99 on general offending in this population. All of these AUCs would be considered significant and would be what considered in moderate to low moderate range. Viljoen et al. also reported on the few studies that directly compared the instruments, and there were three studies that compared the JSOAP-II to the ERASOR and two studies that compared the JSOAP-II to the STATIC-99. In all cases, there was no significant difference in the predictive validity of the instruments.

It appears that across studies these instruments are better than chance in identifying recidivism. However, an important caveat is that there is significant variability between studies. Therefore, the results are not consistent across studies. Viljoen and colleagues attempted to analyze factors that could be moderators. Factors they investigated were setting (mental health or other type setting), whether youth were in a treatment program or not, publication bias (published or unpublished), allegiance effects (whether any of developers were authors), country where the studies were conducted (United States or others), sample size (greater or less than mean of 150), base rate of offending (greater or less than 10 %), length of follow-up (greater or less than 5 years), and

inter-rater reliability (strong inter-rater or no information). However, none of these factors helped explain the differences between studies. It should also be noted that compared to the adult risk assessment area, there are limited studies and their relatively small sample sizes make it difficult to find moderator effects. One study (Rajlic & Gretton, 2010) provides one possible factor that needs further investigation. They compared the JSOAP-II and ERASOR in two groups of offenders, one who had sex offenses only and one who had sex offenses and non-sex offenses. They found that these instruments were only predictive in the sex offenses only group.

Viljoen and colleagues also summarized data for individual subscales of the ERASOR and JSOAP-II. For the JSOAP-II, all subscales were significantly related to sexual reoffending, although sexual drive preoccupation was not related to general reoffending. For the ERASOR, only the psychosexual functioning and family environment scale were individually significant predictors of sexual offense recidivism. However, for both the JSOAP-II and ERASOR, many of the subscales have few items which would reduce the probability of the subscales on their own being stable predictor.

Summary

Research on risk assessment instruments for adolescents who engage in sexual behavior lags behind that of studies with adults. The meta-analysis of Viljoen et al. would suggest that these instruments perform better than chance but the issue of variability between studies suggests caution when using them clinically. The level of validity might suggest that the instruments could inform decision making on such things as intensity of supervision or intensity of treatment. However, they should be used carefully in decisions related to civil commitment or if an adolescent should be placed on a sex offender registry; that is, they should be used in the context of a comprehensive and individualized evaluation of a specific adolescent who has engaged in sexually abusive behavior. In addition, few studies provide actual recidivism rates for various risk levels and therefore when youth are classified as low, medium, or high risk that is not necessarily tied to specific percent of recidivism. In addition, recent perspectives regarding adult sexual offenders indicate that actual sexual offense recidivism rates appear to be associated with the level of Psychological Meaningful Risk Factors (PMRF; Mann et al., 2010) or dynamic risk factors: low, medium, or high rates of sexual offense recidivism will vary across samples based both on more static risk factors but also on the degree of risk factors external to the risk assessment instruments (e.g., PMFR; www.static99.org). As noted, there is limited information on dynamic risk factors for adolescent offenders which may impact the ability to accurately predict reoffending and as importantly to determine the most important treatment targets.

Physiological Measures

The physiological measures that have been used and are used with adolescents who engage in sexual behavior include penile plethysmography (PPG), viewing time measures (VTM), and the polygraph. McGrath et al.'s (2010) Safer Society Survey indicates that approximately 9 % of U. S. adolescent programs used PPG while approximately 20 % of such Canadian programs reported the use of PPG. Viewing time was used by approximately 34 % of US programs and 13 % of Canadian programs. Approximately, 38 % of US programs reported using either PPG or VTM, as compared to 26 % of Canadian programs. In contrast, polygraphy in some form is used in almost half of US programs; interestingly no Canadian programs reported use of the polygraph. McGrath et al.'s (2010) data clearly indicated that there has been a gradual decline in the use of penile plethysmography with youth in the United States, but a concomitant increase of the use of the polygraph. Viewing time has only been assessed in the last two surveys and has shown a slight increase in use from 25 % in 2002 to 31 % in the 2009 survey. Of these methods, the use of PPG and polygraph with adolescents has been the most controversial. It should be noted that for the PPG and the polygraph, there tends to be two objections, one being from a scientific standpoint and the second being from an ethical standpoint. All three of these methods will be briefly reviewed.

Penile Plethysmography

While the use of penile plethysmography, PPG, in adults has a long history, it is not without its controversies (Laws, 2009). It is a somewhat better accepted procedure with adult sexual offenders than with adolescents. As critics of the PPG have pointed out (Worling, Bookalam, & Litteljohn, 2012), the research literature related to PPG in adolescents is somewhat limited. The most consistent finding has been that adolescents who sexually abuse boys show greater arousal to child stimuli than those who victimize girls (Becker et al., 1989; Murphy et al., 2001; Seto, Lalumière, & Blanchard, 2000) and gender of victim may interact with history of sexual victimization (Becker et al., 1989; Murphy et al., 2001), although there have been exceptions (Hunter, Goodwin, & Becker, 1994). In addition, Seto, Murphy, Page, and Ennis (2003) also found in three separate data sets significant correlations between deviant sexual interest in the laboratory and the Screening Scale for Pedophilic Interest (SSPI; Seto & Lalumière, 2001). The SSPI has been found to relate to sexual arousal measures in adults and to

be predictive of offending in adults (Seto, Harris, Rice, & Barbaree, 2004). The SSPI is composed of items related to male victim, unrelated victim, multiple victims, and victims under 12. It should be noted that two of the samples had rather small sample sizes (45 and 67) while the third sample had a larger sample of 141. It should also be noted that each of the samples used different types of stimuli, one using films, one using slides, and one using audiotapes. The fact that deviant sexual interest has generally been limited to those with male victims has been criticized as reflecting a weakness of the assessment (Worling, 2012). However, it is notable that most of the risk assessment measures developed for adolescents include male victims as one of the risk factors.

There have also been studies on the ability of sexual arousal as measured by the PPG to predict recidivism (Clift, Gretton, & Rajlic, 2007; Clift, Rajlic, & Gretton, 2009; Gretton, McBride, Hare, O'Shaughnessy, & Kumka, 2001; Rice, Harris, Lang, & Chaplin, 2012). In the first studies by Gretton and colleagues in 2001, they found no relationship between pretreatment PPG measures and recidivism. They did find an interaction between PPG measures and psychopathy with the group high both in deviant arousal per PPG and psychopathy showing the highest rate of violent crimes overall (but not sex offending specifically). In the second study in 2007, they again found no association between pretreatment deviant indexes and recidivism but did find four deviant indices posttreatment (that represented arousal to stimuli that depicted forced and non-forced sexual interactions with male and female children) which were predictive. In the third study, in 2009, they again found a relationship between posttreatment arousal to male and female children and recidivism. They also found a relationship between inability to suppress arousal to male and female children at posttreatment to be related to increased recidivism. However, it should be noted that these appear to be overlapping data sets and therefore cannot be considered independent replications.

Rice et al. (2012) found that a child preference index on the PPG predicted both violent (ROC = 0.71) and sexual recidivism among adolescents (ROC = 0.73). They also found that a history of prior sexual abuse was also related to the child preference index.

Worling (2012) has provided a very thoughtful critique of the use of PPG with adolescents. As noted above, he raised two issues, one being the scientific basis for its use and the other more ethical. One of his criticisms is that the PPG is supposed to be an objective measure of sexual interest but in some studies has been found to be influenced by such factors as adolescent's age (Kaemingk, Koselka, Becker, & Kaplan, 1995), racial background (Murphy et al., 2001), and history of sexual abuse as outlined above. They also noted that variables that should statistically correlate with sexual arousal such as number of victims and force are not reliably correlated with deviant arousal in adolescents (Becker, Kaplan, & Kavoussi, 1998; Hunter et al., 1994). Although Kaemingk et al. (1995) did find age of victim related to PPG, two other studies (Murphy et al., 2001; Seto et al., 2003) did not find a relationship with age. The finding of Murphy et al. (2001) on racial background being related to arousal measures was a finding that African American youth tended to show lower arousal across stimuli. However, it should be noted that the audiotapes used in that study were recorded by a Caucasian and in the area where the study was conducted it is highly likely that the African American youth would have identified the voice as Caucasian which may have impacted arousal. Within the field, there needs to be more attention to cultural and racial factors including in our theories, assessments, and treatment. For example, Miner et al. (2010) also identified race as a factor in his study on attachment style, interpersonal involvement, and hypersexuality in adolescents, but this study did not involve arousal measures.

The finding that pedophilic interest as measured in the laboratory may be related to history of being sexually abused may actually be supportive of the construct validity of these measures. Many of the current theoretical models (as described in the etiology section) such as those by Knight, Malamuth, and Hunter suggest that one of the pathways to sexual offending is through a sexual pathway related to being a victim of child sexual abuse. To the extent that this model is correct, then one would expect higher levels of deviant sexual interest in those youthful offenders who have been sexually abused.

Worling also points out that there is research to suggest that 50 % of adolescents who denied their sexual offense showed low arousal to all stimuli (what is termed "flat liners," e.g., Becker et al., 1992). This finding is actually consistent with the adult literature and is a clear limitation of PPG measures. Freund and Blanchard (1989) found that the sensitivity of the PPG was low in identifying pedophilia in adult sex offender non-admitters. Thus, the lack of manifest sexual arousal in the laboratory setting provides little information in decision making.

Worling has also raised some ethical issues which need to be strongly considered in the use of PPG. Concerns include the potential iatrogenic effect of exposing youth to deviant sexual activities in the context of an adolescent still developing sexual identity. As Worling noted, this possibility has never been investigated but requires careful consideration. At the same time, while data are limited, there are some emerging patterns from research suggesting some construct validity and predictive validity. However, there are few studies of the use of the PPG with adolescents and use with adolescents should be considered carefully and ethical issues should be weighed against possible benefits in particular cases.

Polygraph

Polygraph testing has become one of the most frequently used assessment methods and procedures with adult offenders and increasingly with adolescent offenders (McGrath et al., 2010). Generally, several rationales exist for using the polygraph with individuals who have engaged in sexually abusive behavior; research suggests that it helps to identify additional victims, provides more details about the pattern of offending, can improve the monitoring of adherence to risk/safety plans (and therefore can be used to enhance supervision), and assists in the identification of treatment targets and in monitoring ongoing risk (English, Jones, Pasini-Hill, Patrick, & Cooley-Towell, 2000). For adults, there is research support that polygraphs lead to greater admissions, both in terms of number of victims and range of offending (Ahlmeyer, Heil, McKee, & English, 2000; Heil, Ahlmeyer, & Simons, 2003). However, whether such information leads to better treatment planning, better management, and a concomitant decrease in recidivism has yet to be fully determined.

Rosky (Online First version, August, 2012), in a review of polygraph testing, questions the overall accuracy of the polygraph and whether it leads to improvement in treatment planning and prevention of reoffending. The overall accuracy of the polygraph to assess deception has been questioned by the detailed review by the Council (2003). The most well-controlled study in adults on whether polygraphy impacts reoffending (McGrath, Cummings, Hoke, & Bonn-Miller, 2007) did not find that the use of the polygraph had an impact on future sexual offending. They did find a difference between groups on new violent offenses (2.9 % for those receiving a polygraph and 11.5 % for those who did not), but this was based on three violent reoffenses in the polygraph group and 12 in the no polygraph group. Given that there were no differences for offenses or violations for just sexual, sexual, and violent combined, or nonsexual/nonviolent offenses, the finding could be considered spurious.

When one turns to adolescent offenders, there is even less data on the utility of the polygraph. In a very early study by Emerick and Dutton (1993), they found the same pattern that has been observed with adults in terms of greater admissions of sexual offending. There are no studies that we know of that have looked at the impact of the use of polygraph with adolescents on reoffense rates. One study (Arsdale, Shaw, Miller, & Parent, 2012) presented data that they felt suggested that the polygraph provided information that was helpful in the treatment of adolescents who have engaged in sexually abusive behavior. In addition to the youth disclosing more victims and types of victims, youth also reported a greater amount of peer-related sexual activity and were more likely to disclose that they were themselves victims of abuse. The authors felt that these kinds of disclosures helped in treatment, especially addressing issues such as personal abuse. It is not clear, however, how these disclosures actually changed the course or outcome of treatment.

As with the PPG, there have been concerns raised in using the polygraph with adolescents (Chaffin, 2011; Craig & Molder, 2003; Prescott, 2012). Although these critiques have focused somewhat on the available data (which are even more lacking in adolescents than the PPG), they have also focused on ethical concerns. Chaffin (2011) suggested that the use of polygraphs in treatment effectively leads to mental health therapists being involved in an involuntary interrogation of minors. Even though the mental health professional may not administer the polygraph, it is required in some programs and therefore places the therapist in what could be considered a dual role of representing the client and the community. Prescott (2012) has argued that requiring adolescents to be polygraphed may set up an adversarial relationship between the therapist and the youth, which could be counter to the importance of therapeutic alliance in behavioral change. These observations need to be considered; thought and research should be given to whether the use of polygraph has a negative impact on the therapeutic relationship and/or actually contributes to treatment planning and positive outcomes.

Viewing Time

One of the newest approaches designed to assess sexual interest is the use of viewing time. Viewing time basically measures the time a subject spends viewing various stimuli; the underlying theory is that a person will look longer at a stimuli he/she finds sexually attractive than one he/she does not find sexually attractive. Research has shown the viewing time in adult samples correlated with self-reports of sexual arousal [see Worling (2012) for review] and shows some concordance with PPG results (Abel, Huffman, Warberg, & Holland, 1998; Gray & Plaud, 2005; Letourneau, 2002). The viewing time assessment most frequently used is Abel's Sexual Assessment for Sexual Interest (Abel, 2007). However, its use with adolescents has been limited. Abel et al. (2004), in a study of over 1,700 adolescents, found that males who offended against children viewed slides of children longer than males who had not offended against children and that viewing time was correlated with number of victims and number of acts of sexual abuse. It should be noted that those who did not offend against children were not from a non-offender population but were youth with other types of sexual offending behavior. The second type of viewing time measure, the Affinity (Glasgow, 2007), was investigated by Worling (2006). This study involved 78 adolescent males, and it was found that the viewing time correlated with self-reported rating of sexual attractiveness across most stimulus categories and could differentiate adolescents who had offended against one male child or against male children exclusively from offenders with peer/adult victims.

These findings are consistent with those for the PPG. To date, there is very limited data on viewing time with adolescents who have engaged in sexually abusive behavior. However, the procedure appears less controversial and is seen by some as an alternative to PPG. It has yet to be determined if the procedure will prove valuable in identifying treatment targets and/or be related to outcome. There have been fewer ethical concerns raised in the literature regarding viewing time measures as compared to PPG or Polygraph. However, like the PPG, there is no data on how nonsexual offenders respond.

Treatment

This chapter is not designed to provide a comprehensive review of treatment considerations for adolescent sex offenders, but rather the intent is to provide an overview of core components and considerations.

Historical Perspective

Treatment of adolescents who have engaged in sexually abusive behavior has evolved significantly since the early days of the field. Despite the growing data that adolescents accounted for a significant proportion of sex offenses, initially those involved faced the challenge of getting systems to take the issue/problem seriously. At the time treatment approaches were being formulated for this group of youth, there was a lack of research and knowledge to guide these efforts (Chaffin & Bonner, 1998). Not unexpectedly, the field turned to the adult field and borrowed from their approaches and models as this was perceived as at least providing some direction in addressing the serious issue of adolescents' sexually abusive behaviors. The adolescent field has since moved away from some of the early beliefs and approaches as research has informed practice.

Typically, reviews about the treatment of sexually abusive youth acknowledge or critique the early application of adult models to adolescents (Chaffin, 2006; Dwyer & Letourneau, 2011; Thakker, Ward, & Tidmarsh, 2006). As noted the field was without research initially. While there have been significant changes in our approach to working with adolescents, at times reflecting on where we started and how we got to where we are today serves as a reminder of the importance of continued research and staying current with the relevant literature as this is an evolving field.

Early on it was believed that adolescents who engaged in sexually abusive behavior were indeed similar to adult sex offenders; it was assumed that they had deviant sexual interests, were high risk, and needed long-term intensive treatment often in a residential setting due to their chronic condition that would require life-long management. The treatment model was a group sex offender specific cognitive behavioral therapy model (Chaffin, 2006) with an emphasis on full disclosure of offense patterns and focus on deviant sexual interest and attitudes supportive of offending and increasing victim empathy. The relapse prevention framework and cycle of abuse were typically core components of treatment programs. Treatment was also often confrontational in nature and there was a lack of recognition of developmental differences of adolescents.

Research and literature have shown that these initial beliefs and assumptions are not supported. We now know that adolescents who engage in sexually abusive behavior are a heterogeneous group with differing levels of risk, types of need, and varied responsivity factors. The majority of these youth do not require long-term intensive treatment and are appropriate for treatment in the community. Deviant sexual interest was a main focus early on, but research shows that only a small percentage of adolescents have deviant arousal patterns similar to adult offenders. The early style of confrontation in sex offender treatment for youth is now recognized as not being helpful with adults or adolescents.

Historically, relapse prevention and "cycle" approaches heavily influenced work with adolescents who had engaged in sexually abusive behavior. However, in general there is a lack of evidence for the traditional relapse prevention framework and approaches that suggest a single pathway to offending. Research shows that there are different causes and varied trajectory pathways for youth who engage in sexually abusive behavior. In turn, these findings support the need for a variety of approaches in working with these youth. In addition, there has also been an increased awareness of the developmental differences between adolescents and adults who commit sexual offenses, and more providers are recognizing the need to be well versed in child/adolescent development.

Overview

Effective treatment of sexually abusive youth is grounded in the research and literature relevant to this population. This encompasses the areas of child/adolescent development, juvenile delinquency, and sexually abusive youth. The knowledge base about adolescents who have engaged in sexually abusive behavior has grown significantly and provides information about some evidence-based practices, but to a higher degree provides information about evidence informed and evidence supported practices and approaches.

Current data supports that skills-based, cognitive behavioral interventions that focus on dynamic risk factors take socio-ecological factors into consideration, involve the family, and promote a therapeutic relationship that are likely the most effective when working with sexually abusive youth and general delinquent youth. There is emerging support in quasi-experimental studies that treatment can be effective with adolescents who have engaged in sexually abusive behavior (Reitzel & Carbonell, 2006; Worling & Cruwen, 2000; Worling et al., 2010). While there have been randomized controlled trials of Multi-Systemic Therapy that support treatment effectiveness with sexually abusive youth (Borduin, Henggeler, Blaske, & Stein, 1990; Borduin, Schaeffer, & Heiblum, 2009; Letourneau, Hengler, Bourdin et al. 2009), there have been few such trials involving other types of treatment.

Risk-Need-Responsivity and Treatment

As referenced in the Assessment Section, over the last decade there has been an increase in the utilization of the risk-need-responsivity principles as a framework for work with this population. The risk principle identifies who to focus on as it examines risk, the need principle informs what to focus on related to needs linked to reoffending, and the responsivity principle looks at how to approach the youth, his/her family, and serves as a reminder to utilize effective methods and take into consideration factors that impact the youth and his/her family's response to treatment. Protective factors are also taken into consideration in the treatment of sexually abusive youth. Kirby and Frazer (1997) define protective factors as "the internal and external forces that help children resist or ameliorate risk." Protective factors can mitigate risk and be built on as strengths in treatment and case planning.

Questions to be answered from assessment related to risk include the intensity of treatment and level structure and supervision needed. Intensity of services can range from outpatient to specialized residential programming with structure and security spanning the continuum from home placement to a correctional facility. While the majority of these youth can be served with an outpatient level of treatment intensity in the community, there are some youth who are in need of more intensive and extended services and/or may require a more structured and/or secure environment. The assessment of the individual youth's level of risk for sex offending, general delinquency and violent behavior, mental health needs, and the youth's and family's strengths should collectively guide decisions related to intensity of services and the degree of structure and supervision needed by the youth.

In short, the field has moved away from the early one size fits all response to these youth. Adolescents who engage in sexually abusive behavior are a diverse group with varying needs. While it is important to focus on factors relevant to both sexual reoffending and general reoffending, it is also important to remember that these youth and their families can present with a variety of issues. Many youth also present with other issues including: trauma, victimization, and comorbid psychiatric issues that need to be addressed. The youth and their families also present with a number of strengths and these need to be acknowledged and built on in treatment.

One approach to balancing treatment focus is to view the needs as varying across three major dimensions: sexually abusive behavior, general delinquency or violence, and general mental health needs (Murphy et al., 2005); there are factors such as family functioning, impulsivity, and social competency that can cut across all three dimensions. Youth can be at different points on each of these continuum, and assessment can help guide the focus of treatment.

While not all youth present with the same dynamic risk factors and needs, the following is a summary of what is currently thought to be the most relevant dynamic risk factors to address in treatment with adolescents who sexually abuse.

- Attitudes and Justifications Supportive of Offending
- Emotional Management
- Social Competence/Relationship Skills
- Healthy Sexuality
- Ability to Establish Peer Relationships
- General Self-Management Skills
- Family Education/Functioning
- Sexual Deviation or Sexual Preoccupation (if applicable)
- Development of Positive Life Goals
- Individualized Issues as Needed

Given that adolescents who sexually abuse are more likely to re-offend nonsexually than sexually, it is important to recognize that there are several evidence-based programs for youth with juvenile delinquency issues. Meta-analytic work (Lipsey, 2009) supports the effectiveness of programs that are skill-based and cognitive behavioral in reducing reoffending in youth engaged in general delinquent behavior. Aggression Replacement Training is recognized by the Office of Juvenile Justice and Delinquency Prevention (OJJDP) as a Model Program. The program focuses on interpersonal skills, anger control, and promotes values that respect others.

Further, youth who engage in sexually abusive behavior do not live in a vacuum and their behavior is impacted by a number of systems including family, peers, school, and community. Treatment needs to recognize both the positive and negative impact the systems have, and can have, on the youth. As previously reviewed, factors within the youth's environment such as use of leisure time, peer selection, and school have been shown to be important factors impacting youth and his/her risk for general re-offending. Interventions

that fail to focus on the socio-ecological components and instead focus only on the youth are less effective. Socio-ecological models of intervention include Multi-Systemic Therapy and Functional Family Therapy, both of which have been identified as a Blueprint program for delinquency/criminal behavior by the University of Colorado's Center for the Study and Prevention of Violence.

Specific to socio-ecological models, families are a central aspect of the lives of adolescents and as such have a major role in the treatment of sexually abusive youth.

The importance of the family involvement is supported by the literature (Borduin, Schaeffer, & Heiblum, 2009; Letourneau et al., 2009). Like the individual youth, families also vary in regard to their strengths and needs, and treatment is adapted to the situation of the particular family. Efforts need to be made to directly involve the family of the abusive youth in treatment unless this is contraindicated due to abuse, neglect, or other significant issues.

Application of the responsivity principle can directly impact the effectiveness of treatment of sexually abusive youth through the use of effective intervention for the problem, cognitive behavior treatment and social learning model, and modifying how interventions take into consideration individual and family factors, including bio-social factors, learning style, motivation, as well as strengths and protective factors.

While the responsivity principle is important in the treatment of any sexually abusive youth, it is of specific importance when working with subpopulations such as adolescent females, youth with developmental disabilities, youth exhibiting trauma symptoms, and youth with autism spectrum diagnosis. While there has been a substantial increase in research related to sexually abusive youth, research specific to subpopulations is limited and professionals treating subpopulations can gain helpful information from areas of relevant literature such as gender responsive treatment, developmental disabilities, autism, trauma, learning, and education. Treatment and interventions need to be developed or adjusted and adapted to meet the individual differences of the youth in these subpopulations.

Approach Versus Avoidance

An increasingly common theme in the treatment field involves moving away from relying on avoidance goals and promoting approach goals. Change is more likely when the person is working towards a positive, or approach, goal rather than the goal being restrictive in nature (Ward & Stewart, 2003). Part of the criticism of the traditional relapse prevention model is its reliance on avoidance-based strategies for managing risk situations. Mann, Webster, Schofield, and Marshall (2004) proposed that the strong avoidance focus may be related to why some offenders resist or rebel against relapse prevention interventions. The Good Lives Model is described as a strength-based perspective concerned with promoting offenders' goals while managing their risk (Ward & Stewart, 2003) with a goal of assisting the offender in understanding their offense pattern and to effectively cope with situations and psychological factors that increase their risk (Ward & Hudson, 2000). The Old Me/New Me approach (Haaven, 2006; Haaven & Coleman, 2000) has a long history of being used with adult sex offenders with developmental disabilities as well as being applied to other sex offenders and adolescents who sexually abuse. This approach involves changing dysfunctional behavior through skills building, identification of pro-social activities, and taking responsibility with an emphasis on what the person will do rather than on what they will not do. The focus is on setting positive goals involving approach behavior to meet needs and function as a New Me. A focus on approach changes does not negate the reality that there will be some avoidance aspects in goals for the youth. Treatment should strive for a balance as addressing risk sometimes means avoidance, but also means incorporation of approach goals and positive life goals that promote healthy living. Balanced treatment of the whole youth is consistent with the goal of preventing sexual abuse in that this approach supports the youth reaching their maximum potential for a healthy, fulfilled, non-abusive life.

Engagement, Motivation, and Therapeutic Relationship

Engagement and motivation are aspects of treatment that have received more focus in recent years and can be viewed as responsivity factors. Another aspect of treatment that has received more focus is the role of engagement and motivation. Treatment is viewed as a collaboration between the abusive youth, his/her family, and the therapist (Shingler & Mann, 2006). Motivational interviewing-based philosophy and techniques are more frequently incorporated into treatment, and some clinicians have adapted the transtheoretical model of change (Prochaska, Norcross, & Diclemente, 1994) into their approaches. Rather than a youth being viewed as "resistant," he/she is viewed through the lens of the stages of change: pre-contemplation, contemplation, preparedness, action, and maintenance. This approach in turn supports the development of therapy goals and interventions that view change as a process and assist the youth and his/her family through the stages of change.

The role of the therapeutic relationship is often a focus in general treatment literature and has the same importance in

work with sexually abusive youth. With adult sexual offenders, Marshall (2005) showed that a therapist style that was direct, warm, and empathic and showed concern for the welfare of the offender resulted in a higher level of change in dynamic risk factors than a style not embracing these qualities. Similarly, there is clear support for the value of the therapeutic relationship/therapeutic alliance in treatment of youth and families (Karver, Handelsman, Fields, & Bickman, 2006; McLeod, 2011), and this appears to be applicable in working with youth with general delinquent behavior (Florsheim, Shotorbani, Guest-Warnick, Barratt, & Hwand, 2000) and sexually abusive youth (Smallbone, Crissman, & Rayment-McHugh, 2009). It appears that treatment in which the youth and his/her family are treated with respect and that conveys hope is most effective, while treatment that incorporates a harsh, confrontational style or approach will be least effective.

Group Versus Individual

There is no evidence suggesting that group treatment with adolescents who engage in sexually abusive behavior is any more or less effective than individual treatment. The benefits of group treatment include youth feeling more comfortable discussing their behavior among other youth with similar problems and being more willing to hear feedback from a peer. In addition, the group setting provides opportunities to practice social skills and is more economical than individual or family therapy. However, there are also areas of caution associated with group treatment including concerns that youth in the group setting may influence each other in negative ways especially with this being more concerning in groups where high-risk and low-risk offenders are mixed together (Dodge, 2008). While the nature of individual therapy does not allow for the pluses of the group format, and is more expensive, it also has its advantages in that it removes the potential of negative influence from peers and is focused on only one client which allows for easier adaptation of approaches and interventions specific to the individual.

Summary

Treatment has changed significantly since the early days of the field. There is a concerted effort and focus on incorporating research and relevant literature into treatment and therapeutic approaches and interventions, and the increased application of the risk-need-responsivity framework supports evidence-based practices. Research will continue to increase our knowledge of adolescents who have sexually abused and will guide our treatment and interventions.

Public Policy

Public policies impacting adolescents who have engaged in sexually abusive behavior have been the focus of significant discussion in the field over the last several years. Much of the discussion has been related to efforts in the United States to reduce sex offending through legislation focusing on community notification, residency restrictions, and registration. The United States' Federal government and state governments have enacted public policies related to the management of sex offenders since the early 1990s. While the intent of the legislation is to increase community safety with a focus on the management of sex offenders, such policies have not been shown to be effective with adults (Levenson & D'Amora, 2007) and policies designed for adults are being applied to adolescents despite the significant differences between juvenile sex offenders and adult sex offenders (Miner, 2007).

Pittman and Nguyen (2011) noted that 35 states had laws that required juveniles who had been adjudicated for sex crimes to register with law enforcement, some with life-long registration, and 18 of the states disclosed the youth's private information to the public. At times, juveniles adjudicated on sex offenses are subject to residency restrictions that negate them living near places where children may gather including parks and schools. Sanctions that involve labeling, registration, and notification are viewed as having negative impact on the youth and his/her family. Such sanctions can result in the youth being stigmatized and rejected by others which impact their peer groups and some youth adjudicated on sex offenses and required to register have been limited or prohibited from involvement in activities that are viewed as part of normal teenage life and support healthy development (ATSA, 2012; Miner, 2007).

While much of the discussion has centered on the United States and its policies, the issue of application of adult policies to juveniles is a universal concern. The application of adult sanctions to juveniles is in part due to misinformation and assumptions about adolescents who have engaged in sexually abusive behavior and such sanctions are viewed as being inappropriate and ineffective and may be harmful (Letourneau & Miner, 2005; Zimring, 2004). Community notification with juveniles has not been shown to be effective (Caldwell, Ziemke, & Vitacco, 2008; Letourneau & Armstrong, 2008; Letourneau, Bandyopadhyay, Sinha, & Armstrong, 2009) but rather is viewed as having a negative impact. Miner (2007) noted that the culmination of the impact of restrictions (rejection by others, impact on peer groups, decreased participation in pro-social activities, decreased involvement in schools and churches) may actually worsen the situation by increasing risk for offending, rather than achieving the goal of preventing sexual abuse.

In addition to the above-mentioned public policies, serious concern has been raised about children as young as 6 years of age being prosecuted on sex offenses, the process of juveniles being waived to adult court to face sex offense charges, and the issue of civil commitment of juveniles.

Application of adult sanctions and policies to adolescents raises serious concerns for the youth and society; policies and management strategies need to take into account what is actually known about youth engaging in sexually abusive behavior. Ensuring that decisions about juveniles who have engaged in sexually abusive behavior recognizes that rehabilitative efforts are effective with most youth (Greenwood, 2008: Lipsey, 2009) and takes into account what is known about sexually abusive youth as well as the individual youth's risk and need provides a foundation for effective practice and policy. Such public policy issues relating to adolescents who have engaged in sexually abusive behavior are important issues that have been and will continue to be addressed within the field.

Conclusion

The field working with adolescents who have engaged in sexually abusive behavior has seen many changes, especially during the last decade. An increased base of knowledge about this group of youth exists that is rooted in research and relevant literature. Risk, need, and responsivity principles are recognized as a framework for working with this population, and the knowledge base has supported the development of evidence-based, evidence-supported, and evidence-informed practices and approaches. The developmental characteristics and individualized needs of the youth are recognized and impact our work. Gains have been made in assessment and evaluation, including ongoing research of risk assessment tools. Studies have shown that treatment of sexually abusive youth can be effective, and research has provided insight into possible developmental pathways to offending and different classifications of youth engaging in sexually abusive behavior. States and other jurisdictions have developed practice guidelines or protocols specific to adolescents rather than relying on adult focused guidelines. The Association for the Treatment of Sexual Abusers is currently developing practice guidelines for adolescents who have engaged in sexually abusive behavior and in October 2012 updated their policy statement related to this population.

Many advances have been made regarding the understanding, assessment, and treatment of adolescents who have engaged in sexually abusive behavior. However, more research across these domains is needed to support continued advancement in the field. High quality studies of treatment effectiveness, continued research to increase understanding of both static and dynamic risk factors, and longitudinal studies to help identify targets for prevention efforts are needed. The field continues to move forward in its efforts towards evidence-based assessment and treatment and research informed public policy for adolescents who have engaged in sexually abusive youth.

Female Sexual Offenders: An Overview

Franca Cortoni and Theresa A. Gannon

Female Sexual Offenders

Women are different from men. In comparison to men, women commit considerably less crimes and they diverge in the paths that brought them to the attention of the criminal justice system. Women also diverge in their responses to custody and community supervision, likely due to their lower risk of reoffending and the differing nature of their risk and needs (Blanchette & Brown, 2006). In the sexual offending field, like in the general offending field, gender matters. Although in its infancy, the emerging empirical information on women who sexually offend indicate that a blanket application of research knowledge based on *male* sexual offenders is not a viable option. As we will see in this chapter, while men and women appear to share some characteristics, important differences in risk of recidivism and factors related to their sexually abusive behavior indicate that a *gender-informed* as opposed to a *gender-neutral* approach to the assessment and treatment of female sexual offenders is warranted. The term "gender-neutral" refers to characteristics that are linked to the criminal behavior that are equally applicable to men and women. The term "gender-informed" refers to factors unique to women offenders. This chapter will provide a two-part review of the current knowledge on female sexual offenders, highlighting similarities and differences between female and male sexual offenders. The first part will review current theoretical and empirical knowledge on female sexual offenders, including prevalence, sociodemographic features, developmental history, and offense characteristics. Within this context, typologies of female sexual offenders will be described. The second part will discuss recidivism rates of female sexual offenders, risk factors, and current best practices in the treatment of these women.

Prevalence and Incidence of Female Sexual Offending

Both prevalence and incidence statistics are required in order to understand the scope of female-perpetrated sexual abuse. *Prevalence* statistics provide overall estimates of the numbers of individuals who self-report at least one occurrence of sexual victimization over a fixed time period. *Incidence* statistics provide officially recorded crime figures documented over a fixed time period (typically one year).

In a comprehensive study focusing on sexual abuse prevalence, Finkelhor, Hotaling, Lewis, and Smith (1990) interviewed US men ($n=1{,}145$) and women ($n=1{,}481$) via telephone. Previous sexual abuse was disclosed by 16 % of men ($n=169$) and 27 % of women ($n=416$), the majority of which was reported as being male-perpetrated. Nevertheless, 17 % of the abused men reported having been abused by a female. Interestingly, however, only 1 % of abused females reported having been abused by a female. More recent research conducted in the UK (NSPCC, 2007) has also shown that, for children who report sexual abuse via confidential phone line, and identify the gender of their perpetrator, 5 % of girls and 44 % of boys identify the perpetrator of their abuse as female. Finally, Adshead, Howett, and Mason (1994) performed an overview of sexual abuse prevalence studies conducted between 1979 and 1990. The studies reviewed focused on a number of participants (e.g., convicted male rapists, Groth & Burgess, 1979; mixed gender college students and prisoners Condy, Templer, Brown, & Veaco, 1987). Perhaps unsurprisingly, female-perpetrator prevalence varied extensively across studies ranging from 0.5 % (reported by female college students) to 46 % (reported by male prisoners).

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_10

An important US source of incidence statistics is the FBI's Uniform Crime Reporting Program (UCR) which reports national arrest figures. Recent UCR releases document 3,167 arrests of adult females for sexual offenses in 2005 (excluding forcible rape and prostitution). Clearly, however, these figures on *arrests* do not necessarily provide professionals with key information concerning the *numbers* of females contributing to this arrest data. The National Crime Victimization Survey of the US Department of Justice provides data from US residents aged 12 years and above about their crime experiences. For 2005, these data show that 2.2 % of sexual victimizations appear to have been perpetrated by an unaccompanied female, while 23.4 % were estimated as having been perpetrated by a female in the presence of a male. While this survey is less dependent on official reports, that notoriously underestimate instances of abuse, this survey does not provide detailed information concerning the *types* of individuals who fall victim to female sexual offenders (i.e., child or adult).

Using data obtained from a 1998 Health Canada national survey of child maltreatment cases investigated by child welfare workers, Peter (2009) examined the prevalence of female sexual victimization by women among 345 cases of child sexual abuse and found that women were responsible for 10.7 % ($n=37$) of the reported sexual abuse. When rates of victimization by women were split by the gender of the victims, the data showed that the female abusers were responsible for the sexual abuse of 9.3 % of the female victims and 14.1 % of the male victims. Peter (2009) was also able to examine the specific sexual acts committed by women. She found that less than five cases involved penetration of any kind or oral genital contact, although 19 % had attempted such behaviors. Half the women had engaged in touching/fondling of genitals, while an additional 16 % exposed their genitals to the children for sexual purposes. In contrast, while half the male offenders had engaged in touching of genitals, 16 % had engaged in penetration and/or oral genital contacts, and an additional 32 % had attempted such behaviors.

Fromuth and Conn (1997) conducted a particularly novel study in which 546 female students were asked to self-report previous sexual practices involving young children. Fromuth and Conn discovered that 4 % of female students ($n=22$) self-reported sexually abusive activities with young children. It is noted, however, that the majority of these sexual activities were reported as having taken place when respondents were children themselves (i.e., 10–14 years), and so it is unclear how many of these sexual activities were part and parcel of normal childhood sexual explorations.

In efforts to provide more systematic information about the prevalence of female sexual offenders, Cortoni and Hanson (2005; Cortoni, Hanson, & Coache, 2009) estimated the proportion of sexual offenders who are women from two general sources of information. The first source of information was official police or court reports that detailed the gender of the offender. The second source of information was victimization surveys. For both sources, information was available for North America (Canada and the USA), Australasia (Australia and New Zealand), and Europe (England and Wales). Results from the updated 2009 review were consistent with the earlier 2005 findings. Based on official records, the proportion of all sexual offenders who were female ranged from 0.6 % in New Zealand to 8.7 % in the USA. When these numbers were averaged across all countries in the study, women constituted approximately 4.6 % of all sexual offenders. It is worth noting, however, that the types of offenses constituting female-perpetrated sexual abuse vary across countries, as does the original *source* of the statistics. When victimization studies were examined, the proportion of sexual offenders who were female, as reported by victims, ranged from 3.1 % for New Zealand to 7.0 % for Australia. Across the various victimization studies, women constituted an average 4.8 % of all sexual offenders.

Interestingly, official reports and results from victimization surveys were remarkably consistent with each other and showed that women are responsible for 4 to 5 % of all sexual offenses. Based on these international data, Cortoni, Hanson, and Coache (2009) concluded that official reports and victimization surveys, on average, indicate a ratio of female to male sexual perpetrators of 1:20. Using data from the USA in 2002, the only country and year for which direct comparisons between official rates and victimization reports were possible, Cortoni and Hanson (2005) noted differential rates of police arrests according to the gender of the offender in relation to victimization survey results. Specifically, 34 % of the sexual offenses committed by men resulted in police arrest, whereas 57 % of the sexual offenses committed by women resulted in police arrest. These findings suggest that further research is needed to understand the personal and criminal justice responses to victimization by female offenders versus male sexual offenders.

In summary, the full extent of female-perpetrated abuse is very difficult to estimate, and the various prevalence and incidence figures that we have reported appear to fluctuate greatly according to the varying methods and samples used. However, various researchers have suggested that female-perpetrated sexual abuse is likely to be more underreported than male-perpetrated abuse due to strong sociocultural denial and lack of knowledge regarding female-perpetrated sexual abuse (Denov, 2004; Giguere & Bumby, 2007; Hetherton, 1999; Longdon, 1993; Robinson, 1998). As yet, it is unclear exactly if and how such issues affect prevalence and incidence estimates relative to those provided for male sexual offenders. However, even with the estimated ratio of

1:20 of female vs. male-perpetrated abuse, this estimate equates to sizeable numbers of victims and offenders in need of clinical intervention.

Characteristics

Research suggests that female sexual offenders—like any group of offenders—represent a diverse group of individuals with heterogeneous treatment needs (Adshead et al., 1994; Gannon, Rose, & Ward, 2008; Miccio-Fonseca, 2000; Sandler & Freeman, 2007; Vandiver & Kercher, 2004). Nevertheless, as will become apparent later in this chapter, the majority of research efforts have focused not on the treatment needs of female sexual offenders but more on socio-demographic and offense characteristics relevant for typological classification of female sexual offenders. In the following section, we outline current evidence regarding the socio-demographic, developmental, and offense features of female sexual offenders. Given the biases that we have raised concerning the potential extent of underreporting surrounding female-perpetrated sexual abuse, caution should be taken when interpreting information pertaining to female sexual offenders' core characteristics. Just like with male sexual offenders, such characteristics are only relevant for those female sexual offenders who have already come to the attention of the criminal justice system.

Socio-Demographic Features

Some researchers have reported findings suggesting that female sexual offenders are generally younger than their male counterparts (Faller, 1987, 1995). For example, Faller (1987) found that, relative to a clinical sample of male child sexual offenders, female child sexual offenders were significantly younger (26.1 years versus 35.8 years, respectively). It is unclear why apprehended females would be younger in age relative to males but one explanation is that females—who are more likely to co-offend—are coerced into their offending by older and more experienced males (see Faller, 1987). In terms of ethnic origins, apprehended female sexual offenders—similarly to male sexual offenders—are generally reported as being Caucasian (Faller, 1987, 1995; Lewis & Stanley, 2000; Vandiver, 2006; Vandiver & Kercher, 2004). Research evidence suggests that female sexual offenders generally hold few educational or vocational qualifications (Matravers, 2005; Nathan & Ward, 2001; Tardif, Auclair, Jacob, & Carpentier, 2005), fit within low or middle socio-economic status categories (Lewis & Stanley, 2000; Travin, Cullen, & Protter, 1990), and are significantly less financially secure than their male counterparts (Allen, 1991).

Developmental Features

Female sexual offenders, like male sexual offenders, appear to experience adverse developmental experiences characterized by physical, sexual, or emotional abuse and neglect (Fromuth & Conn, 1997; Gannon et al., 2008; Green & Kaplan, 1994; Hislop, 2001; Lewis & Stanley, 2000; McCarty, 1986; Nathan & Ward, 2001). For example, Gannon et al. (2008) found that half of their sample of UK females apprehended for sexual offenses ($n = 11$) reported *multiple* abusive experiences in childhood (e.g., sexual *and* physical abuse or physical *and* emotional abuse). Similarly, Lewis and Stanley (2000) found that 80 % of females charged with sexual assault ($n = 12$) reported past sexual abuse experiences, typically perpetrated by a caregiver. Research suggests that female sexual offenders experience abuse that is both more frequent and severe than that reported by male sexual offenders (Allen, 1991; Mathews, Hunter, & Vuz, 1997; Pothast & Allen, 1994). It is unclear, however, how such abusive experiences lead females to sexually offend. Recent research suggests that female sexual offenders—relative to female offender controls—show a strong tendency to view adult males as dangerous (Gannon & Rose, 2009). It is possible that early abusive experiences at the hands of males may play a role in the development of passive and dependent personality traits that leave such women vulnerable to potential coercion and grooming from male sexual offenders. Of course, there are many etiological pathways that require exploration concerning the association between childhood abuse and sexual abuse perpetrated by adult females.

Other Associated Features

Unsurprisingly given the severe developmental adversities experienced by female sexual offenders, many researchers have reported that female sexual offenders exhibit emotional dependency and passivity (Green & Kaplan, 1994; Hislop, 2001), low self-esteem (Hunter & Mathews, 1997; Mathews, Matthews, & Speltz, 1989), inadequate social skills (Hislop, 2001), poor self-identity (Green & Kaplan, 1994; Hislop, 2001; Mathews et al., 1989), and fear of men (Beech, Parrett, Ward, & Fisher, 2009; Gannon, Hoare, Rose, & Parrett, 2012; Gannon & Rose, 2009). Research also suggests that female sexual offenders have a high rate of mental health disturbances in the form of depression, bipolar disorder, schizophrenia, or personality disorder (Faller, 1995; Green & Kaplan, 1994; O'Connor, 1987; Tardif et al., 2005). However, the association between mental illness and female sexual offending is a contentious issue since (1) it is likely that only the most pathological female sexual offenders are apprehended by the authorities, and (2) current study sampling

techniques (i.e., lack of suitable comparison groups or inappropriate recruitment methods) make it impossible to come to valid conclusions about the true relationship between mental illness and female sexual offending.

Offending Characteristics

Perhaps the most noteworthy feature of female sexual offenders, particularly those who target children, compared to their male counterparts, is their propensity to offend in the company of a co-offender (Grayston & De Luca, 1999; Green & Kaplan, 1994; Matravers, 2005; Nathan & Ward, 2001; Vandiver, 2006). Typically, females who co-offend do so with a male partner (Lewis & Stanley, 2000; Vandiver, 2006), although female co-offenders are also found. For example, in her comparison of solo ($N=123$) and co-offenders ($N=104$), Vandiver (2006) found that while 71 % had male co-offenders, another 21 % ($n=22$) had both male and female co-offenders, and 8 % ($n=8$) had sexually offended only in company of other females. Females who have co-offenders may offend of their own volition alongside the co-offender, or they may offend in the context of considerable coercion and physical threats of violence (Gannon et al., 2008; Vandiver, 2006).

Similarly to male sexual offenders, females who sexually abuse usually know their victims (Faller, 1995; Kercher & McShane, 1984; Vandiver & Kercher, 2004; Vandiver & Walker, 2002). For example, females who abuse children typically hold caregiver responsibilities towards that child (e.g., mothers, relatives, or babysitters; Faller, 1987, 1995; Lewis & Stanley, 2000; Vandiver & Walker, 2002). Females who sexually abuse children are also likely to target younger children than their male counterparts (Faller, 1987; Rudin, Zalweski, & Bodmer-Turner, 1995). For example, Faller (1987) found that nearly two-thirds (or 60.3 %) of female child sexual offenders' victims were below the age of 6 years. Comparable figures for male child sexual offenders were just 48 %. Although results vary according to studies, it appears that solo offenders tend to assault a greater proportion of males, while those with male co-offenders tend to have more female victims (e.g., Vandiver, 2006). In terms of physical force and aggression used in the commission of the offense, some researchers have argued that females are less physically aggressive than males (see Grayston & De Luca, 1999). However, other researchers have not supported this contention (Mathews et al., 1997).

Typologies of Female Sexual Offenders

There is very little research or theory available to aid professionals entrusted with the task of rehabilitating female sexual offenders. Because of this, professionals have focused their attention on developing typologies that attempt to reduce the confusing heterogeneity of female sexual offenders into more manageable subcategories (Adshead et al., 1994; Faller, 1987; Hines & Finkelhor, 2007; Mathews et al., 1989; Matthews, Mathews, & Speltz, 1991; Nathan & Ward, 2001; Sandler & Freeman, 2007; Syed & Williams, 1996; Vandiver & Kercher, 2004). Such typologies are typically based on offense, offender, or victim characteristics, and/or attendant hypothesized motivational factors.

Ruth Mathews and her colleagues (1989, 1991) were the first researchers to document a typological description of female sexual offenders. Using qualitative and quantitative information (e.g., interview and questionnaire data), Mathews et al. (1989) subdivided 16 female sexual offenders into three main categories according to the hypothesized fundamental motivators driving their sexual offenses. These categories described female sexual offenders as either being *predisposed and intergenerational* (i.e., females with previous sexual abuse experiences who independently replicate this abuse as adults), *teacher/lover* (i.e., females who abuse adolescents and seemingly view this abuse as an adult like relationship or "affair"), and *male-coerced* (i.e., passive or dependant females who abuse children under direct coercion, pressure, or threats from a male co-offender). It should be noted that previous to this typology, Mathews (1987, as cited in Mathews et al., 1989) highlighted the important distinction to be made between women who are pressured into abusing children (as described by the coerced type) and those who play a more active or equal role in the abuse, yet abuse in the company of a man (*male-accompanied* female sexual offenders).

Since presentation of this basic typological distinction of female sexual offenders, researchers have suggested various refinements and additions to this original typology (e.g., Hines & Finkelhor, 2007; Nathan & Ward, 2001) or have presented very similar typologies (Adshead et al., 1994). However, the majority of these stem from clinical observations or experiences and there are few empirical validation efforts.

In one Canadian validation study, Syed and Williams (1996) examined the fit between Mathews et al. (1989) typology and the file profiles of 19 female child sexual offenders. Because some file information was inadequate for making definitive classifications only 11 final classifications were made, the majority of which fell into the *male coerced* subcategory ($n=9$). However, Syed and Williams observed that many of these females ($n=5$) played a key or lead role in the sexually abusive behavior; seemingly supporting the earlier *coerced* versus *accompanied* distinction proposed by Mathews (1987 - cited in Mathews et al. 1989). Thus, Syed and Williams' work highlighted the need to carefully examine the underlying motives and characteristics of females who sexually abuse in the company of males.

A more robust approach to the typological classification of female sexual offenders was recently conducted by

Vandiver and Kercher (2004). Using the offender and victim profiles of all registered female sexual offenders in Texas over a 7-year period ($n=471$),[1] Vandiver and Kercher conducted a combination of loglinear modeling and cluster analyses to reveal six subtypes of female sexual offenders. The largest group discovered were labeled *heterosexual nurturers* ($n=146$) who appeared similar to the teacher-lover females identified by Mathews et al. (1989). The *noncriminal homosexual offenders* ($n=114$) represented females with little criminal history who tended to target female children. The *female sexual predators* ($n=112$) tended to target male children and were notably "criminal" relative to other subtypes. The *young adult child exploiters* ($n=50$) tended to target extremely young victims—sometimes family members—of either sex. The *homosexual criminal* subtype ($n=22$) tended to have generally criminal profiles, and offended against females, often in an attempt to profit financially (e.g., forced prostitution). Finally, *aggressive homosexual offenders* ($n=17$) represented the smallest group of women who were most likely to target adult female victims.

Vandiver and Kercher (2004) have provided professionals with one of the most convincing empirically based typological classification of female sexual offenders to date. However, one key limitation of their study is the fact that they were unable to acquire co-offender information for the female sexual offenders that they classified. In other words, it is unclear how many of the females categorized acted alone or in the company of males. Another key limitation is the inclusion of prostitution-related offenses such as forcing someone into prostitution as "sexual offenses" (an artifact of the State of Texas registration law, but common to many American states [Jeff Sandler, personal communication, June 11, 2009]), therefore blurring the definition of what constitutes "sexual offending" among women.

Sandler and Freeman (2007) recently attempted a replication of Vandiver and Kercher's findings using a sample of New York registered female sexual offenders ($n=390$) similar on core age, race, and victim age variables. Victim sex did, however, differ across the samples. It should also be noted that Vandiver and Kercher's offenders targeted nearly equivalent amounts of male and female victims. However, Sandler and Freeman's sample showed a preponderance of male victims. Thus, it was not possible to entirely replicate the characteristics of Vandiver and Kercher's sample, and missing data regarding victim–offender associations compounded this issue further. Statistical analyses similar to that used by Vandiver and Kercher indicated six subtypes of female sexual offender (two of which appeared similar to Vandiver and Kercher's original clusters). The largest group discovered were *criminally limited hebephiles* ($n=158$) who exhibited features similar to Vandiver and Kercher's heterosexual nurturers. The second largest group discovered were *criminally prone hebephiles* ($n=105$) who were similar to criminally limited hebephiles but—as the name suggests—were generally more criminal. *Young adult child molesters* ($n=27$) were the only other group who appeared similar to Vandiver and Kercher's typology. These females exhibited characteristics similar to young adult child exploiters since they tended to target very young children. The fourth largest cluster found were labeled *high risk chronic offenders* ($n=25$) since they exhibited considerable levels of arrests for sexual or nonsexual offenses. The next largest cluster—*older non-habitual offenders ($n=20$)* were the oldest group of offenders who showed relatively few criminal tendencies outside of their sexual offending. Finally, a small *homosexual child molester* cluster was noted ($n=11$) who showed a marked tendency to target females, yet were characterized by relatively crime free backgrounds similar to that displayed by the *non-habitual offenders*.

A major limitation of Sandler and Freeman's (2007) study, similarly to Vandiver and Kercher's (2004), is the lack of available information concerning co-offenders. The absence of this information significantly limits the usefulness of this taxonomy for providing guidance on the types of treatments required for specific types of female sexual offender. It is also possible that inclusion of co-offender influences as a variable would have impacted on and altered the final cluster groupings.

In summary, the typological classification systems that we have described offer professionals who work with female sexual offenders a very broad view of the main categories of females who sexually abuse [i.e., females who target adolescents, females who offend in the company of males (at times coerced, at other times not), females who target prepubescent children, and females who sexually offend in the context of a diverse criminal career]. However, such typological classifications offer professionals little in the way of specific guidance for the assessment and treatment of these women.

Theoretical Developments

Unfortunately, there are no comprehensive multifactorial theories available to explain the etiology of female-perpetrated sexual abuse. It is unclear exactly why existing theory relating to female sexual offenders is so underdeveloped. Presumably, theory development has been significantly obstructed by a lack of rigorous empirical research conducted with female sexual offenders. Thus, professionals' knowledge of why females sexually offend and of their associated treatment needs lags significantly behind professionals' knowledge of male sexual offenders. Recently, Gannon and colleagues (Gannon et al., 2008; Gannon, Rose, & Ward, 2010) sought to rectify this situation via

[1] Including offenders with child and/or adult victims.

construction of an *offense chain theory* of female sexual offending. Offense chain theory, put simply, involves developing a detailed theoretical description of the sequence of events leading up to a sexual offense using offenders' offense narratives (i.e., inductive theory development using qualitative data analysis). This method has been used successfully with male sexual offenders, and is particularly useful for highlighting not only *how* and *why* the offense process unfolds but also particular *patterns* of sexual offending relevant for relapse prevention work (see Ward, Louden, Hudson, & Marshall, 1995).

Gannon et al. (2008) developed an offense chain model—the Descriptive Model of the Offense Process for Female Sexual Offenders (or DMFSO)—from the offense narratives of 22 UK female sexual offenders who had offended against children and/or adults. The resultant DMFSO shows the lifetime sequence of contextual, behavioral, cognitive, and affective events that facilitate and maintain female-perpetrated sexual abuse. Following DMFSO development, two raters independently examined each female offender's progression throughout the model to identify any specific patterns or evidence of offender subtypes who progressed through the model via distinct pathways. Gannon et al. found evidence that female sexual offenders followed one of two main pathways. *Directed-Avoidant* females were typically child sexual abusers who were characterized by sexual offense avoidance and negative affect; they offended either out of extreme fear for their lives or because they wanted to obtain intimacy with their male co-offender. These females were often oblivious to, or passive to, the early planning of child sexual abuse initiated by the male co-offender. *Explicit-Approach* females, on the other hand, were either child or adult abusers and appeared to explicitly plan their offense in order to achieve various goals (e.g., sexual gratification, intimacy with victim, financial reward). These females experienced positive affect (e.g., excitement) in anticipation of their offense. Gannon et al. (2008) also noted tentative evidence for an *Implicit-Disorganized* female subtype who offended against either children or adults and appeared to be characterized by little organized planning and sudden and disorganized offending associated with either negative or positive affect.

A core strength of the DMFSO lies in its potential to account for various subtypes of female sexual offender without grouping females according to simplistic motivational themes or victim characteristics. Thus, there is some potential for the DMFSO to guide not only relapse prevention work with offenders but also the formulation of key treatment plans for each subtype of offender. Nevertheless, this model has been constructed from the experiences of very few UK female sexual offenders and requires further external validation before any of the identified subtypes can be examined in more detail.

Assessment of Female Sexual Offenders

Recidivism Rates Among Female Sexual Offenders

While tremendous advances have taken place in understanding the recidivism rates of male sexual offenders (e.g., Hanson & Morton-Bourgon, 2005), similar knowledge is only starting to accumulate for female sexual offenders. In an initial review of the recidivism rates of 380 female sexual offenders, Cortoni and Hanson (2005) found a sexual recidivism rate of 1 % with a 5-year follow-up period. As with male sexual offenders, female sexual offenders also demonstrated other types of re-offending. Specifically, 6 % of the women had committed a new violent (including sexual) offense and 20 % had committed a new crime. The number of female offenders included in that review, however, was small and a number of large sample studies have appeared since that review was completed. As well, Cortoni and Hanson (2005) did not provide a meta-analytic summary of recidivism rates; it was therefore impossible to know whether the variability across studies was significant. Consequently, Cortoni, Hanson, and Coache (2010) conducted an updated meta-analytic review of the recidivism rates of female sexual offenders.

Cortoni et al. (2010) analzsed the results from a total of 10 recidivism studies with an aggregated total number of 2,490 female sexual offenders. These studies included two published papers, four conference presentations, one government report, and three official sources of recidivism data. The average follow-up time was 6.5 years. Recidivism was defined as being charged, convicted, or incarcerated for a new offense. Sexual recidivism included a new charge, conviction, or reincarceration for a sexual offense. Violent recidivism was defined as a new violent charge, conviction, or incarceration for a new violent offense (including sexual offenses). Any recidivism was defined as any new charge, conviction, or incarceration, all categories confounded. Consequently, and consistent with research on the recidivism rates of male sexual offenders, the categories of recidivism were cumulative rather than mutually exclusive.

The analyses revealed more variability across studies than expected by chance, with one study identified as the outlier (Vandiver, 2007). The finding that Vandiver's (2007) study was a consistent outlier in the analyses of sexual recidivism rates is not surprising. In her study, Vandiver counted as sexual recidivism any offense that led to the registration of the woman as a sexual offender, as defined by the State of Texas (D. Vandiver, personal communication, October 14, 2008). As a result, sexual recidivism in Vandiver's study included behaviors that are not typically counted as sexual offenses in the male sexual offender

recidivism studies (e.g., compelling prostitution; kidnapping; court or board ordered registration), thereby likely artificially inflating the rate of sexual recidivism among the female sexual offenders. For example, although the female sexual offenders had sexual recidivism rates virtually identical as the male sexual offenders in the study (10.8 % vs. 11.4 %; an anomaly by itself since research consistently shows that *all* women offenders have lower rates of recidivism than males; Blanchette & Brown, 2006), only the female offenders had offenses related to prostitution. It is also possible that the recidivism rates in the Vandiver study included instances of pseudo-recidivism (Harris, Phenix, Hanson, & Thornton, 2003). Pseudo-recidivism occurs when a currently convicted offender receives new additional sexual offenses convictions but for offenses that temporally took place before the current offenses (Harris et al., 2003).

Given the variability among studies created by the Vandiver (2007) study, Cortoni et al. (2010) analyzed the recidivism rates of female sexual offenders with and without the results from Vandiver. When data were analyzed with the Vandiver study, the weighted observed sexual recidivism rate for all 10 studies was 3.2 % and fixed and random effects analyses showed aggregated estimates of sexual recidivism ranging from 1.2 % to 2.4 %. The rate of any violent recidivism (including sexual) was 6.5 % and fixed and random effects analyses showed aggregated estimates of violent recidivism ranging from 4.4 % to 7.6 %. Finally, the rate of any recidivism (including violent and sexual) across all studies was 24.5 %. Fixed and random effects estimates of any recidivism ranged between 22 % and 24 %. However, when the data were reanalyzed without the Vandiver study, the variability across studies disappeared and the aggregated estimates of recidivism dropped significantly. Specifically, weighted averages computed without the Vandiver study showed a sexual recidivism rate of 1.3 %. Violent recidivism was 4.3 % and the rate of any recidivism was 20 %.

The recidivism rates of female sexual offenders need to be put in context of those of males. Meta-analyses of large samples of male sexual offenders show that the 5-year recidivism rates for male sexual offenders are 13–14 % for sexual crimes, 25 % for any violent crime (including sexual offending), and 36–37 % for any new crime (Hanson & Bussière, 1998; Hanson & Morton-Bourgon, 2005). Not surprisingly, Cortoni and Hanson (2005) noted in their earlier review that the differences between the recidivism rates for the male and female sexual offenders were statistically significant for all types of recidivism, confirming that female sexual offenders have much lower rates of all types of recidivism than male sexual offenders. Their updated meta-analytical review confirmed that the rates of all types of recidivism among female sexual offenders are indeed significantly lower than those of males.

Assessing Risk of Recidivism

Static Risk Factors

Just like with male offenders, the assessment of risk among female sexual offenders needs to take into consideration both static and dynamic risk factors. Among male offenders, static risk factors for general and violent (nonsexual) recidivism include being at a younger age, being single, and having a history of lifestyle instability, rule violations, and prior criminal history (Andrews & Bonta, 2007; Hanson & Morton-Bourgon, 2005). Static factors specifically related to sexual recidivism include prior sexual offenses and having male, stranger, and/or unrelated victims (Hanson & Thornton, 2000).

Despite the low recidivism rates among female sexual offenders, the recidivism research on these women now contains sufficiently large numbers to permit tentative conclusions about some of their static risk factors. First, just like with males, research with female sexual offenders suggests that a prior criminal history is also indicative of a *higher* risk of recidivism among women. In her follow-up of 471 women, Vandiver (2007) found that the number of prior convictions for any type of offense predicted rearrest for new general and violent offenses. Vandiver could not, however, establish any factor that specifically predicted new sexual offenses among the women in her sample.

Freeman and Sandler (2008a) also established a number of characteristics that differentiated women who committed new crimes from those who did not. In their study of 390 female sexual offenders registered in the State of New York, Freeman and Sandler (2008a) noted that as with the Vandiver (2007) study, a prior criminal history was related to recidivism. Specifically, the number of prior drug offense arrests; the number of prior violent offense arrests; the number of prior incarceration terms; and being younger at arrest for the index sexual offense were related to a rearrest for new general (i.e., nonsexual and nonviolent) offenses. In addition though, Freeman and Sandler (2008b) found that a high risk (as assessed by the New York State risk assessment system), the number of prior arrests for sexual offenses, and interestingly, the number of prior child abuse offenses (of any type) were specifically related to sexual recidivism among the women in their sample.

The finding that prior criminal history is related to future recidivism among female sexual offenders is not surprising. This finding holds true for all types of offenders, whether males or females (Andrews & Bonta, 2007; Blanchette & Brown, 2006). The finding by Freeman and Sandler (2008b) that prior child abuse (nonsexual) offenses were related to sexual recidivism appears, however, unique to women. Perhaps because women tend to be the primary caregivers, they are more likely than men to come to the attention of the criminal justice system for nonsexual abuse of children.

Alternatively, it could be that the sexual abuse of children, for these women, is part of a broader pattern of abuse against children. Future research should investigate this specific question as it may provide some clues about the factors that lead to sexual molestation by women.

A final, albeit extremely limited, interesting finding comes from Williams and Nicholaichuk (2001)'s follow-up of 61 female sexual offenders incarcerated in Canada between 1972 and 1998. In their detailed analysis, these authors found that the two sexual recidivists in their study were the only ones who had exclusively engaged in solo offending. This particular finding is noteworthy and may serve as an important risk marker for sexual recidivism among women, but it requires additional validation. Unfortunately, the presence of a co-offender did not appear to have been explicitly examined by Vandiver (2007) or Freeman and Sandler (2008a), rendering any direct comparison of this factor among these different samples difficult. Future research should attend to this issue.

Dynamic Risk Factors

Dynamic risk factors are those aspects of the offender that are amenable to change and that are directly related to the offending behavior (Hanson, 2006). Although dynamic risk factors are very well established for male sexual offenders, the situation is completely different for females who have sexually offended. To date, no research has established the dynamic risk factors related to recidivism, sexual or otherwise, among these women. Consequently, at this point, the assessment of risk of *sexual* recidivism among women can only be based on the elements that appear common among female sexual offenders and that are revealed through the examination of the offending patterns of these women. Clinical research suggests that relationship problems, attitudes, and cognitions that support the offending behavior, the use of sex to regulate emotional states, and emotional dysregulation problems are common among female sexual offenders (Eldridge & Saradjian, 2000; Grayston & De Luca, 1999; Nathan & Ward, 2002). Sexual gratification, a desire for intimacy (with either a victim or a codefendant), or instrumental goals such as revenge or humiliation are also associated with female sexual offending (Gannon et al., 2008). Finally, as female sexual offenders, just like their male counterparts, also engage in other criminal behavior, factors such as the presence and extent of antisocial attitudes, antisocial associates, and substance abuse as a precursor to the offending behavior should also be considered in the assessment (Ford & Cortoni, 2008).

Problematic relationships appear particularly relevant for female sexual offenders. As discussed earlier in this chapter, an element unique to female sexual offenders is the frequent presence of a co-offender. Of the women who have a co-offender, a subgroup is clearly identified as having been coerced into the offending, typically by a male, while another subgroup of offenders co-offend willingly. In addition, some women will actually be the initiators of the offending behavior or co-offend with another woman. From these findings, the role of the co-offender needs to be carefully assessed to determine the full extent of the woman's willingness to participate in the abuse. Different issues are likely to emerge if the woman was coerced into the abuse, as opposed to being a willing participant or an initiator. For example, a coerced offender may demonstrate significant deficits in assertiveness and an exaggerated dependence on her co-offender. In addition, women with co-offenders may hold gender-specific cognitions, likely related to their own experiences as well as social-cultural norms, which view men as entitled to control others (Gannon, Hoare et al., in press). In the context of the assessment, an in-depth examination of the elements that motivated the offender to co-offend and her current views of the offending behavior will be enlightening.

An interesting finding from Wijkman and Bijleveld (2008) bears discussion. These authors coded all recorded sexual offenses in the history of a subset of female sexual offenders in the Netherlands ($N = 111$). Using Cox regression analyses, they found that the presence of a prior violent partner, a history of having been physically abused, and having been bullied while at school were related to the number of sexual offenses committed by these women. Similarly, in their examination of the offense process of female sexual offenders, Gannon et al. (2008) found that practical and emotional support from family and friends were lacking in all cases, and that they were frequent victims of domestic violence. These elements, taken together, suggest that the presence of intimacy deficits and problematic relationships are important aspects to sexual offending by women.

Research results suggest that the nature of problematic relationships may be quite different for female sexual offenders in contrast to males. Among male sexual offenders, intimacy deficits tend to manifest themselves through some form of emotional identification with children, instability in his current intimate relationship, hostility toward women, general social rejection/loneliness, and a general lack of concern for others (Hanson, Harris, Scott, & Helmus, 2007). In contrast, female sexual offenders appear to exhibit a pattern of relationships characterized by abuse on the part of the partner (Gannon et al., 2008; Wijkman & Bijleveld, 2008) as well as excessive dependence or over-reliance on the men in their lives (Eldridge & Saradjian, 2000; Grayston & De Luca, 1999; Matthews, 1993). Perhaps this finding is not surprising given that female sexual offenders tend to have much more extensive histories of sexual victimization themselves in comparison to other offender populations (Johansson-Love & Fremouw, 2006). The accumulation of findings on the relationship problems of female sexual offenders indicate that not only are the presence and dynamics of the relationship with the co-offender important components of the evaluation

of female sexual offenders but also the general quality of their social and familial support.

As mentioned above, a victimization history is likely related to relationship problems. In contrast to males, past victimization is related to future recidivism among general female offenders (Blanchette & Brown, 2006). Among female sexual offenders, a past history of physical, emotional, or sexual victimization may therefore be linked to the woman's sexually offending behavior. If sexual victimization is present, it is important, however, to not assume it is the cause of her sexual offenses. Research has shown that only a proportion of female sexual offenders were themselves sexually victimized (e.g., Wiegel, Abel, & Jordan, 2003), and it is highly unlikely that victimization is the main reason why the woman chose to sexually abuse. Rather, a history of past victimization (sexual or otherwise) is more likely to be related to the offending behavior via dysfunctional patterns of relating to others, as well as patterns of coping, that the woman developed as a result of the victimization (Ford & Cortoni, 2008).

Compared to their rates of sexual recidivism, female sexual offenders have much higher rates of nonsexual recidivism. Although research is required to investigate this issue further, it is likely that female sexual offenders also demonstrate characteristics linked to offending among female offenders in general. These characteristics include antisocial attitudes and associates, substance abuse as precursor to offending, and emotional dyscontrol (Blanchette, 2001). Some women who engage in sexually deviant behavior do present with egocentric or antisocial features (Grayston & De Luca, 1999; Nathan & Ward, 2002), indicating that for at least a portion of female sexual offenders, the antisociality factor commonly found among male sexual offenders is also present. The extent to which antisociality plays a role in sexual offending among women, however, remains an open question.

A Final Note on the Risk Assessment of Female Sexual Offenders

The lower recidivism rates of female sexual offenders have, to date, precluded the development of risk assessment tools specifically for these women. Due to the lack of knowledge on female sexual offenders, many jurisdictions have adopted risk tools for male sexual offenders (e.g., Static-99, Hanson & Thornton, 2000) to assess female sexual offenders. Because tools for male sexual offenders have not been validated for women, using these tools to assess risk of recidivism among female sexual offenders is inappropriate. Instead, since general (i.e., nonsexual) recidivism is much more common among female sexual offenders than sexual recidivism, evaluators should consider the use of tools validated to assess risk of general and violent (nonsexual) recidivism among female offenders (e.g., LSI-R, Andrews & Bonta, 1995).

The use of general risk assessment tools, however, require an understanding of the research on risk factors and recidivism among female offenders in general; as noted earlier, these issues differ according to the gender of the offender (e.g., Blanchette & Brown, 2006; Folsom & Atkinson, 2007; Holtfreter & Cupp, 2007; Manchak, Skeem, Douglas, & Siranosian, 2009). Until sufficient knowledge has accumulated to permit the development of appropriate risk assessment tools specifically for female sexual offenders, the approach to their assessment should consists of a combination of a risk tool validated for women to assess their general risk of recidivism and an empirically guided clinical judgment of the extent and combination of the specific factors related to the sexual offending behavior to separately assess potential likelihood of *sexual* recidivism. Psychometric tools such as the Clarke Sexual History Questionnaire (Paitich, Langevin, Freeman, Mann, & Handy, 1977) and the adult female form of the Multiphasic Sex Inventory II (MSI-II) (Nichols & Molinder, 1994) may be useful adjuncts to this assessment. Should evaluators choose to use such tools, however, they would need to be cognizant of their limits: these were developed and validated mostly on male sexual offenders; very little female norms are available (Ford & Cortoni, 2008). Ultimately, regardless of the method used to assess risk in female sexual offenders, evaluators would do well to always remember that the base rate of sexual recidivism among women is extremely low. Therefore, they should carefully frame their reporting of risk levels within that context (see Babchishin & Hanson, 2009 for recommendations on this issue).

Treatment of Female Sexual Offenders

Treatment

Until we gain a better empirical understanding of the factors that explain sexual abuse by women, treatment efforts remain tentative in that we do not know whether current treatment practices truly address the relevant elements that led to the sexually abusive behavior. Overall, the main goals of treatment should be to address the factors related to the offending, understand the needs that are fulfilled by the sexually abusive behavior, and to develop alternate positive ways to meet those needs. Generally, treatment should focus on five broad areas that include cognitive and emotional processes; intimacy and relationship issues; sexual dynamics; and social functioning (see Denov and Cortoni (2006) and Ford and Cortoni (2008) for in-depth discussions of these issues). The specific work in treatment, however, will be guided by the woman's individual problems within those areas.

To date, a number of approaches have been suggested and a number of treatment programs developed for the treatment of

female sexual offenders (e.g., Correctional Service Canada, 2001; Eldridge & Saradjian, 2000; Steen, 2006). Typically, these approaches adopt a cognitive-behavioral orientation and tend to follow the typical design for the treatment of men. For example, denial and minimization of the offending behavior; distorted cognitions about the sexual offenses; attitudes that condone sexual abuse; intimacy deficits; and the use of sex to regulate emotional states or to fulfil dependence or intimacy needs (Eldridge & Saradjian, 2000), and the development of an offense chain and relapse prevention plan (Steen, 2006) are commonly found in these approaches.

The problem with offering treatment to women based on male models is that it fails to consider how at least some of the elements related to sexual offending are different for women. For example, common to both male and female sexual offenders are denial and minimization of the offending behavior. After female sexual offenders acknowledge their sexual offending behavior, however, they tend to show much less minimization of their behavior than males (Matthews, 1993). Another example of these differences is the presence of a co-offender, a factor not typically found in men. Further, the patterns of cognitive distortions of women with a co-offender are different. For example, many women who co-offended with their partner tend to wrongly take responsibility for the deviant behavior of their offending partners (Matthews, 1993), or even maintain outright denial of the behavior if they are still romantically involved with him (Ford & Cortoni, 2008). Finally, while male sexual offenders tend to disregard the importance of relationships, female sexual offenders instead tend to give them an exaggerated importance, often due to their dependency issues (Eldridge & Saradjian, 2000).

The broad application of male models to the treatment of women means that gender-specific issues are also neglected in treatment. This is particularly relevant when female sexual offenders are required to attend mixed gender treatment groups: women with previous trauma histories, often at the hand of males (Gannon et al., 2008), may find it traumatic to be in treatment with male abusers and may not feel safe to share their innermost thoughts with them. In the general criminological literature, it is generally recognized that the treatment of female offenders needs to take into account women's specific communication styles and relational issues (Blanchette & Brown, 2006; Young, 1993). For example, contrary to popular beliefs, in groups, men talk more and interrupt more than women (DeLange, 1995). Further, men and women tend to listen for different things: men listen for the "bottom line" in order to take action; women listen for details (DeLange, 1995). As another example of differences between men and women, while all offenders require community support, in contrast to men, women tend to be in more need of extensive supportive social networks as these are an important part of their ability to deal with stress (Rumgay, 2004). Similarly, women typically require more extensive support to improve their general community functioning, particularly when the focus is on their ability to develop and maintain a more stable life with less dependence on others.

Conclusion

This chapter has reviewed our current knowledge on female sexual offenders. There is yet much to be learned about women who engage in sexually offending behavior. While the true prevalence of female sexual offending is difficult to ascertain, it is clear that they commit only a fraction of all sexual offenses. Nevertheless, attention must be paid to this population as the effects on victims are just as pervasive as they are for those who are victimized by men (Denov & Cortoni, 2006). Much work remains to be done to better understand the etiological factors that are related to sexual offending among women.

As seen in this chapter, research has now shown quite clearly that female sexual offenders have much lower rates of any types of offending and tend to re-offend sexually or otherwise at much lower rates than males. Further, while a prior criminal history is related to general recidivism among female sexual offenders, a number of risk factors related to recidivism in male sexual offenders have not be found in women, rendering the use of assessment tools validated for males invalid for women. Although female sexual offenders do appear to share some of the same characteristics as male offenders, some important differences must be taken into account when assessing and treating women offenders. Among others, a large portion of women who sexually abuse do so in company of a co-offender, typically a male. Consequently, the context in which the offenses took place in interaction with the woman's life needs to be examined. Women's lives and their societal experiences differ from those of men and their experiences will influence both their criminal behavior and their rehabilitation (Blanchette & Brown, 2006). Given these differences, it is clear that current knowledge on male sexual offenders cannot simply be extended to female sexual offenders and that much research is yet required to improve our understanding of why women engage in sexually offending behavior.

Part II

Assessment and Risk Appraisal of Sexual Offenders

Assessment, Diagnosis, and Risk Management of Sexual Offenders with Intellectual Disabilities

Gerry D. Blasingame

Persons with intellectual disabilities represent a unique and important subgroup of sexual offenders. There is evidence that such individuals commit sexual offenses at rates higher than sex offenders without intellectual disadvantage or delay. Available research indicates that there are both important similarities and differences between the sex offender with intellectual disability and other neurotypical sex offenders. As a result, there can be complex issues associated with assessment, diagnosis, and risk management with persons with intellectual disabilities who have sexually offended. The purpose of this chapter is to discuss characteristics associated with intellectual disabilities and those who have sexually offended, address modifications needed in the assessment process including adapting interviewing and testing techniques and procedures selected for lower cognitive levels of functioning. In addition, issues related to comorbid psychiatric and psychological conditions and, more broadly, diagnostic challenges are addressed. The applications of actuarial risk assessment, as well as other approaches to risk assessment, are considered relative to offenders with intellectual disabilities. Finally, evidence-based interventions are considered, including both those designed to assist the offender-client in reducing his own risk and interventions to assist persons in the offenders' "risk management circle."

A primary area of concern for evaluators and treatment providers working with sexual offenders who have intellectual or other developmental disabilities is that of risk of reoffense. Evaluators are also concerned with other forms of aggression, mental health diagnosis, and treatment planning. Evaluating sexual offenders typically entails evaluating the degree of risk of *what behavior* occurring under *what circumstances* or contexts. Evaluators attempt to discern what the individual's needs are and how those relate to his potential for reoffense. Finally, evaluators also look into how to implement treatment and supervision in order to gain the maximum therapeutic benefit for both the individual being treated and the people in the individuals' proximity.

Unfortunately, no singular characteristic or trait is so strongly correlated with reoffense that it alone can be relied upon to ascertain an individual person's risk of sexual reoffense (Hanson & Morton-Bourgon, 2007). This makes comprehensive, holistic assessments necessary (Beech, Fisher, & Thornton, 2003; Blasingame, 2005). This is true for neurotypical as well as intellectually disabled sexual offenders.

Definitions and Characteristics Associated with Sexual Offenders with Intellectual Disabilities

Researchers unfortunately do not always use the same criteria or definition of intellectual disability or cognitive impairment. Some studies include individuals with full-scale IQs up to 80, while other studies do not (Crocker, Cote, Toupin, & St-Onge, 2007; Lindsay, Hastings, Griffiths, & Hayes, 2007). It is commonly understood that two individuals with the same FSIQ score will have different strengths and weaknesses. Clinicians often take liberties regarding which clients they describe as developmentally or learning disabled. This affects how they manage treatment planning for various individuals, based on the effects of chronic mental illnesses, general learning disabilities, borderline intellectual functioning, and illiteracy. However, with these diverse levels of cognitive abilities in different studies, it makes it difficult to compare various studies and findings.

For the purposes of this chapter, persons whose full-scale intellectual quotient (FSIQ) is 70 or below are considered to be intellectually disabled and those whose FSIQ is 71–84 are characterized by "borderline" intellectual functioning (APA, 2000). Borderline intellectual functioning implies the person is on the border between normal cognitive functioning and

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_11

mental retardation. Many persons with borderline intellectual functioning appear to function in the normal range in some skill areas or may present as if they understand an evaluator's vocabulary or meanings of words that they actually don't understand. Upon further questioning, however, individuals with borderline intellectual functioning often demonstrate a lack of understanding and a tendency to acquiesce as if they understand when they do not. This may undermine assessment accuracy if not attended to or if measurement tools used do not consider this. Evaluators often recognize that many individuals whose FSIQ is between 71 and 84 would more readily benefit from assessment and treatment approaches similar to those commonly used for persons with intellectual disabilities.

By definition, intellectual disabilities (previously known as mental retardation in the USA and often referred to as learning disabled in the UK) have their onset before the age of 18 (APA, 2000). They have ongoing, lifelong effects on the individual. Having cognitive functioning two standard deviations below the mean of the population as well as functional impairment in two or more adaptive skills domains is an element of the formal APA diagnostic criteria.

Intellectual disabilities are themselves heterogeneous conditions. Two primary pathways are commonly identified as influential in development or appearance of intellectual disability. One is related to low functioning cultural-familial upbringings; the other is based on genetic and/or organic contributions (APA, 2000; Dykens, Hodapp, & Finucane, 2000; Holland, 2004). The impairing contributions from the genetic and organic etiologies undermine development of cognitive and social competencies, among others. Behavioral phenotypes have varying degrees of expression. There is no question that genes have influences on behavior in multiple, nonspecific ways (Dykens et al., 2000). There are hundreds of genetic etiologies for intellectual disability (Dykens et al., 2000) but with a similar outcome of impaired cognitive and social functioning and adaptive behavior deficits. Authorities agree that intellectual disability alone does not dismiss culpability for criminal or sexual conduct; it nonetheless affects court disposition, treatment planning, and risk management (Baroff, Gunn, & Hayes, 2004; Blasingame, 2005; Melton, Petrila, Poythress, & Slobogin, 1997).

Prevalence Issues

Intellectual disability occurs in a small percentage of the overall population. The diagnosis of intellectual disability requires the individual have an FSIQ two or more standard deviations below the population norm. The broader category of intellectual disability represents about 2.5 % of the general population (Kaufman & Lichtenberger, 2006). Those with mild mental retardation/intellectual disability comprise approximately 85 % of those individuals who have any level of intellectual disability (APA, 2000). Those with FSIQs of 71–84, those with borderline intellectual functioning, represent 14 % of the population.

A question is often raised regarding the co-occurrence of crime and intellectual disability and the prevalence of intellectually disabled persons in the criminal justice system (Crocker et al., 2007; Lindsay & Taylor, 2005). There is a large contingent of intellectually disabled persons among the criminal justice population, but percentages vary from setting to setting and state to state (Petersilia, 2000). Several studies report a strong link between low IQ and later delinquency (e.g., Babinski, Hartsough, & Lambert, 1999; White, Moffitt, & Silva, 1989). A study of Ireland's prison inmate population found that 28 % of the inmates had intellectual disabilities/mental handicaps (Murphy, Harrold, Carey, & Mulrooney, 2000). The frequency in a Canadian study was approximately 20 % (Crocker et al., 2007). An international review found that the range was from 2 % to 40 % depending on varying methodological strategies and definitions (Jones, 2007). The fact that different studies use different methods of measurement or degrees of intellectual functioning makes it very difficult, if not impossible, to compare groups or studies.

An older study reported that 25 % of sex offenders who have intellectual disabilities also had histories of other violent behavior (Lund, 1990). Lindsay (2002) reported that of 62 offenders with intellectual disabilities, 62 % had prior convictions or documented evidence of prior sex offenses. Other studies reported that community-based outpatient samples have a low frequency of serious crimes (Hayes, 1991). Again, however, the setting in which the study occurs has a significant relationship with such prior histories.

Although it is clear that there is an overrepresentation of persons with intellectual disabilities within the criminal justice system, it is not clear that people with intellectual disabilities as a group commit more crimes (Holland, 2004; Lindsay & Taylor, 2005). Holland describes *filter points* or decision points that affect who is criminally charged or otherwise held accountable. These include whether a criminal behavior is detected or identified, whether that behavior is reported to the authorities, whether law enforcement action follows the report or if it is dropped, whether the alleged offender is arrested, and whether the individual is charged, taken to court, and if he is found guilty. Studies investigating the percentage of offenders who have intellectual disabilities are challenged by differences in criteria for intellectual disability (as discussed above), undetected intellectual disabilities among the general criminal population, tolerance of victims due to the subject's apparent disability, a victim's credibility as a witness due to having her/his own disability issues, and whether the law enforcement community believes the alleged offender understood that what he was doing was

actually a crime (Holland, 2004). These factors all influence how prevalence data is tracked and tallied.

Ward, Trigler, and Pfeiffer (2001) estimated that approximately 5 % of persons with intellectual and/or other developmental disability engage in some form of sexually inappropriate behavior. People who have developmental disabilities often do not face adjudication for their sexual misconduct; only 15 % of a community-based sample had ever experienced incarceration for their misconduct (Ward et al., 2001). This suggests that as many as 80 % of offenders with intellectual disabilities are never incarcerated for a particular sex offense. Thirty-seven percent of community-based programs in their survey do not serve those with sexual behavior problems. Per Ward et al., 81 % of the respondents indicated that services in their regions were inadequate to serve the people with developmental disabilities who have sexual behavior problems. This lack of community resources may have an impact on court decisions regarding disposition of cases.

Differentiating subtypes of sexual offenders who have intellectual disabilities is another complex issue. Offenders with intellectual disabilities known to have victimized a child may well have other forms of sexual misconduct and other types of victims (Blasingame, Abel, Jordan, & Wiegel, 2011; Heil, Ahlmeyer, & Simons, 2003; McGrath, Livingston, & Falk, 2007b). McGrath and colleagues found that 54 % of their sample of 153 adult males had a history of more than one type of sexual offense. Of the subjects in the McGrath et al. study, 27 % had assaulted adults, 27 % had male victims of child sexual abuse, 17 % had female child sexual abuse victims, nearly 12 % had committed incest, and 16 % were identified as noncontact sexual offenders.

Description of Sexual Offenders Who Have Intellectual Disabilities

There are a number of similarities between intellectually disabled and intellectually typical sexual offenders (Courtney, Rose, & Mason, 2006; Crocker et al., 2007; Haaven & Coleman, 2000; Haaven & Schlank, 2001; Kalal, Nezu, Nezu, & McGuffin, 1999; Leonard, Shanahan, & Hillery, 2005; Lindsay, Elliot, & Astell, 2004; Quinsey, 2004). Common characteristics among offenders include having poor social support, attitudes supportive of sexual abuse, antisocial lifestyles, poor self-regulation and self-management, poor cooperation with supervision and treatment, and increased anger and stress prior to reoffending (Lindsay et al., 2004). Negative problem-solving strategies and poor skills are correlated with sexual deviancy among persons with impaired as well as normal intellectual functioning (Nezu, Nezu, Dudek, Peacock, & Stoll, 2005). The correlations of several of these characteristics with risk for sexual reoffense are also known (Hanson, 1997; Hanson & Bussiere, 1996; Hanson & Morton-Bourgon, 2007), but no singular characteristic is predictive of reoffense (Table 1).

There are many additional needs and challenges for persons who have intellectual disabilities. Low cognitive functioning impairs the person's ability to manage information, formulate concepts, create internal cognitive scripts, and absorb information. Low cognitive functioning, as measured by intelligence or achievement tests, indicates inadequate vocabularies; slower performance on timed skills tasks; limited working memory, i.e., how much information the person can manage at a given moment in time; and a slower speed for processing the information at hand. This also causes deficiencies in recalling information, i.e., short-term and/or long-term memory skills are often impaired. These challenges make it difficult to take in information in the short term as well as impair the person's ability to transfer short-term memory to long-term memory. Later retrieval of information from memory is compromised. Many children with learning disabilities attempt to please the authority figures that may be talking to them or asking them questions. These cognitive impairments make these individuals susceptible to leading questions. Others perhaps admit behaviors they actually did not commit out of the belief that they do not always understand things yet they assume the authority figure knows and they trustingly go along with the leading questions, as they want to please authority figures. This is a problematic area for law enforcement and mental health evaluators.

Other challenges come in the form of socialization constrictions. Individuals who have intellectual disabilities often have poor social skills or inappropriate boundaries. As such, their parents can be hypervigilant in their supervision of the children. This functions to protect the child from the consequences of his actions, which would typically be part of the learning process. Without social feedback about one's behavior or not having the ability to learn from the consequences of one's actions, an individual may not have sufficient social learning experiences. This can impair the process of internalizing social boundaries. In addition, children who are so closely supervised often do not have the opportunity to experiment with social-sexual behaviors such as flirting, holding hands, kissing, or making out with a girlfriend or boyfriend. While close supervision is helpful in many ways, it can impair the opportunity for these children to learn through normal experimentation. This can contribute to the child getting the sense that such behaviors, that are otherwise natural and normal, are not acceptable to the parent and the child may learn to sneak about or take advantage of clandestine opportunities to experiment with these behaviors. Given that many people with intellectual disabilities are socialized with younger family members or children, their biological urges for sexual experimentation may be acted upon with the younger mental age-mates rather than their chronological age-mates (Blasingame, 2005).

Table 1 Characteristics of sexual offenders with and without intellectual disabilities

Sexual offenders without intellectual disabilities	Sexual offenders with intellectual disabilities or borderline intellectual functioning
Lower intellectual functioning; average FSIQ of 90	Severe cognitive impairments; FSIQ two standard deviations below the mean
	Severe impairments in adaptive functioning
Poor social support	Poor social support
Attitudes supportive of abuse; cognitive distortions that enable sexual aggression	Attitudes supportive of abuse; cognitive distortions that enable sexual aggression
Antisocial lifestyles and attitudes	Antisocial lifestyles and attitudes
Poor self-regulation and self-management	Poor self-regulation and self-management
Issues with supervision and treatment	Issues with supervision and treatment
Increased anger and stress prior to reoffending	Increased anger and stress prior to reoffending
Negative problem-solving strategies	Negative problem-solving strategies
	Greater inability to manage information; poor working memory
	Communication skills deficits; inadequate vocabularies; poor social interaction skills
	Slower information processing speed
	Memory recall deficits
	Early socialization constrictions; poor social training or socialization/boundary training
Significant frequency of prior sexual or physical trauma	Very high frequency of prior sexual traumatization
Problematic coping skills	Poor and problematic coping skills
	High frequency of comorbid mental disorders; high percentage of dual diagnoses
	Low self-esteem
	Significant frequency of personality disorder traits; antisociality
Small percentage have psychopathy	Small percentage have psychopathy traits
Special education in background; school grade failures	Special education in background; school grade failures
	Inconsistent application of sexual knowledge
	Lack of assertiveness
	Neurodevelopmental impairments undermine learning
	Allowances made by staff members; staff complacency
Significant crossover of areas of sexual interest	Significant crossover of areas of sexual interest; diverse victim selection

Another significant challenge for people with intellectual disabilities is their deficits in communication skills. The poor vocabulary, social understanding, and information processing skills impair these individuals' abilities to formulate ideas and to express those ideas. This impairs their ability to identify internal emotions and conceptualize subjective experiences and needs. The inability to communicate one's needs along with poor coping skills often leads to maladaptive behaviors in attempt to meet one's normal needs. These and a variety of medical, mental health, and behavioral problems are well documented (Alloy, Jacobsen, & Acocella, 1999; APA, 2000; Blasingame, 2005; Dykens et al., 2000; Fletcher, Loschen, Stavrakaki, & First, 2007; Haaven & Schlank, 2001; Seghorn & Ball, 2000; Sherak, 2000).

Parental and/or caretaker limitations, perceptions, and frustrations may further complicate family life, sexuality education, and socialization opportunities for some individuals who have intellectual disabilities (Blasingame, 2005; Lund, 1992). These several factors complicate the decision-making process regarding distinctions made between sexually offensive behavior, sexual offending behavior, and sexual deviance (Blasingame, 2005).

People who have intellectual or other developmental disabilities are reported to have two to four times greater risk of developing any comorbid psychiatric disorder (APA, 2000; Fletcher et al., 2007). Mood disorders, attention deficit hyperactivity disorder, conduct disorder, and movement disorders are common comorbid conditions albeit potentially with atypical clinical presentations (APA, 2000; Fletcher et al., 2007; Hurley, 2006). One of the challenges in making mental health diagnoses is that individuals who experience intellectual disabilities may well lack the ability to verbalize complaints regarding psychological symptoms, internal feeling states, emotions, social distress, or identify symptoms (Fletcher et al., 2007). Interviews with family members or other knowledgeable informants are helpful in discerning the presence of such symptoms.

People with intellectual disabilities *and* comorbid mental illnesses are at higher level of risk for reoffending criminally, particularly if they experience a major mental disorder or substance abuse history (Smith & O'Brien, 2004). Day (1997) reported 25–33 % of intellectually disabled sex offenders are dually diagnosed. Likewise, Lindsay et al. (2002) reported that 32 % of their sample of 62 offenders had a diagnosis of a major mental disorder. In another study, Smith, Quinn, and Lindsay (2000) reported that from a sample of 153 individuals with intellectual disabilities who had sexually acted out, 22 % were diagnosed with a significant mental illness, 12 % with a mood disorder, and 10 % with schizophrenia. These frequencies are in greater proportions than in the general population.

Personality disorders and maladaptive personality traits are also relatively common among individuals who have intellectual disabilities (Lindsay et al., 2007). The frequency of personality disorder diagnosis again varies by setting and methodology for making the diagnosis. Some studies have identified a large percentage of individuals with intellectual disability as having *traits* of personality disorders (e.g., maladaptive personality traits). Goldberg, Gitta, and Puddephatt (1995) found *traits* in 57 % of their sample of institutionalized individuals and 91 % of those in a community setting. By contrast, Flynn, Matthews, and Hollins (2002) found 92 % of their sample of 36 subjects who had severe behavior problems were diagnosed with a personality disorder. Setting and context of evaluation appear to have a significant influence on whether personality disorders are diagnosed. Unfortunately, the wide variations in prevalence reported in the literature make it difficult to generalize the findings.

In a study of 164 cases that have intellectual disabilities from three forensic settings, Lindsay et al. (2007) found a preponderance of antisocial personality disorder but very low percentages of other personality disorders. Thirty-nine percent of these forensic subjects were diagnosed with a personality disorder; no correlation was found between FSIQ level and personality disorder diagnosis. Additionally, Lindsay et al. found through confirmatory factor analysis that there were two primary factor loadings. The first was referred to as *acting out*; the second was *avoidant/rumination/inhibited*. These factors crossed over several personality disorder diagnostic categories and when combined made up 37 % of the variance between diagnostic groupings. It should be noted that this study did not provide separate information regarding subtypes of forensic subjects, i.e., they did not separate sex offender data from violent offenders.

A more severe form of personality disorder is that of psychopathy. The construct of psychopathy is valid among criminal offenders who have intellectual disability (Morrissey, Mooney, Hogue, Lindsay, & Taylor, 2007). However, psychopathy may present differently in offenders who are intellectually disabled, due to their communication and adaptive functioning challenges as discussed above. These individuals may present behaviors that are poor matches for the descriptors used in the PCL-R coding manual. Prevalence studies report that approximately 10 % of criminal offenders have elevated traits of psychopathy (Morrissey et al., 2007). The prevalence rates vary from setting to setting, similar to variations in diagnoses of other mental health disorders discussed above. Morrissey et al. further suggest that while some of the characteristics of psychopathy overlap with characteristics of intellectual disability, such as impulsivity or lack of empathic awareness, there remains strong evidence of a percentage of offenders who have intellectual disabilities who are also psychopathic.

Characteristics of psychopathy that are particularly relevant to offenders who have intellectual disabilities are strongly associated with Factor 1 on the PCL-R (Hare, 1991). These are glibness/superficial charm, inflated self-esteem, pathological lying, conning and manipulation, lack of remorse or guilt, shallow affect, lack of empathy or callousness, and failure to take responsibility. Morrissey et al. (2007) reported that higher scores on the PCL-R Factor 1 scale correlates with problems during treatment such as moves to higher levels of supervision and termination from treatment programs.

The sexual knowledge base of persons who have intellectual disabilities and sexual behavior problems is heterogeneous. For example, Lunsky, Frijters, Griffiths, Watson, and Williston (2007) found that among intellectually disabled persons who were evaluated in association with sexual misconduct, there was a significant variation in the amount of sexual knowledge held by the offenders. Those who committed offenses that are more serious had much higher than expected sexual knowledge, while those who committed offenses such as inappropriate touching or public masturbation were less informed about sexuality. Such variation calls for individualized assessment, diagnosis, and treatment planning.

Although it has been postulated that persons with intellectual disabilities who commit sexual offenses did so with motivations other than sexual deviance, the *counterfeit deviance theory* (Hingsburger, Griffiths, & Quinsey, 1991) has met challenges in recent years. The counterfeit deviance theory postulated that while clearly inappropriate, some of these individuals' sexual misconduct is due to characteristics associated with their disabling conditions. Hingsburger et al. (1991) proposed 11 counterfeit deviance hypotheses. Their theoretical constructs are as follows:

- The Structural Hypothesis: The system of care these individuals are required to live in may have failed to address the needs for sexual expression. The iatrogenic effect of such restricted environments could cause these individuals

to seek opportunities in settings or with individuals that are inappropriate.

- The Modeling Hypothesis: Some sexual behaviors are misguided repetitions or reenactments of "caring behaviors" previously done by family members or staff persons. These might include clients being naked in front of staff for hygienic/bathing purposes. The individual may later fail to discriminate with whom such behavior is appropriate.
- The Behavioral Hypothesis: Some sexual behaviors may be mechanisms to gain attention from family or care home staff persons. Some clients learn that one way to get attention is through negative behaviors, including sexually oriented behaviors. There is significant positive reinforcement (attention) for committing such behaviors.
- The Partner Selection Hypothesis: Because many people with developmental disabilities are not afforded age-appropriate opportunities to develop fulfilling relationships, they may well seek out opportunities to relate to staff or an available child in attempt to develop intimate relationships.
- The Inappropriate Courtship Hypothesis: Lacking the interpersonal skills needed to move through the stages of relationship development and unable to discern the nuances of private versus public behaviors, some persons with developmental disabilities may become too aggressive in their pursuits of personal friendships and relationships.
- The Sexual Knowledge Hypothesis: Given their problems with learning through subtle social learning experiences, some people with developmental disabilities have sexual knowledge deficits. When they are afforded sex education, it is often in the context of biology and body parts rather than in the context of social relationships, appropriate consent, and self-control. Some cases involve individuals being given too much information to process, exciting excessive curiosity.
- The Perpetual Arousal Hypothesis: Some persons with developmental disabilities appear to be perpetually aroused due to their inability to fulfill their sexual needs in a normal way, or they may not have the knowledge or skills required for achieving orgasm.
- The Learning History Hypothesis: People with developmental disabilities brought up in overly protective homes or nonnormative environments may not have normal learning opportunities. This would also include being abused or those who lack socialization opportunities.
- The Moral Vacuum Hypothesis: People with developmental handicaps may not comprehend the effects of their behavior on others. As such they may not realize their behavior can inflict pain or discomfort on others.
- The Medical Hypothesis: Some individuals may not realize that particular symptoms are the result of a medical condition that needs attention. For example, scratching one's genitals, albeit inappropriate in social settings, may be indicative of an infection rather than an attempt at masturbation.
- The Medication Side Effect Hypothesis: Many people with developmental disabilities take psychotropic medications. Some people experience side effects such as inhibited sexual desire or diminished ability to achieve orgasm. If these side effects are not effectively explained to the individual or caregiver, sexual dysfunction or behavioral issues might result.

Hingsburger et al. (1991) recommended interventions such as system modification, policy modification, better sex education, staff education and training, and provision of counseling to the individual to address the problems. From this perspective, the client is not considered criminally culpable for his or her actions that are otherwise sexually inappropriate. Rather, the care delivery system is often considered the source of the problem and/or challenged to make corrective adjustments.

Hingsburger et al. (1991) also defined what they refer to as a hypothesis of "real deviance" for individuals with developmental disabilities.

- Benign Paraphilia: Unusual sexual behaviors typically done in private and not dangerous to oneself or others. Hingsburger et al. suggest that stealing underwear for masturbation is an example of a benign paraphilia. If this were done by a noninstitutionalized or unsupervised person, it would not be known about, e.g., it would be benign. It would have no victim and not be offensive to others.
- Offensive Paraphilia: Offensive paraphilia is a sexual arousal in circumstances or behaving in ways that are harmful to others or are offensive, such as an adult sexually interacting with a child.
- Hypersexuality: Ruminating about sexual themes or sexual acts may leave the individual feeling controlled by sexual obsessions and may interfere with daily life. Hingsburger et al. suggested this type of rumination may be an indication of a physical hypersexuality and may need management with hormone therapy.

Recent research, however, found that different offenders with intellectual disabilities have different levels of sexual knowledge, as discussed above. The research provides mixed results as to whether the *sexual knowledge hypothesis* is a sufficient descriptor for offenders with intellectual disability. Talbot and Langdon (2006) found that intellectually disabled sexual offenders had higher levels of sexual knowledge than their non-offender control group. Michie, Lindsay, Martin, and Grieve (2006) made similar findings.

Another aspect of concern is in that of cognitive distortions. Lindsay, Whitefield, and Carson (2007) found that sexual offenders with intellectual disabilities held to a greater

number of cognitive distortions supportive of sexual offending than did the control group of other persons with intellectual disabilities. In another study, Lindsay et al. (2006) found that those intellectually disabled offenders who abused children held a higher number of child-oriented cognitive distortions than the offenders who abused adults and vice versa. These findings strongly support that cognitive distortions are not only relevant to assessment and treatment of offenders with intellectual disabilities, they also suggest that some offenders with intellectual disabilities have the ability to differentiate their targets of sexual interest.

Recent theoretical developments have identified multiple routes or pathways that people take on their way to becoming sexual offenders (Ward & Hudson, 2000). Different goals and motivations drive the individual to follow different pathways to goal attainment. These pathways involve diverse behavioral scripts and patterns of cognitive distortions (Lindsay, Steptoe, & Beech, 2008). Some offenders may want to offend and make efforts to do so, while others are aware of their potential to offend but want to avoid offending. The former pathway is known as the approach pathway; the latter is known as the avoidance pathway. Offenders are also different in their degree of overt effort and planning invested in their acting out. For the approach-oriented offender, these strategies may include making direct, explicit efforts to achieve sexual conquests or thoughtlessly acting on habituated behavioral scripts that are consistent with sexual offending (Lindsay et al., 2008; Ward & Hudson, 2000). The avoidance-oriented offenders may make efforts to avoid offending that are simply inadequate and do not sufficiently interrupt the underlying propensity to sexually act out.

Keeling, Rose, and Beech (2006) investigated the application of the multiple pathways theoretical constructs with offenders who have intellectual disabilities. Their findings supported the use of the self-regulation model with this group of offenders. Keeling, Rose, and Beech found that more than 90 % of their sample of 16 subjects was classified in two of the four pathways. Thirty percent were classified as approach explicit and 62 % were classified as approach automatic. These findings suggest that there is little difference between mainstream and intellectually disabled offenders in regard to their pathways to offending. Lindsay et al. (2008) also found that over 90 % of the intellectually disabled sex offenders in their sample were classified in the approach pathways. These findings also suggest that those intellectually disabled offenders had intact self-regulation and control and may well have engaged in conscious planning. These findings further suggest that a large percentage of intellectually disabled sex offenders are not as naïve or simply impulsive as previously thought.

Blanchard et al. (1999) found a significant correlation between intellectual deficiencies and maternal age in relation to the prevalence of male-oriented pedophilia. School grade failure and/or assignment to a special education class was found to be a significant educational background variable among sexual offenders (Cantor et al., 2006). Offenders with intellectual disability are less discriminating in their victim selection and offenses than are their neurotypical counterparts (Rice, Harris, Lang, & Chaplin, 2008). These characteristics suggest there is likely a neurodevelopmental disruption that contributes to the onset of maladaptive sexual behaviors (Cantor et al., 2006; Rice et al., 2008).

Blanchard et al. (1999) found that mental retardation or lower intellectual functioning was correlated with a diagnosis of pedophilia. In a large study of adult male sexual offenders, Blanchard et al. report that the presence of lowered intellectual capacities decreased the likelihood of exclusive sexual interest in girls. They also found that maternal age at the birth of the child increased the likelihood of exclusive sexual interest in boys. When both of these characteristics were present, there was a greater likelihood of sexual interest in boys; when only one was present, that likelihood was lessened (Blanchard et al., 1999). Based on penile plethysmography findings, the Blanchard et al. data indicate that the victim selection choices made by child sexual abusers who had intellectual disabilities were not due simply to situational availability; their decisions were made because of relative sexual interest in children.

Recidivism studies in recent years have improved our abilities to identify several characteristics to target in treatment. Lindsay et al. (2004) studied 52 adult male offenders with intellectual disabilities. They included *suspicion* of reoffending in their investigation to attempt to capture those unreported reoffenses. Variables identified with reoffending and suspicions of reoffending were separately considered. Those variables associated with reoffense were antisocial attitudes, low self-esteem, lack of assertiveness, poor relationship with mother, allowances made by staff, staff complacency, poor response to treatment, and offenses involving violence (Lindsay et al., 2004).

In terms of variables related to *suspicion* of reoffending, Lindsay et al. (2004) reported somewhat different findings, with some overlap. They reported antisocial attitudes, attitudes tolerant of sexual crimes, denial of a crime, sexual abuse in childhood, low self-esteem, lack of assertiveness, low treatment motivation, erratic attendance, unexplained breaks from routine, deterioration in family attitudes, allowances made by staff, staff complacency, unplanned discharge, and poor response to treatment. While suspicion of reoffending may include persons who have indeed not reoffended, these characteristics can aid in identifying those offenders who are prone to persist in making poor decisions and putting themselves in situations where they will be scrutinized.

Base rates for sexual reoffense vary depending on the setting the subjects are in, i.e., institutional versus community-based treatment settings. Many studies comingle general

criminal data on violent recidivism, including sexual recidivism, making the findings less useful when attempting to ascertain risk with a sexual offender from another setting (Phenix & Sreenivasan, 2009). Individuals in high security settings such as prisons and forensic hospitals have higher frequencies of prior sex crimes than those in community settings; these differences may well affect how outcome studies can be generalized. Lindsay (2004) reported that several older recidivism studies reported 30–70 % of general criminal recidivism among offenders who were intellectually disabled.

However, when looking specifically at sexual offenders with sexual recidivism, the data is more hopeful. Lindsay et al. (2002) reported on a sample of 48 sex offenders who had a 4 % reoffense rate in the first year of follow-up, 12 % reoffense at 2 years, and 13 % reoffense at 3 years. In their 11-year follow-up study, McGrath et al. (2007b) detected 11 recidivists, or approximately 11 %, who committed 20 new crimes. Eleven of those 20 new crimes involved noncontact crimes, and six of the victims were staff members. Finally, Tough (2001) reported a recidivism rate of 16 % in a sample of 76 treated sexual offenders when including informal file documentation as well as formal arrest and conviction records with up to a 19-year follow-up.

Criminal Investigation and Disposition of Sex Offenders with Intellectual Disabilities

Legal systems are involved in a significant number of cases with intellectually disabled sexual offenders. There are several steps along the way before an offender is found guilty or innocent, sentenced, and/or the case disposed of (Holland, 2004). Some studies have reported high frequencies of false confessions by intellectually impaired suspects, who believed they would be "allowed to go home" if they agreed with the police or otherwise acquiesced to the pressures of the interrogation by authority figures (Petersilia, 2000). The Miranda warning that is read to criminal suspects is estimated to require a seventh grade reading comprehension level, far above the comprehension level of an adult with a mild intellectual disability (Baroff et al., 2004; Petersilia, 2000). As much as some individuals with intellectual or other developmental disabilities try to present themselves as normal, it may be difficult for untrained law enforcement professionals to identify that the person is indeed intellectually impaired (Petersilia, 2000). Without such awareness, investigating officers may not make the necessary accommodations.

Once arrested, it is common for inmates with intellectual disabilities to have their cognitive impairments be undetected (Scheyett, Vaughn, Taylor, & Parish, 2009). Without identifying such impairments, these individuals cannot receive appropriate referrals to support agencies or advocates. Further, protective supervision in custody cannot be provided if correctional staff is unaware of the true level of functioning of the inmate. Inmate rights may well be compromised without such awareness by correctional staff (Petersilia, 2000; Scheyett et al., 2009). Given that the average FSIQ within the prison population tends to be lower than the mainstream population, those with somewhat lower intellectual functioning may not stand out to correctional staff (Hayes, 2007). Even though their needs may be similar to their non-impaired counterparts, the need to address those needs differently is clear (Crocker et al., 2007).

Many individuals who engage with the legal system are not formally prosecuted. Some are released as they are deemed not guilty or there is insufficient evidence to move the case forward at the prosecutor's office. Others are charged but later found not guilty. Some are charged but diverted to community-based programming, such as mandated residential treatment through developmental disability service programs. Some are formally prosecuted and ordered to be supervised by probation or may be sent to prison or mental health facilities. It may not be an easier route for the intellectually disabled person to be diverted to a developmental center or psychiatric hospital, as those placements often turn out to be longer sentences than if they had done regular prison time (Hayes, 2007).

Many individuals who have intellectual or other developmental disabilities, such as autism spectrum disorders, have difficulty dealing with the investigation processes. Some are poor historians due to time frame distortions or have difficulty differentiating what was their own idea versus what someone suggested that they do. Others misinterpret questions and their own answers. Some are incautiously frank in their answers, are overly compliant with authority figures, and use words they do not fully understand (Allen et al., 2008).

Before a trial can take place, competency to stand trial must be determined. Competence to stand trial requires the defendant be able to aid his attorney in his own defense, understand the crime and consequences for the charges he is facing, and understand the roles of the participants in the court processes and the purpose of the trial (Baroff et al., 2004; Blasingame, 2005). If the person is found not competent to stand trial due to issues associated with intellectual disability, he may be incarcerated in a hospital or residential setting for training. The great majority of those with mild intellectual disability are found competent to stand trial (Baroff et al., 2004). In some cases, the charges may be dropped although the individual is still court ordered into a nonjudicial alternative such as care home placement or be placed under guardianship. In some cases, these individuals are trained to be competent and are then returned to court for continuation of the prosecution process.

Another issue facing the court is whether the defendant who has intellectual disabilities should be declared not

guilty by reason of insanity (NGRI; Baroff et al., 2004). Those who are acquitted on the basis of NGRI are determined to have a mental disease or defect that decreases the person's capacity to control their behavior (Melton et al., 1997). Those who are acquitted as NGRI are often ordered into hospital placements for longer sentences than they would have faced if they would have been sent to prison, so being declared NGRI may not be particularly advantageous (Blasingame, 2005; Salekin & Rogers, 2001). Individuals incarcerated in a psychiatric setting due to NGRI status are to receive treatment for the condition that diminished their capacity and be prepared to return to the community (Salekin & Rogers, 2001). In order to return to the community, a judicial hearing must take place and the hospitalization order be altered.

Courts have several legal options for sentencing an offender who has intellectual disability. One of those options is a diversion plan established by the regional service agency responsible for assisting individuals who have developmental disabilities. These types of plans often involve mandated placement in board and care facilities in the community, participation in approved treatment programming, specialized day programs or sheltered work settings, and being evaluated for psychotropic medications. Sometimes these plans also include incarceration in a state hospital or developmental center where the individual can be contained and treated for long periods of time.

Other sentencing options the courts have are to grant probation or to sentence the individual to prison. Individuals with intellectual disabilities are at increased risk of victimization when incarcerated in prison or institutions for persons with developmental disabilities (Haaven & Schlank, 2001). Many states now have civil commitment programs for sexual offenders who have completed their prison sentences. Those civil commitment programs have both mental health and correctional components (Haaven & Schlank, 2001). They nonetheless need to make adjustments to routines and protocols to accommodate the physical and psychosocial needs of those inmates who have intellectual disabilities. Inmate safety becomes a significant concern due to the risk of continued sexual acting out by the offender or his being victimized by other inmates or patients. Some civil commitment programs or institutions have been reported to attempt to include the intellectually disabled offenders in the general sex offender population and simplify the treatment curricula (Haaven & Schlank, 2001). This is inadequate in many ways, as the inmates with intellectual disabilities have a variety of learning problems that are very different from mainstream offenders, as discussed above. The author is aware of State institutions being subject to lawsuits for failure to make appropriate accommodations and adaptations in the programming for those patients who have intellectual disabilities.

Some court orders for probation also include the case management plan noted above in the context of a diversion plan. The intent of such an order is rehabilitation based on the assumption the individual can benefit from such a plan while also maintaining community safety. Collaborative management and treatment of these individuals appears to improve public safety through reduced recidivism (Hayes, 2004).

Community placement after incarceration or hospitalization, or as a diversion from custodial sentencing, requires thoughtful reentry planning, including addressing employment, housing, substance abuse treatment, mental health treatment, and of course sexual offender treatment. Ongoing support services are needed during institution to community transitions, including close supervision from parole or aftercare clinicians (Haaven & Schlank, 2001). Locating housing and appropriate services is both critical and difficult, as most communities do not have sufficient resources (Ward et al., 2001).

General Assessment Issues for Individuals with Intellectual Disabilities

Interviewing and testing individuals who have intellectual or other developmental disabilities has several inherent challenges. Evaluators need to be thoughtful about matching their vocabulary with these individuals to ensure accurate communication. The usual interview techniques of asking questions and expecting a relatively prompt response may not generate helpful information. Evaluators need to monitor their voice for suggestive tones, avoid leading questions, and slow the pace of the interview process. Providing multiple-choice options and the use of plain language are strongly recommended (Blasingame, 2005).

Acquiescence is a significant concern when evaluating individuals who have intellectual disabilities (Finlay & Lyons, 2002). Many of these individuals have a yea-saying response pattern, regardless of what is being asked. This may be associated with fears of disapproval from the evaluator, confusion about the questions being posed, feared consequences of disclosing certain information, or simply wanting to be compliant. Acquiescence should not be confused with dissimulation, lying, or socially desirable responding (Blasingame, 2005; Finlay & Lyons 2002).

For diagnosis, treatment planning, and case management purposes, measures of adaptive functioning should commonly be used in conjunction with intelligence tests to ascertain behavioral functioning levels, i.e., in what skill areas can the individual function independently and/or in what skill areas might the individual need supports and assistance (Fletcher et al., 2007). The *Adaptive Behavior Assessment System, Second Edition* (ABAS-II; Harrison & Oakland, 2003) and the *Supports Intensity Scale* (Thompson

et al., 2004) are examples of standardized tools for this purpose. Such assessments are needed to discern environmental supports and contextual factors associated with risk management and intervention.

Intelligence tests are about information processing and accomplished learning. Intellectual functioning levels reveal information about one's ability to learn, what he has learned, and the person's adaptation to the environment (Kaufman & Lichtenberger, 2006). When assessing persons with intellectual disabilities, evaluators need to be cautious when interpreting results from instruments that have high demands of the executive functioning system, abstract thought, and information processing. Ultimately, to qualify for a diagnosis of mild intellectual disability, one has to obtain an intellectual quotient (IQ) score between 55 and 70, manifesting subaverage intelligence (American Psychiatric Association (APA), 2000; Fletcher et al., 2007). As mentioned earlier, this represents about 85 % of persons with intellectual disability. Individuals in this mild level of intellectual disability are said to be able to achieve about a sixth grade level of academic skills, significantly impacting treatment strategies and risk management efforts. Persons diagnosed with moderate intellectual disability, having IQ scores between 40 and 55, are said to be able to achieve about a second grade level of academic functioning (APA, 2000). To be diagnosed with intellectual disability, there needs to be evidence the person met or would have met the criteria prior to the age of 18 (APA, 2000).

A baseline risk assessment based on an actuarial procedure is very useful in treatment planning (Boer, Tough, & Haaven, 2004; Quinsey, 2004). However, the actuarial risk estimates (a) do not include all risk factors known in the literature and (b) do not discern the conditions under which that baseline risk may be increased or decreased dependent on a given offender in a given situation. The latter variables, also known as dynamic risk factors (Hanson, Harris, Scott, & Helmus, 2007), may be of keen interest to those performing risk assessments on individuals with intellectual disabilities particularly due to the issue of inaccurate or incomplete "official records" (Beech et al., 2003; Boer et al., 2004; Keeling et al., 2006; Tough, 2001). It is important to assess each individual in the primary areas associated with changes in risk, specifically self-management, socio-affective functioning, degree of deviant sexual interests, and pro-offending attitudes (Thornton, 2002). Therefore, holistic assessments for persons with intellectual disabilities should include not only the actuarially based risk estimate (discussed below) as a beginning baseline; they also should address the following additional areas:

- Psychiatric or mental health assessment
- Psychosexual assessment
- Psychosocial assessment
- Contextual assessment

Persons with intellectual disabilities are sometimes marginal to poor historians and reporters. Parents and/or other caretakers should participate in collateral clinical and/or psychosocial interviews when possible (Harrison & Oakland, 2003). Additional knowledgeable informants include care home staff members, previous treatment or care providers, teachers, physicians, probation officers, or service coordinators/case managers. Discussing the case history and current functioning with these informants may also help ascertain the reasonable veracity of any client testing or interview information.

Assessing Psychiatric or Mental Health Conditions Among Persons with Intellectual Disabilities

Individuals with intellectual disabilities have an increased risk for comorbid mental disorders, as discussed above (APA, 2000; Fletcher et al., 2007). The presence of these additional mental disorders may impact the individual's capacity to self-regulate his or her behavior, meaningfully participate in an assessment or treatment process, and may or may not diminish his or her capacities to such an extent as to undermine culpability for their actions (Melton et al., 1997). These of course may also be relevant concerning the needs, risks, and responsivity factors when treatment planning (Andrews & Bonta, 2003).

Due to the diversity of issues and idiosyncratic nature of challenges faced by these individuals, mental health assessments are also complex but not overwhelmingly difficult. Comprehensive review of case records, client interviews, informant interviews, and, in some cases, psychological testing are called for (Blasingame, 2005; Fletcher et al., 2007; Hurley, 2006; Mikkelsen, 2004).

The types of file information needed for evaluative processes are fairly broad in range, including early social and behavioral histories, academic and school testing, school behavioral concerns, child protective services and/or police reports, court reports, civil commitment reports, leisure activities and recreational interests, index (present concern) incident reports, medication history, and treatment history (Blasingame, 2005). If the client has resided in institutional or residential care, summary information about in-home and out-of-home placement functioning is also helpful in determining any behavioral problems of a pervasive nature. Indeed, many intellectually disabled offenders' victims may be other care home or institution residents. The evaluator needs to have access to this full range of background information in order to perform a comprehensive evaluation (Blasingame, 2005).

Mental health conditions among persons with intellectual disabilities may not easily yield themselves to the traditional

diagnostic interview process (Fletcher et al., 2007; Hurley, 2006). In some diagnostic situations, it may be necessary to discern the presence of behavioral phenomena and consider these as "behavioral equivalents" in place of diagnostic criteria (Hurley, 2006). As such, maladaptive behavioral symptoms may be considered as substitutes for some criteria when reviewing diagnostic checklists, e.g., when completing a diagnosis based on the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition* (DSM 5; APA 2013), or the *Diagnostic Manual-Intellectual Disability* (DM-ID; Fletcher et al., 2007).

Mental disorders are neither static variables nor are they always associated with increased risk for sexual or violent reoffense. Nonetheless, it is important to recognize that having a mental disorder may undermine, at different points in time, the individual's capacity to self-regulate and self-manage his behaviors, subsequently contributing to behavioral dysregulation and/or impulsivity.

Psychosexual Assessment of Persons with Intellectual Disability

Significant research points to the fact that the presence of deviant sexual arousal involving children or other sexual deviations is indicative of increased risk for sexual reoffense (Hanson & Bussiere, 1996). Hanson and Morton-Bourgon (2004) further identified indicators of current risk for reoffense to include, among others, sexual preoccupation, emotional identification with children, having any deviant sexual interests, and general self-regulation problems.

These findings strongly suggest that measurement for these factors is important in the assessment and risk management processes. Psychosexual variations are measured by a variety of means. These include the following:

- Penile plethysmography
- Attentional or viewing behavior measurements
- Self-report questionnaires
- Clinical interview

These methods each have its own strengths and weaknesses such that these should not be used independently or outside the clinical domain (Keeling, Beech, & Rose, 2007; Kalmus & Beech, 2005). It should not be expected that all sexual abusers would exhibit measurable preferences during phallometric or similar assessment (Reyes et al., 2006). Sexual arousal or sexual attraction assessment procedures should not be used independent of other sources of information gathering and clearly should not be used in the courtroom as evidence of guilt or innocence (Association for the Treatment of Sexual Abusers (ATSA), 1997).

Many child sexual abusers have what appear to be "normal" patterns of sexual interest under laboratory conditions (Reyes et al., 2006). Nonfamilial child sexual abusers with multiple victims are identified as more deviant during assessments compared to nonfamilial offenders with one victim or incest-only abusers. In fact, incest-only abusers are often nonresponsive to child stimuli in phallometric tests (Marshall, Anderson, & Fernandez, 1999). Marshall et al. note that nonfamilial child sexual abusers have the most consistent phallometric measurement results, i.e., they exhibit the most consistent sexual attraction for children. Nonetheless, there is significant variance in outcomes of phallometric assessments even within the subtypes of nonfamilial child sexual abusers, rapists, or exhibitionists (Kalmus & Beech, 2005; Reyes et al., 2006).

Not all individuals who sexually abuse children have deviant fantasies about children prior to the offense behavior (Marshall et al., 1999). Nonetheless, it is important to rule in or out the presence of sexual deviance, current sexual interest or arousal involving children, or other forms of sexual preoccupation if one is to assess current risk for reoffense and develop realistic intervention plans and programming to manage any current risk for reoffense.

A confounding issue regarding penile plethysmography (PPG) or the viewing time measures (discussed below) in assessing sexual abusers has to do with undisclosed offenses in the histories of the offender. Heil et al. (2003) summarize a number of studies as well as their own data which demonstrates that a majority of sexual offenders have fluid interests and victim types, i.e., offenses that cross over the lines of age and gender differing from the victim of record. Official records often do not have complete information about other, non-adjudicated victims such as other adults, children, or animals (Blasingame, 2005; Heil et al., 2003). Therefore, it should be no surprise that the tools attempting to assess sexual preferences and interests will often be perceived as falling short given that sexual abusers' interest patterns are not as discriminating or as stable as had previously been assumed.

Penile plethysmography is used with intellectually disabled males and is effective in ascertaining sexual arousal patterns (Haaven & Coleman, 2000; Haaven, Little, & Petre-Miller, 1990; Haaven & Schlank, 2001; Hingsburger et al., 1999; Reyes et al., 2006; Seghorn & Ball, 2000). Programs using it adjust the administration protocol to allow more adaptation time between stimuli and making sure the client understands the instructions. There is no research regarding the lower limits of intellectual functioning for use of PPG with persons with intellectual disabilities. Some programs perform pre- and posttreatment phallometric assessments to assess change of arousal patterns over time.

In a PPG study involving adult male sex offenders with developmental disabilities, Reyes et al. (2006) found three

response patterns. While their sample size was only ten, they found one subset of sexual abusers who showed distinct differentiated arousal to deviance, another subset who showed undifferentiated deviant arousal, and the third subset of sexual abusers who showed no measured deviant arousal. Differentiated deviant arousal was defined as measured arousal to the presence of a specific gender or age, and this was measured higher than neutral stimuli or other categories. Undifferentiated deviant arousal was defined as measured arousal to deviant and nondeviant stimuli at a higher level than arousal to neutral stimuli. The nondeviant subset of offenders did not demonstrate measured arousal to deviant stimuli and was at a comparable level with neutral stimuli (Reyes et al., 2006). The subjects in this study all had child victims; the data indicates that not all intellectually disabled sex offenders with child sex abuse victims will exhibit measurable sexual interest/arousal in the testing situation despite their known history of abusive behaviors.

Another method for attempting to measure the sexual interests of abusers is that of viewing behavior measures. These have also been called stimulus viewing time, viewing time, and visual reaction time. Abel, Huffman, Warberg, and Holland (1998) reported high reliability and validity comparing the *Abel Assessment for Sexual Interest* visual reaction time (VRT) assessment with penile plethysmography. Others have also found the *Abel Assessment for Sexual Interest* (AASI) outcome comparable to penile plethysmography outcome data (Johnson & Listiak, 1999; Letourneau, 2002).

One viewing time instrument that has been used in the evaluation of individuals with intellectual disabilities or other developmental disabilities is the *Abel-Blasingame Assessment System for individuals with intellectual disabilities* (ABID; Abel & Blasingame, 2005). The ABID was adapted from the Abel Assessment for Sexual Interest and is designed specifically for the evaluation of individuals with intellectual disabilities or borderline intellectual functioning. The ABID has two components: a self-report questionnaire administered by the clinician as a semi-structured interview and an objective measure of sexual interest, using visual reaction time. The design of the ABID questionnaire intends that the evaluator will read the questions aloud to the test subject and record the responses on the computer. The questionnaire requires only a second grade level of reading comprehension for the questions.

The ABID questionnaire inquires about involvement in 16 problematic sexual behaviors or potential paraphilic sexual behaviors. In addition, the questionnaire component of the ABID is of value to evaluators as it includes endorsement of sexual fantasy vignettes, measurement of cognitive distortions, social desirability, alcohol and drug history, social-sexual history, and additional self-report information. The ABID contains a number of concrete visual aids, scheduled breaks, and instructions to facilitate transitioning between content topics. The stimuli used in the objective measure of sexual interest are the same as used with the AASI; however, the instructions have been simplified. The VRT portion of the ABID assesses sexual interest in several age categories, including preschool, grade school, adolescent, and adult in both males and females. These components combine as a system of assessment rather than the seemingly more popular focus on the viewing component alone.

The self-report data collected on the questionnaire portion of the *Abel-Blasingame Assessment System for individuals with intellectual disabilities* (Abel & Blasingame, 2005) indicates a significant amount of sexual behavior crossover between age of victims, gender of victims, and a variety of other potential paraphilic behaviors. The preliminary data, based on a sample of 495 adult males, on the utility of the ABID questionnaire is very promising as it solicits significant information from subjects in sixteen areas of sexual history. ABID data evidences significant increases in the number and types of sexual misconduct admitted in the assessment processes of the ABID; increased reporting of paraphilic behaviors, types of victims, and types of sexual misconduct improve the clinicians' ability to discern clinical and protective supervision needs of these offenders. Preliminary data analyses indicated that there was an average of about a 50 % increase in disclosure of the 16 problematic sexual behaviors as a result of the administering the ABID, with the more significant disclosures found among domains involving behaviors done in secret. Preliminary analyses of the fantasy vignette card sort found that endorsement of the female child sexual fantasies correlated ($r = .34$) with the number of self-reported child victims. Endorsement of the male child sexual fantasies also correlated ($r = .33$) with the number of self-reported child victims (Blasingame et al., 2011).

Viewing time measurements, as well as plethysmography, are confronted with the issue of crossover interests and behaviors among sexual offenders. The sexual interests of sexual offenders who have intellectual disabilities appear to be fluid and are often undifferentiated. Other times their interests are fixed and clearly defined. Additionally, offenders often use measures to try to "beat the test" including socially desirable responding and purposeful means of preventing the evaluator from discerning the person's deviant sexual interests or preferences. Using the visual reaction time portion alone of the ABID should not/will not necessarily discriminate between perpetrators referred for evaluation of child sexual abuse as opposed to those who are identified as having adult victims due to the fluidity of interest measured and reported on the ABID (Blasingame et al., 2011).

Other card sorts and similar questionnaires seek to discern the presence of sexual interests, fantasies, and/or preferences by presenting the individual with information and soliciting responses associated with the degree of sexual desirability or interest the person may have in the stimulus.

The Multiphasic Sex Inventory (MSI; Nichols & Molander, 1984) has 560 items on 20 scales but requires a seventh grade reading ability (Keeling et al., 2006). Scales include child molest, rape, fetish, voyeurism, social-sexual desirability, cognitive distortion, immaturity, and others. The MSI is able to detect faking by subjects and level of denial (Kalmus & Beech, 2005).

The Questionnaire of Attitudes Consistent with Sexual Offending (QACSO; Broxholme & Lindsay, 2003; Lindsay et al., 2006) measures cognitive distortions supportive of sexual offending among intellectually disabled males. The QACSO surveys the offender's attitudes regarding rape, voyeurism, exhibitionism, dating abuse, stalking, homosexual assault, and sex with children (Lindsay & Taylor, 2005). It is reported to be able to discriminate intellectually disabled offenders from non-offenders as well as non-offenders without intellectual disability (Keeling et al., 2006; Lindsay et al., 2007).

While measurements of cognitive distortions, fantasies, and attitudes have the risk of transparency, these tools have demonstrated adequate effectiveness and should be incorporated within the evaluation process. A combination of these tools is recommended to assist in ascertaining the psychosexual histories and interests of individuals with intellectual or other developmental disabilities who have sexual behavior problems. Discerning these potential risk areas is critical in the later development of risk management strategies.

Psychosocial and Contextual Variables Associated with Assessment and Risk Management

Self-report information gained during clinical interviews with intellectually disabled offenders can be helpful. Many individuals with intellectual disabilities referred for treatment for sexual behavior problems are sufficiently motivated to make disclosures regarding their sexual histories and interests in an effort to engage with an evaluator. While this information may be held with some degree of question, it may be possible to ascertain the veracity of the information through review with knowledgeable informants or by reviewing the person's file information to discern the degree of credibility to attribute to the self-report information. This self-report information may be helpful in determining the presence of additional factors not included in the actuarial or other procedures administered. Given the low level of accuracy of assessments based on clinical judgment (Hanson & Bussiere, 1996), reliance on self-report information alone, such as that from a psychosocial interview, is counter indicated.

Assessment of persons with intellectual disabilities who have sexual behavior problems may require consideration of a number of idiographic factors associated with the offender himself *and* the environment he lives in (Boer, McVilly, & Lambrick, 2007). Within this paradigm, staff members and other care providers become part of the risk management equation (Boer et al., 2004).

Boer et al. (2004) outlined a number of contextual, dynamic risk management variables that need to be assessed in the course of ascertaining the degree of risk an individual presents at a given time. These include the following:

- Staff member attitudes toward intellectually disabled sex offenders and the degree of effort they are willing to put forth to understand them
- Communications among supervising staff persons including care providers, therapists, and case managers
- Client-specific knowledge retained by supervisory staff persons
- Consistency of and between supervisory staff members
- Consistency of the environment and environmental changes
- The presence of new staff members and changes in support system
- The degree of monitoring of the offender by staff members
- The degree or opportunity for victim access
- Offender compliance with supervision and attitude toward supervision and treatment
- Offender knowledge of his own problem thinking, crime history, risk factors, and relapse prevention plan
- Offender sexual knowledge and self-regulation of sexuality and degree of sexual preoccupation
- Offender capacity to manage impulses, cope with change, and manage emotions (Boer et al., 2004)

These dynamic factors can be discerned by observing and interviewing care providing staff members, family members, and the offender-client himself in pursuit of this information.

The *Treatment Intervention and Progress Scale for Sexual Abusers with Intellectual Disability* (TIPS-ID; McGrath, Livingston, & Falk, 2007a) is another structured approach to gathering dynamic variable information that is well documented. The TIPS-ID has 25 factors that are examiner-scored on a four-point scale of zero to three. Items rated involve domains such as sexual knowledge, attitudes, and behaviors; criminality; mental health and substance abuse; social influences; cooperation with treatment and supervision; and risk management application. The TIPS-ID serves as a structured approach when evaluating dynamic, changeable characteristics within the individuals' psychosocial and contextual environment.

Actuarial Risk Assessment of Sex Offenders with Intellectual Disabilities

Risk assessment of sexual offenders with intellectual disabilities is approached by multiple strategies: actuarial assessment, structured clinical assessment, or by use of a combination of these (Blasingame, 2005; Boer et al., 2004). Quinsey (2004) has noted that while intellectual disability is an associated risk factor for general antisocial behavior and pedophilia, it does not correlate in and of itself with general sexual reoffense.

Actuarial assessment focuses on a limited number of clear and distinct factors or offender characteristics identified from the research literature. Completing actuarial ratings typically relies on official records, e.g., from official criminal records. Actuarial instruments yield a specific score so the offender can be compared to other offenders with similar histories and a comparison of reoffense rates can be done. While the accuracy of actuarial risk assessments regarding groups of persons with a similar score is very high, the application of group-based actuarial ratings to individuals has been challenged (Hart, Michie, & Cooke, 2007). This is likely exacerbated when discussing individuals with intellectual or other developmental disabilities. The use of actuarial estimates is nonetheless recommended in the formation of baseline risk assessments, particularly if used in the larger context of the evaluative process, i.e., not as stand-alone assessment procedures (Blasingame, 2005; Boer et al., 2004; Hart et al., 2007; Tough, 2001). Structured clinical assessments are more idiosyncratic and contextual; these were discussed earlier in this chapter.

Actuarial procedures rely on a limited number of variables associated with reoffense that are delineated in advance of the assessment (Boer et al., 2004). There are limitations to these tools; they do not encompass every risk factor that is identified in the research literature (Quinsey, 2004). Nonetheless, they are well researched and offer validation data to support their use. Actuarial tools offer a baseline risk rating that can aid in determining an individual's needed level of case management, supervision, and/or treatment intensity (Boer et al., 2004; Hart et al., 2007).

Actuarial tools validated on samples of males with intellectual disabilities who had committed sexual offenses include the following:

- The Violence Risk Assessment Guide (VRAG; Quinsey, Harris, Rice, & Cormier, 1998; Rice et al., 2008)
- The Static-99 Structured Risk Assessment (Hanson & Thornton, 1999; Tough, 2001)
- The Rapid Risk Assessment of Sex Offender Recidivism (RRASOR; Hanson, 1997; Tough, 2001)

The *Violence Risk Assessment Guide* (Quinsey et al., 1998) estimates long-term risk for violent and/or sexual recidivism. It has been cross-validated on a variety of offender types, including forensic psychiatric and correctional facility populations and offenders with intellectual disabilities. The VRAG includes 12 domains, including psychopathy measured by use of the Psychopathy Checklist-Revised (PCL-R; Hare, 1991). Due to the use of the PCL-R, the VRAG is somewhat more complicated to use with persons with intellectual disabilities as the PCL-R relies significantly on information in the person's file. Since a significant number of intellectually disabled persons referred for sexual behavior problems have poor documentation and/or no official charges in their file information, it may not be possible to complete the PCL-R (Quinsey, 2004). Nonetheless, in the original development samples for the VRAG, it was as accurate with persons with intellectual disabilities as it was with intellectually typical individuals (Quinsey et al., 1998).

PCL-R trait scores are reported to correlate with IQ scores among sex offenders who have normal intellectual functioning (Beggs & Grace, 2008). PCL-R scores were found to correlate ($r = .18$; $p < .01$) with prior sexual offenses and with reoffending ($r = .25$; $p < .01$) although the IQ scores did not. Beggs and Grace report that higher PCL-R *trait* scores are associated with increased risk of reoffending and that there is an interaction between PCL-R score and IQ. This particular study did not use the traditional cut-point of 25 or 30 for PCL-R scores; the authors considered scores of 12–15 as high. Beggs and Grace found the "high" PCL-R /lower IQ group to have the highest reoffense rate. Given the low level of psychopathy reported in the study, it may be more accurate to refer to these phenomena as antisociality rather than psychopathy. These findings suggest that evaluators can strengthen their assessments by including the PCL-R in the assessment regimen and that there should be raised concern if there are more modest PCL-R scores in combination with lower intellectual functioning.

Another advance in the development of risk assessment procedures is the *Static-99* (Hanson & Thornton, 1999). The research included two large meta-analyses of sexual offender recidivism studies. On the Static-99, points are assigned based on the presence of several factors. These are prior offense convictions, age over/under 25, male gendered victims, the presence or absence of a relationship with the victim, prior nonsexual crimes, offense of immediate concern relating to nonsexual violence, having stranger victims, length and presence of marital/relational status, and the total number of prior sentencing dates. Individual cases are compared to the frequency of recidivism known among groups of individuals with similar ratings.

The Static-99 was slightly more accurate than the RRASOR (discussed below; Hanson, 1997) in classifying risk categories among the general sexual offender popula-

tion (Hanson & Thornton, 1999). The Static-99 requires access to criminal justice documentation such as police or court records. For a variety of reasons, many persons with developmental disabilities that are referred for evaluation and treatment of sexual behavior problems have no formal criminal record (Beech et al., 2003). There does not appear to be an interaction of Static-99 scores and IQ (Beggs & Grace, 2008).

Harris, Phenix, Hanson, and Thornton (2003) note that the original data samples for the Static-99 included developmentally delayed offenders. They indicate that research to date supports the utility of the Static-99 with the developmentally delayed population, and where formal legal documentation does not exist, the use of documentation from informal hearings and sanctions such as placement in treatment facilities and residential moves are counted as both a charge and a conviction for a sexual offense. When such documents are available, the Static-99 is a useful tool in classifying levels of risk for reoffense among intellectually disabled offenders.

The *Rapid Risk Assessment of Sex Offender Recidivism* (RRASOR; Hanson, 1997) is another tool useful for sexual offenders with intellectual disabilities. Tough (2001) found the RRASOR to provide a good estimate of overall risk for recidivism among intellectually disabled sex offenders.

The RRASOR consists of only four items: prior history of sexual convictions, age of the offender at the time of the RRASOR assessment, victim(s') gender, and the offenders' relationship to the victim. The coding rules for the RRASOR can be modified, as discussed above regarding the Static-99, to overcome the fact that many offenses committed by intellectually disabled persons are not reported to law enforcement or that the legal system may dismiss the charges due to the individual having a developmental disability (Harris et al., 2003; Keeling et al., 2006; Tough, 2001). In her study, Tough used institutional and counseling center records in addition to official legal system records in scoring the RRASOR. Tough suggests the RRASOR to be the more appropriate tool for use with the intellectually disabled population of sexual offenders as it has fewer items than the Static-99. She suggested that her finding that the RRASOR more accurately classified risk for sexual reoffense than the Static-99 may be related in part to the fact that the additional six items on the Static-99 may be absent or poorly documented in intellectually disabled individuals' charts, given the documentation problems noted above. By using institutional and/or clinical records that include information regarding what would otherwise have been a matter brought to the attention of the criminal justice system, except that the alleged perpetrator was an individual with intellectual or other developmental disability, Tough found that the subjects' risk estimate scores were indeed increased as was the overall accuracy of the RRASOR.

Evaluators must recognize the weight of their opinion and how these opinions influence restriction of civil liberties (Blasingame, 2005; Hart et al., 2007). Further, it is understood that given a number of documentation challenges and complications, an individuals' risk estimate may be an underestimate (Keeling et al., 2006). Nonetheless, the current data on these actuarial tools does support their use in assessment and risk management with those sexual offenders who have intellectual disabilities (Phenix & Sreenivasan, 2009).

Actuarial tools offer a baseline risk rating that can aid in determining an individual's needed level of supervision and/or treatment intensity (Boer et al., 2004). However, evaluators should be cautious in making decisions from outcomes based on documents that have not been subject to legal scrutiny and due process in the legal arena. Additionally, given the limitations of actuarial tools, it is critical to integrate all sources of information in the evaluation and treatment planning process. Incorporating the individuals' psychosocial and sexual histories, the PCL-R, sexual interest measures, and measures of cognitive distortions, along with the actuarial risk measures creates the most helpful evaluation. The *TIPS-ID* (McGrath, 2005) provides a structured format for summarizing information about 25 risk factors that should be addressed. Bringing all these various pieces of information together in a systematic fashion allows evaluators to accomplish more holistic assessments with more specific discernment of an individual's risk, needs, and strategies to engage the individual in treatment.

Current Treatment Strategies

Therapeutic treatment of individuals with intellectual disabilities has been described from a variety of approaches. These include behavior management, problem-solving skills training, psychoeducational activities, and cognitive-behavioral therapies (Blasingame, 2005; Lindsay & Taylor, 2005). Many programs, including the Developmentally Disabled Sexual Offender Rehabilitative Treatment model (DD-SORT; Blasingame, 2005), integrate multiple components using these varied strategies, making it difficult to ascertain which individual elements of treatment have significant, if any, effects.

At least one meta-analysis of studies on the effectiveness of psychotherapy with individuals with intellectual disabilities found a moderate level of effectiveness (Prout & Nowak-Drabik, 2003). This exploratory study suggested that individual therapies might be more effective than group therapies. The study also suggested that behaviorally oriented treatments showed more promise for bringing about change.

Cognitive-behavioral approaches have been the most popular in recent years and have relatively good support in the literature (Blasingame, 2005; Lindsay & Taylor, 2005).

While randomized control studies are yet to be located, cognitive-behavioral treatments have been reported to reduce recidivism among intellectually disabled sex offenders (Lindsay & Taylor, 2005; Rose, Jenkins, O'Conner, Jones, & Felce, 2002). Small sample sizes challenge broad-based comparisons, but these findings are promising. These findings are also consistent with various studies suggesting that cognitive-behavioral treatment helps reduce recidivism in the mainstream population.

McGrath et al. (2007b) reported a skills training and cognitive-behavioral group therapy program was the primary treatment approach for intellectually disabled sex offenders in their statewide program. As discussed earlier, this study found an approximate 11 % reoffense rate among over a hundred subjects. The authors included in their reoffense data incidents that may not have been prosecuted, but under state law, the behaviors could have been considered criminal had prosecution been pursued. The findings from this study suggest that a multifaceted management strategy, including cognitive-behavioral treatment, can be an effective tool in reducing recidivism among intellectually disabled sexual offenders.

Keeling et al. (2006) found that the self-regulation model of relapse prevention can reasonably be applied to intellectually disabled sex offenders. While the great majority of these offenders were classified in the approach pathways, these findings aid in defining the types of risk and needs issues that are to be addressed, particularly self-regulation deficits and abuse-oriented goals. Suggested treatment, teaching, and training targets include correcting cognitive distortions and pro-offending attitudes, developing victim empathy or awareness, controlling deviant sexual interests, and developing motivation to change (Blasingame, 2005, 2006a, 2006b; Haaven & Schlank, 2001; Keeling et al., 2006).

Effective and adaptive solutions to the problems of day-to-day life need to be developed (Nezu, Fiore, & Nezu, 2006). Teaching an individual with intellectual disabilities to consciously monitor his own reaction to a situation and purposely change his reaction to a problem is part of this approach. Internal thoughts, fantasies, and habituated scripts each contribute to problem interpretation and efforts at solving those problems. However, some individuals avoid their problems and therefore fail to implement any problem-solving efforts. Reducing sexual aggression can be aided by discovering alternative ways to cope and resolve issues. Problem-solving interventions need to be multimodal and address cognitive, affective, and behavioral skills development (Nezu et al., 2005). Addressing problems directly, developing a positive attitude about problem solving, and reducing impulsive approaches to problem solving are examples of this multimodal schema.

Collaborative Management of Sex Offenders with Intellectual Disabilities

There are a large number of potential factors influencing an individual client's functioning at any given time. These affect risk management strategies for offenders who have intellectual disabilities. Until the offender can reduce and manage his own risk, treatment providers, family members, and supervising care providers pursue risk management to prevent further sexual misconduct (Blasingame, 2005).

Andrews and Bonta (2003) articulately point out that engaging the offender-client in a manner that increases responsivity to treatment is associated with reduced recidivism. The methods discussed above address ways of discovering the offenders' comparative risk level for sexual recidivism and the criminogenic needs which have accumulated in the person's life.

Risk management efforts will need to address at least seven areas. These are environmental contingencies, coordinated case management, supervisory staff competencies, psychiatric care, cognitive-behavioral treatment, law enforcement supervision, and victim advocacy (Table 2).

Environmental Contingencies: Risk management efforts in this domain include restricting access to children or potential opportunities to engage in inappropriate sexual conduct; restriction of access to alcohol or other mind-altering substances that might contribute to impulsivity and undermine self-regulation; monitoring types of peers and associates; creating opportunities to have pro-social and age-appropriate social interactions; and providing line-of-sight supervision when the offender is in the proximity of potential victims (Blasingame, 2005). Providing housing and supported employment, access to medical and psychological care, and transportation services are important aspects of the overall life management assistance for these offenders, provided in effort to reduce risk of harm to others in their communities.

Coordinated Case Management: Risk management efforts in this domain include concerted collaborative communication and shared responsibilities between the multiple professionals and supervisory staff persons who form the offenders' risk management circle. Regular communications between such persons provides for greater continuity across venues, such as case managers, residential facilities, day programs, therapeutic services, and psychiatric services (Blasingame, 2005).

Staff Competencies: Risk management efforts in this domain include having well-trained and adequately motivated staff persons involved in the day-to-day life of the offender. Many intellectually disabled sexual offenders who are known to the service delivery system will be placed in board and care

Table 2 The risk management circle for individuals with intellectual disabilities

facilities and attend sheltered workshops or day programs. The staff members in these settings play a key role in risk management. Staff members who supervise the daily activities of the offender need to be competently trained across a number of areas (Blasingame, 2005; Mussack, 2006).

Psychiatric Care: Risk management efforts in this domain include evaluation and prescription of appropriate psychotropic medications for those individuals who have dual diagnoses. The frequency of comorbid mental disorders is high and should be attended to in effort to assist the individual in self-regulation of mental health issues, relapse prevention efforts, and the pursuit of a better life for the individual.

Cognitive-Behavioral Treatment: Risk management efforts in this domain include provision of relapse prevention training, sexual education training, relationship skills, adaptive functioning skills, self-regulation skills training, pragmatic problem-solving skills, and other sex offender-specific training based on his needs, risk level, and strategies for garnering engagement. The use of behavioral reinforcement principles and developmentally appropriate adaptations to the therapy delivery is critical (Blasingame, 2005).

Law Enforcement Supervision: Risk management efforts are enhanced for many offenders who have intellectual disabilities when there is significant collaboration with the law enforcement supervision agents, such as probation officers or parole agents. Not all offenders with intellectual disabilities have probation or parole status. When this is the case, it is imperative that all the members of the risk management circle understand the legal conditions imposed on the individual and that there is open communication between the professionals and care providers.

Victim advocacy: Risk management efforts in this domain require that the offender and all the professionals and paraprofessionals involved are working toward the goal of no more victims. While a better life for the offender is desirable, that is secondary to prevention of further harm to other children or other vulnerable persons.

Conclusion and Recommendations for Future Research

Sexual offenders who have intellectual disabilities present evaluators and treatment providers with a number of unique challenges. While the needs of these individuals who have intellectual impairments are very similar to neurotypical offenders, how their needs are assessed and met requires thoughtful intervention. This chapter has reviewed a number of these areas and identified strategies and potential tools to aid evaluators, treatment providers, and other members of the risk management circle.

Research in this specialized area of sexual offender treatment and management has flourished in the recent decade. However, there continue to be a number of areas that

need further investigation and clarification. These include developing additional assessment procedures to evaluate mental health, personality characteristics, applied treatment strategies, risk assessment and management procedures, and continued cross-validation of the few tools that have been specifically developed for offenders who have intellectual disabilities. Many of the extant studies involving sex offenders who have intellectual disabilities have small samples from select settings, making it difficult to generalize the findings. Using different definitions or criteria also complicates use of the data. Researchers are encouraged to be more consistent in inclusion/exclusion criteria and collaborate across settings to help remedy these issues.

Ultimately, these sexual offenders will require a risk management circle of professionals, family members, and others to communicate effectively and work in support of the individuals' success. The evidence is that treatment and intervention with offenders who have intellectual disabilities can be effective in reducing recidivism. Our shared mission is to have no more victims and better lives for these individuals.

Overview of Assessment of Sexual Offenders

Anita Schlank, Saprina Matheny, and Jessica Schilling

Introduction

The most popular topic related to sexual offenders over the past decade appears to be how to assess the risk they present to society (Beech, Erikson, Friendship, & Hanson, 2002; Beech, Fisher, & Thornton, 2003; Doren, 2002; Hanson & Harris, 2000; Hanson, Morton, & Harris, 2003; Hanson & Thornton, 2000; Thornton, 2002). However, this is just one of many types of assessments a clinician may be asked to perform related to a sexual offender. For example, assessments are often needed of alleged perpetrators of sexual abuse in child custody situations, and in the 20 states in which sexually violent predator laws were adopted, assessments are needed to determine whether sexual offenders meet legal criteria for civil commitment. In addition, presentencing evaluations are often sought to help with disposition planning, and sexual offenders are also often evaluated prior to their release on probation or parole. Also, once sexual offenders have been civilly committed, they usually require an assessment for treatment planning purposes, since the civil commitment evaluation was likely to focus mainly on risk and legal criteria rather than treatment needs. Finally, assessments are also needed to determine when civilly committed sexual offenders have lowered their risk sufficiently to be released into the community. This chapter will discuss aspects of comprehensive clinical assessments of sexual offenders in a variety of contexts.

Guiding Principles of Sex-Offender Assessment

Before undertaking an assessment of a sexual offender for any purpose, clinicians should first ask themselves if they are comfortable working within the legal arena with cases that are often adversarial. Clinicians should be comfortable taking on a neutral consultant role, rather than an advocacy role, and should feel comfortable with the possibility of making recommendations that might displease the individual being assessed. Regardless of the purpose of the evaluation, assessments of sexual offenders need to be individualized and comprehensive. With the exception of the rare case in which an offender voluntarily seeks treatment for sexual deviance even though offenses were never reported, it will be extremely important to rely on multiple sources of data, as self-report will be inherently unreliable. Clinicians should use research-supported tools and need to keep abreast of the recent research on those tools, and they should also recognize that different populations will require the use of different tools. Clinicians should ensure that they are properly trained before attempting to use these tools. They should be aware that while physiological assessment might be valuable, it is also fallible and may be inappropriate for certain individuals. Finally, no clinical assessment should ever be used to offer an opinion about whether an alleged offender is guilty or innocent of a crime. There is no set "profile" of a sexual offender, and no measure or tool will provide information about guilt or innocence; therefore, to offer such an opinion would be unethical (ATSA Professional Issues Committee, 2005). When reporting findings, it is important to clearly demonstrate how conclusions were drawn and to highlight any inconsistencies in the data or limitations to the

A. Phenix, H.M. Hoberman (eds.), *Sexual Offending*, DOI 10.1007/978-1-4939-2416-5_12

conclusions. When an offender refuses to participate in the assessment, it is important to note the significant limitations to the evaluation posed by the lack of opportunity to conduct a clinical interview. There are also several ethical issues to consider when conducting sex-offender assessments. Evaluators should not have had a prior treating relationship with the offender since the evaluator might know information that would not be normally revealed to someone conducting an evaluation, and it could betray the trust of the client who had been seen in treatment and could impair the evaluator's objectivity since a therapist often takes on an advocacy role for the client (Greenberg & Shuman, 2007) or might experience countertransference if the client was extremely resistant or challenging. Evaluators should also be careful about conducting assessments which recommend placement in the evaluator's treatment program, as there may be unconscious bias toward recommending this treatment or at least it may appear that there are financial incentives associated with the recommendation. In rural areas or small towns, where there is essentially only one sex-offender treatment program, it would be wise for the assessments to be conducted by neutral evaluators not employed by the program to avoid any appearance of a conflict of interest (ATSA Practice Standards and Guidelines for Members of the Association for the Treatment of Sexual Abusers, 2005).

Alleged Sexual Abuse in Child Custody Situations

Sexual abuse allegations may appear during divorces or after the parties have already agreed to a custody/visitation arrangement. Courts often seek psychological assessments in these complex cases, but assessment of an alleged perpetrator is extremely difficult since, as mentioned above, there is no way for a clinician to determine their guilt or innocence. Many inventories about sexual interests and behaviors have obvious face validity, making it very easy for an alleged perpetrator to deny sexual deviance. In addition, there are no set guidelines for assessment of sexual abuse allegations in custody evaluations. Bow, Quinnel, Zaroff, and Assemany (2002) did propose a model for conducting such evaluations. They stress that first the evaluator should have no prior involvement in the case and should be court appointed to preserve their neutral, objective role. Evaluators should have access to all records, including police documents, medical records, social service records and therapy notes, and it is important that these be reviewed prior to clinical interviews. They suggest that it is crucial for an evaluator to assess the nature, sequence, and circumstances of the allegations, including the plausibility of the alleged occurrence. Collateral contacts should be sought, and it is recommended that each party be interviewed a number of times, with attention paid to inconsistencies. They recommend psychological testing of the alleged perpetrator, as well as an assessment of their use of mood-altering chemicals and, if there is a criminal history, an assessment of psychopathy. At times, psychological testing of the alleged victim will be required as well. A complete sexual history of the alleged perpetrator should be obtained, and parent–child observations may provide useful information but may not be possible or even recommended in certain cases.

Assessment for Civil Commitment

Beginning approximately 20 years ago, a wave of new sexual offender laws spread throughout the nation. These laws allowed for the indeterminate commitment of a sexual offender after the offender had completed a term of incarceration. While each state has a slightly different statute, there are commonalities, including determining the presence of a mental disorder and determining that the offender presents a risk for reoffending sexually because of that disorder. Some statutes require a history of having committed certain types of offenses and others require an assessment of the offender's volitional impairment. Those conducting assessments for possible civil commitment need to be aware of the specific statutes and the burden of proof used in their state and must keep abreast of relevant case law.

With regard to the first criterion, states have been quite broad in what they accept as a qualifying "disorder," including personality disorders. There has been some controversy regarding the use of the diagnosis Paraphilia Not Otherwise Specified (in the DSM-IV, or Other Specified Paraphilia in the DSM-5), which is often used for offenders who appear to have significant deviant arousal to forced sexual activity. Some have argued that Paraphilic Coercive Disorder was expressly rejected from the DSM-IV (Zander, 2008) and also from the DSM-5; however, many have recognized that there is a group of individuals who clearly have significant deviant arousal to coerced sexual activity (Abel & Rouleau, 1990; DeClue, 2006; Thornton, 2009; Vognsen & Phenix, 2004). In addition, the DSM Casebook (Spitzer, Gibbon, Skodol, Williams, & First, 2002) contains an example for this diagnosis of an offender with deviant sexual arousal to rape but who does not have a history of other general criminality. Case law also exists supporting the use of this diagnosis to describe such individuals. McGee v. Bartow (2010) and Brown v. Watters (2010) are both cases in which the US Court of Appeals upheld the use of this diagnosis for civil commitment. When assessing for this diagnosis, it is important to distinguish between this disorder and the general criminality associated with Antisocial Personality Disorder. In addition, some men who commit rapes are not necessarily aroused by the coercion but have cognitive distortions in which they are convinced the victim is enjoying or wanted the sexual activity. Therefore, evaluators should look for signs that the offender stopped when emotional distress was evident or evidence that he believed the victim was consenting

(such as attempting to make a "date" to meet later), which would contraindicate such a diagnosis (Doren, 2002).

With regard to the use of Other Specified Paraphilia (Paraphilia NOS in the DSM-IV) for what was formerly known as hebephilia, there are arguments both for (Blanchard et al. 2009) and against (Moser, 2009; Zander, 2009). If the decision is made to use this diagnosis, the evaluator should look for a clear fixation on adolescents, a continued sexual abuse of adolescents following consequences for that behavior, and a tendency to end relationships when the adolescent "ages out" of the preferred range.

There is an extensive body of literature concerning the assessment of an offender's risk to reoffend, and this topic is covered in other areas of this book, so this will not be addressed in any detail here. However, clinicians should be aware that it is generally accepted that actuarial instruments or structured guides to clinical judgment are superior to clinical judgment alone. In addition, assessors should be aware of the latest publications regarding these risk assessment tools and to which populations each are applicable. Finally, assessors should be familiar with recent research which has suggested that those sexual offenders who were civilly committed in the past may not have been as high risk as initially believed (Duwe, 2013).

Predisposition Evaluations and Treatment Planning Evaluations Following Civil Commitment (Adult Male Offenders)

Predisposition evaluations and treatment planning evaluations following civil commitment are very similar in that both require a comprehensive evaluation of the offender's history, sexual behavior and interests, cognitive functioning, and specific treatment needs. In addition, for the predisposition evaluations, an assessment of the offender's risk will be necessary to determine the context in which he/she can receive treatment. In addition to using risk assessment tools, it will be important to acknowledge the offender's past behavior while under supervision when making that determination. Unlike evaluations prior to civil commitment or evaluations related to allegations of sexual abuse related to child custody, the offender is more likely to be forthcoming with personal disclosures, although many may remain guarded due to plans to appeal the conviction or commitment. Therefore, it remains important to utilize multiple data sources for the evaluation. A more detailed description of the specific areas for such an assessment follows.

Clinical Interview

When interviewing a sexual offender, the first step should be obtaining informed consent or, if the evaluation is court ordered, informing the offender about the nature of the evaluation and the limits to confidentiality. Specific information should be given regarding mandatory reporting laws and duty-to-protect requirements. It is helpful to instruct the offender regarding how he may discuss past undisclosed offenses in a manner that will not trigger the need for a mandated report. Following these warnings, it is often beneficial to have the offender take some self-report questionnaires, such as the Multiphasic Sex Inventory (MSI) (Nichols & Molinder, 1984) prior to the clinical interview. In the experience of the first author, seeing some deviant sexual interests in print can allow the offender to realize that others have similar interests and may make it more likely for the offender to honestly endorse certain interests prior to the interview. It is useful to begin the interview by obtaining general background information, as this can help establish rapport before beginning any discussion of the more difficult topic of sexually deviant behavior. History regarding family of origin, juvenile conduct problems, academic problems and achievement, work history, medical history, substance abuse history, nonsexual criminal history, and history of romantic relationships, marriage, and children should all be obtained. A thorough sexual history should also be obtained, including information regarding early parental messages regarding sexuality, sexual orientation, history of sexual behavior, frequency of masturbation, and interest in various sexual themes. Then, the offender's account of the sexual offense(s) can be obtained. It is often useful to allow the offender to provide this historical information without any confrontation regarding inconsistencies first, before going back over the information to challenge any answers. The clinicians should have carefully read background information and reviewed self-report questionnaires prior to the clinical interview, so that inconsistencies between verbally provided history and data contained in the records can be challenged.

Assessment of Intellectual Functioning

An assessment of intellectual functioning is important to determine if any offenders admitted for treatment have intellectual deficits that require special programming. Several researchers have noticed a relatively high incidence of cognitive deficits in sexual offenders (Gross, 1985; Lund, 1990), and sexual offenders with intellectual disabilities may appear more likely to commit offenses across categories of offenses and may seem less discriminating in their victims (Lindsay, 2002), which suggests that they require special attention. To save time in the assessment process, many programs choose to start with a quick screening test and then use a more comprehensive test if the screening results suggest a score at or below the borderline range or lower. The Shipley Institute of Living Scale (SILS) (available www.wps.publish.com) is a very brief screening test of intellectual abilities; however, it has not yet been updated to include an estimate based on the

more recent Wechsler comprehensive batteries and relies heavily upon verbal abilities, so it may underestimate IQ in those with cultural and socioeconomic differences. In addition, it was standardized on a group containing few older adults and tends to overestimate the lower ends of cognitive functioning and underestimate the scores which are higher than average. A better choice for a brief intellectual estimate may be the Wechsler Abbreviated Scale of Intelligence (WASI) (available from www.pearsonassessments.com), which is a standardized, independent scale based on the WAIS-III and the Wechsler Intelligence Scale for Children-III (WISC-III) (available at www.harcourtassessment.com). It provides more information than is typically received from other brief intelligence tests and yields the three traditional indices of Verbal IQ, Performance IQ, and Full-Scale IQ. While the WASI is useful for screening purposes, it is not comprehensive enough to be used to diagnose mental retardation, and some psychologists have expressed concern about the differences obtained in these scores as compared to the more comprehensive Wechsler batteries (Axelrod, 2002). Therefore, it would still be recommended to use the more comprehensive test if a Full-Scale IQ falling in the borderline range or lower was obtained on the WASI. If initial screening suggests functioning in the borderline range or lower, assessment with a test such as the Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV), which is available at www.pearsonassessments.com, is recommended. The WAIS-IV was released in August 2008. Like the Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV), it eliminates the dual IQ but provides a Full-Scale IQ and important Index Scores. This revision reportedly takes an average of 67 min to administer (as opposed to approximately 80 min for the WAIS-III). It has updated the norms and added five points to the floor and ceiling IQs measured (FSIQ range of 40–160 as opposed to 45–155 of the WAIS-III). In addition, the Picture Completion subtest now has enlarged visual stimuli, and the Digit Span subtest now contains a sequencing task. In addition, there are two new Perceptual Reasoning subtests entitled "Visual Puzzles" and "Figure Weights" and a new Processing Speed subtest entitled "Cancellation." Besides clarifying possible borderline intellectual functioning, this test provides useful information when data about processing speed or working memory is needed, since specific Index Scores for those abilities are provided.

Assessment of Educational Achievement/ Learning Disabilities

While the assessment of all aspects of educational achievement can be beneficial for educational planning purposes, an assessment of reading comprehension is the most important for planning sex-offender treatment. Obtaining information about one's ability to understand written materials is crucial because so much of sex-offender treatment strategies assume that the resident is capable of reading written handouts and materials. In addition, the validity of self-report questionnaires used later in the assessment process often rely on the ability of the offender to be competent at reading information provided at least a sixth-grade level. Therefore, at least a brief screening of reading comprehension should be administered early in the assessment process, before an offender is given any self-report questionnaires. This should be done even with those reporting a high school diploma, since graduation requirements vary from state to state, as do the diploma and certificate of completion options that are offered to students. Therefore, it is possible that an individual could have received a diploma without mastering a sufficient level of reading comprehension.

Tests of reading comprehension often use one of three response formats: cloze, question answering, and retellings. Cloze format tests present sentences or passages with blanks in them, and the examinee must read the text and suggest an appropriate word for the blank. The question-answering format requires a passage to be read and an answer given to either a multiple-choice or open-ended question about the passage. Retellings require the client to paraphrase a passage to demonstrate adequate understanding and use a coding system for scoring the quality of the response.

The Wide Range Achievement Test-Fourth Edition (WRAT-4) contains a brief measure of reading comprehension (available at www.psychpress.com). This fourth edition is an improvement over previous editions of the WRAT because it has added a Sentence Comprehension subtest (a cloze format test) where previously the reading score was based entirely on word recognition. The age-based norms are also now extended to include ages up to 94 years. The Sentence Comprehension subtest takes approximately 15–20 min to administer. However, learning disabilities should not be diagnosed based on this brief screening test, and those receiving low scores on the Sentence Comprehension subtest should be administered a more comprehensive measure of reading skills, such as the Wechsler Individual Achievement Test-Second Edition (WIAT-II) or the Woodcock–Johnson-III Tests of Achievement (WJ-III).

The WIAT-II (available at www.harcourtassessment.com) is an achievement battery empirically linked with the Wechsler Intelligence Scales, and tables (Psychological Corporation, 1997) offer the expected WIAT-II scores based on the Wechsler IQ scores. However, the Reading Comprehension subtest of the WIAT-II can be fairly lengthy, and some portions of the question-answering format are possible to be answered simply by repeating words from the passage without fully understanding what has been read.

The WJ-III (available at www.riverpub.com) includes tests and clusters that are meant to directly parallel those outlined by the Individual with Disabilities Education Act of 2004 (20 USC Statute 1400). Administration time is approximately 5 min per subtest, and this test has shown good reliability.

Assessment of Psychosexual Disorder/Sexual Compulsivity

The assessment of disordered sexual arousal is very important for treatment planning, as it has been closely linked with risk for reoffending (Harris et al., 2003). One instrument which the current authors have found helpful for eliciting information about deviant sexual interests beyond what is obtained in a clinical interview is the Multiphasic Sex Inventory (MSI) (Nichols & Molinder, 1984). The MSI is a self-report questionnaire which asks about sexual activities, experiences, and problems. It also contains scales that assess the level of openness about the deviant sexual behaviors. Research on the MSI suggests that it offers information not provided by traditional psychological tests (Kalichman, Henderson, Shealy, & Dwyer, 1992; Schlank, 1995) and has adequate internal consistency and convergent validity (Kalichman et al., 1992). The second edition of the MSI (MSI-II) was made available in 2000, which is an expanded version, with the wording of some questions clarified and some items eliminated because they were found not to be useful for discrimination purposes (Nichols & Molinder, 2000). In the MSI-II, the client's scores can be compared to the scores of known groups of child molesters and rapists, and there are additional paraphilia indices. New scales to assess an offender's justifications for his/her offenses were also added, and further inquiry has been made into physiologic dysfunction. In addition, items regarding gender identity and gender orientation are also included. Unlike the original MSI, the MSI-II cannot be scored by the clinician but must be sent to Nichols & Molinder, who return an interpretative report. While this version appears to have important additions not found in the MSI, and it appears especially useful for those men who openly admit their deviance, some treatment providers have made a decision to continue using the old MSI because of the relative lack of independent research on the MSI-II. In addition, it requires a seventh-grade reading level. While a cassette tape version is available, the vocabulary used is at a level where even an auditory administration might prove problematic for some.

Other self-report questionnaires are also available, such as the Wilson Sex Fantasy Questionnaire (Wilson, 1978), which is a 40-item questionnaire that questions about four types of sexual fantasies: exploratory, intimate, impersonal, and sadomasochistic. Other options include the Clarke Sex History Questionnaire (Paitich, Langevin, Freeman, Mann, & Handy, 1977) and the New England Sexual Compulsivity Scale (Kalichman & Rompa, 2001).

The penile plethysmograph is an objective measure of sexual arousal which records the changes in penile responses during the presentation of a variety of sexual stimuli (either visual or audiotaped). Most experienced sex-offender treatment providers have had the experience of clients who claim no deviant sexual interest, but objective results such as these might indicate differently. Therefore, the use of an instrument such as the penile plethysmograph can offer useful information about disordered arousal. However, the plethysmograph is not without controversy. For example, some subjects are capable of manipulating their erectile responses (Hall, Proctor, & Nelson, 1988; Murphy & Peters, 1992; Quinsey & Laws, 1990), even though there are several techniques to try to prevent this occurrence. Some clinicians believe that the method is intrusive or too expensive. In addition, the most significant concern about the plethysmograph is its misuse, as some have inappropriately attempted to use it to determine guilt. This is an inappropriate use of the measure as not all sex offenders have disordered arousal patterns, and the presence of a disordered arousal pattern does not confirm any acts of sexual deviance (Freund & Watson, 1991; Marshall & Eccles, 1991; Murphy & Peters, 1992).

The Abel Assessment for Sexual Interest (AASI) (Abel, Huffman, Warberg, & Holland, 1998) and the Affinity Measure of Sexual Interest (available from http://www.pacific-assmt.com) are other options for objective measures, although they measure sexual interest through visual retention time rather than actual sexual arousal. This type of procedure measures the length of time a subject spends viewing different slide photographs of clothed individuals of various ages against a plain background, with no distracting stimuli in the picture. This assessment technique is sometimes preferred because it is less intrusive and potentially less embarrassing than the PPG, and some research has shown that visual retention time can reliably predict sexual interest categorization (Abel et al., 1998). Additional research has suggested that the AASI can be as accurate as the plethysmograph in identifying some categories of sexual interest, better than the plethysmograph in other areas, but less accurate in additional areas. For example, Letourneau (2002) found that both the AASI and the plethysmograph were accurate in identifying sexual interest in young boys, and the AASI identified offenders against adolescent girls, but neither method was able to accurately differentiate offenders against adult women or young girls. However, some researchers (Fischer & Smith, 1999) have had concern about the validity and reliability of this technique.

One final method for assessing sexual interest is the Implicit Association Test (IAT) (Greenwald, McGhee, & Schwartz, 1998). The IAT is described as measuring "the strength of automatic associations in memory between a

concept (e.g., child) and an attribute (e.g., sexual attractiveness) is inferred from the relative speed with which one sorts stimulus words or pictures into categories….Respondents must sort each word or picture into one of four categories by pressing one of two keys on a computer keyboard....Response speed is thought to depend on the extent to which the categories that share one key are associated in one's memory" (Babchishin, 2008, pp. 15–16). While the IAT may be able to complement more commonly used measures of assessing sexual interest, further research is required to examine its convergent validity with these other measures.

Assessment of Substance Abuse

It is important for evaluators to obtain a thorough assessment of a sexual offender's substance use history, as it is one of the "central eight" risk/need factors that is predictive of criminal behavior (Andrews & Bonta, 2006). Offenders frequently minimize the extent of their past use and collateral information is important in order to obtain an accurate assessment. In addition, the use of the Substance Abuse Subtle Screening Inventory-3 (SASSI-3) can be extremely helpful (available from www.sassi.com or www.parinc.com). The SASSI-3 requires a fifth-grade reading level and takes approximately 15 min to administer and score. In addition, its scales include both obvious and subtle items associated with substance abuse or dependence, and it includes a scale that measures a defensive response pattern. It is particularly useful in identifying individuals who are experiencing substance abuse problems but who minimize their use history. The decision rules suggesting a high probability of a substance dependence disorder have been found to yield a 95 % agreement with clinical diagnoses of substance dependence (Lazowski, Miller, Boye, & Miller, 1998). While there are many other self-report questionnaires regarding substance use, those measures tend to provide little information above and beyond that could be obtained in a clinical interview and do not specifically address the difficulties presented by offenders who minimize their substance use.

Assessment of Psychopathology

For obvious reasons, the presence of major psychopathology can interfere with a sexual offender's ability to benefit from treatment. Assessment of psychopathology can often be accomplished during a thorough clinical interview and record review, although some evaluators may wish to use an objective personality inventory, such as the Minnesota Multiphasic Personality Inventory-Second Edition (MMPI-2), the Minnesota Multiphasic Personality Inventory-Second Edition-Revised Format (MMPI-2-RF) (available from www.pearsonassessments.com), or the Personality Assessment Inventory (PAI) (available from www.parinc.com). The MMPI-2 is one of the most popular and most researched self-report personality inventories in use today. The MMPI-2's clinical scales had much overlap, which led to some criticism. Therefore, in 2003, the Restructured Clinical Scales were developed, removing the contribution of demoralization from each clinical scale and resulting in more pure and distinct clinical dimensions (Tellegen et al., 2003). The most recent revision of this test is the MMPI-2 Restructured Form (MMPI-2-RF), which was released in July 2008. This version of the MMPI-2 is only 338 items (as opposed to 567 items) and contains 50 scales, including the Restructured Clinical (RC) Scales, but which eliminates the older clinical scales. Replacement of the original clinical scales with the RC Scales has been criticized by some who fear that they might measure pathology which is markedly different from that which was measured by the original scales or that the research based on the original scales will now be irrelevant. Others believe that the new scales are as good or better as the original scales because of the lower inter-scale correlations and no inter-scale item overlap (Tellegen et al., 2006). In addition, the RC Scales have been found to offer improved information for certain types of assessments, such as for police preemployment evaluations (Sellbom, Fischler, & Ben-Porath, 2007), and the fewer number of items in the MMPI-2-RF should be a relief to many clinicians who had difficulty asking clients to take such a lengthy questionnaire (especially those with attentional deficits).

The PAI is a 344-item self-report questionnaire which can also be used to assist with clinical diagnosis, treatment planning, and screening for psychopathology. Some clinicians preferred this to the MMPI-2 because of the fewer number of items and the lack of overlapping items in the scales (an issue corrected in the MMPI-2-RF). In addition, clients can respond to each PAI item on a four-point scale, ranging from "not at all true" to "very true." The PAI has a high degree of internal consistency and research shows good convergent and discriminant validity (Morey, 1991; Rogers, Ustad, & Salekin, 1998).

While symptoms of depression and anxiety would usually be adequately addressed during the clinical interview, some may wish to add measures such as the Beck Depression Inventory-II or the Beck Anxiety Inventory (both available from www.harcourtassessment.com). The Beck Depression Inventory-II is a 21-item self-report questionnaire with each answer being scored on a scale value of zero to three. Higher total scores indicate more severe depressive symptoms. This test demonstrated good concurrent validity with other measures of depression (Beck, Steer, & Brown, 1996). However, like most self-report inventories, the scores can easily be exaggerated or minimized by the client (Bowling, 2005).

The Beck Anxiety Inventory is also a 21-item scale with each answer scored from zero to three and was developed to screen anxiety while discriminating it from depression. The psychometric properties of this test have proven to be quite good (Fydrich, Dowdall, & Chambless, 1992).

Assessment of Psychopathy

Psychopathy is a construct that overlaps but is not identical to Antisocial Personality Disorder and includes traits such as a lack of a sense of guilt, a lack of empathy, egocentricity, pathological lying, irresponsibility, impulsivity, repeated violations of society's norms, shallow emotions, and a history of taking advantage of or victimizing others. Because psychopathic traits in an offender can lead to a higher risk for reoffending and may suggest the possibility of the psychopathic offender being disruptive to other members of the program, assessing this construct is important for treatment planning. While researchers have recently attempted to devise a self-report measure of these traits (Lilienfeld & Andrews, 1996; Lynam, Whiteside, & Jones, 1999; Poythress, Edens, & Lilienfeld, 1998), the most commonly used method is the use of the Hare Psychopathy Checklist-Revised (PCL-R) (Hare, 2003), which is coded based on a combination of a record review and a structured clinical interview.

Assessment of Cognitive Distortions

Treatment providers focus a great deal of attention on the assessment and replacement of cognitive distortions, including distortions at the initiation of and maintenance of sexual offending, as well as justifications that might be used following the offenses. Modification of these cognitive distortions is often seen as indicative of progress in treatment (Auburn, 2005; Bumby, 1996; Marshall & Barbaree, 1990; Moster, Wnuk, & Jeglic, 2008; Murphy, 1990), and the presence of pro-criminal attitudes is considered one of the "central eight" risk/need factors associated with future criminal behavior (Andrews & Bonta, 2006). Initially, many clinicians used the Abel and Becker Cognition Scale (Abel, Gore, Holland, Camp, & Rathner, 1989) to assess myths about child sexual abuse and the Burt Rape Myth Scale (Burt, 1980) to assess cognitive distortions about rape victims. One weakness of those scales was the odd number of Likert scale response options, which allowed for the offender to assume a "neutral" position on each item. In addition, several items of the Burt Rape Myth Scale were not directly related to rape myths but appeared to be more highly related to an individual's likelihood to believe rape reports from various subgroups of people.

Kurt Bumby introduced two new tools in 1996 which appear to be an improvement over the abovementioned scales. His MOLEST and RAPE Scales contained derivations of those scales but appeared less transparent and utilized an even number of Likert scale items, preventing the neutral response. In one pilot study, 91 % of new admissions to a civil commitment program for sexual offenders endorsed a higher percentage of cognitive distortions on either the MOLEST or the RAPE Scale, as compared to their scores on the Abel and Becker Cognition Scale and the Burt Rape Myth Scale (Schlank & Bumby, 1997). These results suggested that the Bumby Scales might be more useful for treatment purposes than the earlier scales because of the higher number of cognitive distortions identified. In addition, other scales have been used to assess cognitive distortions, including subscales from the MSI, the Empathy Scale (Empat) (McGrath & Konopasky, 1995), and the Child Molester Scale (CMS) (Cann, Knopasky, & McGrath, 1995).

Neuropsychological Screening

The presence of symptoms of Attention-Deficit/Hyperactivity Disorder (ADHD) may interfere with an individual's ability to benefit from treatment, so evaluators may wish to consider some screening of neuropsychological deficits in their assessment of treatment needs. One extremely quick screening test for attentional deficits is the Stroop Neuropsychological Screening Test (available from www.parinc.com). This test requires only 5 min to administer and has been found to have good discriminant validity and test–retest reliability.

The Conners' Adult ADHD Rating Scales (available from www.pearsonassessments.com) can also provide useful information about symptoms of ADHD. This is a self-report questionnaire that takes approximately 10–15 min and assesses symptoms of inattention/memory problems, impulsivity/emotional lability, and hyperactivity/restlessness. There is also an observer-rating form of this test, to provide collateral information about ADHD symptoms.

Other tests and tools that can be used to assess for ADHD in adults are the Copeland Symptom Checklist (available from Resurgens Press), the Brown ADD Scale (available from www.harcourtassessment.com), and the Wender–Reimherr Adult Attention Deficit Disorder Scale (available by contacting Fred Reimherr, M.D., Mood Disorders Clinic, Dept. of Psychiatry, University of Utah Health Science Center, Salt Lake City, UT 84132).

The Neurobehavioral Cognitive Status Examination (COGNISTAT) (available at www.cognistat.com) is a brief screening test of neurocognitive abilities. It screens for significant difficulties in language, constructional ability, memory, calculation skills, and reasoning/judgment. This screening test takes only approximately 10 min for cognitively intact clients and 20–30 min for those who are cognitively impaired. Research has shown it to be a sensitive

measure of cognition that can identify areas of cognitive impairment (Doninger et al., 2006; Kiernan, Muller, Langston, & Van Dyke, 1987; Wallace, Caroselli, Scheibel, & High, 2000) in several areas.

Other Issues in the Assessment of Adult Sex Offenders

After the initial assessment process has been completed, assessment will likely continue during treatment based on the Self-Regulation Model to determine which pathway an offender uses toward offending (Ward et al., 2004). Assessing whether offenders consciously decide to engage in sexually abusive behaviors (approach pathways) or seek to avoid them but are unsuccessful (avoidant pathways) provides useful information for planning treatment interventions. In addition, at later stages in treatment, an offender can be assessed to determine whether they require social skills training and have any history of domestic violence and the extent of any personal victimization. Nearly all offenders will benefit from strategies to improve their relationships with others and their use of leisure time, so their individual needs in these areas should also be addressed. Finally, an assessment of their values and how they prioritize their goals in life can be helpful for assisting them to develop a "good lives" plan for a life worth living (Ward & Gannon 2006).

Special Populations

Adolescent Offenders

Sex offenses committed by adolescents account for 25 % of adjudicated sexual offenders and are responsible for one-third of sexual offenses against minors (Finkelhor, Ormrod, & Chaffin, 2009). However, Finkelhor and colleagues (2009, p. 1) echo a common sentiment that "relatively little population-based epidemiological information about the characteristics of this group of offenders and their offenses has been available." This creates a number of problems in effective assessment, treatment, risk management, and social understanding of such offenders.

The assessment and treatment of juvenile sex offenders (ages 12 and up for the purpose of this chapter) is a unique field given the heterogeneity of the population and the offenders' critical and dynamic developmental stages. Historically, information about typology, treatment, and risk assessment has been extrapolated from the adult literature; however, the basic assumption of similarities between the populations seems largely erroneous. Unfortunately, this lack of age-specific literature has meant that juveniles largely receive generic treatment models (Hunter, Figueredo, Malamuth, & Becker, 2003). Therefore, a disservice is being done to the juveniles, victims, and society as a whole. Despite the sometimes egregious acts of the juveniles, it makes little sense to conceptualize adolescents who commit sex offenses in the same way as adults convicted of similar crimes, particularly given current literature on recidivism.

Worling and Langstrom (2006) identify five logical outcomes of adolescent sexual offending. Some adolescents may commit assaults, are never detected, and stop on their own. A second group commits assaults and stops when they are caught or reported. A third group commits sexual offenses and will stop only after being both detected and treated. The final two groups are perhaps of more concern: those that offend as adolescents, are never caught, and continue to offend into adulthood and finally those who continue to offend after both being detected and undergoing treatment. In the studies reviewed by Parks and Bard (2006), more than half of the research reported recidivism below 10 %, although international samples were frequently closer to 20 %. It appears that, similar to delinquent offenders, a small number of juvenile offenders continue to offend, some into adulthood, after being detected (Worling & Curwen, 2000). In short, the vast proportion of juvenile offenders who are detected will not likely commit sexual offenses later in life, although a significant portion of adult offenders identify that they began to engage in sexually inappropriate behavior as an adolescent. Therefore, there is a high need for more adequate methods of addressing, and intervening with, high-risk adolescent offenders.

The current social and political climate has created an environment in which adolescents are treated similarly to adult offenders in all too many cases. Additionally, they are subjected to punitive and life-altering consequences, such as registration and labeling as sexually dangerous persons. The reality is that most adolescents do not continue to offend into adulthood (Parks & Bard, 2006), and identifying those at greatest risk for continued offending appears to be the best use of ever-shrinking social service and criminal justice resources. Doing so could lead to "improved treatment by targeting specific risk factors for intervention and better use of risk management resources in the community, while preserving the most restrictive treatment options for the highest risk offenders" (Parks & Bard, 2006, p. 319).

Several attempts have been made to create a comprehensive typology of offenders and understand more about the etiology of offending in order to provide adequate treatment. Certainly some adolescents offend in a time-limited, sexually reactive way. Others offend related to behavior modeling, such as premature sexual exposure (Saleh & Vincent, 2004). Hunter and colleagues (2003) suggested that some youth with impaired functioning may commit opportunistic offenses. There are youths whose offenses may be related to poor integration of social skills and to mental health

diagnosis. Another group may demonstrate conduct-disordered behaviors, and sexual offending may or may not be part of a more typical pattern of interpersonal exploitation and aggressive behavior (Saleh & Vincent, 2004).

The lack of comprehensive typologies and empirical methods for determining treatment needs and recidivism risk identifies the need for quality, clinically sound assessments. For many juveniles, certainly the impact of their behavior may have life-altering effects, but inaccurate or incomplete assessment should not needlessly compound those effects.

Juvenile assessment and treatment must take into account static and dynamic variables given that adolescence is a time of dramatic physical, physiological, emotional, mental, and social change. It may be that the rapid changes during the teenage years present somewhat of a risk factor themselves. Another key variable in adolescent assessment is familial and environmental factors, as teenagers may have little power over their home environment. They may also be greatly influenced by their parents' issues, denial, support, or lack of support.

There may be many purposes for the clinical assessment of adolescents convicted or alleged to have committed a sexual offense. Those purposes may include assisting in determining sentencing recommendations, identifying treatment needs, assessing future risk of sexual behavior, providing information regarding needed level of care, and assessing environmental variables that may support or inhibit treatment.

Adolescent assessment should include a comprehensive record review, collateral contacts with those who know the adolescent, clinical interview, substance use assessment, intelligence testing, personality testing, and sexual history.

A comprehensive record review should include all available documentation of the offense, given the frequency in which initial reactions to questions regarding the offending behavior result in denial or minimized responses. Victim reports may be useful in identifying modus operandi and severity of the offending behavior. Medical records and mental health records may be helpful in identifying early developmental issues or concerns regarding abuse and neglect. Education records may highlight behavior issues in school, poor school performance, learning disabilities, or special education services.

Collateral contact, particularly with parents, is frequently necessary to obtain early developmental history (e.g., teratogenic exposure to chemicals, early attachment issues), information about general socialization patterns, emotional reactivity, and the ability of parents to monitor or influence the adolescent's behavior. Parents of adolescents may be in difficult circumstances as they naturally struggle to believe that their child could have committed such an act. Their own levels of minimization, denial, or offender rejection are often clinically relevant. Parents' support of sex-offender-specific treatment is an item rated on the Estimate of Risk of Adolescent Sexual Offense Recidivism (ERASOR) (Worling & Curwen, 2001), while caregiver consistency and positive social support are rated on the Juvenile Sex Offender Assessment Protocol-Second Edition (J-SOAP-II) (Prentky & Righthand, 2003). Adolescents may struggle to overcome their own denial but may face additional challenges if they fear parental rejection for being forthright. This may be compounded if a male juvenile is alleged to have offended against another male.

A thorough clinical interview is also an important part of sex-offender assessment. Such an interview should include a psychosocial history, particularly focusing on family and social functioning, trauma history, and history of emotional, physical or sexual abuse, or neglect. The adolescent's report of school and social functioning, as well as problems they report that impact their well-being, can greatly assist in evaluating insight, willingness to alter attitudes, and level of maturity and help inform decisions regarding the level of care. Social skill deficits may contribute to sexual offending, which is another topic that may be addressed through both the clinical interview and collateral contact. Evaluation for mental health issues, including developmental disabilities, should be included in the interview. It is difficult to discern the relationship between mental health diagnosis and sexual offending (Saleh & Vincent, 2004), but it is logical that certain disorders may contribute to sexually offending dynamics. An example of this would be bipolar disorder, in which excessive sexual behavior is one way the disorder manifests itself.

Assessment of Substance Abuse

Given that drug and alcohol use may play a role in offending, behavioral control, or general antisocial actions, a drug and alcohol assessment is essential in a thorough assessment. The Substance Abuse Subtle Symptoms Inventory-Adolescent Version (SASSI-A2) (available from www.sassi.com) is an 81-item questionnaire that addresses alcohol and other drug use for use in adolescents ages 12–18. Research has suggested that the SASSI-A2 can be highly accurate (94 %) in distinguishing substance-abusing and substance-dependent adolescents from those without a substance use disorder (Miller & Lazowski, 2001). This accuracy did not appear to be significantly affected by the juvenile's age, gender, ethnicity, education, living situation, or prior history of legal involvement.

Cognitive Assessment

Intelligence testing may be a frequently overlooked aspect of a thorough assessment. It is possible that limited cognitive abilities may contribute to sexual offending. Such individuals may be coerced into sexual activity or may be more drawn to younger peers engaging in inappropriate behavior. They may also have a more difficult time understanding and

interpreting social cues, mores, and perspective taking. Performance and verbal subscales are also helpful in the development of appropriate treatment planning given that those with low verbal skills may struggle in a group environment or those with high verbal abilities combined with lower nonverbal abilities may have difficulty integrating information learned in a treatment context. As mentioned earlier in this chapter, the Wechsler Abbreviated Scale of Intelligence (WASI) can be used with either adults or adolescents, though if a score in the borderline range or lower is obtained, a more comprehensive measure of intellectual functioning is recommended. When a more comprehensive battery is needed, the Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV) and the Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV) are good options. The WAIS-IV may be used for those adolescents aged 16 or older, while the WISC-IV may be used for children between ages 5 and 16 (both available from www.pearsonassessments.com). The identification of learning disabilities or attentional issues may affect how treatment is presented and the manner in which assignments are given or structured.

Personality Assessment

Personality testing may be an additional component of a thorough assessment. The Millon Adolescent Clinical Inventory (MACI) offers information about personality variables and may provide information about emerging personality disorders, while the Minnesota Multiphasic Personality Inventory-Adolescent Version (MMPI-A) assesses psychiatric symptoms (both available from www.pearsonassessments.com).

Sexual History

A comprehensive sexual history is a necessary component when assessing adolescent sex offenders. The evaluator taking the history must have a thorough understanding of normative sexual development. Such an understanding allows one to determine when, if, and in what ways an adolescent sex offender deviated from a normative developmental path. This also provides information about treatment targets and explores the possibility of deviant arousal patterns and paraphilias. Information such as initial exposure to sexual material, pornography, sexual victimization, attitudes about sexual maturation, masturbation, and sexual fantasies greatly informs risk assessments and treatment planning. It is also important to have an awareness of how adolescent offenders may presently access or be exposed to sexual material. Presumptive questioning is generally helpful in eliciting embarrassing information such as masturbation habits. Information about values regarding relationships may illicit information regarding cognitive distortions.

The sexual history should also include information about the current offense. This allows for assessing levels of denial and minimization, empathy, defensiveness, insight, planning, and potentially offense characteristics. The Multiphasic Sex Inventory (MSI) (Nichols & Molinder, 1984) is a 300-item self-report questionnaire that measures psychosexual characteristics of sexual offenders. The MSI was initially developed for adults, and although there is an adolescent form, there is limited data on the reliability and validity of the tool. The subscales include measures of validity of responses, sexual deviance, sexual knowledge, sexual dysfunctions, atypical sexual behavior, motivation for treatment, and cognitive distortions. Again, the MSI may be more useful in providing information regarding treatment direction and severity of disturbance.

Juvenile Risk Assessment

Unfortunately for adolescents, no actuarial assessments exist currently. Worling and Curwen (2001) developed the ERASOR, and 2003; and Righthand et al., (e.g., 2005) developed the J-SOAP and J-SOAP II, which have some initial promise in determining risk. However, neither has been sufficiently studied to have adequate reliability and predictive validity. Both can be useful in assisting in an empirically guided risk and needs assessment. Other tools, such as the Juvenile Sex Offender Recidivism Risk Assessment Tool-Second Edition (JSORRAT-II) (Epperson, D. L., Ralston, C. A., Fowers, D., & DeWitt, J. (2005). Development of a sexual offense recidivism risk assessment tool-II *(JSORRAT-II)*. Unpublished manuscript, University of Iowa, Ames.), Structured Assessment of Violence Risk in Youth (SAVRY) (Borum, Bartel, & Forth, 2003), and the Psychopathy Checklist: Youth Version (PCL:YV) (Forth, Kosson, & Hare, 2003), may also be useful in guiding risk assessment. As stated earlier, such assessments may be central in determining the level of care needed and the areas of dynamic risk which should be targeted through the course of treatment.

The ERASOR is designed to be used with adolescents over the age of 12 to determine the risk of sexual reoffending. It was developed using a comprehensive review of available literature that identified variables found to correlate with sexual offending/reoffending. It is not an actuarial assessment; however, it uses both static and dynamic factors that have been empirically linked to sex offending. The 25 factors include historical sexual assaults; sexual interests, attitudes, and behaviors; psychosocial functioning; family and environmental variables; and treatment status. Risk is based on a combination of the total factors and clinical judgment. This assessment can be completed several times during the course of treatment. Variables such as escalation in negative affect, parental support, and willingness to alter deviant attitudes may relate to treatment targets.

The J-SOAP-II was developed by Prentky and Righthand (2003). It contains significant modifications from the original

version. The J-SOAP-II is an attempt to develop an actuarial assessment; however, it is experimental at this time and not recommended for forensic use, pending additional research to improve reliability and predictive validity. It has been designed for use with males ages 12–18 who have been adjudicated for sexual offenses. An advantage of this assessment is that it can also be used with non-adjudicated youth who have a history of sexually coercive behavior. Similar to the ERASOR, it uses risk factors identified in professional literature as related to both criminal and sexual reoffending. The J-SOAP-II contains 23 items with four subscales. There are two static factors: sexual drive/sexual preoccupation and impulsive/antisocial behavior; and two dynamic factors: clinical/treatment and community stability/adjustment. Cutoff scores do not exist at this time. The J-SOAP-II may be useful in treatment planning and informing the level of care (Calley, 2007). This instrument may be used every 6 months or more frequently if there are relevant changes.

The JSORRAT-II was developed by Epperson and colleagues [(2005). Development of a sexual offense recidivism risk assessment tool-II *(JSORRAT-II)*. Unpublished manuscript, University of Iowa, Ames.]. It contains 12 variables from 7 groups. It is intended to be used as a file review of all official documents for male sexual offenders between the ages 12 and 18. The first 6 items relate to the sexual offense itself, and the seventh item relates to treatment status. Other groups include documented physical and sexual abuse, special education services, school discipline history, and nonsexual offenses. Some items scored as 0 or 1 and others on a 3-point or 4-point scale accounting for various degrees of severity. Initial predictive validity of sexual recidivism is positive. The drawback is that the JSORRAT-II contains no dynamic factors.

The Juvenile Risk Assessment Scale (JRAS) (Hiscox, Witt, & Haran, 2007) is a newer empirically guided risk assessment. It utilizes a mathematical algorithm for determining a risk score, based on risk factors found to be related to recidivism in a standardization study. The 13 items are divided into 3 broad areas (sex offense history, antisocial behavior, and environmental characteristics) and scored on a range from 0 to 28 points. The score is divided into 3 tiers which are related to New Jersey's registration system.

Much has been written about the association of delinquent behavior with risk for both sexual and nonsexual recidivism (Parks & Bard, 2006). Assessment of general antisocial or delinquent behavior may be helpful in assessing a more global risk, and those youths demonstrating delinquent behaviors may benefit from a more intense and specialized interventions (Parks & Bard, 2006). Clearly identifying those youths may allow for a more efficient and effective allocation of resources. Two common global risk assessments are the SAVRY and the PCL:YV.

The SAVRY (Borum et al., 2003) is a general violence risk assessment for adolescents that consists of ten historical variables (e.g., history of violence, early initiation in violent behaviors), seven clinical/individual variables (e.g., substance abuse, anger management problems), contextual variables (e.g., peer delinquency, peer rejection), and 6 protective variables. Like the J-SOAP-II, it is one of the few assessments that take into account protective factors such as social support, positive bonds, and school commitment. The lack of protective factors may also be used as treatment targets to increase if absent. Both static and dynamic factors are considered on the SAVRY.

The PCL:YV (Forth et al., 2003) is completed based on information obtained from structured interviews, observations, and file review. It contains 20 items, with four scales: interpersonal, affective, behavior, and antisocial scored from 0 to 2 for offenders 12–18.

Parks and Bard (2006) found that the Impulsive/Behavior Scale of the J-SOAP-II and the Interpersonal and Antisocial factors of the PCL:YV were significant predictors of sexual recidivism. And, logically, the Behavioral and Antisocial factors on the PCL:YV predicted nonsexual recidivism. Viljoen and colleagues (2008) noted that the J-SOAP-II and the PCL:YV may be less useful for adolescents under the age of 15 due to developmental variables that impact the score, such as difficulty with empathy and impulsivity. The SAVRY and J-SOAP-II were able to predict nonsexual aggression although neither the J-SOAP-II nor JSORRAT-II predicted sexual recidivism (Viljoen et al., 2008).

The purpose of assessment may be related to the level of care recommended for an adolescent to ensure optimal treatment and community safety. The Youth Level of Service/Case Management Inventory (YLS/CMI) is a 43-item instrument designed to measure risk, need, and response to treatment factors in adolescents involved in the criminal justice system. It has been validated for use with both males and females.

More recently, the Child and Adolescent Service Intensity Instrument (CASII) was developed for use with children from ages 6 to 18 (available from the American Academy of Child and Adolescent Psychiatry at www.AACAP.org) to aid in determining the appropriate level of service for an individual. "Initially, the CASII was developed to objectively determine the service needs of children and adolescents with serious emotional disturbances, but the instrument applies equally well to children and adolescents with the full range of presenting problems, including mental illness, substance use disorders, and developmental disorders" (p. 5). It contains six dimensions: risk of harm (which addresses physical and sexual aggressiveness), functional status, coexisting conditions (including developmental and substance use issues), recovery environment (including both environmental stressors and support), resiliency, and treatment acceptance and engagement for both the child/adolescent and the parent. The resulting score leads to one of seven levels of care,

ranging from basic services (e.g., available to the general public) to 24-h secure placement with psychiatric management. The dimensions are scored using all available records. This instrument may be particularly useful with youth who have comorbid issues. The CASII largely addresses dynamic factors that can be reassessed with treatment changes and can provide information regarding what services may be necessary to step-down placement to a least restrictive level.

Polygraph Assessment

Polygraphs have been used with adults as a part of treatment, related to determining honesty regarding offending histories, as well as probation and treatment compliance. There is little information on the use of polygraphs with juvenile sexual offenders (Hunter & Lexier, 1998). It may be common for adolescent sexual offenders to be less than forthcoming when questioned about their sexual behavior and offending history. Rather than as an initial assessment instrument, a polygraph may be better used as an adjunct to treatment, providing feedback regarding progress toward treatment goals.

Offenders with Autism Spectrum Disorders and Fetal Alcohol Spectrum Disorders

While they represent a small minority of sexual offenders referred for assessment, it is important to consider the impact of possible diagnoses of Autism Spectrum Disorders (ASD) and Fetal Alcohol Spectrum Disorders (FASD) when completing assessments of both juvenile and adult offenders. This is crucial because the difficulties associated with these developmental disorders can increase the likelihood of engaging in inappropriate sexual behaviors and can affect their response to treatment. There are some commonalities among these two disorders related to impairment in social reasoning, communication, and awareness, as well as the possible impact on cognitive domains. When considering these two distinct types of developmental disabilities, it is important to recognize that there are varied and differing clinical presentations, including a continuum of functional impairment and severity of difficulties. For this discussion, the most common diagnoses subsumed under the ASD umbrella (e.g., Asperger's Disorder, Autistic Disorder, Pervasive Developmental Disorder Not Otherwise Specified [NOS]) will be grouped together. Similarly, the term FASD refers to the various labels associated with prenatal exposure to alcohol (e.g., Fetal Alcohol Syndrome [FAS], Partial FAS, Fetal Alcohol Effects [FAE], and Alcohol-Related Neurodevelopmental Disorder [ARND]).

Autism Spectrum Disorders

Haskins and Silva (2006) argued that individuals with Asperger's Disorder are overrepresented in forensic criminal settings in general, although rates of sexual offending in individuals with an ASD diagnosis are difficult to determine, and varying proportions have been reported (Allen et al., 2008; Hare, Gould, Mills, & Wing, 1999, Langstrom, Grann, Ruchkin, Sjostedt, & Fazel, 2009). It is believed that the difficulties that are core to an ASD are associated with why individuals with ASD commit criminal offenses, including difficulty understanding social relationships and accurately reading nonverbal cues, poor perspective taking/lack of empathy, being socially misunderstood, demonstrating poor impulse control, difficulty understanding the consequences for behavior, obsessional focus on narrow areas of interest, rigid adherence to rules or expectations, and being vulnerable to being taken advantage of by others (Allen et al., 2008; Haskins & Silva, 2006).

Therefore, identifying whether an ASD diagnosis is present in a sexual offender aids in understanding the possible reasons underlying his behavior. In addition, it aids in tailoring interventions so they are optimally effective. Comprehensive assessment of possible ASD includes obtaining a thorough developmental history, usually involving collateral contact from a parent or caregiver during childhood, assessing possible comorbid conditions, and examining the examinee's cognitive profile. Psychological assessment should include measurement of intellectual functioning to rule out global cognitive delay. However, various areas of cognition, including executive functions (e.g., impulse control, planning, problem-solving, cognitive flexibility), social understanding, communication skills, and adaptive behavior, should also be further assessed if concerns have been identified.

Diagnostic assessment can be supported through the use of various rating scales, structured interviews, and semi-structured observations, most of which involve obtaining ratings and/or observations provided by someone who knows the examinee well, such as a caregiver or teacher. Information about currently available diagnostic instruments and psychometric data for the measures can be found in Lord and Corsello (2005) and Attwood (2007).

Social problem-solving deficits have been identified as a core area of difficulty, with adults with Asperger's Disorder demonstrating less detailed and less effective social problem-solving compared to individuals without ASD (Goddard, Howlin, Dritschel, & Patel, 2007). Social reasoning can be screened using the subtests that exist on measures of general intellectual functioning (e.g., Comprehension and Picture Arrangement subtests from the Wechsler Intelligence Scales). A semi-structured interactive assessment, the Autism Diagnostic Observation Schedule (ADOS) (Lord, Rutter, DiLavore, & Risi, 1999), can also provide helpful information about the child's or adult's social interaction and communication skills. Referral for speech/language evaluation may also be indicated if the examinee is observed to

have difficulty expressing himself/herself verbally, has a history of speech/language delays, and/or demonstrates significantly poorer verbal reasoning abilities. In addition, measuring adaptive behavior (the capacity for translating cognitive ability and potential into real-life skills) is also critical because individuals with ASD often demonstrate a large discrepancy between their potential and their ability to translate skills into actual independent living skills (Klin, Saulnier, Tsatsanis, & Volkmar, 2005). The Vineland Adaptive Behavior Scales-2nd Edition (Sparrow, Cicchetti, & Balla, 2005) and the Scales of Independent Behavior-Revised (SIB-R) (Bruininks, Woodcock, Weatherman, & Hill, 1996) provide an overall adaptive behavior score and normative data regarding socialization and communication skills.

Executive dysfunction has been found to be a common difficulty for individuals with ASD. Sanders, Johnson, Garavan, Gill, and Gallagher (2008) reviewed the research on selected executive functions in individuals with ASD and found deficits in orienting attention, response inhibition, and set shifting, though sustained attention was not impacted. Some of the assessment tools that exist for use with examinees ranging in age from childhood to adulthood include the various tests contained in the Delis–Kaplan Executive Function System (D-KEFS) (Delis, Kaplan, & Kramer, 2001) and the Behavior Rating Inventory of Executive Function (BRIEF) (Gioia, Espy, & Isquith, 2000).

Fetal Alcohol Spectrum Disorders

Rates of sexual offending in individuals with FASD appear higher than rates for individuals without prenatal exposure to alcohol. Streissguth et al. (2004) found 49 % of 415 adolescents and adults with FASD demonstrated inappropriate sexual behaviors on repeated occasions. Similar to individuals with ASD, individuals with a diagnosis of FASD tend to struggle with social communication skills, understanding cause-and-effect relationships, poor judgment, difficulty learning from past mistakes, poor impulse control and planning skills, and naïveté in interpersonal interactions. Individuals suspected of having an underlying diagnosis of FASD are usually evaluated by a multidisciplinary team to determine whether the features indicative of FASD are present currently or historically, including: (1) growth deficiency, (2) malformation of specific facial features, (3) degree of central nervous system (CNS) impairment, and (4) information regarding extent of prenatal exposure to alcohol (Astley, 2004). It is important to note that studies have repeatedly demonstrated that cognitive deficits can be present, even when facial malformations are absent (Mattson & Riley, 1998).

Several researchers have cited FASD as the most common cause of mental retardation (Wacha & Obrzut, 2007). However, even individuals with average to above-average intellectual functioning show marked cognitive difficulties (Baumbach, 2002). Individuals with FASD can also experience difficulties in language, learning/academic, motor, visual–spatial, attentional, memory, and adaptive behavior skills (Mattson & Riley, 1998; Mattson, Riley, Gramling, Delis, & Jones, 1998; Wacha & Obrzut, 2007). Studies of children have identified increased rates of externalizing behaviors, such as alcohol and drug use, hyperactivity, impulsivity, delinquency, poor social skills, and poor communication skills (Mattson, Schoenfeld, & Riley, 2001). These difficulties and the interactions of such difficulties pose increased risk for sexually inappropriate behaviors, among an array of other difficulties.

During assessment of sexual offenders, Baumbach (2002) recommended exploring whether FASD has been suspected or tentatively diagnosed in the past in the examinee or sibling(s); information suggesting maternal alcohol use during the pregnancy; observation of physical features, developmental delays, or neurological problems suggestive of FASD; observation of incongruities between the examinee's presentation and actual performance (e.g., adaptive functioning, communication, and social skills fall lower than expected given measured IQ); and behaviors indicative of FASD. Baumbach (2002) referenced the Fetal Alcohol Behavior Scale (FABS) developed by Streissguth and her colleagues to identify behaviors that commonly occur with FASD and to distinguish these from behaviors of individuals without FASD. Gathering this information can help the examiner to decide whether a referral to a multidisciplinary team that specializes in diagnosing FASD is warranted; the examiner is cautioned against independently making a diagnosis of FASD based on the above information (Baumbach, 2002).

Assessment of general intellectual functioning is needed to determine whether global cognitive delay (e.g., mental retardation) is present. In addition, it is recommended that psychological and neuropsychological evaluation explore possible areas of difficulties cited above. For example, utilization of measures of academic achievement (particularly reading comprehension, as noted earlier in the chapter), executive functions [e.g., attentional abilities (e.g., continuous performance tests), verbal and nonverbal fluency measures, planning and problem-solving tasks, measures of cognitive flexibility, tasks assessing verbal and visual memory], visual–motor integration, and independent living skills/adaptive functioning is recommended (see above for several examples of measures that can be utilized). Screening of language abilities (e.g., receptive and expressive language skills) may also help identify whether further evaluation through a speech/language pathologist is needed. Collateral contact with others who can provide information about the examinee's abilities and behaviors in unstructured, real-life situations, either through the use of rating scales or through an interview, is recommended in order to gather information about the ability–performance gap that is frequently present.

Female Sexual Offenders

Although national criminal justice statistics suggest that less than 10 % of individuals arrested for sexual offense are female, the number of adolescent girls coming to juvenile courts for sex offenses has significantly increased (Female Sex Offenders, 2007). However, currently, there is still very little research on the assessment and treatment of female sexual offenders. Given that limitation, there have been some attempts to identify typologies of sexually abusive women. For example, Mathews and colleagues (1989) identified three subgroups, including women who were coerced by their male partners to commit sexual offenses (often against their own children), women with histories of incestuous sexual victimization and sexually deviant fantasies, and women struggling with age-appropriate relationships who perceive themselves as having a sexually mentoring "relationship" with an adolescent male. Unfortunately, most sex-offender-specific assessment tools were developed for and normed on male sexual offenders, making it questionable to attempt to use them for assessment of female sexual offenders. The Multiphasic Sex Inventory-II (available at www.nicholsandmolinder.com) does have a form for use with women. However, given the low frequency with which women get arrested for sexual offenses, the sample size on which it was normed is very small. There is also a version of the penile plethysmograph developed for women. Vaginal photoplethysmograph measures blood flow through the walls of the vagina as this is believed to increase during sexual arousal, and more recently measures of blood flow in the labia and clitoris have been developed (Gerritsen et al., 2009; Prause, Cerny, & Janssen, 2005), but there is little research available on the validity and reliability of these techniques. Most risk assessment tools have also been developed for use only with male offenders, with the exception of the Level of Service Inventory-Revised and the Youth Level of Service/Case Management Inventory (Andrews & Bonta, 1995; Hoge, Andrews, & Leschied, 2002; Schmidt, Hogue, & Gomes, 2005). Most recently, some early data on the Iowa Sex Offender Risk Assessment (ISORA8) (State of Iowa, 2010) appeared promising for use with women, but much more research in this area is needed.

Assessment of Civilly Committed Offenders for Release

When assessing whether an offender has sufficiently lowered his risk for return to the community, it is crucial to be aware that most actuarial tools focus on static risk factors, so such will not capture the benefit achieved from the treatment program. Civilly committed sexual offenders have already been assessed using actuarial tools and have been determined to fall in the group that presents a high risk for reoffending. Therefore, to assess their progress since the time of commitment, the clinician will need to focus on dynamic (or changeable) risk factors. The STABLE-2007 and the ACUTE-2007 (Hanson, Harris, Scott, & Helmus, 2007) are tools which were designed to assess and track changes in risk status over time. "Stable" dynamic risk factors are deficits, predilections, and learned behaviors that can be changed through involvement in treatment. "Acute" dynamic risk factors are highly transient conditions that can last a very short period of time, such as hours or days. Currently, these are the dynamic risk factor assessment tools that have been researched most extensively, although the Risk for Sexual Violence Protocol (RSVP) (Hart et al., 2003), The Violence Risk Scale: Sexual Offender Version (VRS:SO) (Wong et al., 2003), and the Sex Offender Treatment Intervention and Progress Scale (SOTIPS) (McGrath & Cumming, 2003) show promise as well for their predictive ability related to recidivism (Olver et al., 2007; McGrath et al., 2012).

Summary and Future Directions

There are many different contexts in which an evaluator may be asked to complete an assessment on a sexual offender, each requiring separate skills and knowledge bases and each of which presents potential ethical dilemmas. For some, such as evaluations for those referred for civil commitment, it can seem an almost overwhelming task to keep up with the quickly changing literature regarding risk assessment tools. Relatively little has been written about assessments of sexual offenders for treatment planning purposes. This is somewhat surprising given that there is frequent mention that a "one-size-fits-all" program is insufficient (Hanson et al., 2002; Marques, 1999; Ward, 2002), and effective treatment of sexual offenders, whether they are juveniles or adults, must begin with a comprehensive assessment of their individualized needs. Knowledge of a wide range of tests and assessment tools, and maintaining updated information about those tests and tools, is crucial for clinicians to have the basis to develop appropriate treatment plans. Those offenders with developmental disabilities or significant cognitive deficits secondary to severe and persistent mental illness require special attention and may even need referral for a separate track or program. The presence of severe mental illness, personality disorders, substance abuse, psychopathy, and psychosexual disorders can all influence an individual's sexual behavior and need to be carefully evaluated. One often neglected area is an assessment of Autism Spectrum and Fetal Alcohol Spectrum Disorders, although increasing awareness of these disorders can increase the effectiveness of a therapeutic approach. It is only through such a comprehensive assessment that clinicians can have greater confidence that they are recommending the best treatment to minimize the potential for additional sexual offenses in the future.

Clinical Strategies for Evaluating Sexual Offenders

Robert J. McGrath

Evaluating Sex Offenders: Practical Clinical Strategies

Comprehensive sex offender evaluations form the foundation for designing and delivering appropriate services to this population. Evaluations provide an opportunity to collate and synthesize information about offenders to inform a variety of important clinical, management, and legal decisions. These include decisions regarding sentencing, institutional placement and treatment planning, civil commitment, release decisions, reentry planning, community supervision and treatment, registration and notification, and family reunification. Assessment is an ongoing process. As offenders move through the criminal justice and mental health systems, later evaluations should build on information contained in earlier ones.

Sex offenders are typically not voluntary clients. Rather, a third party, such as a court, correctional agency, or social service organization, has compelled the offender to undergo evaluation. Consequently, the offender's relationship with the evaluator can be adversarial in nature. This is especially true when what is at stake in the evaluation is at great odds with what the offender considers to be in his best interests. Examples of high stakes evaluations include criminal sentencing hearings and civil commitment trials where the potential outcome includes a lengthy period of confinement. In these cases an offender's interest in freedom may conflict with the community's interest in public safety or exacting just deserts.

On the other hand, the offenders and evaluators often have interests that overlap, such as when their mutual goals concern rehabilitation. Evaluations ideally should help offenders begin to recognize and do something about their problems. The chances of successful rehabilitation are enhanced when the evaluator and offender are able to form a collaborative working relationship.

Collaboration is particularly important when the evaluator also will be the treating clinician or affiliated with the treating clinical team. Although clinicians may distinguish between the evaluation and treatment phase of services, clients may not see it the same way. How they are treated during the evaluation phase of a program likely spills over into how they initially view the treatment phase. This can be critically important because the therapeutic relationship between offender and clinician typically stabilizes in the first few sessions (Miller & Rollnick, 2002).

The manner in which evaluators interact with offenders, however, has received little attention (Shingler & Mann, 2006) and collaboration typically has not been viewed as a necessary endeavor. Early approaches toward criminal justice clients emphasized authoritarian and confrontational approaches (Miller & Rollnick, 2002) and this style has been recommended as well by some of the early writers in the sex offender field (Salter, 1988). This is not to say that evaluators should not challenge offenders and ask difficult questions during an evaluation, nor to ignore the power differential between the offender and evaluator; rather, it is to recognize the importance of the therapeutic relationship which begins with the first contact the offender has with an evaluator.

The general psychotherapy literature is clear that the manner in which a clinician interacts with clients is equally or even more important than the specific treatment techniques that he or she uses (Lambert, 1992; Lambert & Barley, 2001). Therapeutic relationship is enhanced when evaluators are respectful, direct, genuine, and empathic. As well, these factors have been found to be equally important in interacting with correctional clients (Andrews & Bonta, 2010; Dowden & Andrews, 2004). More recently in the sex offender field, a series of studies found that these same clinician characteristics associated with success in other areas of

mental health practice are the same as with those associated with effective sex offender treatment interventions (Beech & Hamilton-Giachritsis, 2005; Marshall, 2005).

This chapter focuses on evaluation strategies for obtaining information from sex offenders for clinical decision-making activities. It emphasizes throughout the importance of evaluators developing a good collaborative working relationship with clients. Six broad areas are examined: (1) preparing for the clinical evaluation, (2) describing a conceptual evaluation framework, (3) matching evaluation strategies to the client's stage of change, (3) recommending a sequenced interview protocol, (4) identifying discreet interview strategies, (5) identifying offender's treatment needs, and (6) formulating appropriate disposition plans. Because most sexual offenders are male, discussion will be limited to this population.

Preparation for the Clinical Evaluation

Although sex offenders are referred for clinical evaluations for several reasons, this chapter focuses on those that concern known sex offenders' psychosexual characteristics. A known sex offender is defined here as an individual who admits to having committed a sexual offense or who has been determined to have done so by a legal entity such as a court, professional practice review board, or state child protection agency. Clinicians are cautioned against conducting evaluations where the explicit or implicit request involves determining an individual's guilt or innocence.

As the Association for the Treatment of Sexual Abusers (2005) Practice Standards and Guidelines state, "There is no known psychological or physiological test, profile, evaluation procedure, or combination of such tools that prove or disprove whether an individual has committed a specific act" (p. 10). It is the function of the criminal and civil justice system, not the mental health system, to determine guilt or innocence.

Having established that an individual referred for evaluation has committed a sexual offense, obtaining clarity early on in the referral process about the context and purpose of the evaluation is critical. Relevant and common referral questions concern the nature of the individual's sexual deviancy, psychiatric diagnosis, dangerousness, supervision and treatment needs, amenability to services, and disposition recommendations. Referral questions should be clarified with the referral agent at the time of referral. This is a critically important communication, as it is often the case that the clinician will have to educate the referral source about what are and are not appropriate issues to address during the evaluation (McGrath & Purdy, 1999).

Before actually accepting a referral, evaluators need to assess whether they are ethically able and qualified to address the referral request. First, as already noted, clinicians should not conduct evaluations to determine guilt or innocence. Second, evaluators should not accept referrals where they have an irresolvable conflict of interest as defined by their professional code of ethics (e.g., American Psychological Association, 2002; Association for the Treatment of Sexual Abusers, 2005). Last, evaluators in this field, as all mental health professionals, must limit their practice to areas in which they are competent. Professionals who evaluate sex offenders should have education, training, and experience working with this population consistent with professional guidelines (e.g., Association for the Treatment of Sexual Abusers, 2005). Competent professionals also recognize that some types of evaluations in this field require more expertise that others. Civil commitment evaluations, for example, are highly technical and require a determination of whether an individual's risk to reoffend meets a specific statutory requirement. In comparison, evaluations to determine an individual's primary treatment needs may require less exacting professional skills.

Prior to interviewing an offender, the evaluator should review all relevant background documents. These include victim statements, police affidavits, court orders, presentence investigation reports, institutional incident reports, criminal record checks, medical and psychological reports, and relevant treatment notes and progress reports. Reviewing records not only enables one to learn about the offender and what he did, but helps determine how he is describing and making meaning of the offense behaviors for which he has been convicted. Because sex offenders commonly misrepresent their history for a variety of reasons such as embarrassment and fear of unwanted evaluation outcomes, prior records often provide a more objective account of his history than he may report himself. Reviewing prior records helps one strategize how to approach the interview. The interested reader can obtain further guidance about screening offenders referred for assessment using a decision tree that details the recommended steps in this process (McGrath & Purdy, 1999).

Evaluation Framework

To organize the considerable offender data that evaluators typically collect, one should identify and utilize a clear conceptual organizing framework. Three empirically based correctional principles that guide the delivery of effective services for sexual offenders can serve as such a framework. They are the principles of risk, need, and responsivity (Andrews & Bonta, 2010; Association for the Treatment of Sexual Abusers, 2005). Interventions that adhere to these principles are found consistently to be more effective than those that do not, both for general criminal offenders (Andrews & Bonta, 2010) and sex offenders (Hanson,

Bourgon, Helmus, & Hodgson, 2009). These principles provide evaluators a "who, what, and how" framework for organizing and making meaning of information they obtain during the evaluation.

The risk principle concerns "who" will need the most intensive interventions. Treatment and supervision services are more effective when they are applied to higher versus lower risk offenders. Evaluators should employ one or more empirically supported risk assessment instruments to evaluate offenders' risk to reoffend. This approach and several instruments are reviewed in other chapters and are not repeated here.

The need principle helps evaluators evaluate "what" problems an offender has that are directly linked to offending behavior and therefore should be a focus of intervention. The "Treatment Needs" section in this chapter examines this topic in further detail.

The responsivity principle helps evaluators recommend "how" services should be delivered so that the offender can respond optimally to services. Responsivity considerations include an offender's learning style, intellectual ability, personality characteristics, and motivation. The responsivity issues of denial and motivation for change are examined in the following "Stages of Change" section of this chapter.

Stages of Change

The attitude with which an offender begins the evaluation process is an important responsivity consideration. Sex offenders present themselves for an evaluation with varying degrees of engagement. Evaluators should meet clients where they are. The seminal work on stages of change by psychologists Prochaska, DiClemente, and Norcross (1992) is a good starting point for assessing client cooperativeness and readiness to change, and it has been applied to the evaluation and treatment of sexual and other criminal offenders (Ginsburg, Mann, Rogers, & Weeks, 2002; McGrath, 2003; Shingler & Mann, 2006). The basic idea is that different types of evaluation and interview strategies should be used to help offenders at the different stages of change.

Sex offenders, as do other people who succeed in making changes in their lives, typically move through several distinct stages of change (Prochaska et al., 1992). These stages concern the degrees to which individuals recognize that a problem exists and are ready, willing, and able to do something about it. The number of stages of change reported in the literature has varied (Miller & Rollnick, 1991, 2002), and here a five-stage model is examined. It is comprised of the precontemplation, contemplation, preparation, action, and maintenance stages. Although an evaluation is not "therapy" per se, it can help begin to move an offender in the direction of positive change, namely, from the earlier stages of change to later ones. Because it is common for sex offenders to initially deny or minimize having committed a sexual offense or having a current problem, the early stages of change are emphasized.

Precontemplation

In this stage the offender sees no need or reason to make a change. It is often a simple matter for the evaluator to determine prior to the interview whether a sex offender is in this stage. The referral source, be it probation or parole officer, correctional caseworker, or attorney, often knows whether the offender is in denial or refusing to enroll in rehabilitation programs. As is discussed later, knowing this beforehand is helpful so that the evaluator can attempt to prevent the offender from beginning the interview protesting his innocence, thereby further entrenching his denial.

Initially, a sex offender may say he did not commit a sexual offense for a variety of reasons. Setting aside the rare individual who was unjustly convicted, an offender can express denial for several self-protective motivations. An offender may deny to avoid accountability, feelings of personal shame or guilt, and fear of retribution and to keep jobs, spouses, or friends. Some offenders who do admit their offenses often deny having a current problem because they believe or argue that they have resolved the issues related to their sexual offenses, such as alcohol abuse or marital discord.

At this stage, the issue of problem recognition is primary as it is generally viewed as an essential initial condition in the change process (Miller & Rollnick, 2002). In order to change a problem behavior, it is typically necessary to recognize and acknowledge the problem. Once an individual acknowledges that he has a sexual offending problem, it is easier to identify the specific nature of the problem in order to begin developing an individualized treatment plan.

The evaluator should provide information to raise the offender's awareness of the problem and the consequences of not admitting to or being willing to do something about the problem. It is also often helpful to normalize people's tendency to deny or minimize problems and indicate that you as an evaluator understand the many reasons why someone might do so. This all should be done in a direct, matter-of-fact, and respectful manner. Giving advice at this stage is usually counterproductive as it often elicits or magnifies offender resistance and resentment. Rather, this is a time to "plant a seed" and leave the door open for change.

Contemplation

In the contemplation stage, the offender recognizes the problem and is considering change. This stage of change is marked by ambivalence. The offender may vacillate in his

view about the seriousness of the problem. Similarly, the offender may understand the potential positive reasons for tackling the problem, but is conflicted about giving up benefits associated with sexual offending or fears the consequences of admitting to others that he indeed has committed sexual offenses.

An offender who recognizes and admits he has a sexual offending problem is unlikely to be successful giving up the behavior unless he is motivated to do so. The individual needs to perceive that the benefits of giving up offending outweigh the advantages of continuing to offend. Motivation for positive change may include the fear of the negative consequences of getting caught, desire to prevent victim harm, and a general desire to lead a "good life."

The goal of interview strategies at this stage of change is to tip the balance toward change, helping offenders weigh the risks of the status quo and the potential benefits of change. Emphasizing the positive aspects of change and that change is possible is critical, because offenders who have little hope of changing or are overwhelmed at the difficulties of change tend to focus on only the obstacles. Encouragement and support here are key.

To help tip the balance toward positive change, the evaluator can encourage an offender to meet with treatment staff to get accurate information about available programs. They can ask an offender to meet with individuals who have been successful in treatment programs and boost the offender's confidence that he or she can benefit from these programs as well. Helping offenders get accurate information with which to make informed decisions at this time facilitates their moving into the preparation stage. Giving advice at this stage is usually counterproductive, as offenders often become defensive if preached to or if challenged too forcefully.

Preparation

Some sex offenders come to an evaluation session having decided to change. The evaluator's task here is to help the offender develop an effective plan for action. This may include reviewing treatment options and the pros and cons of each. If the program to which an offender will enter has already been determined, the evaluator can prepare him by reviewing the program's expectations and, if appropriate, going over the treatment program's informed consent documents, especially those that describe the actual content of treatment.

Action

In this stage, the offender is actively in the process of doing things to positively modify his behavior. Evaluations here are usually designed to assess client progress during a midpoint or toward the end of a treatment program. The goal of the evaluation here may be to ascertain whether the individual is ready to move on to a more advanced stage in a treatment program or whether he is ready to be moved to a less restrictive environment. Evaluators should focus on encouraging an offender at this stage to continue his good efforts. Evaluators can encourage an offender by positively reinforcing the progress they may have made in identifying and addressing their treatment needs and goals (described in the Treatment Needs section of this chapter). They may highlight an offender's progress since the previous evaluation and reference-positive treatment, caseworker, and probation or parole reports.

Maintenance

Sex offenders in the maintenance stage are in the process of maintaining and solidifying changes that they have made. They may be completing treatment, and the changes appear to be solid. They are living a lifestyle that is inconsistent with offending. They are able to identify factors that place them at risk, have developed strategies to either avoid or cope with risk, and demonstrate behaviors that show that they are using what they have learned in treatment effectively and consistently. The goal of interviewing here is to reinforce offenders' efforts to stabilize change.

Interview Protocol

Each evaluation and offender will present unique challenges but most interviews with this population address common issues. The following protocol, adapted from recommendations previously made by the author (Cumming & McGrath, 2005; McGrath, 1990), suggests a basic format for initial interviews. The interviewer should modify the protocol and strategies as circumstances dictate. The goal is to begin developing a therapeutic alliance with the offender while, at the same time, gathering information necessary for making various clinical decisions. The evaluator, having previously established that an interviewee has committed a sexual offense, clarified the referral questions, determined competence to conduct the evaluation, and reviewed available background records, is ready to conduct the interview.

Establish Credibility

An initial step in the interview process is to establish credibility with the interviewee. If the interviewee perceives you as competent and fair, you are likely to have better rapport with him and be able to obtain information more efficiently and thoroughly than if you are not.

When you meet the individual and introduce yourself to him for the first time, you should provide some information about your background and experience. To the degree that your reputation has preceded you and it is negative, whether this appraisal is fair or not, you will need to do damage control. It is not uncommon for other sex offenders or even an attorney to have told the interviewee information about you or the program with which you are associated. If the information is erroneous, it is important to correct it if possible.

Having prepared carefully for the interview also will help establish your credibility. For example, letting the individual know that you have obtained relevant documents about the case and have reviewed them makes a statement that you are interested and thorough.

Provide Informed Consent

Providing informed consent is an additional way to establish credibility with an interviewee. Taking the time to explain the evaluation process to the offender is a demonstration of respect for the individual. Certainly, offenders who are given a clear explanation of the purpose of the interview and how the information will be used often approach the interview with less anxiety and guardedness.

Providing informed consent is also a professional obligation. Increasingly, professional organizations, including the Association for the Treatment of Sexual Abusers, enjoin evaluators to obtain informed consent not only verbally but in writing as well. This association has detailed the elements of informed consent and its definition provides a good reference for professionals evaluating sexual offenders.

> Informed consent provides clients with information about the purpose, goals, techniques, procedures, limitations, consequences of not consenting, limits of confidentiality, alternatives to the services offered, potential risks, and benefits of services to be performed. Providers ascertain the client's ability to understand and utilize the information. When providing services to persons unable to give informed consent, providers obtain consent from the client's guardian (Association for the Treatment of Sexual Abusers, 2005, p. 52).

Take a Social History

It is recommended that the evaluator begin the data gathering process by eliciting the offender's social history and informing him that the offense itself will be delved into later. By doing so, the evaluator is likely picking the "low hanging fruit" first, that is, inquiring first about information that is likely the least threatening to the individual and most easily obtained. The evaluator then gradually moves on to more sensitive topics. Proceeding in this manner tends to help the person be more at ease and help the evaluator establish rapport.

This approach may also discourage the individual from beginning the interview by denying that he has ever committed a sexual offense. Certainly, at the outset of the interview, the offender may be more guarded, closed, and anxious and less likely to admit to engaging in embarrassing behaviors than later in the interview when hopefully greater rapport has been established. A goal at this stage of the interview is to prevent placing the individual in the dilemma of having already told you a falsehood and then not wanting to lose face later in the interview but perhaps feeling internal pressure to stick to their original story.

Social history interviews are a standard procedure for most mental health professionals and their common content is not reviewed here. With sex offenders, however, certain areas require a more in-depth examination, and detailed outlines have been presented elsewhere (Cumming & McGrath, 2005; Groth, 1979; McGrath, 1993). Recommended topics include information about the individual's developmental history, family of origin and current family, social, relationship and marital history, education, employment, military involvement, criminal history, accommodation history, money management, physical and mental health, alcohol and drug use, social supports, and leisure activities. Deficits and excesses in several of these areas are linked with risk for reoffending and are discussed in more detail in the "Treatment Needs" section of this chapter.

Dispel Myths

After the evaluator has elicited the individual's social history, it is important to prepare the examinee for answering questions about his sexual and sexual offending history. Sex offenders often have the same stereotypes about sexual offending as do other members of the community. Offenders often are confused about why they do what they do and often feel shameful and inadequate. Most have not talked to anyone in detail about their sexual offending behaviors or how they have tried to make sense of their sexual problems. An evaluator who can communicate understanding about the offender's private sexual life is in a good position to create an atmosphere in which the offender can discuss his problems.

The evaluator, during the course of reviewing the offender's records and in the initial stages of the interview, should formulate hypotheses about why the offender was motivated and willing to commit the sexual offenses he did. With this information, and following a strategy described by Yochelson and Samenow (1977), the evaluator can attempt to present an offender with a mirror image of him. The idea is to tailor salient scenarios that resonate with the offender and help him begin discussing his sexual offending. When an evaluator begins to describe certain thoughts and behaviors that the

offender assumed no one knew about, it provides an opening for more honest disclosure.

For example, an evaluator is generally on safe ground reflecting aloud that the offender has probably wondered numerous times why he has committed his sexual offenses. The evaluator can then go to present various hypotheses matched to his particular situation. In the case of an incest offender who is in denial, the evaluators might explain how the general public typically views men who have had sexual contact with children as monsters but that the evaluator knows differently. The evaluator's experience is that many men who have committed these offenses live normal lives in many respects except for their offenses and that most men who have committed these offenses did not intentionally mean to harm the victim. The evaluator may note, if it appears relevant to the individual being interviewed, that many men who commit this type of offense say they were only teaching their daughters about sex or only committed the offenses because they were drunk. Of the men that the evaluator has talked with, however, many recognize that it started for other reasons, such as when they became distant from their wife or began to feel more closeness to their children, and that this emotional closeness led to sexual feelings. And, in the evaluator's experience, most men who have committed these types of offenses acknowledge that they knew it was wrong, but somehow succumbed to those feelings.

The degree to which such accounts match the offender's experience is the degree to which the offender may feel understood and feel more comfortable telling his story. The evaluator presents himself or herself as someone who will not be judgmental and understands the complexity of human behavior.

In using this approach, the evaluator must guard against supporting an individuals distorted excuses. The scenarios should be guided by the evaluator's informed hypotheses, which should be based on the facts of the case and an assessment of the offender's likely modus operandi and motivations. By presenting such scenarios, the interviewer is demonstrating that he or she is well informed about different types of offending behavior, is able to talk about it in a matter of fact manner, can understand the offender's perspective, and expects from the offender an honest description of the offense.

Take a Sexual Offense and Sexual Offense History

The discussion of myths should flow naturally into asking the individual to describe in detail his sexual offenses and sexual history. Evaluators may begin by asking the individual to talk about when he first realized that his sexual interests were of the type that might lead to him getting into trouble, or evaluators may begin by asking the individual to describe the sexual offense that led to the current evaluation and then work backwards to understand the chain of events, thoughts, feelings, and behavior that led up to the most recent offense.

Table 1 Sexual offending history outline

1. Sexual offenses
   a. Charges and convictions
   b. Child protection agency substantiations
   c. Offender self-reports
   d. Other reports
2. Intrusiveness of offenses
   a. Noncontact
   b. Fondling
   c. Oral contact
   d. Penetration
   e. Bizarre or ritualistic behavior
3. Premeditation
   a. Planned
   b. Opportunistic
   c. Spontaneous
4. Victim selection
   a. Age
   b. Gender
   c. Relationship
   d. Situation
   e. Physical characteristics
5. Harm to victims
   a. Level of emotional harm
   b. No physical injury
   c. Injury not requiring medical attention
   d. Treated for injury and released
   e. Hospitalized
   f. Death resulting
6. Method of controlling victims
   a. Verbal manipulation
   b. Bribery
   c. Position of authority
   d. Threats
   e. Incapacitation (e.g., drugs)
   f. Physical force
   g. Weapons
   h. Violence
7. Precipitating and contributing factors
   a. Precursive sexual fantasies
   b. Emotional state
   c. Precipitating stresses
   d. Physical conditions
   e. Psychiatric conditions
8. Course of sexual offending history
   a. Age of onset
   b. Frequency
   c. Duration
   d. Progression
   e. Length of prodromal phase
   f. Previous response to interventions
9. Level of admission and responsibility
   a. Behavior
   b. Fantasy and arousal
   c. Victim impact
   d. Risk to recidivate
   e. Need for treatment

Appropriate areas of inquiry about an offender's sexual history include sex education, formative sexual experiences, victimization history, masturbatory and sexual fantasy history, use of pornography and erotica, sexual outlets and frequency, sexual dysfunction, heterosexual and homosexual experiences, paraphilias, and sexual relationship history. Table 1 lists the topics that the evaluator should examine about an individual's sexual offending history. The evaluator should use relevant court or other official records to challenge individuals who are reluctant to describe in more detail their offending patterns.

Allow Face-Saving

Most sex offenders will not be totally candid about their sexual offending and life history during initial interviews. So, it is important to set the stage for future interviews in which the individual can make further disclosures and still "save face." The goal is to create an atmosphere that will

encourage honesty rather than focusing on how an individual may have been deceitful in initial interviews.

Several strategies can help make it easier for an offender to disclose in the future. The evaluator should acknowledge the difficulty of admitting sexual offending behavior, express approval for disclosures the individual has made already, and grant that complete honesty is rare at this stage of the interview or treatment process. This is especially true if the individual is talking about their sexual and offending behaviors for the first time. The evaluator can also note that it is normal for someone to want to push to the back of their mind unfavorable aspects of their behavior and that by simply being asked questions about his sexual and sexual offending history during the interview, he may begin to find that his memories about these issues begin to become unlocked. It is also important for the evaluator to be clear that he or she would find it typical that an offender would make more detailed disclosures in subsequent meetings and that these would be welcomed as opposed to being viewed as the offender having been resistant.

Instill Hope

Many sex offenders fear that their behavior is out of control and that they cannot change. They promise themselves that they will stop sexually offending and find themselves engaging in abusive behavior again. Client expectations are a powerful determinant in changing behavior and treatment outcome. Sometimes called the "placebo effect," positive expectations are associated with positive treatment outcome in medicine and psychotherapy (Lambert & Barley, 2001; Miller & Rollnick, 2002). Individuals who believe they can change are more likely to do so. Individuals who have service providers who believe they can change are more likely to do so. Clients who are told that they cannot change often do not improve.

By the end of a first interview, communicate reasonable expectations of hopefulness. It can be both comforting and motivating for the offender to know that competent professional help is available. Emphasize again that the first step to resolving a problem is acknowledging the problem. If an offender risks being honest about his behavior, he should know that treatment is available and can be effective.

Additional Interviewing Strategies

In addition to the various approaches previously recommended at different stages of client change and in the interview protocol detailed above, a number of other interview strategies can help evaluators collect important information (Cumming & McGrath, 2005; McGrath, 1990; Miller & Rollnick, 2002). Again, use of these strategies should attempt to balance the dialectic of asking difficult questions for gathering information from the offender and engaging him in a collaborative working relationship.

Do Not Retry the Case

Establish the fact pattern of the case based on the findings of the court or other legal body that determined the individual's guilt. Use that information as the basis for determining the degree to which the individual is openly reporting his offending behavior. It is not the role of a mental health professional, or within his or her expertise, to retry the case. If the offender has issue with a finding of the court, this is something he must take up with the court or his attorney, not the evaluator.

Do Not Tip Your Hand

It is important for the evaluator to convey to the offender that he or she has thoroughly reviewed available background information in the case. This communicates to the offender that you are competent and that his case is important. By being well informed and letting the offender know this, the evaluator decreases the chances that an offender will attempt to distort the facts of the case during the interview. However, do not tip your hand as to all the exact details you know about the case. Some interviewees will attempt to provide only information that they believe the interviewer already knows.

Interview Collaterals Separately

If there are co-defendants in a case, interview them separately. If you are going to interview an offender's family members or significant others, conduct the initial interviews separately. This will put you in a position of being or appearing to be the most knowledgeable person in the system. Just as you should not "tip your hand" with respect to disclosing the content of the documents you have reviewed, you do not need to disclose to the offender everything that collaterals have told you. These circumstances place more pressure on the offender to be honest.

Manage Counter-transference

The behaviors of sex offenders justifiably can elicit strong negative reactions, especially among evaluators who must delve into the details of their offenses.

Nevertheless, evaluators must manage their personal feelings toward the offenders they are interviewing. Gilbar (1998) found that sex offenders were more likely to admit their offenses if they perceived the interviewer's reactions as respectful and nonjudgmental. When one is able to view an offender's behavior from his world view or particular circumstances, it will still not make the behavior right or acceptable, but it may make it more understandable and easier to conduct the evaluation.

Express Empathy

Despite the fact that the offender has harmed others, he has likely suffered a variety of negative consequences as a result of his behavior. He may have lost his job, had to move, had his picture in the paper, received a prison sentence, or been shunned by family and friends. Acknowledging an offender's current difficulties does not mean that one is condoning the offending behavior, but rather that you are viewing him as a person who has made some bad choices and is suffering consequences, as are others, especially the victim. Evaluators who show a genuine understanding of the offender's current circumstances can enhance rapport with him, and this is an important outcome if the offender is to learn from the evaluation process and engage successfully in treatment.

Avoid Arguments

Do not argue with an examinee. Interview questions should push offenders to examine their thinking and behavior, but not in an argumentative manner. When one person argues a position, the natural reaction of the other person is to argue the opposite position. This is generally counterproductive. The more an offender argues in favor of a counterproductive position, the more he will become committed to that position. Client resistance is a signal to respond differently (Miller & Rollnick, 2002). Encourage offenders to present their own arguments for change.

Although the strategies described in this chapter are designed to facilitate open communication with the offender, ultimately, it is the client's choice to cooperate or not. Do not engage in a battle to make him cooperate, as it will likely only invite resistance. Be clear, in a matter of fact manner, your willingness to talk honestly and respectfully with him if wishes. Review with him the potential advantages and disadvantages of his participating in the evaluation.

Ask Open-Ended Questions

Although it is necessary for evaluators to ask some closed questions that require only a "yes" or "no" or other one-word answer, ask mainly open-ended questions. Open-ended questions help draw out and encourage the offender to become more engaged in the interview and disclose more information about his thoughts and behavioral patterns.

Use Behavioral Descriptors

Avoid value laden and imprecise terms, such as "molest" or "rape" when asking the individual about his offending behavior. These terms have different meanings to different people. For example, "sexual assault" in some jurisdictions could mean either forced or cooperative penile-vaginal penetration. An offender who is adamant that he did not "rape" or "sexually assault" the victim may be denying his sexual offense or simply misunderstanding the meaning of the term. Use language that describes behavior in as simple and clear terms as possible. As well, clarify what an examinee means when he uses terms that are ambiguous.

Emphasize What Happened, Not Why It Happened

Although it is important to ultimately understand an offender's motivations, it is generally more important to begin by establishing the facts of the case. Case disposition, treatment planning, and other recommendations are generally based on the facts of what happened, not on issues that one cannot independently substantiate. As the interview progresses, you can ask more questions about how the offender makes meaning about his life and his behavior.

Develop a "Yes Set"

Ask questions or make statements, especially at the beginning of the interview, to which you know the response will be "yes." By getting agreement and cooperation initially, even on small points, the evaluator sets the stage for cooperation later in the interview when more difficult topics are addressed. This strategy is considered the essence of working with resistant clients (Erickson, Rossi, & Rossi, 1976).

Do Not Make Denial Easy

Since the individual has already been convicted of a sexual offense, avoid the mistake of directly asking him whether or not he did so. This would make it too easy for him to simply say "no." Operate with the knowledge that his conviction and guilt already have been established and ask questions that assume these facts. Therefore, ask questions such as "What where you thinking the first time you had sexual

contact with her?" or "What was going on in your life just before you began touching him?" Similarly, avoid questions about other sensitive topics that can easily be answered "no." For example, steer clear of questions that begin with phrases such as "Do you…?" or "Have you ever…?" Instead ask questions that place the burden of denial on the individual, such as "How long have you…?" "How often do you…?" "When did you first…?" Phrasing questions this way assumes that the behavior occurred, increasing the likelihood that offenders will talk about the behavior.

Ignore Untruthful Responses

If you believe an interviewee has lied to you when you have asked a question, simply ignore the answer and move on to another topic. By avoiding an argument, you reduce the chance that the individual will entrench his position. As described in the next section, you can revisit the issue later.

Repeat Questions

Repeating the same question or version of the same question during the interview often results in further disclosures. Return to issues that you believe the individual may have previously answered untruthfully. As well, question offenders about their offending behaviors more than once. If during follow-up questioning his responses are different from his initial ones and appear to be more truthful, accept the new responses in a matter of fact manner. There initially is nothing to be gained by confronting him about the previous lies at this point, if to do so would undermine rapport you may have developed with him.

Accept Some Rationalization and Minimization

Given that one purpose of a clinical evaluation is to understand how the offender thinks, do not challenge his distorted thinking to the degree that it will undermine his trust in you to talk relatively freely. If he feels judged or chastised, he is much more likely to censor his remarks. There will be opportunity to address these issues during the course of subsequent interviews and in treatment.

Use "Successive-Approximation" Strategies

If there is a wide difference between what the offender and official record states occurred, begin interviewing the individual about issues that will be easiest for him to admit. For example, establishing that he was alone with the victim is closer to admitting that he committed an offense than if he denies being alone with her. Questioning can then progress to establish increasing more proximate behaviors associated with the actual offense.

Positively Reinforce Cooperation

Compliment the offender for positive efforts he makes in discussing and understanding his problems. As well, honestly note his personal strengths. Especially with offenders who have developmental disabilities, use some caution in being too reinforcing about their disclosures, least they begin to make up stories about their history to gain more attention.

Test the Limits

Although the emphasis in this chapter is on developing a collaborative working relationship with the offender, by the end of the evaluation, the interviewer should have challenged the offender enough to provoke some emotional responses from him. This is to provide information about how the offender reacts under stress and how he may handle similar situations such as in treatment or correctional supervision.

Treatment Needs

Earlier sections of this chapter focused primarily on the process of conducting evaluations. Here, the content of these evaluations, specifically how to identify treatment needs of individuals, is examined. Treatment needs, also called dynamic risk factors and criminogenic needs, are problems that offenders have that are closely linked to sexual offending. They are the focus of treatment interventions designed to reduce an individual's risk to reoffend (Andrews & Bonta, 2010; Hanson et al., 2009).

Several approaches to assessing treatment needs exist. They include psychometric self-report frameworks (Allan, Grace, Rutherford, & Hudson, 2007; Beech, 1998; Beech, Fisher, & Thornton, 2003) as well as clinician-administered protocols, such as the Sexual Violent Risk: Sexual Offender version (SVR:SO; Olver, Wong, Nicholaichuk, & Gordon, 2007), Stable 2007 and Acute 2007 (Hanson, Harris, Scott, & Helmus, 2007), and Structured Risk Assessment (SRA; Thornton, 2002). The need areas identified in these assessment approaches overlap considerably and are generally consistent with dynamic risk factors identified in a series of meta-analyses of the sex offender recidivism research (Hanson & Bussière, 1998; Hanson & Morton-Bourgon, 2004, 2005; Mann, Hanson, & Thornton, 2010).

In this chapter, another need instrument, the Sex Offender Treatment Intervention and Progress Scale (SOTIPS; McGrath, Cumming, & Lasher, 2012; McGrath, Lasher, &

Table 2 Sex Offender Treatment Intervention and Progress Scale (SOTIPS; McGrath, Cumming & Lasher, 2012) Items

Sexuality and risk responsibility	Self-management
1. Sexual offense responsibility	11. Emotion management
2. Sexual behavior	12. Problem solving
3. Sexual attitudes	13. Impulsivity
4. Sexual interests	Social stability and supports
5. Risk management criminality	14. Employment
6. Criminal attitudes	15. Residence
7. Criminal Behavior	16. Social influences
Treatment and supervision cooperation	
8. Stage of change	
9. Treatment cooperation	
10. Supervision cooperation	

Cumming, 2011, 2012), is used as a framework for identifying and organizing an individual's treatment needs. The SOTIPS is a provider-administered risk measure composed of 16 dynamic risk factors. It is designed for use with a static risk measure such as the Static-99R (Helmus, Thornton, Hanson, & Babchishin, 2011) or VASOR-2 (McGrath, Hoke, & Lasher, 2012).

Each SOTIPS risk factor is detailed in a manual (McGrath, Cumming & Lasher, 2012) and scored using a 6-month recency time frame on a 4-point scale ranging from *minimal to no need for improvement* to *very considerable need for improvement*. Scores are recorded on a scoresheet and summed to yield a total score. Clients are scored at intake and thereafter every 6 months. Item scores are intended to reflect an individual's relative treatment and supervision need on each factor. The total score is intended to provide an estimation of an individual's overall level of need for treatment and supervision. Recent research indicates that it can be scored reliably and predicts sexual reoffending with moderate accuracy (McGrath et al., 2011, 2012; McGrath, Lasher & Cumming, 2012). Combined SOTIPS and Static-99R scores, as well as combined SOTIPS and VASOR-2 scores, have predicted sexual recidivism more accurately than either measure alone when these instruments had similar predictive power. Offender treatment progress, as reflected by reductions in SOTIPS scores, is associated with reductions in sexual recidivism rates (McGrath et al., 2011, 2012, McGrath, Lasher & Cumming, 2012).

The 16 risk factors, shown in Table 2, can be grouped into the following five clusters for collecting information about and reporting on the number and severity of an individual's treatment needs.

Sexuality and Risk Responsibility

Considerable consensus now exists that one of the two broad risk factors consistently associated with sexual reoffending is sexual deviancy. Sexual deviancy is marked by deviant sexual interests, attitudes, and behaviors (Hanson & Morton-Bourgon, 2005; Mann et al., 2010). Deviant sexual interests are those involving children or coercive activities. Offenders who have these interests often evidence offense-supportive attitudes and engage in behaviors that reinforce these interests and attitudes, such as using offense-related pornography and engaging in offense-related masturbation. Because each of these SOTIPS risk factor need areas—sexual interests, attitudes, and behaviors—are linked to sexual reoffending, each is a critical area for evaluation.

A related SOTIPS item concerns sexual offense responsibility. If an individual takes personal responsibility for his sexual offending behavior, as opposed to saying that he is not responsible for committing a sexual offense, it is arguably easier to assess offense-related sexual interests, attitudes, and behaviors. Consequently, acceptance of responsibility is a precondition for admission into many sex offender treatment programs (McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2010). Evaluators must recognize, however, that in recent meta-analyses offense denial and minimization have not predicted sexual recidivism (Hanson & Morton-Bourgon, 2005; Mann et al., 2010). These findings, though, are not without challengers (Lund, 2000). Denial indeed may be a risk predictor for certain types of sex offenders such as incest offenders (Nunes et al., 2007) and some high risk sex offenders (Langton et al., 2008), but more research is clearly needed in this area.

Criminal Attitudes and Behavior

The other broad factor that has been consistently associated with sexual reoffending is having an antisocial orientation (Hanson & Morton-Bourgon, 2005; Mann et al., 2010). Such an orientation is often marked by behavioral problems that manifest themselves in an unstable lifestyle and a variety of self-regulation problems; these are described in following sections. In terms of attitudes supporting crime, these include willingness to justify breaking societal norms and hurting others. Individuals who have both marked deviant sexual interests and an antisocial orientation are at particularly increased risk for sexual reoffending.

Treatment and Supervision Compliance

One item each on the SOTIPS assesses the individual's cooperation with treatment and supervision. A third item in this section is used to identify a client's stage of change, a topic that has been previously covered in more detail.

Self-Management

Sex offenders who manage their emotions effectively and employ solution-focused coping and problem solving skills are less likely to sexually reoffend than those who do not

(Mann et al., 2010; McGrath et al., 2011). Also, those who act with deliberation, thoughtfulness, and planning, as opposed to those who act impulsively, are typically at lower risk to sexually reoffend. Hence, these all are important areas in which an individual's treatment needs should be evaluated.

Social Stability and Supports

Lifestyle instability, marked by problems associated with employment and housing, is clearly associated with increased risk for general criminal recidivism (Andrews & Bonta, 2010). Problems in this area indicate difficulties in general life functioning and have been linked to future sexual offending as well (Mann et al., 2010; McGrath et al., 2011). A related factor that has long been known to predict general criminal behavior and also predicts sexual offending is having an antisocial peer group (Andrews & Bonta, 2010; Hanson & Morton-Bourgon, 2005). Consequently, assessing and encouraging contacts with prosocial family and friends is important.

SOTIPS or other dynamic risk measure results can be shared with offenders to educate them about their dynamic risk factors. This can begin to help the individual map out the goals they can address to reduce their risk of reoffending. The more an individual is able to clearly identify strengths and deficits, the more likely they will be able to target them successfully. To this end, some of our current research with the SOTIPS involves having clients score themselves during treatment sessions and discuss openly how they view their progress in treatment and current needs. As well, involving other group members in this process, especially offenders who live together on dedicated treatment units, has provided useful input and motivational feedback.

Disposition Planning

After conducting the evaluation, the evaluator should have collected and synthesized enough information about the offender to answer the referral questions. Referral questions related to amenability to treatment, sentencing, and treatment progress and completion are reviewed here.

Amenability to Treatment

The courts, correctional agencies, and social service organizations frequently mandate sex offenders under their care to enroll and successfully complete specialized sex offender treatment. Decisions about whether an offender is considered amenable to such treatment typically hinge on three factors. First, the offender must have the ability to engage in the treatment process. If responsivity issues, such as major mental illness or active substance abuse, will prevent the individual from engaging in sex offender-specific treatment, then a first order of treatment intervention should be addressing these issues.

Second, the individual must be willing to enter and participate in treatment. Motivation to enter treatment may be based on a genuine interest in living an offense-free life or a more self-serving interest in having fewer life restrictions, such as getting an early release from prison or community supervision. Whatever the motivation, a reasonable treatment expectation is that the offender must be willing to learn and practice new ways of thinking and behaving that will lead him away from offending. Obtaining written informed consent from the offender about what is expected in treatment is one indication of the individual's intentions as well as being good clinical practice.

The third factor concerns the individual's level of offense admission and responsibility. The Association for the Treatment for Sexual Abusers (2005) advises that, "Clients who completely deny their offenses should not be represented as having successfully completed a sexual abuser treatment program" (p. 20). As has been reviewed previously, the relationship between offense denial and sexual recidivism is complex. Regardless, admitting one's offense behavior certainly makes it easier to examine and modify the factors associated with offending and is a precondition for admission into many sex offender programs. For the evaluator, knowing the admission criteria of the programs to which the offender may be referred is critical for assessing an individual's amenability to local treatment, especially with respect to denial.

Sentencing

When the referral question concerns sentencing decisions, the evaluator should be familiar with what typical sentencing goals judges balance: punishment, deterrence, rehabilitation, and community safety (Cumming & McGrath, 2005). Sentencing recommendations concerning how an offender should be "punished" or made an example of for its "deterrence" effect on others are generally not considered within the purview of mental health professionals (Melton, Petrila, Poythress, & Slobogin, 2007). Evaluators in sex offender cases however often can provide useful information to the court for the purposes of achieving the sentence goals of "rehabilitation" and "community safety." Answers to five critical questions can assist decision makers in crafting sentences to enhance community safety (McGrath, 1992). These are:

1. What is the *probability* of a reoffense?
2. What degree of *harm* would most likely result from a reoffense?
3. What are the *conditions* under which a reoffense would be most likely to occur?

4. Who would be the likely *victims* of a reoffense?
5. *When* would a reoffense be most likely to occur?

Procedures to help evaluators answer these questions are contained in this and other chapters of this volume and elsewhere (McGrath, 1992). How decision makers use the answers to these questions to determine, for community safety reasons, whether to sentence an offender to prison or other secure setting, or what release conditions are appropriate if an offender is placed in the community, vary greatly among jurisdictions and even within jurisdictions over time. What is important however is for the evaluator to provide the referral source with useful information to answer these questions.

From a community safety perspective, offenders most appropriate for community placement are those who score in the low to moderate range on empirically established measures of reoffense risk, have not been convicted of sexual offenses in the past, express a willingness to participate in treatment and modify their behavior, have not failed in prior sex offender treatment, do not have substance abuse or mental health problems that would prevent engagement in treatment, have led a generally prosocial lifestyle, did not use excessive force or violence in the crime, and do not have an established long-term engrained pattern of sexual abusing (Cumming & McGrath, 2005; McGrath, 1991).

Offenders for whom community placement may be contraindicated are those who are considered high risk to reoffend, unwilling to participate in recommended treatment, unable or unwilling to follow conditions of supervision, have committed offenses using weapons or excessive force, and evidence a particularly predatory pattern of offending (Cumming & McGrath, 2005; McGrath, 1991).

Treatment Progress and Completion

Some of the most difficult disposition recommendations involve determining whether an individual has made enough treatment progress to move to a lower level of supervision (e.g., from prison to a community setting) or has "successfully" completed sex offender treatment. Criteria for how these determinations are made vary among jurisdictions, treatment settings, and evaluators, and the offender's individual characteristics and circumstances are critical variables as well. For example, the requirements for successful treatment completion for a first-time statutory rapist referred to a 12-week psychoeducation program will be much less rigorous than for a multi-convicted rapist who has been civilly committed to a sexually violent predator treatment program. Nevertheless, several general criteria are applicable in most situations in which treatment progress or successful treatment completion is the referral question.

A sex offender who is judged to have successfully completed treatment should have meaningfully participated in treatment that is designed to reduce his risk to sexually reoffend. The treatment program or provider should have been approved by the authority responsibility for supervising the offender, which is typically a court, department of corrections, probation or parole authority, or state human service organization. The offender should have substantially accepted responsibility for committing the sexual offenses for which he has been convicted such that he has been able to demonstrate an understanding of the thoughts, attitudes, emotions, behaviors, and sexual arousal that were linked to his sexual offending. The offender should be able to identify when these risk factors are present in his life and has shown a willingness to work diligently on addressing these treatment needs.

The last and arguably most important criterion for successful treatment completion concerns the maintenance of change. The individual should have demonstrated enough sustained change in the thoughts, attitudes, emotions, behaviors, and sexual arousal linked to his sexual offending for the evaluator to conclude that he has reduced his risk to sexually reoffend and has reached maximum benefit from the program. Maximum benefit means that more treatment is unlikely to substantially further reduce the individual's risk to reoffend. Of course, a sex offender may meet all these criteria, but the reduction in risk is not great enough to warrant a reduction in supervision level (e.g., release from civil confinement, release from prison, reduction in community supervision level).

Evaluators can assess treatment progress and completion criteria in a variety of ways. Through interview, an evaluator can assess an individual's knowledge of personal risk factors, adequacy of life management plan, and self-reported use of intervention strategies. Appropriate offender responses to inquiries about these issues are necessary but not sufficient evidence of treatment benefit. Evaluators must also use other sources of information.

Increasing evidence exists that offender scores on treatment progress measures are associated with reductions in reoffending rates (e.g., Hanson et al., 2007; McGrath et al., 2011, 2012, McGrath, Lasher & Cumming, 2012; Olver et al., 2007) and provide a method for assessing treatment gain. To score these progress measures, evaluators should obtain collateral information from those who know how the offender has been functioning. Depending on the setting in which the offender is supervised, collateral informants include facility security staff, treatment staff, and probation and parole officers. Correctional and treatment records can also be helpful. Absence of disciplinary reports in residential settings and violations of release conditions in community settings also provide indications of appropriate behavior management. Most sex offender programs in the United States require clients under their care to undergo periodic polygraph exams to verify that they are successfully managing risk factors (McGrath et al., 2010) and evaluators should

consider this information as well. For programs that use the penile plethysmograph, evaluators should consider the offender's sexual arousal profile (McGrath et al., 2010). Taken together, all of these sources of information should provide a comprehensive picture of the individual's progress in treatment.

Conclusions

Evaluators are in a unique position to effect positive change in offenders' lives and provide decision-makers information that will enhance community safety. The relationship an evaluator develops with an offender during the evaluation process often influences the individual's decisions to take responsibility for his offenses and to engage in treatment. Evaluators are also in a position to begin to educate offenders about issues that they can start to address that will reduce their risk to reoffend. Evaluators who approach the interviewing process in a direct, firm, fair, and respectful manner are typically most successful in obtaining useful information and helping offenders to lead offense free lives.

Structured Psychological Assessment in Evaluations of Sexual Offenders: Nature and Applications

Harry M. Hoberman and Robert G. Riedel

Introduction

Structured psychological assessment should be an essential component of any evaluation of a sexual offender that has significant implications for the individual or the community. *Structured Psychological Assessment* should be understood as a deliberate, ordered means of collecting and organizing both subject self-report and professional ratings that allows a comparison of a particular individual to standards (e.g., diagnostic criteria) and/or normative group data. *SPA* is a critical component to any formal psychological evaluation in that it is an informed, intentional process that involves the collection and integration of information from multiple methods or sources (e.g., life history, collateral data, and clinical observations) specific to the goals of a particular evaluation of an individual. SPA could be viewed as an example of evidence-based assessment (e.g., Hunsley & Mash, 2007) that emphasizes the use of research and theory to inform the selection of assessment targets and methods as well as the process of evaluations. As in other areas of forensic and clinical evaluation, specific components or elements of psychological assessments—particularly, psychological testing and structured clinical ratings and interviews—should constitute a *central* component of any significant comprehensive evaluation of a sexual offender. Typical or conventional assessments based predominantly on either unstructured self-report of suspected or identified sexual offenders and/or unstructured clinical judgments by evaluators are inadequate at providing meaningful information about offenders and are lacking reliability, validity, and predictive accuracy.

Evaluations of sexual offenders may be requested by an offender (or his/her attorney) or mandated by a judicial entity or a treatment program. *Structured Psychological Assessment (SPA)* will almost always be valuable in clarifying the nature and degree of psychosocial and psychiatric issues related to evaluating sexual offenders and in providing the bases of decision-making by others. Such assessments can include understanding the nature and options of an individual voluntarily seeking sexual offender treatment, opinions regarding treatment amenability (in general or for a particular sexual offender treatment program), pre- or post-sentencing evaluations for sexual offenders already involved in the criminal justice system (including the presence of mitigating or aggravating factors or qualification as patterned or repeat offender), determination as a so-called sexually violent predator, potential aspects of the outcome evaluation of participation in a treatment program, appropriateness for release from incarceration or parole/probation status, and/or qualification for a less restrictive status under civil commitment. As a standardized, typically norm-referenced (nomothetic) approach to collecting and organizing self-report and/or professional ratings, *SPA* is critical for both forensic and clinical evaluations of persons suspected of, or convicted of, committing a sexual offense and their dispositions. SPA possesses particularly unique and significant value in any assessment of such offenders. Following the principles of evidence-based assessment, evaluation methods should be standardized, utilize normative data, and possess appropriate levels of reliability and validity; this is the essence of SPA.

The purpose of this chapter is to characterize the nature and role of *SPA* measures in both clinical and forensic evaluations of sexual offenders; to identify the multidimensional personality tests, structured rating scales, and structured diagnostic interviews available to be utilized in such evaluations; and finally to provide a discussion of the particular application of such measures in providing information relevant to

various issues of significance in the appraisal of sexual offenders. Such an approach regards "assessment" as an information-collection and decision-making process in which the evaluator formulates conclusions and opinions by iteratively considering and integrating various sources of information obtained via optimal, available structured means.

Historically, some elements of formal psychological assessments have been common in many evaluations and related dispositions for sexual offenders [e.g., Psychosexual or Sexual Deviance Evaluations, Pre-Trial Evaluations, Pre-Sentence Investigations (PSI), etc.]. Such psychological assessment components of sexual offender evaluations have typically been utilized both to gauge the relative honesty of the offender's presentation and to provide measures of relevant psychosocial characteristics of an offender that could be compared to one or more normative groups. *SPA* has also played an essential role in risk assessment and management by providing a basis for hypotheses and potential explanations in understanding the nature of particular sexual offenders for assistance in case formulation. Summarizing more specifically, Lanyon (2001) suggested that psychological assessment of sexual offenders could be useful relative to several areas of concern. First, impression management: to what degree is the individual engaging in "self-serving misrepresentation" at the time of the evaluation? Second, deviant sexual interests: to what degree has the person been characterized by the range of deviant sexual ideation (including fantasies), motivational urges, and/or behaviors? Third, general psychological or psychiatric characteristics: what types of personality traits and/or symptoms of various mental health conditions are present? Fourth, treatment amenability: in what ways and to what degree does the individual appear to be amenable to available treatments? Fifth, risk assessment: what type and degree of dangerousness does the individual pose to the community and what aspects of the individual contribute to his risk?

As the field of both clinical and forensic sexual offender evaluation has broadened over the past 20 years, the relative value of *SPA* has actually increased as the issues in the field of sexual offending have become both psychologically and legally more complex and sophisticated. Psychologically, an expanded body of research has identified a subset of static and potentially more mutable (e.g., dynamic) risk factors for sexual offense recidivism. Beyond their role in providing estimates of sexual offense recidivism, such risk factors include characteristics of individuals that have been identified as or inferred to be causally related to an increased propensity for sexual offending. Consequently, such factors can be understood as providing a significant perspective in developing an explanation about why a given person has or may commit sexual offenses as well as serving as elements of a risk assessment. Prominent among these domains of risk factors are particular dimensions of personality, sexual ideation and behaviors, social functioning, psychosexual attitudes, dimensions of self-regulation, and specific psychiatric diagnoses. From a legal or forensic perspective, statutory language regarding patterned or "predatory" sexual offenders and "sexually violent predators" (e.g., mental abnormality, serious difficulty in control, emotional and volitional impairment, etc.) can also be informed by the methods and information provided by SPA. In particular, psychological tests and their interpretations can provide particularly useful measures of an individual's self-report that can speak quite directly and objectively to those issues.

From the perspective of meta-analyses and other multivariate studies, the primary identified risk factor pathways to sexual offending are a deviant sexual interest/preoccupation and a set of "antisocial" and other personality-related characteristics. Further, the most recent development in the past 10 years of sexual offender research can be seen as the research into what has been known as "dynamic" risk factors (e.g., Allan, Grace, Rutherford, & Hudson, 2007; Hanson & Harris, 2001; Hanson, Harris, Scott, & Helmus, 2007; Knight & Thornton, 2007) or "psychologically meaningful risk factors" (PMRF; e.g., Mann, Hanson, & Thornton, 2010). Thus, the Sex Offender Treatment Evaluation Project (STEP) test battery (Beech, Fisher, & Beckett, 1999), the Initial Deviance Assessment (IDA) [related to Thornton's Structured Risk Assessment (SRA) model (Thornton, 2002)], and the Structured Risk Assessment-Forensic Version (Knight & Thornton, 2007) were developed as means of advancing case formulation, treatment planning, and risk assessment. Conceptualized around psychologically meaningful behavioral dimensions, these procedures and models involve the measurement of psychological and social factors that are presumed to predispose individuals toward sexual offending. In addition, Hoberman (2015) has indicated a set of nonsexual predisposing psychological/psychiatric conditions [categorized as motivators and dimensions of disinhibition (broadly, deficits in executive functioning, self-regulation, and/or self-control)] that appear to act either individually, cumulatively, or interactively to increase the likelihood of sexual offending particularly given permissive contexts or situations. More generally, there is increasing evidence that the conditions of most interest and significance regarding psychological and psychiatric characteristics are dimensional in nature (e.g., presenting across a continuum of polarity and/or severity) and may be best captured by dimensional measurement tools. Most of the identified risk factors (including deviant sexual interests/preoccupation and nonsexual predisposing conditions) can be measured and informed by one or more measures of *SPA*. Thus, these models and procedures for the identification and measurement of so-called psychologically meaningful risk factors for sexual offense recidivism invite—if not demand—the application of *SPA* to identify and quantify the presence and degree of many psychological and social factors predisposing individuals toward sexual offending.

Both clinical and forensic questions regarding the nature and disposition of sexual offenders have increasingly been

discovered to be complex as more research accumulates regarding sexual offenders. Given the largely adversarial context of sexual offender evaluations, the importance of multiple sources of information, quantified and norm referenced, and informed by gauges of impression management expands the scope of the information collected and interpreted about a particular person. Further, the implications for the individual (e.g., extended detention and registration) and for costs to society (e.g., potentially preventable recidivism and its multiple ramifications, the high costs of possibly ineffective psychosocial treatment) dictate that *SPA* occupies an increasingly important and central role in the evaluation of sexual offenders. In fact, we would argue that the scientific study of sexual offenders has, in effect, swung full circle from an early emphasis on psychological characteristics of such individuals, then away from the presumed centrality of such dimensions, and now is characterized by a return to a renewed interest and significance of the measurement of such characteristics (albeit now under a different rubric such as criminogenic or dynamic "needs" or psychologically meaningful factors). Consequently, *SPA*, as the preferred means of obtaining standardized information regarding such needs/conditions, seems increasingly important as a central component of any multifaceted approach to the evaluation of sexual offenders.

Evaluations of Sexual Offenders: Almost All Evaluations Are Effectively Forensic Evaluations

As Hoberman and Jackson (2015) have suggested, forensic evaluations of sexual offenders have generally been viewed as ones that speak to their consideration by and mandate by the criminal justice legal system (e.g., pre-plea evaluations and presentencing evaluations, determinations of enhanced sentencing), treatment amenability, release from detention, and, in certain jurisdictions, identification as a so-called sexually violent predator (SVP) or some similar designation. While historically, some or many of such evaluations have been viewed as "clinical" evaluations, as Hoberman and Jackson emphasize the *reality* is that many or most assessments of sexual offenders are either directly or indirectly of a forensic nature. "Forensic" is generally defined or conceptualized as the application of scientific, technical, or professional information or procedure for the courts, legal system, and/or for the purpose of community protection. Consequently, any evaluation that occurs as a result of or in anticipation of a judicial process or within a "judicial context," such as court-mandated sexual offender treatment or conditional release recommendations, is by definition a forensic evaluation. Per this view, any evaluation of a potential sexual offender that occurs for considerations of public safety and/or as a result of a judicial, law enforcement, or child protective services process is necessarily of a *forensic* nature. As a result, almost all evaluations regarding "sexual deviance" or "psychosexual" issues, treatment amenability, risk assessments, initial treatment assessments, treatment progress reports, and treatment summaries, where that treatment results from a sentencing condition or other judicial disposition, are inherently "for the court." In fact, perhaps the only type of evaluation of a sexual offender not to be considered as forensic relates to those relatively uncommon assessments of sexual offenders who voluntarily seek treatment relative to a self-defined problem (e.g., distress with paraphilic experiences) and prior to actual or anticipated legal involvement. If the only "duty" is to a particular client, such an evaluation can be considered as a "pure" clinical evaluation rather than a forensic one. However, since almost all other evaluations of sexual offenders take place either as a result of or in anticipation of a legal context, various "duties" and obligations exist, as Monahan (1981) noted that the evaluator serves not just the individual but, in all likelihood, many others as well (e.g., the court, the community, and the attorneys involved).

Thus, as Hoberman and Jackson emphasize, following Greenberg and Shuman (1997), Heilbrun (2001, 2003), and other similar writers, virtually all evaluations of sexual offenders should be guided by "forensically informed" practices: a goal of providing assistance primarily to the identified decision-maker; an objective or quasi-objective perspective regarding the individual or examinee; an assumption of possible unreliability of response style and a skeptical view of information provided by the evaluation subject; and a comprehensive assessment process and product, with detailed findings, reasoning, and conclusions to be viewed by others. A primary issue in most evaluations of sexual offenders is that significant motivation may exist for the person being evaluated to consciously present a distorted self-presentation for an "obvious, identifiable, secondary gain" (Goldstein, 2003, p. 8), commonly called a "fake-good" response set. Consequently, most types of evaluations of sexual offenders performed by mental health professionals (MHPs), traditionally considered of a more purely "clinical" nature, should truly be informed and even governed by forensic principles: objectivity with regard to outcome; skepticism relative to the self-report of a subject and concern for potential impression management; and a comprehensive, standardized, and norm-referenced approach to collecting and organizing information.

The Limitations of Unstructured Self-Report Among Sexual Offenders and Unstructured Judgment by Mental Health Professionals

For the purposes of evaluations, significant issues exist in relying on unstructured self-report of alleged or suspected sexual offenders as well as the unstructured "clinical" judgment of

evaluators. One potential source of information when evaluating sexual offenders is their own self-report regarding themselves and their potential risk factors for reoffending, what might be referred to as "unstructured self-report" (USR). In general, but even more specifically in forensic evaluations, there may be obvious contextual motivations for persons to present themselves with one or more particular ends in mind. Generally, persons who have committed criminal behavior have been shown to recognize socially acceptable responses and are likely to respond to assessments in ways that are self-advantageous and that minimize their involvement in criminal behavior (e.g., Rogers, 2003; Rogers & Dickey, 1991); such responding is often accentuated in sexual offenders (who are being asked not just about illegal behavior per se but sexually atypical or "deviant" behavior and typically in an adversarial context with important negative consequences for themselves). In addition, dispositional factors common to persons who commit antisocial and/or violent offense also affect the veracity of their self-report. As Logan (2009) noted both insight and honesty are likely to be questionable in the assessment of egocentric or narcissistic individuals and thus are likely to be more meaningfully assessed via record review or other collateral sources.

The extant scientific literature, in general, indicates that dissimulation, particularly lying and defensiveness, is a highly common, if not, endemic characteristic of both alleged and convicted sexual offenders. Sewell and Salekin (1997) provided a summary of understanding and detecting dissimulation among sexual offenders. Numerous writers have commented on the tendency of sexual offenders to dissimulate, particularly when queried about their sexual offense history (e.g., Beckett, 1994). Marshall and Barbaree (1989) noted that general reliance on the self-report of sexual offenders regarding their offenses is "unwise" because such reports are so unreliable. Similarly, as another writer stated, "… sexual aggressors have a marked propensity to lie about, deny, and minimize information concerning their deviant sexual behavior" (McGrath, 1990, p. 507). Earls (1992) noted: "The reticence on the part of the offender is different from most clinical situations … it also poses difficulties when attempting to determine the nature and magnitude of the problem" (p. 233). Per Vitacco and Rogers (2009): "sexual offenders often engage in gross misrepresentations of their offending behavior," (p. 137) including denial and minimization. Similarly, Clipson (2003) wrote:

> The evaluation of sexual offenders offers a challenge unlike that found in either a general clinical practice or even in a forensic setting. All forensic assessments must address the possibility that the person being interviewed may minimize, deny, exaggerate, or feign a psychiatric disorder to obtain a desire outcome. The sexual offender in particular is prone to be dishonest about his behavior for several reasons. (p. 128)

Gudjonsson (1990) showed that "other deception," or impression management, was particularly characteristic of violent and sexual offenders in a forensic evaluation, indicating that they underreported undesirable personality characteristics and psychopathology. He speculated that such persons attempted to give the impression that they were basically considerate people in contrast to or irrespective of what their alleged offenses suggested.

A related notion concerns the degree to which personality traits and psychosexual characteristics are experienced as ego-syntonic or ego-dystonic by the offender. The latter, for example, refers to an individual's experience of a personality characteristic and/or sexual preference as in conflict with that person's self-image or desire (e.g., experiencing distress about their recurrent anger or sexual interest in children). In contrast, the former, for example, refers to an individual's experience of a personality characteristic and/or sexual preference as consistent with that person's self-image or desire or acceptable to their goals or desires. It appears that a significant portion of sexual offenders evidence little or no distress about their own experience of maladaptive personality characteristics or deviant sexual behaviors nor are they conscious of or concerned by social disapproval or judgment of those aspects of themselves (e.g., Vitacco & Rogers, 2009).

In addition, contextual aspects (e.g., setting, nature of interviewer) of the evaluation of a sexual offender can greatly influence the information obtained. Kaplan, Abel, Rathner, and Mittleman (1990) compared reports of sexual offenders on parole in two different settings. In a criminal justice setting, offenders disclosed only 5 % of the sexual offenses that they later admitted to in a mental health setting (where confidentiality was provided); that is, under conditions of confidentiality, sexual offenders disclosed a much higher frequency of perpetrated sexual offenses. Abel, Becker, and Skinner (1983) reported that offenders revealed approximately 20 % more types of sexual deviancy when reinterviewed by an experienced relative to inexperienced interviewers. Consequently, as Earls noted: "… there is surprisingly little empirical research concerning the reliability and validity of the information obtained in a clinical interview…we can expect the validity of data obtained in the initial interview is fairly low" (p. 234). Unstructured interviews by relatively inexperienced evaluators appear to have little reliability and little construct and predictive validity.

Just as the self-report(s) of sexual offenders has profound limitations as valid sources of information so do the "typical" assessment methods and decision-making of MHP across varied settings. Historically, "clinical" judgment has taken the form of a MHP reviewing information regarding a sexual offender and then applying their own "experience" in making findings, assessments, predictions, and recommendations. However, unstructured "clinical" approaches used in either clinical or forensic settings have been repeatedly demonstrated to be unreliable and inaccurate, with high rates of error even among more "experienced evaluators" (e.g., Garb, 1998). This has clearly been demonstrated in the clinical

research purposes (Feighner et al., 1972; Spitzer & Endicott, 1978). For both forensic and clinical evaluations, the increasing importance of differential diagnosis (given overlapping symptoms among presumptively different disorders) has placed a greater emphasis on accurate and normative data-based assessment utilizing structured assessment methods. In an early study of the nature of disagreement among clinicians, Ward, Beck, Mendelson, Mock, and Erbaugh (1962) found that information variance (differences among clinicians in the scope and type of questions asked and observations made) accounted for 33 % of the differences, while criterion variance (differences among clinicians in applying uniform standards of the nature and degree of symptoms/problems present) accounted for 63 % of those differences. Variability in the client's "presentation" accounted for only 5 % of the differences in clinician disagreement. Further, Blashfield (1992) also showed that clinicians' utilizing unstructured methods often did not systematically apply available diagnostic standards; such an example of criterion variance resulted in misdiagnosis in over 50 % of the instances studied. Rogers (2003) concluded that the failure to use structured interviews leads to MHPs missing a significant proportion of both Axis II and Axis I diagnoses present for an individual. More generally, even in attempts to formalize practice, many or most practitioners base their practices on an "intuitive" sense of what was appropriate (e.g., Garland, Kruse, & Aarons, 2003) and ignored the results of formal assessment procedures. Thus, the structure (e.g., number, scope, and degree of questioning) and process of an interview experience and the scrutiny and analysis of information collected produced enormous differences in the findings of evaluators. As a consequence of such practices, traditional unstructured clinical interviewing has long been recognized as lacking in both test–retest and inter-rater reliability and, as a result, in validity. In general, then, in "traditional clinical evaluations," evaluators are likely to miss or underdiagnose a significant percentage of present problematic psychological or psychiatric conditions; more specifically, in forensic settings (with a contextually distorted self-report by the subject of an assessment), the likelihood of underdiagnosis would likely be substantially greater.

Similarly, for various forensic purposes [e.g., questionable allegations of child sexual abuse (Kuehnle, 1996, 2003) and the risk assessment of sexual offender (Hanson & Morton-Bourgon, 2004)], unstructured clinical or professional judgment has been demonstrated to be no better or even worse than "chance." Historically, "intuitive" clinical judgment dominated assessment processes. Such intuitive judgment typically involved a qualitative approach in which beliefs of experienced clinicians provided the sole basis for evaluation conclusions. However, such inferences typically lacked a scientific or empirical basis and/or were developed in an unstructured, asystematic manner. Studies have indicated that clinicians (clinical judges) were often uncertain or disagreed on relevant variables to be considered, the relative importance of variables and/or how to combine such factors (Garb, 2005). In an earlier review of research, Garb (1998) pointed out that clinicians are often uncertain of the variables on which a judgment should be based (or at least the relative importance of relevant factors related to a judgment) and more commonly rely on factors with little demonstrated relationship to the decision at hand. An extensive body of research has accumulated that clearly suggests that *unstructured* clinical assessment and judgments are problematic, particularly in comparison with more structured methods of assessment and decision-making. Meehl and Grove (1996) conducted a meta-analysis of clinical judgment and originally found that "mechanistic" or actuarial methods significantly outperformed clinical decision-making. However, more recently, Grove, Zald, Lebow, Snitz, and Nelson (2000) conducted a similar set of analyses with rather different results: "On average, mechanical-prediction [e.g., actuarial] techniques were about 10 % more accurate than clinical predictions. Depending on the specific analysis, mechanical prediction substantially outperformed clinical prediction in 33–47 % of studies examined…in only a few studies (6–16 %) were [clinical predictions] substantially more accurate…Clinical prediction performed relatively less well when predictors included clinical interview data" (p. 19). Grove et al. elaborated that general interview data (likely of an unstructured nature) tended to *degrade* the accuracy of the evaluator's judgment, perhaps by providing excessive, unnecessary information and by cuing various common errors in human judgment. To their credit, Grove et al. significantly modified earlier claims regarding the relative advantage of mechanistic methods: "…our results qualify overbroad statements in the literature opining that such superiority [for mechanical prediction] is completely uniform; it is not. In half of the studies, we analyze the clinical method is approximately as good as mechanical prediction and in a few scattered instances, the clinical method was notably more accurate" (p. 25). A similar set of findings was reported by Ægisdóttir et al. (2006). However, Weiner (2012) summarized the results by noting that the increase in accuracy of statistical over clinical judgments was modest, with statistical judgments being 13 % more accurate on average than clinical judgments in the Ægisdóttir et al. (2006) study and 10 % more accurate in the Grove et al. (2000) study. Garb (2005) reviewed studies that demonstrated that clinicians are no better than laypersons in making judgments regarding personality and based simply on face-to-face interactions. Widiger (2002), in a review of 35 studies, found that convergent validity improved as the degree of structure in assessment methods increased. Further, Garb (2005) identified that specialized training, not experience, is critical to increased reliability and validity, particularly for specific professional tasks. Overall, then, in certain circumstances, certain clinical approaches to assessment may be acceptable for particular

types of tasks (and less acceptable to the degree that they rely on unstructured interview data with a subject); however, structured, mechanical, and/or actuarial approaches will generally be more accurate. Given their relative rigorousness, structured, norm-referenced psychological tests, which are rooted in actuarial findings, are preferred for most forensic and/or "high-stakes" evaluations.

The utilization of formal structured psychological and psychodiagnostic methodology has come to be the sine qua non of scientific research into the nature of and treatment of mental conditions generally. Empirical research lacking such elements is neither funded nor published. Consequently, evidence-based evaluation procedures such as psychological assessment methods should be the practice or aspiration of all clinical and forensic evaluators in all cases. Consequently, for some period of time, there has been an increased emphasis for MHP in both clinical and forensic settings to utilize available and scientifically validated structured psychological assessments. Certainly, SPA now occupies a central role in almost all types of forensic evaluations, including those in the criminal area [competency to stand trial (e.g., Goldstein, Morse, & Shapiro, 2003) and mental status at the time of a crime (e.g., Stafford, 2003), parenting and child custody matters (e.g., Otto, Buffington-Vollum, & Edens, 2003), and personal injury cases (e.g., Greenberg, 2003)]. As each of those authorities indicates, psychological testing involving multiscale or multidimensional inventories and/or professional ratings are useful if not essential, even if they do not always provide a definitive answer to the specific forensic questions. Such instruments provide critical perspectives on a litigant's self-report (ones interpreted relative to standardized norms or structured professional ratings) for the range of issues that must typically be addressed to provide useful information for court-related matters. Relative to sexual offenders, in the UK, standardized batteries of assessment methods have been and continue to be utilized routinely both in the community and institutional forensic evaluation of sexual offenders (Quackenbush, 2003). In addition, most Sex Offender Management Boards and the Association for the Treatment of Sexual Abusers (ATSA) Practice Standards endorse or mandate the use of various structured psychological assessment measures.

Heterogeneity of Sexual Offenders

The purpose of both clinical and forensic evaluations of specific sexual offenders is to identify both the common and unique characteristics of those offenders as they relate to the assessment goals. The three central meta-analyses of risk factors associated with sexual offense recidivism (e.g., Hanson & Bussière, 1996, 1998; Hanson & Morton-Bourgon, 2004, 2005; Mann et al., 2010) have consistently identified common psychosocial characteristics associated with repeat sexual offending (to be distinguished from those characteristics which might be associated with initial or onset of sexual offending). Several things are important to consider relative to these research findings. First, they identify a set of variables which show significant association with sexual reoffending that fall into several categories: for example, deviant sexual interests; antisocial orientation, including antisocial attitudes; personality disorder(s) and varied maladaptive personality characteristics; indices of rule violations (e.g., parole/probation and institutional violations); and issues in intimate relationships (e.g., absence of or conflicts in such relations). Second, as meta-analyses, they necessarily ignore or minimize the importance of variables that may be difficult to measure or may only apply to subgroups of offenders. Third, none of the variables identified by the meta-analyses demonstrates a uniquely potent or dominant relationship with sexual offense recidivism. As with other etiological studies of different mental health conditions (i.e., major depressive disorder, eating disorders), no one risk factor on its own accounts for a predominant percentage of the variance associated with the appearance of that condition; thus, the strongest single risk factors for sexual recidivism typically have *d* values between .15 and .35 (Hanson & Morton-Bourgon, 2005). Rather, it appears that a number of factors must be present and function in concert for an individual to commit a sexual offense. As Susser (1966) emphasized some time ago, the most common causes of pathological conditions may be contributory, and not necessarily or by themselves, sufficient. In addition, and one set of particular risk factors may be more critical for one specific offender committing a sexual offense, while another set of factors may be critical for another sexual offender's actions. In short, persons commit sexual offenses, even similar sexual offenses, for multiple and different reasons and/or based on varying degrees and combinations of risk conditions. Thus, in considering one or more sexual offenses perpetrated by a particular sexual offender, an evaluator is attempting to identify the degree to which common characteristics (i.e., nomothetic ones, similar to the larger group of sexual offenders) are present as well as more unique characteristics (i.e., idiographic ones, which may be more uniquely related to a particular individual's sexual offending). There appears to be no absolutely prototypical sexual offender. For each sexual offender, a goal of utilizing SPA in the evaluation is to identify those factors that are common as well as those which may be unique or difficult to identify in the larger body of research, which may be of special explanatory value relative to a particular offender.

Psychological Tests and Rating Scales: Definitions

An objective psychological test is the one that measures an individual's characteristics in a way that is independent of rater bias or an examiner's own beliefs, usually by the administration of a set of questions that are answered by the individual

(self-report) and then scored, scaled, and interpreted by standardized procedures. On a psychological test, the person being evaluated responds to a fixed set of questions or self-referential statements using a fixed-response format. Several things are worth emphasizing. Self-report tests obviously rely on the responses or endorsed statements of the person being evaluated at a particular time and in a particular context. Self-report tests require some cooperation, some degree of literacy and reading ability, and theoretically, some limited self-insight on the part of the individual.

Standardization is a critical component of psychological testing and assessment. Standardized tests are administered under relatively uniform conditions (e.g., in a similar way, regardless of the subject or setting), scored objectively (the procedures for scoring the test are specified in detail so that the test or scale ratings by trained scorers produce the same score for the same set of responses), and designed to measure relative performance (e.g., standardized tests are interpreted with reference to a comparable group of people, the standardization, or normative sample). Such psychological tests (sometimes referred to as psychometrics) involve procedures where samples of behavior (e.g., typically self-report or ratings by others) are collected from an individual to measure one or more constructs or characteristics of interest; this information is typically scored, and the responses are compared to the responses of normative samples or groups. That is, psychological tests are interpreted in a *norm-referenced* or *criterion-referenced* manner where the sample norms are considered to be a representative of a population.

Sometimes referred to as a *nomothetic approach*, a norm-referenced score interpretation compares an individual's results on a test or rating scale with presumably representative samples of the population which provides a group norm or set of norms. [This does not mean that the results of the test are necessarily always "true" since individuals can choose not to be open about his/her personality or past behavior. Sometimes a person can attempt to misrepresent himself in their responding to test items, and the test results will not accurately reflect the nature of that individual.] The administration and interpretation of psychological testing becomes a central part of SPA, which entails a more comprehensive assessment of an individual beyond just test results. Similar to risk assessment instruments, the results and interpretation of most psychological testing are essentially actuarial in nature. That is, the development and application of a psychological test is based on the process of collecting information from observations of samples with particular responses to test items; test development allows conclusions to be made about response patterns which then allow an evaluator to infer and make conclusions about a particular individual's test response patterns. Consequently, a particular psychological instrument's interpretation provides hypotheses about individuals who endorse particular responses. Test statements are based on behavioral probabilities. Each interpretive statement can be viewed in the following light: in one or more research studies, a clinically significant number of people who had similar answers exhibited the stated characteristic(s). The fact that one is applying data from a group to an individual should always be noted. However, as Weiner and Greene (2008) point out: "the fact that statistical judgments concern a group of individuals rather than any specific, unique individual does not preclude their providing accurate information about a persons who has been examined. To the contrary, although reliably information from other sources may indicate that certain statistically based interpretations do not apply in a particular case, a set of carefully developed statistical rules is likely to include many that describe most persons" (p. 59).

Evaluation Assessment: The Integration of Sources of Information

Assessment as part of an evaluation of an individual not only includes psychological testing and/or rating scales but also involves a more comprehensive assessment of the individual, typically involving multiple sources and methods of information about an individual. Evaluation assessment is a process that involves the collection, analysis, and integration of information from various sources, including multiples tests of variables of interest (e.g., several personality tests), information from direct structured and unstructured interviews, and collateral information about the person being evaluated. Most commonly and most importantly, archival records are the primary collateral sources of information that serve as the backbone of evaluation assessment; they represent a collective body of collateral or external observations. In one sense, archival records also provide the basis for what methods of SPA are necessary in a particular evaluation by establishing potential questions for further inquiry; they also provide a central basis for structured rating scales providing a primary source of data for answering existing questions. Thus, standardized psychological tests provide a structured, norm-based source of data provided by the individual being evaluated at the time of the evaluation; structured interviews and clinical rating scales provide a standardized means of collecting both current and past information and quantifying that information about the person being evaluated. By necessity and by professional standards, SPA is a complex, detailed, in-depth process that seeks to use multiple norm-referenced means to collect and interpret information about an individual in conjunction with existing materials about that individual.

An important concept in SPA for both clinical and forensic evaluations is the importance of what is known as multi-trait, multi-method evaluations (MTMME) (e.g., Campbell

& Fiske, 1959). This involves collecting information about multiple aspects of an individual (e.g., varied personality, social and psychosexual characteristics) from multiple perspectives (e.g., sources of information). MTMME recommends or requires that an evaluator utilizes multiple methods of self-report (records, self-report testing, current interviews) and collateral or "other" reports (records, especially those of previous evaluators, institutional, or other observers). Convergence and divergence within a complex and extensive set of data can provide a valuable perspective and may direct additional evaluation methods.

Moreover, a MTMME involving SPA offers a significant opportunity for incremental validity in the process of evaluations of individuals. This seems particularly true regarding the assessment of sexual offenders, given the aforementioned limitations of non-standardized self-report of such offenders or non-standardized clinical judgment by evaluators. Incremental validity is the concept that the use of psychological tests and structured clinical ratings adds to the clarification of the presence and nature of psychological/psychiatric conditions above what results from other available data (e.g., Hunsley, 2007; Hunsley & Meyer, 2003). Typically, the available data regarding a sexual offender is their potentially self-serving self-report, the report of potential victims and various collateral sources (e.g., police, previous observers), and an unstructured "clinical" interview. The addition of standardized, norm-referenced psychological assessment approaches to an evaluation would, on its face, seem to offer unique and potentially rigorous data about individuals for comparative purposes.

Garb (1984, 1998) reviewed the incremental validity of sources of information. He found that in general, biographical data and objective psychological testing (e.g., the MMPI) each had incremental validity for assessing the psychological functioning of adults in prediction contexts. Of note, Garb (1998) found that unstructured interview data tended to add little incremental validity; however, Garb (2005) noted that diagnostic results were improved by the use of self-report inventories in conjunction with interviews. Following Garb (2005), Carlson and Geisinger (2009) stated:

> In terms of personality and psychopathology, incremental gains were evident when a variety of assessment information was collected, including information from interview data, personality inventories, projective techniques, and self- and clinician-rated measures. Using a multi-faceted assessment approach provides the most complete understanding of the clinical symptom picture. (p. 75)

In short, it seems clear that appropriate interviews (e.g., structured) in conjunction with standardized psychological tests and rating scales provide incremental validity to the evaluation process.

With regard to the "routine" clinical/forensic context of sexual offender evaluations, most authorities in the field recommend MTMME evaluations, involving record review informed by standardized testing and formal interviews (e.g., SPA) [e.g., Association for Treatment of Sexual Abusers (ATSA), 2014; Center for Sex Offender Management (CSOM), 2008, 2014; Clipson, 2003; McGrath, 1993]. CSOM (2008, 2014) emphasizes that many varied concerns direct that sexual offender evaluations be comprehensive and rely on multiple sources of data, highlighting the unreliability of unstructured self-report of and heterogeneity among sexual offenders. Thus, ATSA (2014) Practice Standards for Psychosexual Assessments indicates that members rely on multiple sources of information when conducting such assessments, noting that "ideally" those sources include "Psychometric testing." Further, various jurisdiction statements regarding "Elements of Comprehensive Sex Offense Specific Evaluations" mandate the inclusion of standardized psychological testing (e.g., Illinois's Administrative Code from their Sex Offender Management Board) among other sources of information for Presentence Evaluations (among other assessments). Similarly, relative to "Mental Health Sex Offender Evaluations," the Colorado Sex Offender Management Board (2000) recommended the use of multiple assessment instruments and techniques, including psychological testing and structured interviews. The San Diego County Sex Offender Management Council that approved the standards for forensic psychological evaluations for adult sexual offenders endorsed the "use of multiple assessment instruments and techniques" and "a structured clinical interview"; in particular, they recommended the use of a number of broadband multidimensional personality tests.

Oddly, in the realm of what is presumably the highest level of forensic evaluations, those related to SVP commitment evaluations, limited available research indicates that relatively few evaluators utilize either multiscale inventories (or other standardized testing) or structured/semi-structured interviews (e.g., less than 10 % of evaluators in Washington State per Jackson & Hess, 2007). However, select writers (e.g., Hoberman, 1999a, b) have long advocated for the essential importance of conducting forensic evaluations of sexual offenders—particularly in the civil commitment context—with the same comprehensiveness of methodological rigor and information collection as is commonly obtained in more general forensic evaluations of parties in legal contexts (e.g., those for child custody, competency to stand trial, personal injury, and so on) by relying on structured self-report tests and rating scales. Thus, as in virtually all other forensic realms, forensic evaluation and reports are strongly recommended to include the results of structured, direct evaluations [e.g., psychological testing, ratings scales, formal (structured) interview formats] in developing opinions regarding key constructs and issues related to the range of litigation involving psychological issues. Currently, several factors seem likely to increase the utility of MMTE in SVP

commitment procedures. First, as noted, they are commonly relied upon in more general sexual offender evaluations. Second, with the increased emphasis on dimensions of psychological functioning and psychiatric symptomatology [as per the psychiatric realm (DSM-5, APA, 2013) and the legal realm (e.g., issues of "serious difficulty in control" and "volitional impairment")], such tests and rating scales are likely to become increasingly relied on to obtain standardized self-report of current impression management, psychosocial characteristics, and psychiatric symptomatology.

Formal Issues Regarding Psychological Testing as Part of SPA

In 1985 a set of standards was published that have guided test development over the last two and a half decades; the most recent version was published in 1999 (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999). This set of standards concerns the development of tests and their psychometric properties. In addition, the standards identify who may use tests, how they may be used, and how results are to be reported. Issues such as test security are crucial since knowledge of test contents and items can invalidate a testing session. Many psychological tests are generally not available to the public, but rather have restrictions both from publishers of the tests and from psychology licensing boards that prevent the disclosure of the tests themselves and information about the interpretation of the results. Generally, the overwhelming majority of licensing boards in the USA and Canada prohibit professionals other than psychologists from conducting psychological testing; approximately 90% of such jurisdictions restricting the use of the term "psychological."

Further, test publishers consider both copyright and matters of professional ethics to be involved in protecting the secrecy of their tests, and they sell tests only to people who have proved their educational and professional qualifications to the test maker's satisfaction. Purchasers are legally bound from giving test answers or the tests themselves out to the public unless permitted under the test maker's standard conditions for administration of the tests or, in select cases, by court order. Under the requirements of the standards, test publishers should provide a professional manual that presents a description of test development, norms, and the basis for scoring, reliability, and validity as well as proper interpretation. Test manuals are typically available from the publishers for all published psychological tests and rating scales. The application of a test is generally limited to persons sharing similar characteristics to that of the normative samples.

Some tests are more restricted than others so that professional standards identify who is deemed qualified to administer and/or interpret psychological tests, including graduate degree status and/or specific graduate level coursework. Some forms of SPA, particularly psychological tests and structured professional judgment or rating scales, require extensive specialized training for interpretation and/or scoring (e.g., the MMPI-2, the MCMI-III, the Psychopathy Checklist-Revised) even though their application in an evaluation might appear ostensibly simple. The accepted basis for interpretation of SPA requires appropriate understanding of the development of, psychometric properties of, basis for, and satisfying the established qualifications for test scoring and interpretation. It is the responsibility of the MHP administering and "using" such psychological measures (e.g., applying the test or scale results via interpretation) to ensure that they possess the requisite knowledge of and/or training for the test or rating scale. It is also their responsibility to ensure that the conditions under which the measures are administered are appropriate.

Clearly, psychological tests and rating scales as elements of SPA must be scientifically acceptable in order to provide meaningful measurement of their intended foci. In particular, such instruments must have demonstrated psychometric properties, particularly reliability, validity, and well-defined norms. As Rogers (2003) and others (e.g., Heilbrun, 2001, 2003) have noted that psychological tests (which were originally developed for traditional clinical purposes) are commonly utilized for forensic purposes, such tests are viewed as providing reliable and valid, norm-referenced information about various constructs that have relative bearing on the psycholegal issue but do not completely or specifically address the focal forensic issue in a particular case. Nonetheless, the results of those tests, properly interpreted, provide important perspectives that contribute to or strongly direct a particular psycholegal perspective.

The ability of a test to give consistent results is known as its reliability. One form of test reliability is internal consistency, which refers to how well the set of test items relate to one another. Such consistency is commonly measured as Cronbach's alpha or intra-class correlation coefficient (based on inter-item correlations of the specific items on the scale or subscales) and ranges between 0 (low) and 1 (high). Test–retest reliability refers to how well results from one administration of the instrument are correlated with the results from another administration of the same test at a later time. In a similar, although an analogous manner for clinical rating scales, inter-rater reliability is the correlation between scores assigned by different raters based on the same information and is highly related to training and supervision. Test–retest reliability reflects the stability of an instrument and the extent to which a test is *repeatable* and yields *consistent* scores across time and across raters.

Validity is the extent to which a test measures what it is supposed to measure and how well does the operational definition

of the test or subscale match the conceptual definition? To create a measure with construct validity, the developer must first define the domain of interest (i.e., what is to be measured) and then identify or create measurement items that are designed in an attempt to adequately measure that domain. Subsequently, a scientific process of rigorously testing and modifying the measure is undertaken. Validity can refer to the usefulness or accuracy of an instrument. In order to be valid, a test must be reliable; it is a necessary and sufficient condition. However, reliability does not guarantee validity. In addition, a test or rating scale may be valid for some situations and not for others as well as for some individuals or groups and not for others.

The validity of SPA is of particular importance in the context of adversarial settings such as forensic evaluations. Particularly in forensic evaluations, which most evaluations of sexual offenders are, it seems clear and likely that individuals may or will affect particular presentations related to their "goals" or secondary gain. In certain contexts, the "press" is to appear more maladaptive or impaired (e.g., personal injury evaluations, criminal responsibility evaluations), and as a result there is likely a tendency to endorse test items so as to appear to have more symptoms or negative characteristics (e.g., to "fake bad" or negative impression management) than may be the case to secure compensation or a preferred disposition (e.g., treatment versus prison). Conversely, and more commonly in sexual offender evaluations, a motivation to appear less symptomatic or deviant leads to a "press" to respond to test items or present information in such a way as to minimize maladaptive personality traits or deviant sexual behaviors or interests (e.g., to "fake good" or positive impression management).

A related point is that in forensic or clinical/forensic settings, one must be aware that there is evidence that a significant number of attorneys may attempt to "coach" or advise their clients in responding to standardized psychological assessment. For example, in one study, almost half of a sample of practicing attorneys and a somewhat smaller percentage of law students surveyed believed that when clients were to participate in psychological testing, they should "always" or "usually" be given information about the nature of validity scales used in such testing, as well as coaching as to what types of answers to provide or to avoid (Wetter & Corrigan, 1995). In addition, information about psychological tests and clinical ratings scales is now available on websites and anecdotally in most institutional settings. The Internet supports the spread of this information so that attempts at "test sophistication" are no longer limited to those who have technical assistance from their attorneys. Consequently, there is always reason to be concerned that some individuals who are provided with or obtain information about the nature of tests and rating scales may be able to and/or attempt to affect their presentation style on a test or to manipulate detection of maladaptive or deviant characteristics or traits.

Practically speaking, it is typically important to ask an offender in what ways he has prepared for the evaluation; many forensic evaluators include language in their informed consents in which the examinee is asked to acknowledge if they have obtained or prepared for the administration of psychological testing. Specifically, an offender should be asked what he has read or been told about the proposed nature, content, or approach for the evaluation, whether he has read or been told about any material regarding the specific tests chosen for administration (e.g., books about the MMPI-2 or MCMI-III), whether he has received advice from any person on responding to the specific tests or ratings chosen for administration, or if he has sought or obtained information from the Internet about evaluations or specific tests and what he knows about how responses to the particular tests or ratings are used. This may become a particularly important concern if an offender's most recent test results are markedly discrepant from the results of previous testing or if the offender seems unusually "prepared" with circumscribed, seemingly "pat" descriptions of his sexual offense history.

Key Elements in the Evaluations of Sexual Offenders

In conducting both forensic and "forensic-like clinical" evaluations of sexual offenders in almost all settings, certain elements are ubiquitous from the perspective of MTMME: a thorough record review, the administration of psychological tests and rating scales, one or more structured and other interviews of the offender, and, if possible and relevant, collateral sources of information beyond the records. Effectively, these are the common elements of clinical and forensic evaluations across almost all domains or subjects of such assessments.

Commonly Utilized Multidimensional Psychological Tests

In practice, many of the commonly recommended and utilized psychological tests in the clinical and forensic evaluation of sexual offenders are comprehensive or "broadband" tests, typically personality tests, that include questions and produce results about numerous relevant areas for the evaluation of sexual offenders, including response style (e.g., impression management, such as defensiveness) and multiple substantive areas of interests (e.g., likely personality traits, psychiatric symptoms, information about attitudes, and nature of deviant sexual interests and sexual preoccupation). Such instruments generate information about clinical symptoms and personality dispositions (including maladaptive personality traits), as well as response styles, that can be

integrated without sources of information to optimize decision-making about psycholegal issues. We would term such tests as multidimensional psychological tests (MDPT). Consequently, each of these MDPT will be reviewed initially in terms of its history, relative psychometric properties, and use.

According to Archer, Buffington-Vollum, Stredny, and Handel (2006), a survey of forensic psychologists indicated that several of MDPT were used frequently in several different types of forensic evaluations of adults, including those involving sexual offenders. The purpose of these measures was to examine underlying psychopathological constructs, including maladaptive personality traits. Further, Davis and Archer (2010, 2013) provided a critical analysis of the ability of multiscale inventories to distinguish between sexual offender and non-offender control groups as well as to discriminate sexual offenders from other types of offenders and reported favorable results. Similarly, an article in a psychiatric journal stated: "Properly used, many psychological tests are very useful diagnostic and clinical tools. They often clarify ambiguous information, elicit previously unavailable data, and add objective, validity, and reliability to patient interactions and record reviews." (Rogers, 2003, p. 316) However, Rogers raised questions about the use of MDPT by MPH lacking in specialized psychometric training. He also noted that they typically do not provide definitive answers to specific psycholegal issues, stating, "They perform well for severity of purposes but do not excel at any highly specialized tasks" (p. 16). That is, they provide information that may or may not go toward the presence or severity of psychiatric symptomatology, personality characteristics, and/or response style but are best used as components of an evaluator's final opinion.

All current MDPT are essentially self-report instruments with a majority of the items having obvious, face valid content that can be influenced easily by the accuracy of an examinee's self-report. Virtually any person being evaluated can easily use a general strategy to report more or fewer problematic personality characteristics, behaviors, or symptoms. Scores on these tests are thus heavily influenced by whether the subject is willing to report problematic behaviors, personality characteristics and symptoms of psychopathology, and the ability of validity scales to correct for these potential distortions in the admission of undesirable qualities and behaviors. Thus, "… in both civil and criminal forensic settings, there may be a reasonable expectation for increased reporting of problematic behaviors and symptoms of psychopathology (e.g., monetary compensation for personal injury, competency to be executed) and decreased reporting (e.g., child custody, personnel screening, parole, or probation hearings)" (Greene, 2007, p. 85). In addition, as writers such as Greene (2007) has noted, research specifically in the forensic context has demonstrated that examinees may describe their problematic personality characteristics, behaviors, and symptoms differently depending on their perception of the allegiance of the evaluator (e.g., perceived as whether acting on behalf of their defense or the "state"). That is, they are more likely to report a decreased degree of maladaptive personality characteristics and problem behaviors to an evaluator perceived as not allied with their interests. Consequently, in most evaluations of sexual offenders, reports to such evaluators should be considered as potentially distorted and a likely underestimation of an individual offender's likely characteristics.

Currently, it should be noted that most test interpretations of self-report MDPT are obtained from computerized interpretation programs. The concept of computer-based test interpretations is based on the view that tests will be more accurately and substantively interpreted via an actuarial manner than through unstructured clinician-based interpretation strategies. As Caldwell (1997) noted, narrative computer-generated reports are actuarial in the sense that the interpretive material is case based; as he writes "the contents of the sentences come from thousands of cases seen over many years and inconsistencies of behavior that have emerged in each of the 'code types'… There is also a large literature on the meanings of different patterns on the MMPI that is integrated into the interpretations…" (p. 57). Further, "The computer-generated report or 'actuarial function' is a delineation of what is typical or characteristic of a person with the same or a sufficiently similar pattern of scores.... The sentences are probabilistic in wording…" [Caldwell distinguishes that from a 'clinical function' of how a person came to that likely pattern of psychological states and attitudes]. Per Butcher (1995), a computer-generated interpretation report consists of objectively applied personality and clinical symptom descriptions that have been established for the specific test scales or patterns of scales and are more accurately combined by machines than reports derived by individual practitioners. For the most part, computer-generated clinical reports can be viewed as predetermined statements that are applied to individuals who obtain particular psychological test scores or test patterns. Butcher (1995) and Caldwell (1997) offer several reasons for the widespread use of computer-based objective test interpretation. First, computer-based interpretation systems usually provide a more comprehensive and objective summary of relevant test-based hypotheses than a clinician has the time or resources to develop. Second, in interpreting profiles, a computer will attend to all relevant scores; the computer cannot ignore or fail to consider important information, whether through simple bias or error, as might be the case when an evaluator faces a large set of complex information (e.g., several hundred test responses). Third, computer-assisted test interpretations are also typically more thorough and better documented than those typically derived by clinical assessment procedures.

Fourth, the use of computer-based test results avoids or minimizes subjectivity in selecting and emphasizing interpretive material. Fifth, computer-based psychological test interpretation of results offers a particularly efficient means of obtaining information since they can be obtained quite rapidly. The computer interpretation systems are considered to be almost completely reliable, according to Butcher (1995), which is to say that they always produce the same results for the same set of scores for similar responses by an examinee to the same test items.

However, it is always important that computerized interpretive reports be utilized in conjunction with other sources of information about an individual obtained from other sources. In forensic contexts when computer-based testing is used, it is very important to be able to establish the chain of custody for the test protocol in question. Typically that means being able to document that an individual has taken the tests in the evaluator's (or their professional designee) presence and that the evaluator has been responsible for either scoring the test responses on a computer or in submitting the answer sheet to a testing service.

MMPI-2 The revised and re-normed Minnesota Multiphasic Personality Inventory-2 (MMPI-2) (Butcher et al., 1989) and its predecessor, the original MMPI (Hathaway & McKinley, 1943), are and were the most commonly used multiscale, self-report tests across various clinical and forensic settings. The MMPI was and remains the most frequently studied psychological test (e.g., Butcher & Rouse, 1996; Sellbom & Anderson, 2013); per Sellbom and Anderson, the number of journal articles, book chapters, and textbooks regarding the MMPI-2 likely exceeds 3,000. The original MMPI was the most frequently used self-report inventory measuring personality and psychopathology for many years (Lubin, Larsen, & Matarazzo, 1984; Piotrowski & Keller, 1989) as well as the most researched psychological test (Reynolds & Sundberg, 1976). The MMPI was re-standardized on a stratified, national, randomized sample of adults in the USA and released in 1989 as the MMPI-2. The MMPI-2 (Butcher et al., 2001) has been and continues to be used in a variety of settings (Camara, Nathan, & Puente, 2000). Since its availability, the MMPI-2 has been and remains the most frequently studied psychological test (Butcher & Rouse, 1996; Otto, 2002).

The original MMPI was developed in 1939 using an "empirical" approach; it was not theoretically based. Rather, items were selected by statistically comparing those endorsed by a clinical or diagnostic group to those of a "normal" comparison group, who were predominantly white, rural, blue-collar, Protestant males. Items that discriminated between and among the "diagnostic" groups and the non-patients were selected for inclusion in the clinical scales (e.g., Hathaway & McKinley, 1943). Consequently, since the construction of the MMPI was atheoretical and empirical in nature, a particular advantage of the MMPI is it is not always possible for an individual to know why a specific item might distinguish a criterion diagnostic group from so-called normal individuals.

A limited number of services are licensed to *score* the MMPI-2, including Pearson Assessments, the Caldwell Report and Psychometric Software (www.psychometric.us). Beyond scoring, however, *test interpretation* is available from several sources. The most commonly used MMPI-2 test interpretation is that of Pearson Assessments. Psychological Assessment Resources (PAR) (www.parinc.com) publishes an interpretive program by R. L. Greene et al. (2006) that is quite useful in providing a broader set of possible interpretations for the results (including diagnostic impressions and treatment prognosis). The PAR program is also valuable because it "deconstructs" the narrative interpretation and allows an evaluator to identify the specific scale scores that account for particular interpretative statements, as well as a detailed breakdown of possible interpretations subscale by subscale. These subscale interpretations are useful to "fine-tune" an interpretation relative to what aspects of personality appear to "drive" a particular elevation on a clinical scale. Test interpretation is also available from Psychometric Software (www.psychometric.us) and the Caldwell Report (www.caldwellreport.com). Both Graham (2006, 2011) and Greene (2010) have produced increasingly updated interpretive handbooks for configural interpretations of MMPI-2 scores as well as for actuarial interpretations of elevations on specific clinical, supplementary, and content scales.

The MMPI-2 consists of ten clinical scales, a number of validity scales, and 21 content and supplementary scales; the test consists of 567 items. Typically, the MMPI-2 takes between 1 and 2 h to complete; it is generally utilized with persons with at least a sixth-grade reading level. Scale *T*-scores greater than 65 are considered to be high scores although inferences about persons with scores at different *T*-score levels can often be made as well. As Graham (2006) noted: "It should be understood that the *T*-score levels specified have been established somewhat arbitrarily and that clinical judgment will be necessary in deciding which inferences should be applied to scores at or near the cutoff scores for the levels" (p. 65). Similarly, he points out that it is likely that not every inference presented will apply to every person with a *T*-score at a specified level, but that greater confidence should be placed in inferences based on more extreme scores and pairs of scores. Similarly, Caldwell (1997) wrote: "Qualitatively, the behavioral tendencies and emotional dispositions measured by the MMPI/MMPI-2 scales change very little between the 'normal' and 'abnormal' ranges. Rather, the changes are mostly in terms of the range of symptoms, their severity and the general level of impairment"

(p. 36). He argues that profile patterns or code types in the normal range essentially identify stylistic patterns of domains like inhibition, responsibility, unusual attitudes social conformity, tendencies to take advantage of others, and so on. That is, when scores are in the nonclinical range, they reflect personality tendencies or features. The research literature regarding the MMPI translated well to the MMPI-2 [e.g., for correctional inmates, Megargee (1994)]. Most recently, Sellbom and Anderson (2013) reported that the MMPI-2 remains the most studied psychological test; they noted that it was unparalleled in the number of validity studies that it has generated, indicating that well over 3,000 journal articles existed regarding the test. They noted: "The strengths of the MPPI-2 include the vast research literature on the scales supporting their convergent validity as well as effectiveness in detecting a variety of clinically relevant problems…" The most prominent limitations of the MMPI-2 include some degree of intercorrelation among the clinical scales and the fact that the scales do not cover the full range of clinical symptomatology.

One finding should be emphasized about the MMPI-2's utility and admissibility with regard to evaluations of criminal offenders and sexual offenders more particularly. An accumulation of studies has clearly determined that the MMPI-2 cannot be used to determine if an individual denying a specific offense has committed that particular offense (e.g., by virtue of fitting a "pattern" of responses), and, consequently, it lacks a basis for evidentiary admissibility for the specific purpose of determining guilt or innocence.

Present forensic applications of the MMPI-2 are extensive and considered appropriate for almost all forensic questions (Sellbom & Anderson, 2013). Certainly, there is data that indicates that the MMPI-2 has many uses for evaluations of criminal offenders generally (e.g., Grover, 2011; Megargee, 2006; Megargee, Carbonell, Bohn, & Sliger, 2001; Megargee, Mercer, & Carbonell, 1999) and more specifically among identified sexual offenders (e.g., Kalichman, Dwyer, Henderson, & Hoffman, 1992; Schlank, 1995). Clearly, the utility of the MMPI-2 is widely or generally accepted; as noted above, it has consistently been admitted in legal proceedings for various types of information that it can provide about the characteristics of a sexual offender and their implications. Otto (2002) reported that the MMPI-2 was the most widely used psychological test generally, while Graham (2006) has noted that it is the most commonly used test in mental health assessment and treatment centers, typically utilized to identify clinical conditions, personality traits, and their implications for functioning and treatment. Sellbom and Ben-Porath (2006) noted: "Present forensic applications of the MMPI-2 are extensive" (p. 28); they pointed out: "The MMPI-2 is unparalleled in terms of the number of validity studies that it has generated." (p. 25). Several surveys have indicated that the MMPI-2 is more frequently used in forensic settings than any other test (Lees-Haley, 1992) and is considered appropriate for most forensic questions (Lally, 2003). More specifically, in their sample of 131 forensic psychologists, Archer et al. (2006) found that 129 mentioned the MMPI-2 as a test that they used in their work and that 60 of those used the test either "almost always" or "always."

Meloy (1989) identified the MMPI as the forensic evaluator's "workhorse" in adult forensic evaluations "due to the enormous amount of research available concerning its clinical use, and the sensitivity of its various indicators of distortion" (p. 333). Weiner (1995) in reviewing the psychometric properties of the MMPI-2 for forensic use concluded:

> The MMPI-2 is a basically sound instrument that can readily be defended in the courtroom with regard to it standardization, reliability, and validity… The MMPI-2 can be used most effectively in forensic, as well as clinical assessment when combined with other sound instruments to provide opportunities to compare and contrast indications of problems, complaints, and characteristics as manifest on both relatively structured and relatively unstructured assessment instruments. The issues considered in arriving at these conclusions are by no means unique to the MMPI-2; rather, they are applicable to all psychological assessment procedures, each of which has its own particular blend of strengths, applications, limitations and aspects in need of further study. (pp. 78–79)

Greene (2007) stated that "The MMPI-2 is well-suited for forensic examinations because of the extensive number of validity scales and indexes to assess whether the examinee may have increased or decreased reporting of problem behaviors and symptoms of psychopathology. There is a long history of empirical research that validates its use. Such research can be used to provide the scientific evidence needed for specific cycle legal issues that are being evaluated in the forensic examination" (p. 93). While the MMPI-2 or in fact any psychological test can determine guilt or innocence, they can support many aspects of a decision such as the typical second prong in SVP proceedings of the presence of a mental illness or personality disorder. Sellbom and Ben-Porath (2006) noted that, in general, the MMPI-2 meets both the criteria of evidentiary admissibility under both *U.S. v. Frye* (1923) and *Daubert v. Merrell Dow Pharmaceuticals, Inc*. (1993). While certain states have slight variants on these admissibility criteria (e.g., Minnesota's Frye-Mack standard), such rules appear more similar than different, and we are aware of a few (if any) admissibility failures to date.

Otto (2002) reported that the MMPI-2 is the psychological testing instrument most frequently used in forensic treatment and evaluation contexts "and likely reflects the empirical derivation and rich research base of the instruments. Given its use and acceptance by psychologists, expert testimony based on the MMPI-2 has rarely been excluded from legal proceedings." (p. 71). Lally (2003) found that the MMPI-2 was rated as acceptable for an assessment of risk of

sexual violence by 81 % of a group of experienced forensic psychologists. Per Bow, Flens, and Gould (2010), forensic [AU16] psychologists view Scale 4 as the most useful of the MMPI-2 clinical scales. Clinical scales 4 and 9 and ASP, as well as RC4 and RC9 and ASP, are viewed as providing useful assessment of antisocial personality traits (e.g., Lilienfeld, 1996; Sellbom, Ben-Porath, & Stafford, 2007).

More recently, Davis and Archer (2010) provided a critical analysis of the ability of multiscale inventories to distinguish between sexual offender and non-offender control groups as well as to discriminate sexual offenders from other types of offenders. They found that the MMPI-2 was "clearly the most widely used instrument … in sex offender populations" (p. 1255); in particular, the "Pd scale has shown moderate to large effect sizes when distinguishing between sex offender and nonsex offender groups" (p. 1254), and Davis and Archer's review noted that such elevations appear to be associated with a greater chronicity of offending and was most frequently elevated among sexual offender samples; while Pd is often elevated, they also point out that not all offenders produce high scores on Pd and that Pd elevations did not discriminate among subsets of sexual offenders. Coxe and Holmes (2009) found that for sexual offenders identified as "high risk," three clinical scales were typically elevated [e.g., 4 (Pd, Psychopathic Deviate scale), 6 (Pa, Paranoia), and 8 (Sc, Schizophrenia)] and concluded that the high-risk group was characterized by a greater degree of psychological maladjustment than the lower-risk group. Greer et al. found that elevated scores on Scale 4 (Pd) characterized persons who failed to complete sex offender treatment. Grover (2011) in a review of the application of the MMPI with correctional populations (and convicted sexual offenders more specifically) noted that the test was the most widely used objective personality measure in all settings and was particularly useful in correctional settings. They wrote: "In evaluating it's use with sexual offenders, it seems that certain scales including the L [Lie], F [Infrequency], Pd, and Sc scales are elevated with this population of offenders" (p. 641); they also concluded that there was a heterogeneity of personality styles found in populations of sexual offenders.

MMPI-2-RF An alternate version of the MMPI-2 has been developed employing particular statistical methods that were used to develop the restructured clinical (RC) scales in 2003 (Tellegen et al., 2003). The MMPI-2 Restructured Form (MMPI-2-RF; Ben-Porath & Tellegen, 2008) is also owned by the University of Minnesota and published by Pearson Assessments. The goal in developing the restructured clinical scales was to preserve the valuable predictive features of the existing clinical scales while attempting to improve their distinctiveness; the MMPI-2-RF reflects an attempt to reduce the effects of general negative affect and item overlap on clinical scales. However, as Greene (2011) and Nichols (2006) have pointed out that the numbers of items that are scored on a single clinical scale are still outnumbered by the number of items on the RC scales that overlap with at least one other clinical scale. Thus, the RC scales did not seem to eliminate the problem of overlapping items that characterizes the MMPI-2 clinical scales, raising questions about the relative success of identifying a "distinctive substantive core" within each clinical scale. In addition, the MMPI-RF has also been criticized as less ecologically valid given that persons with mental health issues, in fact, typically present with complex patterns of symptoms. Further, as Greene (2011) noted "*…because the MMPI-RF scales are direct/obvious measures of problematic behavior and symptoms, it is relatively easy for the client to present an inaccurate self-description*" (emphasis added); he pointed out that low scores on the MMPI-RF can be true or simply reflect "the client's reluctance to acknowledge the presence of such symptoms" (p. 328). MMPI-2 experts such as Caldwell (on his blog/website) have pointed out the problem with the transparency and face validity of the items on MMPI-2RF and opined that such characteristics render the newer version of the test as potentially problematic for forensic evaluations. Thus, the context of the administration for the MMPI-RF takes on increased importance and concern in the interpretation of its results; given its greater face validity, this form of the MMPI-2 may be less useful for forensic or forensic-like evaluations of sexual offenders. Pope et al. (2006) have reviewed and discussed the utility of the MMPI-2 in forensic psychological evaluations across three editions of their volume. Ben-Porath (2012, 2013) has recently written about the empirical research and applicability of the MMPI-2-RF to forensic work. He noted that the RC-4 scale (Antisocial Behavior) was most strongly associated with a measure of psychopathy.

MCMI-III The Millon Clinical Multiaxial Inventory-III (MCMI-III) is also a multiscale self-report test intended to provide information on psychopathology, particularly diagnoses related to personality disorders. According to Weiner and Greene (2008), the MCMI-III "is the self-report inventory most widely used to assess personality disorders. The MCMI-III should be considered any time the presence of a Personality Disorder is expected in an individual…" (p. 279). The original MCMI was first published in 1983. The test is now in its third iteration, and the MCMI-III developed by Millon, Davis, and Millon (1997); Millon, Millon, and Davis (1994); and Millon, Millon, Davis, and Grossman (2006, 2009) and the other versions are no longer available for use. This test was constructed by a combination of theoretical and empirical approaches. The MCMI-III consists of 175 true–false questions, included to parallel the substantive nature of the then-new DSM-IV (American Psychiatric Association,

1994). Raw scores are converted by computer analysis to Base Rate scores in a complex manner. The test has a total of 28 scales including 5 response style scales, 14 personality disorder scales, 10 clinical syndrome scales, and the relatively new Grossman Personality Facet scales (Grossman & del Rio, 2005). The Grossman facet subscales were derived via factoring of the clinical scales; they provide a perspective on the particularly salient dimensions of clinical scales endorsed by the individual. The administration of the MCMI-III typically takes approximately 30 min and requires an 8th-grade reading ability. The test was normed on samples of persons assessed and/or treated in a variety of mental health settings (e.g., the normative group was clinical populations, including 998 male and female patients in psychiatric hospitals or persons with existing mental health problems). Per Craig (2006), this pool was divided into a group of 600 clinical patients (who composed the developmental sample) and a group of 398 other patients that were used for cross-validation. Of note, correctional inmates made up approximately 9 % of the samples.

The MCMI-III is scored and/or interpreted by Pearson Assessments. In addition, as with the MMPI-2, PAR (www.parinc.com) publishes an interpretive report written by R. J. Craig, which relies on the score report from Pearson Assessment. Various writers have written regarding interpretive strategies for the MCMI-III (e.g., Choca, 2004; Choca & Van Denburg, 1996; Craig, 2005; Jankowski, 2002; Jankowski & Millon, 2002; Millon et al., 1997; Strack, 1999, 2002).

Historically, there has been greater debate about the appropriateness of the MCMI, in its earlier forms, for forensic as opposed to "purely" clinical applications (e.g. Schutte, 2001). McCann and Dyer (1996), Dyer (1997), Dyer (2005), and Craig (2006) have advocated for its use in forensic settings, while Rogers et al. (1999) have offered a more critical view of the test in such settings. Dyer and McCann (2000) have pointed out that the criterion for personality disorders per the MCMI-III satisfies criterion for most scales and may be viewed as better than the MMPI-2. Craig (2006) wrote:

> The strengths of the MCMI include these: (a) test development was anchored to theory, (b) the scales are reliable and internally consistent, (c) there are precise cutting rules for the classification of personality disorders, (d) and there is more research on all versions of the MCMI than on all other self-report personality disorder assessment instruments combined. (p. 35)

Borum and Grisso (1995) found that the MCMI was the second most frequently used test in criminal forensic proceedings; over 10 years later, Archer et al. (2006) found that, in addition to the MMPI-2, the MCMI-III was clearly the most widely used instrument in evaluations of sex offender populations. Several authorities have written about the MCMI and the evaluation of sexual offenders (e.g., Chantry & Craig, 1994; Lehne, 2002). In a study of sexual offenders on community probation in the UK, Craissati, Webb, and Keen (2008) utilized the MCMI-III; they found that 73 % of the sample reported a high level of personality difficulty and 37 % reporting personality dysfunction "sufficient to warrant possible diagnoses of personality disorder" (p. 129). Most recently, Craig (2013) notes that the MCMI-III various advantages and issues related to forensic cases remain the second most commonly used personality test (after the MMPI-2) in both civil and criminal forensic evaluations.

Personality Assessment Inventory Published in 1997 and later revised in 2000, the Personality Assessment Inventory (PAI) is also a broadband measure of the major dimensions of psychopathology found in Axis I disorders and two Axis II disorders of the DSM-IV-TR (APA, 2000). The PAI has demonstrated increasing use in both clinical and forensic evaluations. The PAI is also a multiscale self-report inventory consisting of 344-items. Rather than simply responding to an item as true or false, individuals rate themselves as to the degree to which statements are true of themselves based on a four-point scale (very true, mainly true, slightly true, or false). This format provides the opportunity for individuals to self-report in a more nuanced manner. The test is published by Psychological Assessment Resources (PAR) (www.parinc.com).

The PAI items are utilized to form 22 *non-overlapping* scales, including 4 scales for assessing test-taking validity or response bias, 11 scales for assessing clinical syndromes, 5 scales for assessing treatment considerations, and 2 scales for identifying interpersonal style. There are also 3–4 subscales for 9 of the 11 clinical scales and for one treatment consideration scales. Unlike the MMPI-2 and the MCMI-III, each scale consists of 20 items, and there is no item overlap between scales. However, since the PAI was originally developed as an instrument for purely clinical purposes, most PAI items are relatively obvious in terms of what they are attempting to measure; they have high face validity or transparency (in contrast to the MMPI-2). Consequently, on a number of the PAI scales, individuals can easily produce lower scores if motivated to do so; for example, it is quite common for sexual offenders who have been or are being considered for civil commitment to manifest "normal range" scores on the antisocial scales, despite relatively long histories of criminal behavior. Nonetheless, for Morey and Hopwood (2006): "… it has been suggested that the PAI has particular utility in forensic contexts as a screener, diagnostic instrument, and descriptive tool for describing offender populations…" (p. 108). More recently, Morey and Meyer (2013) have further discussed the nature and issues with the PAI for forensic purposes; they conclude by noting that more research on the PAI in forensic contests "would be helpful" (p. 162). Lally (2003) found that the PAI was rated as acceptable by 55 % of experienced forensic psychologists for sexual violence evaluations. Edens, Cruise, and

Buffington-Vollum (2001) discussed forensic applications of the PAI; later, the PAI and its use in forensic settings per case law have been discussed by Mullen and Edens (2008). Mullen and Edens pointed out that the PAI rarely appears to be utilized in forensic cases in isolation but rather in conjunction with other MDPT including the MMPI-2 and/or the MCMI-III.

The Multiphasic Sex Inventories The Multiphasic Sex Inventory (MSI) includes two measures specially designed to assess psychosexual characteristics of sexual offenders (rapists, child molesters, and exhibitionists). The original MSI (Nichols & Molinder, 1984) and the more recent MSI II (Nichols & Molinder, 1996, 2000) were designed to measure the sexual characteristics of adult male sexual offenders and can be used both to as part of psychosexual or sexual deviance evaluation and also to measure treatment progress. Information about the MSIs is only available from the tests' developers (www.nicholsandmolinder.com). A particular value of the MSIs is that they can provide information that is independent of the broadband personality and psychopathology tests, which essentially contain no specific sexual deviancy items.

Per the developers of the MSI:

> Research toward the development of a sexual test began in 1977 at a state hospital sex offender program. The original Multiphasic Sex Inventory (MSI) designed for adult male sex offenders and was published in 1984; 2 years later a form designed for adolescent male sex offenders was published. The MSI is formatted much like the MMPI, but is a sexual inventory and not a personality test. It may be used routinely with other tests for the evaluation of sexual offenders and may also be used during the treatment process to determine the degree of openness and progress that an offender may be making in treatment. The MSI was specifically developed for use by clinicians who evaluate and treat admitting sex offenders.

The original MSI is a 300-item self-report questionnaire of true–false questions. Those items are utilized to provide six types of scales: validity, accountability, attitudes toward treatment, paraphilias (select atypical sexual outlets), sexual dysfunction, and sexual knowledge and beliefs. It requires a 7th-grade reading level and typically takes approximately 45 min to complete. A 50-page manual is available. Kalichman, Henderson, Shealy, and Dwyer (1992) reported that in studies of five independent samples "the MSI provides information not tapped by traditional psychological tests … the MSI demonstrates moderate to high levels of internal consistency, considerable convergence and divergence with other measures" (p. 384). Thus, the MSI provides significant information that is not tapped by a test like the MMPI. Kalichman, Henderson, Shealy, and Dwyer (1992) also noted that the MSI is characterized by high face validity or transparency; the possibility of response bias on some MSI scales allows for denial and faking of sexual deviance. In particular, they found that high correlations between higher scores on scale F and lower scores on scale K were associated with increased reporting of sexual deviance. They recommended that the interpretation of scale scores on the MSI be interpreted with "careful consideration of the assessment setting and respondent motivation." Kalichman, Henderson, Shealy, and Dwyer (1992) found that while the MSI Sex Obsessions and Cognitive Distortion/Immaturity scale tended to covary with MMPI general psychopathology, analysis showed that only 30 % of common variance or overlap could be accounted for between the MSI and MMPI. This study concluded that "Thus, the MSI contributes a substantial amount of information that is independent of the MMPI" (p. 394). They also pointed to earlier research that had provided evidence corroborating an association of MSI scale scores with physiological indices of arousal.

Multiphasic Sex Inventory II The MSI II (Nichols & Molinder, 1996, 2000) was designed to measure the sexual characteristics of an adult male alleged to have committed a sexual offense or sexual misconduct. Interpretations can be obtained for both a "sexual deviance evaluation" and to measure treatment progress. It can be useful in the evaluation a person who has been alleged to have engaged in sexual misconduct but who denies any such behavior. The MSI II is an expanded and updated version of the original MSI, with a larger number of items (560 true–false items); the test typically takes 90 min to administer. The MSI II requires a 7th-grade reading level. The current MSI II data was nationally standardized using approximately 2,000 subjects (drawn from a pool of 7,000) who had been census matched to the 1990 census on variables of age, ethnicity, education, occupation, marital status, and coming from 1 of 5 geographic regions. Both the original MSI and the MSI II include a number of validity scales as well as scales that allow comparisons with reference groups of identified child molesters and rapists. The MSI II test responses provided by the offender on an answer sheet are submitted to Nichols and Molinder as the primary source of data in conjunction with information provided by the evaluator regarding details of the criminal sexual history of the sexual offender. Nichols and Molinder provide a detailed computerized, norm-referenced interpretive report specific to the offender subject. An extensive test manual for the MSI II is available which documents the test's psychometric properties among other domains. Independent investigators have also confirmed the validity of the MSI II. Tong (2007), Stinson and Becker (2008), and Stinson, Becker, and Sales (2008) all found good concurrent validity, and Stinson and Becker (2008) also found good predictive validity of the MSI II. These studies indicated that the MSI II appears to measure similar phenomena to the penile plethysmograph, and Abel Screen for Sexual Interests, in some instances, showed stronger associations with a past history of particular sexual offending.

The Multidimensional Inventory of Development, Sex, and Aggression (MIDSA) The Multidimensional Inventory of Development, Sex, and Aggression (MIDSA, 2007) is a computerized, self-report inventory whose stated goal is to provide a report to support therapeutic interventions with juveniles and adults who are identified as having committed a sexual offense. Developed by Knight and various colleagues, the MIDSA is copyrighted and available via Augur Enterprises (www.midsa.us). It was normed on adult sexual offenders. The MIDSA represents a unique psychological assessment instrument in that it was originally developed for theory development about the nature of sexual offending in both adult and juvenile sexual offenders but has now been made available for the identification of criminogenic needs or PMRF that might be the appropriate target of treatment for specific sexual offenders. The MIDSA was normed on sexual offenders from several states and normed on community (e.g., adults and adolescents who have committed sexual offenses and a community sample of adult males). All of the samples were originally administered versions of the MASA (Multidimensional Assessment of Sex and Aggression, Knight and Cerce, 2001), typically over a number of years. Currently, the MIDSA has been transformed into a contingency-based questionnaire that can only be administered by a computer. It includes questions that (1) allow the development of a developmental history, (2) provide life history information, (3) form duplicity and compliance measures relative to social desirability issues, and (4) form unique questions appropriate for and only administered to child molesters. The language of the MIDSA has been simplified to a 4th-grade reading level for all offenders. In addition to developmental and life history items, the MIDSA computerized report presents the result of 53 and 51 scales for adult and juvenile sexual offenders, respectively, that assess "constructs that have been found important in the etiology and continuance of sexually aggressive behavior" (p. 11). Most of these scales were developed through factor analyses, but a small number of scales were developed through rational means. The test must be administered by a "session manager" familiar with the technical aspects of administration and with the computer used to administer the test and various procedures to follow in initiating the testing and monitoring the test through the session and with content of the inventory, so as to be able to respond adequately to any questions that a respondent might have.

The MIDSA report provides information about 14 "overarching domains," with numerous subscales of items that compose or are subsumed by those domains. A total of 53 scales and subscales currently exist for the MIDSA, and a detailed manual is available. Because the MIDSA was developed for and is being utilized in current research efforts, the manual provides a truly unique perspective on the empirical work to date regarding the identification, interrelationship, potential risk, and therapeutic meaning of the various scales.

Measures of Psychopathy

As noted, the broad category of antisocial behavior and attitudes has been identified as one of the primary pathways to repeat sexual offending. An assessment of psychopathy should be central to any evaluation of a sexual offender. Per Hare (1993), psychopathy, or being a psychopath, is described as having a distinct personality pattern, involving interpersonal, affective, and behavioral characteristics:

> Interpersonally, psychopaths are grandiose, egocentric, manipulative, dominant, forceful and cold-hearted. Affectively, they display shallow and labile emotions, are unable to form long-lasting bonds to people, principles, or goals, and are lacking in empathy, anxiety, and genuine guilt and remorse. Behaviorally, psychopaths are impulsive and sensation seeking, and they readily violate social norms. The most obvious expressions of these predispositions involve criminality, substance abuse, and failure to fulfill social obligations and responsibilities. (p. 5)

Hare (1985) developed the Psychopathy Checklist (PCL) which was revised in 1991 as the Psychopathy Checklist-Revised (including scoring sheet, rating booklet, and technical manual) and appeared in a second edition in 2003 (along with an updated form of the PCL-R rating scale scoring sheet, a new interview guide and a significantly expanded technical manual, all published by Multi-Health Systems). The PCL-R is a structured professional rating scale designed to assess the personality traits and behaviors related to traditional concepts of psychopathy. In accord with Hare's description, the PCL-R measures psychopathy in terms of 20 interpersonal, affective, and behavioral characteristics, including such domains as impulsivity, lack of empathy, lack of remorse, conning/manipulative, etc. Ratings are based on the degree [e.g., not at all (No), applies to a certain extent or degree (maybe/in some respects), applies or a reasonably good match in essential respects (Yes)] *to* which an offender has manifested the traits or behaviors covered by the checklist *over his entire lifetime*. That is, per Hare (2003a), PCL-R items are rated on the basis of the person's lifetime functioning as revealed by the collective assessment data. Items should not be rated solely or primarily on the basis of present state or relatively recent behavioral history; per Hare and others, for example, PCL-R scores would not change simply as a result of completion of some type of treatment program or as a result of confinement in detention, and the PCL-R cannot be utilized as measure of treatment progress (e.g., Hare, 2003a). The PCL-R is considered to be the best exemplar of structured professional judgment, used with a combination of archival (records) data and interview. However, Hare (2003b) also concludes that substantial research validates the use of the PCL-R being rated on the basis of sufficient archival records alone.

Per the 1991 manual, exploratory factor analyses of the PCL-R produced two correlated factors: Factor 1 (interpersonal/

affective features) and Factor 2 (social deviance features). In 2003, Hare utilized both exploratory and confirmatory factor analysis to identify a four-factor model of psychopathy. Under Factor 1, two facets [(1) interpersonal and (2) affective] were identified, and under Factor 2, two facets [(3) lifestyle and (4) antisocial] emerged. Total scores continued to range from 0 to 40. The higher the score, the more the individual being rated is considered to be similar to the "prototypical" psychopath. Thus, the PCL-R can be used dimensionally to determine the degree of psychopathic traits to characterize an offender; the higher the score, the greater the degree such traits have characterized an individual. In addition, scores on the PCL-R can be used categorically via cut-scores or ranges to classify individuals as a "psychopath." Per the technical manual (Hare, 2003a), a cut-score of "30" is used to identify an individual as a "psychopath." However, it should be clear given the research on dimensional scoring of the PCL-R that such a cut-score is a heuristic strategy and that there is no sharp dividing line in predictive accuracy among scores close to a score of 30. In studies that have relied on scoring the PCL-R based on only archival records (e.g., when subjects of evaluation refuse or are unavailable for a direct evaluation), several studies have demonstrated that a cut-score of 25 identifies offenders as a "Psychopath" (e.g., Harris & Rice, 2003; Rice & Harris, 1997); Hare (2003a) noted that a cutoff score of 26 (designating "psychopathy") is utilized by both the UK and Swedish criminal justice systems.

Regarding reliability of scoring of the PCL-R, although concerns have been raised about the reliability of the instrument in adversarial sexual offender proceedings (e.g., Murrie, Boccaccini, Caperton, & Rufino, 2012), Harris, Rice, and Cormier (2013) showed that file-only scoring of the PCL-R based on good archival material closely matched the clinical scoring typical of routine forensic practice. Harris et al. (2013) also found that "file-only" (e.g., no interview) total scores were significantly higher than file-plus-interview scores. Agreement was best for PCL-R Factor 2 and Facet 4 scores (e.g., the more behavioral items). Harris et al. indicated that lower agreement in "clinical" use of the PCL-R were related to (1) lower degrees of training and practice regarding the PCL-R (leading to measurement error), (2) "partisan allegiance" to outcome, and (3) the effect of more psychopathic subjects to contaminate the interview data and experience (as a result of their psychopathic traits) to affect a reduced psychopathic impression. In support of this last point, it should also be noted that, in their large updated meta-analysis, Leistico, Salekin, DeCoster, and Rogers (2008) also found that the association between violence and file-alone PCL-R scores were significantly larger than scores based on file plus interviews.

Some studies have shown that PCL-R scores are "strongly correlated with other conceptually relevant clinical assessment tools including symptom counts of ASPD, Scale 4 of the MMP-2, the antisocial scale of the MCMI-III, and the ANT scale of the PAI" (Book, Clark, Forth, & Hare, 2006). However, Douglas, Guy, Edens, Boer, and Hamilton (2007) found that the PAI ANT scale and other subscales did not add incremental validity to the PCL-R and concluded that their results offered limited evidence of convergent validity between the PAI and the PCL-R. There was more evidence of correlation with Scale 2 of the PCL-R, but Douglas et al. concluded that the ANT scale could not serve as a proxy for PCL-R scores. Thus, some studies show that the PCL-R is only moderately correlated with select self-report measures of psychopathy. Edens et al. (2001) pointed out that such poor convergence of particular self-reported and professional-rated psychopathy may stem from greater dissimulation on self-report on particular measures such as the PAI as well as limited insight on the part of more psychopathic individuals relative to their own personality characteristics.

Salekin, Roger, and Sewell (1996) reviewed the extant literature on the PCL-R via a meta-analysis of 18 studies; they found adequate reliability and moderate to strong effect sizes for validity. They concluded that the PCL-R represents a good predictor of violence and general recidivism. Barone (2004) referred to the PCL-R as the gold standard for the measurement of psychopathy. In 2005, the Buros Mental Measurements Yearbook review listed the PCL-R as "a reliable and effective instrument for the measurement of psychopathy" and also noted that it "is considered the 'gold standard' for measurement of psychopathy" (Burros, 2005, p. 5). Widiger (2006) also concluded that "Psychopathy, particularly as measured by the PCL-R, has established itself as an important clinical construct, especially within forensic, prison settings. The ability of the PCL-R to predict future violence, substance use, and recidivism clearly has implications for making decisions related to sentencing, conditional release, and institutional placement." (p. 167) In a meta-analysis of risk factors by Hanson and Morton-Bourgon (2004), they found that higher PCL-R scores were associated with an increased risk of sexual offense recidivism. More recently in another meta-analysis, relative to the by Hanson and Morton-Bourgon meta-analysis, Hawes, Boccaccini, and Murrie (2013) found even stronger associations between PCL-R scores and sexual offense recidivism, particularly for Factor 2 and Facet 4. Lally (2003) found that the PCL-R was rated as recommended for sexual violence evaluations (and violence evaluations more generally) by 62 % of experienced forensic psychologists; it was the only psychological measure that was recommended by the majority of those psychologists surveyed. DeMatteo et al. (2014) reported that challenges to the admissibility of the PCL-R in court were rare and typically unsuccessful.

Narrowband Measures of Constructs Potentially Related to Sexual Offending

Numerous studies have attempted to determine if psychological measures can be effectively utilized to measure specific constructs believed to be clinically or etiologically related to sexual offending. Such domains have included offense responsibility, offense-supportive attitudes, intimacy/relationship skills, social skills more broadly victim empathy, self-monitoring, emotional regulation, and problem-solving. Quite recently, Grady, Brodersen, and Abramson (2011) reviewed the available literature regarding such instruments, particularly ones that might be applied as measures of treatment outcome for primarily cognitive-behavioral forms of treatment. Unfortunately, they found few instruments that could be shown to be either reliable or valid or effective measures of core treatment targets. Grady et al. (2011) concluded that while many instruments had been studied relative to their applicability to sexual offenders, "This study demonstrates that there are few valid and reliable instruments as available to research and clinicians to accurately measure sex offender's deficits areas, either prior to or after treatment" (p. 237). Rather, than to repeat such a recent and comprehensive review, later in this chapter, select instruments will be discussed that have been demonstrated to be useful measures of relevant domains in the assessment of sexual offenders.

Interviewing Sexual Offenders: The Need for Structured and Semi-structured Interviews

Clinical interviews are attempts to collect information from a respondent, both via direct questions and observations of the individual's behavior, in the course of discussing the topics and issues presumably related to the context of the questioning. They vary both in the structure of the questions (e.g., unstructured, semi-structured, and structured) and in the degree of judgment or interpretation that an evaluator applies to the information that is provided by an individual.

From a practical perspective, the most thorough assessment of a sexual offender through interview can only be accomplished through considerable contact time with the respondent. This is of particular importance in conducting an interview within a forensic context and is similar to evaluations in other forensic contexts. Thus, forensic interviews should be comparable in length and rigor to interviews conducted where significant issues are at stake, including to such domains as possible insanity defense, personal injury, sexual harassment, or civil commitments of persons as "mentally ill and dangerous." Further, as in all forensic or clinical interviews, the length of the respondent's sexual history, the complexity and severity of his psychological and psychiatric characteristics, and his manner of presentation at interview times further guide the actual length of time of interview contact. Ideally, the actual face-to-face contacts with the respondent should consist of longer evaluation sessions (e.g., multiple hours) and, ideally, should take place over several days depending on the respondent's defensiveness, cognitive capacity (including intellectual and attentional abilities), and the extent of his sexual offending and other criminal, correctional, and treatment history.

Information acquisition can be greatly facilitated by multiple interviews over a number of days, as just noted; this allows for multiple questions directed at similar areas of behavior, framed in somewhat different contexts to facilitate information comparison across interviews. In addition, evaluation over several days provides opportunities to administer and score psychological tests (e.g., obtaining computerized scoring of standardized tests can take up to 2 weeks) and then to use interview time to seek to confirm or disconfirm hypotheses generated by these tests. Finally, multiple interviews provide a much greater opportunity to observe a respondent's interpersonal style over time and across substantive domains of the interview.

To the extent that interviews with sexual offenders occur within a forensic evaluation—or any "clinical" evaluation that occurs within an adversarial context—the evaluator should maintain a skeptical perspective on the veracity or truthfulness of the information provided by an individual. Within the mental health realm, there is a large body of data that indicates that both interviews by MHPs and the interpretation and conclusions that they apply to the information can be significantly flawed by various biases. Such issues are especially applicable to the behavior of sexual offenders in interviews as well as the behavior of sexual offender evaluators both in conducting and interpreting interviews. As noted previously, Earls (1992) concluded that little empirical research exists concerning the reliability and validity of the information obtained in a clinical interview and that the validity of interview self-report by sexual offender is likely to be low. Despite—or even because of—these potential or likely limitations, the same standards for psychosocial and diagnostic interviews applicable in other clinical and forensic settings should apply in evaluations of sexual offenders.

Generally, particular strategies for the structure of the interview process in evaluating sexual offenders, many of which were suggested by McGrath (1990), are ethical and useful to the goals of such interviews; such strategies can work to minimize denial and maximize self-disclosure and discussion. These are actually quite similar to other interventions recommended by Meloy (1989) to "ferret out" distortion in forensic interviews in general.

In the 1970s, psychiatric researchers began to examine the use of research diagnostic criteria and structured diagnostic interviews to determine if specified and systematically collected information from patients would itself increase the reliability of identifying psychiatric symptoms and maladaptive personality traits. Initially for research purposes, Helzer, Clayton, Pambakian, and Woodruff (1978) utilized a structured diagnostic interview with psychiatric inpatients and found the concordance of diagnoses to be high in most cases. They concluded that the validity of a structured interview was high and that such an approach was useful not only for research but also for the clinical evaluation of psychiatric patients. Further, as Garb (2005) pointed out, the quality or predictive accuracy of interview data collection is most dependent on training and supervision and not experience.

Formal Interviews Regarding Background Information Relative to obtaining background information about individuals, one useful means of using a semi-structured interview to collect select about an individual is to utilize the *Interview and Information Schedule* (IIS), which is included in the kit (www.mhs.com) provided for administering and scoring the Hare Psychopathy Checklist-Revised (PCL-R). This IIS is designed to elicit much of the information necessary to make the judgments required for scoring the PCL-R (Hare, 1991) by providing select coverage of educational, occupational, family, marital, and criminal history ensuring that each of these areas is covered by the evaluator and in sufficient detail. Interviews such as the IIS, as semi-structured instruments, allow for flexibility that allows an individual's potentially characteristic interactional style to emerge. However, there are areas that the IIS does not cover which include developmental and sexual history; these components should be addressed as well in this part of the evaluation. Further, to most effectively use the IIS, an evaluator should be familiar with and experienced in the background and scoring procedures of the PCL-R to allow for sufficient information to be obtained to score the PCL-R using the norms that include interview-derived information. According to Hare (1991), the IIS will take 90–120 min. Other potential areas of questions for the evaluation of personal and social history in sexual offenders are provided by Beckett (1994).

Diagnostic Evaluation: The Value of Structure The formal structured or semi-structured diagnostic evaluation of an alleged sexual offender follows quite naturally from questions concerning general areas of their personal and social history. This is particularly true when assessing potential personality traits utilizing thematically organized structured interviews. Thematic areas of interest concerning an individual's mood, interpersonal relations, reactions to stress, and so on are an effective bridge to more specific questions about episodic psychiatric symptoms. Further, in utilizing a more structured approach, the subject is introduced to what they may experience as unusual questions. However, as in other forensic evaluations, the evaluator can point to the fact that they are using a structured instrument and must ask the same questions because of the structural requirements of the interview. Such interviews also provide continuity in the development of the limited rapport and cooperation that can hopefully characterize forensic evaluations.

Traditional assessment among MHP has typically relied upon unstructured interviews, where individual clinicians pose questions they select based on their experience or "intuition" and/or which "occur" to them in response to particular individuals; they may record t individuals' responses to those asystematic questions and note behaviors demonstrated during the interview according to the clinician's personal perception and judgment. A crucial problem among MHP, affecting clinical and forensic work (as well as research), is the generally low reliability of such common unstructured psychiatric diagnostic procedures. Thus, in an early study of the nature of disagreement among clinicians, Ward et al. (1962) found that information variance (differences among clinicians in questions asked and observations made) accounted for 33 % of the differences in outcome (e.g., diagnosis), while criterion variance (differences among clinicians in applying uniform standards of the degree of clinical symptoms present) accounted for 63 % of those differences. Variability in the client's "presentation" accounted for only 5 % of the differences in clinician disagreement. Blashfield (1992) also showed that clinician's utilizing unstructured methods often did not systematically apply diagnostic standards; such an example of criterion variance resulted in misdiagnosis in over 50 % of the individuals studied. As a consequence of such non-standardized practices, traditional clinical interviewing has long been recognized as lacking in both test–retest and inter-rater reliability and in validity.

Based upon findings such as those of Ward et al. (1962) and Blashfield (1992), researchers have long understood and utilized both diagnostic criteria and more structured interviews directed by those criteria to obtain reliable and valid diagnostic assessments. Such approaches have also been recommended for forensic evaluators as well (e.g., Hoberman, 1999a, b; Hoberman & Jackson, 2015; Nicholson, 1999). For example, as Nicholson (1999) pointed out investigations incorporating the use of structured diagnostic interviews that yield substantially higher reliability estimates for most psychiatric diagnoses. He wrote that "… studies have demonstrated substantial discrepancies between research diagnoses based on structured interviews and diagnoses given in typical clinical practice… moreover, the discrepancies are greater for patients diagnosed in state hospitals and community mental health centers and for those diagnosed in University-affiliated hospitals…" (p. 130). That is, research involving structured/semi-structured

interviews and assigning diagnoses based on formal criteria are typically considerably more accurate and reliable than diagnoses provided for clients diagnosed in naturalistic, community clinical settings.

Structured/semi-structured diagnostic interviews allow the interviewee to provide their own perceptions or opinions of aspects of themselves to standardized sets of questions and allow professional judgment by the evaluator as to whether symptoms or personality traits characterize the individual. As Rogers (1995) stated:

> The essence of structured interviewing is its standardization of the interview process…structured interviewing standardizes (a) the clinical inquiries and subsequent probes, (b) the sequencing of clinical inquiries, and (c) the systematic ratings of patients responses. The resulting uniformity allows for direct comparison across psychologists, clinical settings, and diagnostic groups. (p. 1)

He identified a number of advantages of structured interviews including increased reliability, reduction of information and criterion variance, and comprehensiveness (more diagnostic possibilities are covered, and diagnoses, particularly those of less frequency, are not missed as often). A primary disadvantage of existing structured diagnostic interviews is that existing interviews may not cover all of the diagnostic possibilities of interest.

Rogers (1995, 2001) presented a relatively comprehensive review of many of the available systematic diagnostic interviews for assigning diagnoses previously identified as Axis I and Axis II disorders. Regarding such interviews, a distinction is made between structured and unstructured interviews; in the former, *only* the prespecified questions are asked, while in the latter, evaluators are allowed to utilize their own questions to *supplement* (but not replace) standard, required questions and optional probes.

What were previously known as Axis I psychiatric disorders may well be important to assess as part of an evaluation of sexual offenders, as such disorders appear more common among persons identified or referred for sexual issues (Kafka, 2010; Marsh et al., 2010; Raymond, Coleman, Ohlerking, Christenson, & Miner, 1999). Consequently, particularly for clinical purposes, an example of a structured interview is the Structured Clinical Interview for Diagnosis (SCID) (Spitzer, Williams, Gibbon, & First, 1990a, 1990b), while an example of a semi-structured interview is the Schedule for Affective Disorders and Schizophrenia (SADS) (e.g., Spitzer & Endicott, 1978). Rogers (1995, 2001) has expressed concern that the SCID system involves such brief inquiries that both reliability and validity are compromised. Reliable and valid use of both the SCID and the SADS, evaluators are required to receive an extensive formal training.

Diagnostic Interviews: Paraphilic Disorders It is noteworthy that no structured, standardized interview for any of the paraphilic disorders exists, particularly one that has established reliability and validity. An argument can be made that the lack of such procedures speaks significantly to the issues of veracity regarding self-report of deviant sexual interests (e.g., fantasy, arousal, urges, or behavior). No formal method for inquiring about the presence of atypical sexual fantasies, urges, or behaviors has been developed, scientifically tested, or disseminated (even in a proprietary manner). One surmises that there is no or little expectation that persons in general, let alone identified or alleged sexual offenders, might volunteer reliable and valid information about those aspects of their past or present atypical sexual experiences, such as fantasies, urges, and/or behaviors.

Diagnostic Interviews: Personality Disorders For both clinical and forensic evaluations, a formal assessment of relevant personality disorders is essential, both for treatment planning and in identifying PMRF. Per the DSM-IV-TR and DSM-5, a personality disorder is defined as an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two or more of the following areas: (1) cognition, (2) affectivity, (3) interpersonal functioning, or (4) impulse control. The enduring pattern is relatively inflexible and pervasive across a broad range of personal and social situations and leads to clinically significant distress or impairment in important areas of functioning. A particular issue regarding the assessment of personality disorders is that such conditions are often "ego-syntonic" for the individual; that is, the individual does not experience that their behaviors or traits are maladaptive, problematic, or impairing (relative to themselves, they lack insight and self-understanding). Such persons experience their particular cognitions, emotional style, social relations, and/or self-regulation as acceptable parts of their identity. Ten specific personality disorders are identified in the DSM-IV-TR and DFSM-5, as well as a category formerly known as mixed personality disorder, later termed personality disorder NOS (not otherwise specified) and now identified as other specified (or unspecified) personality disorder per the DSM-5. It is noteworthy that several studies cited by Rogers (1995) indicated that research studies have typically found that a very significant percentage of clinical samples receive four or more personality disorder diagnoses when systematically assessed and that virtually none of clinical samples studied meet criteria for just one personality disorder diagnosis. In particular, if an individual satisfies the criteria for one diagnosis within the so-called dramatic–erratic–emotional cluster, he or she is likely to satisfy the criteria or have other maladaptive personality traits for other diagnoses within that cluster. Similarly, Verheul, Bartak, and Widiger (2007) noted that PDNOS is the most commonly diagnosed personality disorder in clinical practice.

Several formal diagnostic interviews have been developed to assess the presence of maladaptive personality traits and personality disorders. The Structured Interview for DSM-IV Personality (SIDP-IV) (Pfolhl, Blum, & Zimmerman, 1995) is a clinical interview to determine the presence of the individual symptom that in clusters define the personality disorders described by DSM-IV. Using questions that are grouped on a "thematic" basis (e.g., self-concept, social relations, etc.) to minimize response sets, this semi-structured interview allows for the systematic assessment of *all* elements or traits that compose the range of the DSM-IV/5 personality disorders. Although the SIDP was developed to take approximately 90 min to administer, in actual assessments, it is rarely possible to administer the SIDP in less than several hours, particularly if a respondent is quite talkative or there is a need for elaboration (something more common in forensic interviews). Per Rogers (1995), the SIDP's earlier versions (e.g., that for DSM-III-R) demonstrated good inter-rater reliability, relatively clear boundaries for specific personality disorders, and clarity in the assignment of the diagnosis of mixed personality disorder or personality disorder NOS.

Other systematic diagnostic interviews for Axis II disorders include the Structured Clinical Interview for Diagnosis on Axis II (SCID-II) (Spitzer et al., 1987) and the Personality Disorder Interview-IV (PDI-IV) (Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995). On the SCID-II (a structured interview), for each diagnostic criteria, the individual is typically asked 1–2 standard questions and, if affirmative responses are received, to provide examples. As Rogers (2001) pointed out, the major limitation of the SCID-II is "the transparency of the interview format lends itself to manipulation and distortion" (p. 238). [Of note, the SCID-II questionnaire doesn't even include questions about the adult criteria for antisocial personality disorder but only conduct disorder "based on the apparent assumption that patients are more likely to acknowledge childhood than adult antisocial behavior" (Rogers, 2001, p. 239).] Rogers concluded, "The SCID-II is not recommended for the assessment of od key symptomatology." (p. 241). The PDI-IV (Widiger et al., 1995) is identified as a semi-structured interview; it assesses diagnostic criteria for ten established and two proposed personality disorders. The companion book provides detailed information about the personality disorders, their relevant traits, and the interview itself. It can be administered in one of two formats: by thematic area (e.g., the questions regarding personality disorders are organized by nine topical areas, similar to the SIDP) or by disorder. Each personality trait or criterion is assessed by at least two and generally three or four standard questions, and there are a small number of branching questions as well. Given the number of questions, the complete PDI-IV can take up to 2 h to administer. Consequently, its optimal use can be in the application of questions to those disorders of greatest clinical and forensic interest in a particular case or as suggested by available archival information. The section on antisocial personality disorder should always be administered for sexual offenders, with additional utilization of sections on borderline, histrionic, avoidant, schizoid, and/or schizotypal personality disorders as indicated by history or earlier interview responses. There is mixed evidence for the reliability of the PDI-IV relative to the presence or absence of particular personality disorders, with antisocial personality disorder having the highest level of reliability. While the earlier version of the PDI-IV was originally studied using graduate student ratings, experience has demonstrated that "the more talented, dependable, and insightful the interviewer, the better these results" (Widiger et al., 1995, p. 10).

Structured Psychological Assessment and the Appraisal of Key Areas for Evaluation Criminal Responsibility for Sexual Offending

It is important to emphasize that the available research literature and professional standards are clear in indicating that no methods of psychological assessment (e.g., MDPT, structured rating scales, semi-structured interviews), just as no method of physiological assessment, can determine whether or not an individual has committed a specific, alleged sexual offense (Becker & Quinsey, 1993). No psychological tests can indicate whether a particular individual has engaged in specific acts of illegal sexual behavior. Further, as sexual offenders are a heterogeneous group with multiple factors either primarily or in combination resulting in sexual offending, to date, there are no scientific studies that definitively identify specific profiles or patterns of testing or rating results that are definitively associated with specific incidents of sexual offending.

Structured Psychological Assessment and Impression Management

Impression Management Multiple contributors in Rogers (1997) have noted the frequency and issues related to deception in traditional clinical assessment of persons with identified with specific issues and typically seeking treatment ostensibly for their own benefit. In forensic or forensic-like evaluations generally, there is an even greater likelihood of distortion in self-report given the context of such evaluations and the significance of secondary gains for manipulating information provided during the evaluation. As Greene (2007) wrote: "…in both civil and criminal forensic settings, there may be a reasonable expectation for increased reporting of problematic behaviors and symptoms of psychopathology (e.g., monetary compensation for personal injury, competency to be executed) and decreased reporting (e.g., child custody, personnel screening, parole, or probation

hearings)" (p. 85). Personality, dispositional, and situation characteristics can play a significant role in impression management. Thus, Logan (2009) noted that narcissistic or self-centered individuals are not particularly useful sources of information about themselves relative to both defensiveness about recognized weaknesses and (often compensatory) grandiosity. More specifically, Jackson and Richards (2007) indicated that sexual offenders' ability to accurately report on their personality characteristics may likely be hampered by any emotional and/or affective deficits such as those measured by Facet 2 of the PCL-R. Sellbom and Anderson (2013) note that individuals seeking early release from a psychiatric institution are particularly prone to defensiveness on the MMPI-2 as an example; the same would most likely be true for persons seeking to avoid admission to treatment or detention settings. As noted, substantial evidence exists that the self-report of sexual offenders generally tends to be distorted in the direction of minimizing their maladaptive traits and behaviors and describing themselves in more positive terms than their criminal histories might otherwise suggest. Thus, more often than not, sexual offenders are likely to self-report a relatively "self-favorable" presentation. Consequently, obtaining one or more explicit measures of the manner and degree to which sexual offenders do, in fact, represent themselves is a key component to any evaluation of such persons. Paulhus' model of social desirability (e.g., Paulhus, 1984, 1999) distinguished between self-deception and impression management. Per Paulhus, self-deception reflects a motivated unawareness of conflicted thoughts or beliefs about oneself; such persons are thought to believe their positive self-evaluation is an accurate description of themselves (i.e., it is ego-syntonic). Particularly in situations with obvious demand characteristics, impression management is thought of as a "strategic simulation," where a person is consciously motivated to create a favorable impression for others (e.g., Paulhus, 1984, 1999). Scores relative to impression management have implications for both the specific test of which they are a part of and for the broad consideration of the veracity of information provided by the individual. Similarly, it has implications for their amenability to treatment and to a lesser extent their degree of antisociality (e.g., their acceptance of responsibility for their own behavior and its consequences for their victims). Each of the broadband psychological tests (MDPT) discussed above, as noted, includes a variety of validity scales that speak to different dimensions of test-taking attitudes and impression management. Other individual scales can also be useful in providing a measure of impression management. In addition, another indicium, for possible intentional distortion of test results, is a longer than usual time to respond test items and/or to complete a standardized test. Several writers have noted that in experimental settings, individuals assigned to "fake groups" took longer to respond than "control" groups; it appears that the task of inhibiting a response and developing an alternative generally requires "processing time" (e.g., Davies & Hepworth, 2009; Holtgraves, 2004). Based on the findings of Nicholson et al. (1997), Vitacco and Rogers (2009) recommended the use of multiple psychological tests in the assessment of sexual offenders as a means of identifying the degree of defensiveness present in a particular evaluation by an offender. Similarly, Rogers (2003) identified that the value of MDPT, particularly the MMPI-2, was in evaluations where there were specific concerns with an individual's response styles (such as defensiveness).

MMPI-2 The MMPI-2 contains several validity scales, which make the measure of particular value in assessing the response style of an individual taking the test in an adversarial context. VRIN consists of 67 pairs of items that have similar or opposite content. For items of similar content, an individual's responses should be the same, and for those of opposite content, it should be opposite. The TRIN scale consists of 23 pairs of items that must be answered in opposing manner. Consistent (reliable) responding is a fundamental aspect of a valid test. Per most writers, the most common issue in the evaluation of sexual offenders is the underreporting of symptoms and maladaptive personality characteristics. Three MMPI-2 validity scales provide a means to assess this likelihood. The Lie (L) scale consists of items that deal with minor personality flaws and weaknesses to which most are willing to admit. Persons deliberately attempting to present themselves in a highly favorable manner may not be willing to admit to even minor faults and may produce high L scores (e.g., high scores reflect impression management). Elevated L scores suggest the likelihood that the individual has not responded to the test honestly, trying to appear as a particularly virtuous and well-adjusted person. Such elevated scores may also indicate an unsophisticated defensiveness in which persons are denying negative characteristics and claiming positive ones because they believe that it is in their best interest to do so. Thus, as Greene (2007) wrote, the L scale is a key impression management scale and typically "reflects that the examinee understands that the nature of the forensic context is not to report any type of problematic behaviors or symptoms of psychopathology and responds accordingly" (p. 87). The K (Correction) scale was developed as a more subtle measure of attempts by persons to deny psychopathology and to present themselves in a favorable light (or the opposite). The K scale items are subtler than the items on the L scale, making it less likely that defensive persons will understand the purpose of the items. As a measure of self-deception, elevations on the K scale typically reflect, "the examinee actually believes that he or she does not have any problematic behaviors symptoms of psychopathology, and consequently there is nothing to be reported regardless of the forensic setting" (p. 87). Higher scores on the K scale are indicative that the individual approached the test in a more defensive manner than would

be typical; particularly, in clinical/forensic contexts, the higher the score, the more likely that the approach to the test was one of unconscious defensiveness or, per Paulhus (1998), self-deception. [As a note, K scores are also employed in a statistical manner to "correct" scores on some of the MMPI clinical scales.] Regarding the higher likelihood of "faking good" for sexual offenders, Graham, Watts, and Timbrook (1991) found that L and K scale scores were typically much higher than the F scales but noted that the detection of fake-good profiles was more difficult than detecting fake-bad profiles. In a meta-analysis, Baer and Miller (2002) found that traditional indices of underreporting yielded a mean effect size of 1.25, suggesting that underreporting respondents differ from those responding honestly by more than 1 standard deviation, on the average, on these scales. However, they also found that when test takers had been coached about the presence and/or the purpose of validity scales, underreporting is more difficult to detect. Per Greene (2007), the F (Infrequency) scale consists of 60 items that are answered by less than 10 % of the normative population in the scored direction. A high F score or scale score is most often an indication of responding indicative of a person attempting to "fake bad" or exaggerate symptomatology or maladaptive personality traits in their self-presentation. [However, it should be noted that high F scores could also be produced by persons who are very psychologically disturbed and wanting to accentuate their maladjustment, as in a "cry for help" for intervention.] Consequently, elevated F scale scores in evaluations of sexual offenders also provide a useful perspective on the offender but are relatively infrequent.

MMPI-2 RF The validity scales in the MMPI-2 RF are largely minor revisions of those contained in the MMPI-2, which includes three basic types of validity measures: those that were designed to detect nonresponding or inconsistent responding (CNS, VRIN, TRIN), those designed to detect when clients are overreporting or exaggerating the prevalence or severity of psychological symptoms (F, Fb, Fp, FBS), and those designed to detect when test takers are underreporting or downplaying psychological symptoms (L, K).

MCMI-III The modifying indices of the MCMI-III consist of 4 scales—the Validity scale (V), the Disclosure scale (X), the Desirability scale (Y), and the Debasement scale (Z). They are used to determine a patient's response style, such as whether they attempted to present themselves in a positive light (indicated by an elevation on the Desirability scale) or exaggerate the negative aspects of themselves (indicated by the score on the Debasement scale). Scale Y (Desirability) assesses the individual's tendency to appear socially attractive and emotionally "put together"; with higher scores, the person is likely attempting with some diligence to not report any type of maladaptive personality traits or interpersonal difficulties. The Disclosure scale (X) provides a measure of measure whether the test taker was open in the assessment or if they were unwilling to disclose details about themselves; it indicates whether an individual was frank and revealing or, in contrast, provided too little information about himself (presenting as essentially secretive and withholding of personal information). Obviously, in particular cases, the elevated scores on the Debasement scale provide information that may be notable.

PAI The Inconsistency scale and the Infrequency scale measure consistency of item endorsement on the PAI. A Negative Impression scale (NIM) consists of items that were endorsed infrequently either by normal or clinical samples. Self-favorable descriptions of problems on the PAI can be assessed by the Positive Impression Management (PIM) scale; these are items endorsed infrequently either by normal or clinical samples but endorsed more frequently by normal individuals than by clinical patients. It is notable that research has suggested that a lower cutoff score on PIM may be more appropriate as an optimal cutoff for determining positive impression management (Morey & Meyer, 2013; Weiner & Greene, 2008). Further, increasing evidence suggests that the PIM on the PAI can be affected by both self-deceptive enhancement and other deception (impression management). Thus, persons who engage in self-deceptive enhancement are those who view themselves typically more favorably than others perceive them by virtue of decreased awareness of negative characteristics and over-attending to perceived positive characteristics; however, such individuals may not be adequately identified by the PIM or show scores lower than the formal threshold. Such findings were identified by Peebles and Moore (1998). A Defensiveness Index is available for computer-scored versions of the PAI, based on configural features more likely to be found in persons simulating a positive impression.

MSI The original MSI includes several measures that can be related to impression management, generally and with specific regard to sexual issues. The Social/Sexual Desirability scale identifies whether clients are responding in a socially desirable way and the Lie scale, which measures the extent of denial and minimization. Haywood et al. (1994) compared fake-good and fake-bad orientations on the MMPI with psychological distortion on the MSI in 59 alleged child abusers. They found that distortion on the MSI indices of minimization and exaggeration was significantly associated with response bias on the MMPI. Cognitive-distortion indices were highly influenced by response bias where respondents attempt to present in favorable light minimizing any negative psychological aspects. In a recent review of forensic assessment of sexual interest, Kalmus and Beech (2005) noted that while the MSI "remains open to fakeability.... The

MSI's utility is that it is good at identifying when it is being faked. Thus, the MSI is most effective in discerning offender's presentation, for example, level of denial…" (p. 208).

MSI II The MSI II has shown similar properties regarding dissimulation as the original test. Scales measure consistency of responding, openness versus defensiveness, infrequent responses, social desirability, dissimulation, and a Lie scale for admitting sexual offenders. For the MSI II, in addition to the Justifications scale present in the original MSI, there are the added Accountability Scales of Dissimulation (D), Scheming, and Superoptimism. The Social Sexual Desirability (SSD) scale is designed to evaluate a person's attempt to present himself and his sexuality in a highly desirable light. The Dissimulation (D) scale is most promising in that it appears to tap into an offender's denial system in which he defines what his sexual behavior occurred in such a way as not to see it as hurtful or serious enough to be an offense but possibly to see it as "inappropriate." The SSD and D scales both correlated with other standard validity scales. For example, per Nichols and Molinder (2002), the SSD scale significantly correlated with MMPI 2 Lie scale (.47), the Marlowe–Crowne scale for Social Desirability (.75), and the MSI II Dissimulation (D) scale (.78). In addition, the MSI II Dissimulation (D) scale was also correlated significantly with the MMPI 2 Lie scale (.53) and the Marlowe–Crowne scale for Social Desirability (.72). These results confirm the effectiveness of these two MSI II validity scales.

MIDSA The MIDSA includes four Lie scales. All respondents are scored on the Positive Image scale that captures attempts to appear in a positive light to others; item content suggests conscious manipulation that is not apparently believed by the respondent. Three other Lie scales can be obtained from those offenders who take the Attitudes and Behavior Change portion of the MIDSA. These include a Negative Emotion Denial scales (to assess persons tendency to deny negative characteristic, primarily emotional or reluctance to admit that emotions affect heir behavior), an Improbability scale (a small number of items that are highly unlikely to occur), and a Sexual Denial scale (which assesses that the individual is denying engaging in sexual behaviors and having sexual thoughts).

Structured Psychological Assessment and the Identification of Psychologically Meaningful Risk Factors

There are several ways of considering the most relevant domains to be assessed in evaluations of sexual offenders. On the most simplistic level, meta-analyses and other multivariate studies (e.g., Hanson & Bussière, 1998; Roberts, Doren, & Thornton, 2002) have consistently identified that there are two primary pathways related to sexual offending: an antisocial or psychopathic path and a deviant sexual interest/behavior. More recently, a later meta-analysis and other studies of risk factors for sexual offending (e.g., Barbaree et al., 2006; Hanson & Morton-Bourgon, 2004) as well as studies of potentially dynamic risk factors (e.g., Hanson & Harris, 2002; DSP) have suggested an expanded but converging domain of variables related to sexual offense recidivism beyond antisociality and deviant sexual interests to include more general problems with authority and rules, problems in social relations, distorted cognitive attitudes, and deficits in self-regulation and problem-solving.

The most recent model for considering the types of information that one might endeavor to understand via SPA of a sexual offender would be to consider what have been termed psychologically meaningful risk factors (PMRF: e.g., Mann et al., 2010). As noted previously, this approach is derived from earlier work by Beech et al. and by Thornton relative to an Initial Deviance Assessment (IDA) which was converted to a criminological model of "criminogenic" or "dynamic" risk factors before reverting back to a more psychologically based model in more recent conceptualizations such as the Structured Risk Assessment: Forensic Version (SRA: FV; Thornton & Knight, 2014). PMRF focus on individual characteristics that appear to be plausible causes of sexual offending and that scientific evidence has linked to sexual offending, particularly sexual reoffending—what has been termed "long-term vulnerabilities." The notion is that PMRF represent "propensities" or "enduring characteristics that leads to predictable expressions of thoughts, feelings, or behaviors" but which may or may not be manifested during any or all particular time periods or across all situations. The conceptualization of PMRF suggests that sexual offending arises through interactions of these propensities (long-term, enduring psychological vulnerabilities) with aspects of an individual's environment (e.g., actual aspects of or interpretations of environments). Beech and Ward (2004) suggested that static risk factors have predictive significance because they are *proxies* or *markers* of the past operation of dynamic risk factors; that is, static risk factors are the behavioral manifestation of underlying psychosocial vulnerabilities, some of which may be mutable and susceptible to change. Per Mann et al. (2010), the identification of these propensities provides the basis for the assessment, understanding, risk assessment, and treatment of sexual offenders, with some long-term vulnerabilities perhaps being amenable to change or management.

Thornton (2002, this book) has articulated a particular set of PMRF that generally converge with earlier versions of models of dynamic risk factors and so-called criminogenic needs (e.g., Hanson & Harris, 2000; Hanson et al., 2007). These "need" or risk factor domains fall into the following

four areas: sexual interests (sexual preoccupation, sexual preference for children, sexualized violence, and multiple paraphilias), distorted attitudes (offense-supportive attitudes such as hostility toward women and Machiavellianism), relational style/status (conflict in or lack of emotional intimacy in relationships, emotional congruence with children), and self-management (e.g., impulsivity/recklessness, problems with authority, negative social influences, poor problem-solving). It seems useful to consider the utility of SPA with regard to the identification and measurement of such PMRF.

Sexual Interests and Preoccupation

Per Mann et al. (2010), the PMRF domain of sexual interests includes paraphilias, more specifically sexual preference for children, sexualized violence, and sexual preoccupation (including hypersexual behavior, pornography use, etc.). As Marshall (2007) has indicated, "The aspect of comorbidity that has received the most attention the sexual offender literature concerns the possible presence of multiple paraphilias in the same person" (p. 23). Several lines of research have informed this issue, which is sometimes referred to as the "crossover" phenomena among sexual offenders. In a community-based study where protection of confidentiality had been obtained from the US government, Abel, Becker, Cunningham-Rathner, Mittelman, and Rouleau (1988) found that a significant percentage of persons engaged in one type of paraphilic behavior also engaged in other paraphilic behavior (e.g., persons with child victims also had adult victims and persons with exhibitionist and/or voyeuristic behavior also had hands-on contact offenses in addition to non-contact offenses). Convergently, a series of studies involving polygraph administration to sexual offenders being supervised in the community (e.g., Ahlmeyer et al., 2000; Heil, Ahlmeyer, and Simons, 2003; Weinrott & Saylor, 1991) identified that a significant percentage of persons committing one type of sexual crime (e.g., child molestation) also committed another type of sexual offense (e.g., rape or voyeurism). While some sexual offenders may be typified by just one paraphilia (per DSM-5), a significant group of others appear to be characterized by multiple paraphilias and/or multiple paraphilic disorders. Such findings suggest the importance of a comprehensive and dimensional approach to identifying and quantifying paraphilic interests.

MSI

This test provides one of the stronger measures of both sexual interests and sexual preoccupation. The Social/Sexual Desirability scales assess "normal" sex drives and interests, while the Sexual Obsession scale measures an offender's obsession with sex. The Sexual Deviance scales (Child Molest—Gender, Rape, and Exhibitionism) are based on the notion that a sexual offender goes through an identifiable cognitive and behavioral progression leading up to a sexual offense. The offender's cognitions are considered to (a) begin with the thought or fantasy of committing a sexual assault (antecedent thought) (b) through a series of self-justifying positions on to planning and executing the assault. The MSI contains Child Molest and Rape Indices that compare the sexual offender's self-report to samples of known child molesters and rapists.

The *Paraphilia* (Atypical Sexual Outlet) *scales* (five subtests) provide the opportunity for a sexual offender to indicate the nature and degree of select paraphilic behavior including fetishism, voyeurism, bondage/discipline, and sadomasochism and telephone scatalogia (obscene phone calling). Several studies have found that scale scores on the MSI identified deviant sexual interests. Bernard, Fuller, Robbins, and Shaw (1989) used the MSI to help confirm sexual interest and arousal to female child stimuli using the MSI and PPG with molesters of female children. Day, Miner, Sturgeon, and Murphy (1989) compared penile plethysmograph and MSI discriminant analysis findings and found "…that the MSI scales used as self-reports measures were superior to the physiological measures of arousal…classified on the basis of the characteristics of past criminal (sexual) behavior" (p. 122). Thus, the MSI has been found to provide data that generally correlates with physiological indices of arousal. Schlank (1995) found that the MSI was more effective than the MMPI in determining clinically different subgroups of sex offenders and concluded that "The MSI, however, appeared to be better suited for understanding the specific psychological constructs of sex deviance and was effective in distinguishing clinically different subtypes…" (p. 192).

MSI II

The MSI II paraphilia scales and subscales parallel the DSM criteria. For example, the MSI II Child Molest, Rape, and Exhibitionism scales provide a means for offenders to indicate their recognition or admission of various aspects of deviant sexuality: (a) deviant fantasies (deviant arousal), (b) pre-assault experiences and behaviors (i.e., urges), and (c) deviant sexual behaviors (both sexual assault and aggravated/advanced assault subscales). The MSI II also provides an opportunity for individuals to indicate the degree to which they have been preoccupied, currently or in the past, with sex or pornography more specifically.

More specifically, the Child Molest (CM) scale of the MSI II assesses an individual's level of recognition and understanding of the pattern of his molesting behavior.

Scales based on an offender's responses allow a comparison of the offender's scores to the scoring levels of nationally standardized samples of adult male child molesters. The Child Molesting scale is based on the following subscales that assess underlying features of paraphilia disorders related to child molesting or pedophilic behavior: (1) *Sexual Fantasies (Deviant Arousal)* is considered a precursor step in which sexual themes involving children have been used for sexual stimulation and examines the degree to which an individual recognizes or acknowledges ever having been sexually aroused by deviant sexual desires or having been sexually aroused by fantasies involving a child. (2) *Sexual Urges (Pre-Assault) examines* an offender's progression that involves planning, anticipation and targeting, and manipulation of a victim so that a sexually desired outcome (i.e., molest) could occur. (3) *Sexual Behaviors (Sexual Assault)* examines the degree to which an offender reports "a final step in which a purposeful and willful decision has been made to act out latent deviant sexual desires involving touching, fondling, oral contact, and penetration between an adult and a child" (per the language used in the typical interpretive report). A similar scale exists for exhibitionism. Thus, these scales assess the style, magnitude, and duration of various categories and elements of sexually deviant behavior.

The Rape scale of the MSI II assesses a client's level of recognition and understanding of the pattern of his use of force or coercion during a sexual encounter. Scales based on responses allow a comparison of the offender's scores to the scoring levels of nationally standardized samples of adult male rapists. The Rape scale is based on the following subscales which assess underlying features of paraphilia disorders related to rape behavior: (1) *Sexual Fantasies (Deviant Arousal)* provides the opportunity for an offender to indicate a precursor step in which thoughts of using force and threat to control a victim are empowering and stimulating; (2) *Sexual Urges (Pre-Assault)* examines a progression which involves planning, anticipation, and stalking in which there is a determined search for a victim to rape; and (3) *Sexual Assault Behaviors* examines the "final step in which a purposeful and willful decision has been made and acted on involving physical assault, force, intimidation, and threat to get a victim to capitulate and engage in a sex act" (per the language used in the typical interpretive report).

In addition to child molesting issues, the MSI II also can provide information regarding other paraphilic and deviant sexual behavioral issues including "peeping," child pornography, sexual harassment, frottage, fetishism, Internet solicitation of a minor, and obscene phone calling.

Recent research has obtained findings that suggest that both the original MSI and the MSI II provide good measures of deviant sexual interests. In a small sample, Tong (2007) found that the Sex Deviance scales, the Child Molester, and the Rape Comparison scales were consistent with the results of PPG findings as well as those of the Abel Sexual Interest Screen (albeit in a sample of men accused of intrafamilial sexual abuse). However, Stinson and Becker (2008) studied men who had been civilly committed in terms of their sexual history, the PCL-R, and four measures of sexual interest [PPG, Abel Sexual Interest Screen (ASSI), PCL-R, and MSI II]; these variables were studied using external criteria of prior sexual offending behaviors (child molest, rape, exposing, voyeurism). [It was noted that a 1/3 of all failed to evidence any sexual arousal (normative to deviant) on the PPG.] Approximately 2/3 of the men had diagnosis of pedophilia, and 2/3 had a diagnosis of paraphilia NOS (obviously there were offenders with dual or overlapping paraphilias). Stinson and Becker (2008) found that "the MSI II Child Molest scale followed by the PPG had the highest correlations with subjects having engaged in sexually inappropriate behaviors with a child" (p. 383). Additionally they found that "…the MSI II (Rape scale) had the strongest correlation with rape behavior, followed by a modest correlation with the overall score on the PCL-R (factor 2)" (p. 383). Both a history of exhibitionistic behavior and voyeuristic behavior were significantly related to scores on those scales on the MSI II. Additionally, Stinson and Becker (2008) performed a logistic regression analysis using those same four instruments (PPG, ASSI, PCL-R, and MSI II)—to determine which combination of these measures would best identify sexual offense behaviors of molest, rape, sadism, and exhibitionism. The researchers performed a forward stepwise logistic regression that found that only one measure, the MSI II Child Molest scale, correctly classified or predicted 92 % of the child molesters in the sample. Of interest, they found that the combined (four) measures, plus a self-report test of sexual fantasies involving children, identified 98 % of their molester sample. On the other hand, using a logistic regression analysis, the MSI II (significance level >.001), and the PCL-R (significance level >.05), it was "confirmed that only these two tests were the most significant indicators of rape behavior… with 85 % predictive accuracy." The authors conclude that "Overall, the strongest predictor of specific sex behavior in this research was the MSI II…" (p. 387).

Further, the MSI II also includes the Molester and Rapist Comparison scales that were empirically developed to identify nontransparent test items that discriminated between persons who identified themselves as molesting children or raping persons and a control group of census-matched "normal" males.

MIDSA

As might be expected, a number of scales on the MIDSA pertain to deviant sexual interests. The *Child Sexual Arousal* scale consists of items that assess being sexually aroused by

children and fantasizing sexual activity with them. The *Child Sexual Sadism* scale consists of items that assess fantasies and behaviors involving hurting or frightening a child during sex. Two additional scales assess *Sexual Sadism*, one focusing on sadistic fantasies (report becoming aroused by thoughts of scaring, hurting, humiliating, or killing women during sex) and the other on sadistic behaviors (report having scared, hurt, or humiliated women during sex). Responses to each of these scales are standardized against community sample adults. Additionally, there are two also Expressive Aggression scales: *Expressive Aggression Fantasy* (reporting having felt angry toward women and had thoughts of hurting or frightening them in nonsexual situations) and *Expressive Aggression Behavior* (reporting they have beaten or harmed women in nonsexual situations). [Sexual Sadism and Expressive Aggression scales are correlated, but a greater percentage of adult and juvenile males endorse Expressive Aggression toward women than who endorse Sexual Sadism in fantasy or behavior.] In addition, there are *Offense Planning scales* (Intimacy-Seeking Sexual Fantasies, Aggressive Violent Fantasies, Explicit Planning, and Eluding Apprehension). Several scales measure specific *Paraphilias* including voyeurism, exhibitionism, transvestism, (telephone) scatologia, and fetishism.

On the MIDSA, *Sexualization* is considered a heterogeneous domain comprising multiple facets such that deviation can occur in the frequency or intensity of fantasies or behaviors, in the age preference of the partner or victim (e.g., pedophilia), or in the arousal target or preferential arousal behavior (e.g., the paraphilias). Consequently, several scales on the MIDSA address this domain. Three scales in this section focus on the frequency and intensity aspects of Sexualization, including Sexual Compulsivity (reporting being a slave to their sexual urges/being unable to control their sexual urges), Sexual Preoccupation (reporting that they think, daydream, and dream about sex frequently), and Hypersexuality (reporting frequent sexual activity and/or the need to have sex frequently). On the MIDSA, five factor scales that describe an individual's experiences with use of, and attitudes toward, pornography assess Pornography. Among these scales are Early Exposure to Pornography, while three scales are related to the person depicted in the pornographic material (e.g., children, men, and women), and the fourth scale focuses on the amount of violence in the material (Violent Pornography). Responses to each of these scales are standardized against community sample adults.

Other Measures

The Screening Scale for Pedophilic Interests (SSPI) was developed and studied by Seto and Lalumiere (2001). It consists of just four items (male victim, number of victims, victim's age 11 or younger, and unrelated victim). Seto and Lalumiere demonstrated that higher scores on this measure "were significantly related to phallometrically measured responding to stimuli depicting children and identified pedophilic interests among child molesters" (p. 23).

The Sexual Fantasy Questionnaire (SFQ) was designed to measure paraphilic and non-paraphilic fantasies (O'Donohue, Letourneau, and Dowling, 1997). It includes scales measuring bondage, sadism, masochism, rape, child fantasy, and normal hetero/homosexual fantasies. Initial results indicated adequate to good internal consistency and good test–retest reliability. Child molesters were shown to have a higher score on the child fantasy scale relative to college students, indicating some validity for the SFQ.

Self-Report Sexual History Measures

Clarke Sexual History Questionnaire-Revised

The Clarke Sex History Questionnaire-Revised (SHQ-R; Langevin & Paitich, 2003; Paitich, Langevin, Freeman, Mann, & Handy, 1977) "is a comprehensive assessment of an individual's sexual history. It is specifically created to assess male offenders and help evaluate the offender's risk to others and his potential for rehabilitation by determining his specific history of various forms of sexual experiences" (p. #). The SHQ-R consists of 23 scales; it is published by MHS (www.MHS.com), and technical manual and scoring keys are available. An individual responds to 508 questions about that history over 60–90 min; their responses are scored via proprietary software, and report scoring their responses with accompanying narrative is obtained. Key areas measured by the SHQ-R included sexual fantasy, pornography use, fetishism, transvestism, courtship disorders, the nature of sexual outlets, and childhood and adult sexual experiences. With the MHS Scoring Services, respondents complete the SHQ-R questionnaire using item booklets and response sheets. Once completed, the response sheets to MHS for scoring, a report is provided. With the software format, an evaluator can generate reports on their own. Details from the printout allow the examiner to evaluate the truthfulness of the examinee not only for the current evaluation but also in his records and treatment, and to use this to patch "holes" in the history presented in interview or to reinterview with this data.

Psychosexual Life History

The Psychosexual Life History (Nichols & Molinder, 1999) provides another means for an individual to provide information about their criminal sexual history in the context

of a broader set of questions about one's personal history. It is 19 pages in length.

Antisocial History and Orientation (Attitudes, Values, and Traits)

Many sources have identified antisocial attitudes and behavior as one of the primary "paths" or causal factors associated with sexual offending (e.g., Barbaree et al., 2006; Doren, 2005; Roberts et al., 2002), and models of sexual offending also indicate the importance of these characteristics (e.g., Ward & Beech, 2006; this book). Consequently, the assessment of such personality dimensions has particular importance. Antisocial and/or narcissistic, self-interested behavior is often ego-syntonic, and, consequently, persons with such traits and behavioral histories are often unaware of or minimize the presence of such characteristics in themselves. Alternately, they may be well aware of such traits but attempt to present a positive impression, via defensiveness or denial, as a means of manipulating an evaluator's perception of them. As a result, when persons with highly antisocial or psychopathic histories self-report minimal maladaptive personality traits, it can be quite useful to examine their specific responses to the items which compose MDPT that are targeted to identify antisocial, narcissistic, or aggressive behaviors and tendencies, particularly relative to their formal criminal history. Not surprisingly, a significant number of persons with extremely antisocial pasts simply respond "false" to the specific items that, per history via records (including previous testing), are or have been highly characteristic (e.g., mostly or very true).

MMPI-2

In Hanson and Morton-Bourgon's (2004, 2005) recent meta-analysis of predictors of recidivism, measures of antisocial characteristics were among the best predictors of sex offense recidivism. In particular, elevations on scale 4 (Pd; Psychopathic Deviate) on the MMPI-2 were associated with future sexual offending. The Pd scale reflects a range of personality dimensions ranging from constricted social conformity to antisocial, acting out impulses and appears directly related to the tendency to express or inhibit aggressive and/or hostile impulses. It is a characterological scale that intends to assess general social maladjustment, failure to appreciate the interpersonal dimensions of life, complaints about family and authority figures in general, social alienation, and emotional shallowness toward others.

Graham (2006) and Greene (2011) and others have produced interpretive guides for the MMPI and MMPI-2 that include bases for examining both individual elevations on clinical scales and combinations of the two highest clinical scales typically known as "two-point codes" (used for configural or pattern interpretation). Scale 4 (Psychopathic Deviate) on the MMPI-2 was developed to identify persons with antisocial, asocial, or amoral characteristics. Persons included in the original criterion group verse were characterized in their everyday behavior by antisocial behavior; however, of note, no major criminal types were included. All the 50 items in the original scale were maintained in the MMPI-2, so significant compatibility exists with the extensive research on these scales conducted on the original MMPI.

Graham (2006) provides the most clear and concise description of prototypic persons with elevations on individual scale scores and two-point code types, and the following descriptions follow largely from his work. Higher scorers on Scale 4 (particularly those showing a "peak" 4, where their score on the Psychopathic Deviate scale is the single most elevated scale of the ten clinical scales) show characteristics associated with various difficulties in incorporating these values and standards of society and are likely to engage in a variety of a social, antisocial, and even criminal behaviors. Higher scorers on Scale 4 tend to be rebellious toward authority figures and are often in conflict with such authorities. Underachievement in school employment settings and significant relationships are also characteristic of high scores. Higher scorers on the Psychopathic Deviate scale are typically very impulsive persons who strive for immediate gratification of impulses. Such individuals typically do not plan their behavior very well and may act without considering the consequences of their actions. They tend to be very impatient and have a limited frustration tolerance. Their behavior may involve poor judgment and considerable risk-taking. They tend not to profit from experiences, and they find themselves in similar difficulties on repeated occasions. In addition, higher scorers are often described by others as immature and childish. They are often viewed as narcissistic, self-centered, and egocentric. They tend to be insensitive to the needs and feelings of other people and are more interested than others in terms of how such people persons can be used for their own benefit. Often these individuals seem likable, and they create good first impressions. However the relationships tend to be shallow and superficial. They seem to lack the ability to form warm or close attachments with others. Higher scorers on Psychopathic Deviate scales tend to be more extroverted and outgoing and adventurous. However, they tend to lack definite goals, and their behavior may lack clear direction. Higher scorers are likely to be hostile and aggressive. They are resentful, rebellious, antagonistic, and refractory. Their attitudes are characterized by sarcasm, cynicism, and lack of trust, and they often feel that others mistreat them. It has been noted that when persons with higher scores on Scale 4 may appear to show guilt and remorse when their behavior gets them into trouble (e.g.

often at the time of a subsequent evaluation), such responses typically are short lived and disappear; an immediate crisis has passed. Higher scorers tend to receive personality disorder diagnoses of antisocial or passive-aggressive personality disorders occurring most frequently.

As Graham (2006, 2012) notes, among the characteristic descriptors associated with elevated scores on Scale 4 are the following: difficulty incorporating the values and standards of society engaging in antisocial and antisocial behavior, rebellious toward authority figures, problematic relationships with families for which they blame family members, being impulsive and striving for immediate gratification of impulses, not planning their behavior well, act without considering the consequences of their actions, are impatient and have limited frustration tolerance, show poorer judgment and take risks, and not profiting from such experiences. They are also reviewed as narcissistic self, self-centered, selfish and egocentric, or insensitive to the needs and feelings of others, but show interest in others in terms of what they can provide for them. Additionally, they act in aggressive ways, exhibit naysaying guilt and remorse when in trouble, may not be overwhelmed despite stress, and frequently feel empty and bored.

Somewhat similarly, Greene (1999, 2008), both in his books and in his PAR Adult Interpretive System, provided a standard interpretation for persons who produced clinically significant scores on Scale 4 (Psychopathic Deviate):

> He is characterized as angry, belligerent, rebellious, resentful of rules and regulations, and hostile toward authority figures. He is likely to be impulsive, unreliable, egocentric, and irresponsible. He often has little regard for social standards. He often shows poor judgment and seems to have difficulty planning ahead and benefiting from his previous experiences. He makes a good first impression, but long-term relationships tend to be rather superficial and unsatisfying.

One of the more recent meta-analyses of predictors of sexual recidivism found that the median and mean (weighted) values for Scale 4 (Psychopathic Deviate) were among the strongest predictors of repeated sexual offending (Hanson & Morton-Bourgon, 2004). Additionally of note, Davis and Archer (2010) found that the Pd scale was clearly the most frequently elevated scale in the sexual offender samples, although they note that not all offenders produced high Pd scale scores. However, they noted that the Pd scale has shown moderate to large effect sizes when distinguishing between sex offender and nonsex offender groups. To be clear, while elevations on the Pd scale are common among many sexual offenders, such elevations do not necessarily distinguish sexual offender from other criminal offenders. Relative to the Harris–Lingoes subscales for Pd, McCreary (1975) concluded that rapists endorsed more items on the Social Alienation and Authority Problems subscales, while child molesters typically endorsed more items associated with Self-Alienation and Familial Discord in early childhood.

In addition to a peak score on Scale 4, there are several two-point codes that can occur more frequently among sexual offenders although as noted there is no "sex offender profile." The first of the more common profiles is the 34/43 profile. Per Graham (2006, 2011), the most salient characteristic of persons whose scores result in a 34/43 profile is chronic intense anger. Such persons harbor hostile and aggressive impulses and have difficulties expressing their negative feelings appropriately. When the score on Scale 3 (Hysteria) is elevated more than the score on Scale 4, persons are more likely to act in an overcontrolled manner most of the time but also display brief, intense episodes of aggressive acting out. Such persons are typically immature, egocentric, and characterized by chronic problems that are difficult to change. In contrast, when the score on Scale 4 is elevated relative to Scale 3, such persons are more likely to be characterized by poorly controlled anger and irritability that tend to be of a repetitive and cyclic manner. They may be quiet, even withdrawn, but manifest sudden outbursts. They show poor judgment under stress, and their emotional or violent outbursts may be only marginally related to identifiable external stress or provocation. Of note, individuals with the 34/43 code type typically lack insight into the origins and consequences of their behavior and more commonly blame others for their difficulties. They often do not see their own behavior as problematic. In addition, overall, such persons tend to reflect a combination of attention-seeking and rejection sensitivity of persons. That is, they are needy for recognition and affection from others and frequently demand attention and approval from others; however, at the same time, they remain cynical and suspicious of others sensitivity to rejection. They may manifest a socially conforming appearance but inwardly they are often seen as quite rebellious. This profile is often associated with several personality disorder diagnoses, including antisocial, histrionic, and borderline personality disorders.

A profile found among sexual offenders involves elevations on Scale 4 and Scale 6 (Paranoia). Again, per Graham (2006, 2011), persons with the 46/64 code type are likely to be immature, narcissistic, and self-indulgent. Typically they are passive-dependent individuals who put demands on others for attention and sympathy but, conversely, are resentful of even mild demands made on them by others. They tend to have difficulty getting along with others and are uncomfortable around members of the opposite sex. They are suspicious of the motivations of others; their apparent feeling is that they are getting a "raw deal" from life and act to avoid deeper emotional involvement. Again, individuals with the 46/64 code type also tend to deny their own serious psychological problems; rather they rationalize and transfer blame to others. They can be unrealistic and even grandiose in their self-appraisals. Persons with a 47/74 for profile typically alternate between periods of gross insensitivity to the consequences of their actions and then apparent excessive

concern about the effects of the behavior in others. Consequently episodes of acting out, including sexual acting out, may be followed by more temporary expressions of guilt and self-condemnation. However, the remorse typically does not carry forward over time to inhibit future episodes of acting out. Generally persons with the 47/74 profiles are relatively dependent, insecure persons who require significant reassurance of their self-worth.

Another profile found among sexual offenders involves elevations on Scale 4 and Scale 8 (Schizophrenia). Graham (2006, 2011) pointed out that, generally, individuals with the 48/84 code type do not seem to fit into their environments and are seen by others as either odd, peculiar, or unusual. They are also typically non-conforming and resentful of authority; their behavior tends to be erratic and unpredictable, and they may have marked problems with the impulse control. Generally, they tend to be angry, irritable, and resentful and as a consequence may act out in asocial or antisocial ways; they also are likely to not appear to profit from their mistakes. Persons with the 48/84 code type are often viewed as harboring deep feelings of insecurity in conjunction with exaggerated needs for attention and affection. Such individuals typically harbor deep feelings of insecurity and tend to manipulate others to satisfy their needs. They lack basic social skills and tend to be socially anxious, withdrawn, and/or isolated. They see the world as a threatening place, they are quite distrustful of other people, and they avoid close personal relationships. There is a greater tendency to have questions about their sexual identity, to obsess about sexual matters, and to experience anxiety about sexual adequacy. Per Graham (2006), they may "indulge in excessive fantasy and/or antisocial sexual acts in an attempt other cope with these feelings of inadequacy" (p. 106). This code type has been noted to be more common among rapists (Graham, 2006).

A particularly common profile found among sexual offenders involves relative elevations on Scale 4 and Scale 9 (Mania). Generally, persons with the 49/94 code type are likely to be particularly narcissistic, selfish, and self-indulgent; the higher the scale elevation(s), the more apparent they are characterized by a marked disregard for social standards. Such persons tend be quite impulsive and are particularly unable to delay gratification of their impulses. Typically, they show poor judgment, often acting without considering the consequences of their acts. They also fail to learn from their own experiences. In addition, they are likely to be unwilling to accept responsibility for their own behavior. Thus, they tend to rationalize their own shortcomings and failures and blame their problems on others. They usually manifest a low frustration tolerance for stress, particularly frustration of their "wants," and manifest considerable or regular irritability or harbor intense feelings of anger and hostility. Such persons may also be energetic and tend to seek out emotional stimulation and excitement. They tend to be uninhibited and extroverted in social situations but have superficial relationships, keeping others at a distance. A diagnosis of antisocial personality disorder is often associated with a 4/9/94 code type.

Another common presentation on the MMPI-2 by sex offenders involves a primary elevation on Scale 3 (Hysteria). All of the 60 items in the original version of Scale 3 were retained in the MMPI-2. Elevations on the Hysteria scale can identify two types of persons (e.g., Graham, 2006, 2011). First, persons who respond to stress with some involuntary psychogenic loss or disorder of function may produce higher scores; such persons do not typically commit sexual offenses. However another group of individuals with elevated score on Scale 3 are persons characterized by a general denial of psychological or emotional problems or of discomfort in social situations. A particularly salient feature of the day-to-day functioning of persons who score highly on the Hysteria scale tends to be a marked lack of insight concerning the possible causes of their difficulties and little insight concerning their own motivation and feelings. High scorers on Scale 3 are typically described as immature psychologically, at times even childish or infantile. Such persons are often quite self-centered, narcissistic, and egocentric; they expect a great deal of attention and affection from others. They may use more indirect and devious means to get the attention and affection they appear to crave. However, when others do not respond appropriately, such individuals will experience anger and resentment but deny such negative affect or not express those feelings openly or directly.

MMPI-RC

As noted, recently, items on the MMPI-2 were studied for the development of restructured clinical (RC) scales (Tellegen et al., 2003). These scales were found to have improved validity. The number of items on the RC antisocial scale is 22 compared to the 50 on Scale 4 of the MMPI-2; only 9 items overlap between the two (i.e., 33 %), and there are 13 items on the RC scale that are not on Scale 4. The correlation between the Psychopathic Deviate scales and the RC antisocial scale ranges from .55 to .64. (e.g., Greene, 2011, p. 348). Per the manual, high scores on the antisocial scale are associated with individuals who are likely to engage in various antisocial behaviors, tend to behave aggressively toward others, and are viewed as being antagonistic, angry, and argumentative. They may engage in antisocial acts such as lying or cheating. High scorers find it difficult to conform to societal norms and expectations and may, as a result, experience legal difficulties. They are at increased risk for engaging in substance abuse and sexual acting out. They are likely to have conflictual family relationships and histories of poor achievement (p. 56).

Greene (2011) reviewed studies of the RC 4 scale and found that there were statistically significant correlations with criminal history, juvenile delinquency, antisocial behavior, and impulsivity. Of note, correlations with elevated scores on RC 4 scale and Disconstraint (DSIC) scale and with a lack of Social Responsibility (Re scale) were particular high (i.e., .64–.78 and –.72, respectively). However, as noted previously, given the greater transparency or face validity of the RC 4 items, there can be an increased likelihood of dissimulation on the part of an offender.

MCMI-III

Regarding antisocial traits and predispositions, several MCMI-III scales have significance. Scale 6A (Antisocial) shows elevations when offenders have reported behavioral problems in school, having been in trouble with the law, and doing what they want without worrying about what others might think of them. Further, punishment never stops them from doing something they want to do. They are good at making up excuses when they get into trouble. They are generally responsible and impulsive. Of note, for the MCMI-III antisocial scale, there is good evidence of reliability and convergent validity with Scale 4 of the MMPI-2 as well as the results of structured and semi-structured diagnostic interviews (Craig, 2006). Scale 5 (Narcissistic) shows elevations when persons endorse themselves as special or superior individuals who deserved special attention from other people. They do not blame others who take advantage of others who "allow" that to take place. They indicate awareness that persons who know them (e.g., their families) perceive them as selfish and only think of themselves. Finally, Scale 6B (Sadistic/Aggressive) evidences elevations when individuals indicate that they get personal pleasure and satisfaction in ways that humiliate others. They report that they are critical of others who annoy them and are rough or mean to others to "keep them in line." Such persons indicate that they often say cruel things about others just to bring them unhappiness and report that they think it is important to control others. On Scale 4 (Histrionic), elevations result when persons indicate that they see themselves as particularly sociable, outgoing, and looking to make friends. They recognize that they are constantly looking for signs of acceptance and approval from others.

PAI

On the PAI, an obvious scale of potential interest is the Antisocial Features scale (ANT) "designed to assess personality and behavioral features relevant to the construct of antisocial personality and psychopathy" (Morey, 1991, p. 18). The description associated with a significantly elevated score on the ANT scales is as follows: "Individuals have a history of difficulties with persons in positions of authority and have trouble following social conventions. They have a callous attitude toward and lack empathy for other people. They feel little responsibility for the welfare of others and have little loyalty to their acquaintances. They have a willingness to take risk and a desire for novelty. Their behavior is potentially dangerous to themselves and others around them" (Weiner & Greene, 2008). Per the PAI manual, persons with significantly elevated scales are viewed as impulsive, hostile, having a history of antisocial acts, exploitative in relationship, unreliable, and irresponsible. Persons with markedly elevated scores are viewed as likely characterized by prominent features of antisocial personality disorder. Morey (2007) has reported that the ANT scale demonstrated its largest correlations with MMPI scales measuring antisocial personality as well as with measures of psychopathy.

Three subscales were developed to measure distinct facets of antisocial features: Antisocial Behaviors, Egocentricity, and Stimulus-Seeking. Antisocial Behaviors addresses a history of conduct problems, antisocial acts, and criminality. Egocentricity (ANT-E) measures self-centered, exploitative, callous, and remorseless behavior; elevations indicate little responsibility or loyalty toward others or concern about roles as spouse, parent, or employee. Effectively, "ordinary" narcissism is the target of this subscale. Stimulus-Seeking (ANT-S) is directed at a tendency to seek thrills and excitement and low boredom tolerance as manifested by reckless and potentially dangerous behavior. The PAI also includes an Aggression scale (AGG) that "provides an assessment of attitudinal and behavioral features relevant to aggression, anger, and hostility." Subscales tape aggressive attitudes (easily angered, difficult controlling anger, perceived hostility) and both verbal and physical aggression. Salekin, Rogers, and Sewell (1997) found that PAI had poor to mode predictive validity. Walters, Diamond, Magaletta, Geyer, and Duncan (2007) reported that the PAI ANT scale is best viewed as a dimensional or severity measure, identifying the degree of self-reported antisociality and not distinguishing categorical classification of persons as antisocial or not.

As noted, a significant issue with the PAI is that the items are face valid and transparent. Consequently, it is not uncommon to find persons with highly antisocial histories per records, and interview data endorse average or low levels of traits on one or more of these scales, presumably in an attempt to provide a positive impression. Regardless of the validity scale scores, low levels of self-reported antisociality on the PAI cannot negate the reality of repeated and/or severe historical manifestations of antisocial behavior and attitudes. Consequently, it does not seem surprising that in a sample of 1,400 higher-risk sexual offenders, the self-reported antisocial and aggression scales were not predictive

of sexual offense recidivism as measured by arrests during a follow-up period (e.g., Boccaccini, Murrie, Hawes, Johnson, & Simpler, 2010).

The MSI II

Antisocial personality disorder and/or its traits can be diagnosed using the MSI II Antisocial Personality Disorder scale because the scale was developed based on the DSM-III criteria. The Antisocial Behavior (AB) scale of 50 items represents a sum of two 25-item scales: a Conduct Disorder Index and a Sociopathy Index (including Exploitive and Aggressive Behaviors, Stealing Behavior, Financial Irresponsibility, Arrests, and Detentions). Stinson and Becker (2008) compared the MSI II Antisocial Behavior (AB) scale with the PCL-R (Factor 2) and the MCMI Antisocial scale. They demonstrated that the MSI II AB scale correlated significantly with both the MCMI Antisocial scale and Factor 2 of the PCL-R. They also found that the MSI II AB achieved the highest correlation (.92) of the three when measured against known external criteria for antisocial behavior.

The MIDSA

The MIDSA provides scales regarding Juvenile Antisocial (Juvenile Drugs/Alcohol, Juvenile Delinquency, Juvenile Assault), Adult Antisocial (Alcohol and Drug Abuse, Conduct Disorder, Fighting and Assaultive Behavior), Psychopathy and Hypermasculinity (Lack of Perspective Taking, Lack of Empathy, Conning and Superficial Charm, Impulsivity, Negative Masculinity, and Hostility Toward Women), and Pervasive Anger scales (Constantly Angry, Physical Fighting, Cruelty to Animals, and Fantasies of Hurting People). Thus, there are a number of MIDSA scales and subscales that relate to antisocial and/or psychopathic traits or conditions. Most importantly, the MIDSA includes six scales that assess various components of psychopathy and negative masculinity, which the authors argue are correlated domains related to increased probability of sexually coercive behavior against women and age-appropriate females. Two scales relate to *Emotional Detachment*; *Lack of Empathy* involves reporting a lack of feelings or concern for the misfortunes of others, while a *Lack of Perspective Taking* involves reporting difficulty seeing another's perspective and considering both sides of an issue. Another scale *Conning and Superficial Charm* involves admitting to conning others, taking advantage of others, manipulating others by lying, and charming others into doing what one wants. An *Impulsivity* scale allows respondents to report acting on impulse, losing control, and moodiness. Finally, *Negative Masculinity/Toughness* provides the opportunity for persons to endorse attitudes of toughness and "masculine honor defending," while *Hostility Toward Women* regards reporting negative attitudes toward women and endorsement of cognitive distortions about rape.

PCL-R

As noted, the PCL-R is viewed by many researchers and professionals as representing the "gold standard" measure of a propensity for future criminal and violent behavior. Beyond simply the largely behavioral criteria of ASPD, this measure of psychopathic traits also includes measures of various maladaptive personality traits such as need for stimulation, conning/manipulative, lack of remorse/guilt, callous/lack of empathy, shallow affect, and heightened sense of self-worth. The PCL-R has an "asymmetric relationship" with ASPD; "the majority of offenders with high PCL-R scores meet the diagnostic criteria for APD [ASPD], whereas the reverse is not true" (Book et al., 2006, p. 161). Thus, higher scores on the PCL-R identify a subgroup within the criminal population (for which there is substantial evidence relative to risk for various forms of future criminal and violent behavior, including sexual offending). In addition, the PCL-R, as a dimensional measure, provides a range of scores for individuals, while a DSM-IV/DSM-5 diagnosis is a categorical determination (e.g., a person has demonstrated three or more specified behaviors along with evidence of early onset antisocial behaviors). However, when ASPD is scored dimensionally (or prototypically), it is highly and more strongly correlated with ratings on the PCL-R, particularly Factor 2 (Hare, 2003a, 2003b). In short, a higher PCL-R rating indicates the presence of greater antisociality and likely a particular form of antisociality. Both the Structured Risk Assessment: Forensic Version (SRA: FV; Thornton & Knight, 2014) and Violence Risk Appraisal Guide-Revised (Rice, Harris, & Lang, 2013) utilize one or more facets of the PCL-R as proxies for antisocial aspects of a person's history.

Relational Style, Social Functioning, and Socioaffective Issues

A consistent element of theories of sexual offending is that a significant subgroup of sexual offenders are compromised in their ability to develop and maintain healthy interpersonal relationships that provide support, validation, and opportunities for intimacy. Sometimes this appears to be a function of disinterest or inability in interacting with age-appropriate peers, both emotionally and sexually, and sexual offenders who are characterized by emotional distance or even detachment in their social relationships. A more extreme form of

this aspect of personality relates to persons who are callous, who lack the capacity for empathy with others, and whose social behavior is not affected by feelings of guilt or distress at harming others. In other instances, individuals appear to manifest significant anxiety about interacting with age-appropriate sexual partners and, as a result, have great difficulty initiating or maintaining appropriate intimate peer relationships, socially and/or sexually. Finally, another group of sexual offenders appear to have interest but lack the skills to maintain stable relationships due to issues in regulating their negative affect and relationship expectations, leading to frequent interpersonal conflict and relationship terminations or breakups.

MMPI-2

On the MMPI-2, Scale 0 (Social Introversion) was designed to assess an individual's tendency to withdraw from or approach social interactions. All but one of the 70 items in the original scale are maintained in the updated MMPI-2 version of the scale. As with Scales 3 and 4, persons with elevated scores on Social Introversion are of particular note relative to propensity and risk for sexual offending. High scorers tend to be persons who are very insecure and uncomfortable in social situations. They tend to be shy, reserved, timid, and retiring such persons may feel more comfortable either when alone or with a smaller group of known individuals, and they do not participate in many social activities. In particular, they may display particular discomfort around members of the opposite sex. High scorers tend to lack self-confidence, may be hard to get to know, and can be described by others as cold and distant. Thus, the common descriptors for persons who score high on scale 0 are socially introverted; very insecure and uncomfortable in social situations; tend to be shy, reserved, and committed retiring; feel more comfortable alone or with a few close friends; do not participate in many social activities; may be quite over control to not likely display feelings openly or could be described as others is cold and distant; are likely to be troubled by their lack of involvement with other people; and issue particular discomfort around members of the opposite sex.

MCMI-III

Results on the MCMI-III can provide significant information about the nature of an individual's self-reported social functioning. Persons elevated on the borderline scale tend to manifest emotional instability that is characteristically manifest in the interpersonal relationships, with intense ups and downs in those relationships. Elevations on the Schizoid scale identify persons who tend to be socially detached, prefer solitary activities, seem aloof, apathetic, and appear distant from others with difficulties in forming and maintaining relationships. Thus, schizoid traits identify persons who are unable to or uninterested in emotionally connecting with other persons. Persons elevated on the Schizotypal scale appear even more extreme in this direction: individuals seem "spacey," self-absorbed, eccentric, cognitively confused, as well as being socially indifferent. A more common presentation is persons who are elevated on the Avoidant scale; such individuals tend to be particularly socially anxious due to perceived expectations of rejection by others and fearful. Persons elevated on the dependent scales tended to be individuals that are passive, submissive, and feel inadequate; they generally lack autonomy and initiative. Individuals who show elevations on the passive-aggressive (negativistic) scales are likely to be persons who are disgruntled, argumentative, petulant, and negativistic; they keep others on edge.

PAI

Several scales on the PAI speak to aspects of problematic social relations, in particular, elevations on subscales of the borderline scales (BOR), particularly those for subscales measuring affective instability and negative relationships. In the former, the descriptors for elevated scores are "Individuals are highly responsive emotionally, manifesting rapid and extreme mood swings. Their affective instability involves a propensity to become rapidly anxious, angry, depressed, or irritable." On the latter subscale, "Individuals repeatedly become involved in relationships that are very intense and chaotic. When their expectations are not met in relationship, they feel betrayed and exploited." In addition, the PAI's Non-Support scale "provides a measure of perceived lack of social support, tapping both the availability and quality of the respondent's social relationships." The PAI Dom (Dominance) scale measures the extent to which a person is controlling, submissive, or autonomous in interpersonal relationships"; thus, both high (controlling) and low (submissive) scores are of potential interest in evaluating sexual offenders. Finally, the PAI Warmth scale "provides a measure of the extent to which a person is empathic, engaging or rejecting, and mistrustful in interpersonal relationships." Low scores are indicative of someone who has little interest or investment in social interactions or is distant in such relationships.

MIDSA

On the MIDSA, there are several scales that assess the presence of intimacy, attitudes about masculinity, sexual adequacy, and anxiety related to females and issues with

historical caretakers. On the MIDSA, Relationships with Important Caregivers was measured via two scales. *Acceptance-Neglect* is a scale of items that describe ways in which the caregiver expressed love and acceptance to the person. Conversely, Emotional Abuse consists of 11 items, most of which describe the frequency that the caregiver engaged in verbal abuse. The capacity or existence of intimacy is assessed via two scales. One, *Friendship Intimacy* involves reporting whether relationships with important friends included behavioral and emotional support (if the individual has reported that they had such friends). The other scale, *Romantic Intimacy* with females, involves reporting that their relationship was emotionally and behaviorally supportive if the individual had reported a relationship that had lasted more than three months and in which he felt close to the girl or woman. On the MIDSA, there are several scales related to Masculine and Sexual Inadequacy scales. The *Masculine Adequacy* scale consists of items relating to being manly and good in fights and in sex. The *Anxiety with Women* scale consists of items relating to feeling anxious, nervous, inadequate, and guilty around women and sex. *Sexual Performance Anxiety* scale consists of items that measure a man's anxiety about their penis and their sexual performance. Finally, the *Erectile Dysfunction* scale consists of items regarding difficulties with erection and ejaculation.

Distorted Cognitions and Attitudes Related to Sexual Offending

Historically, several lines of thinking have identified the possibility that sexual offending may be related to a variety of "distorted" or "dysfunctional" beliefs or attitudes. These have been referred to as "cognitive distortions" or "offense-supportive attitudes." Both Ellis (1957) and Beck (1970) postulated that distorted thinking was a central factor in the development and maintenance of depression. Later, Abel et al. (1988) also applied the term "cognitive distortions" to refer to seemingly unusual beliefs regarding atypical or deviant sexual behavior, initially among child molesters (e.g., justifications, perceptions, and judgments used to rationalize sexual offending behavior). Subsequently, the range and conceptualization of such distorted attitudes and beliefs among sexual offenders have expanded substantially. In 2011, Schlank wrote: "Cognitive distortions often used by sexual offenders include learned assumptions, self-statements, and attitudes that facilitate the offender's minimization, justification and denial of his sexual offenses" (pp. 20–21). She noted that such conditions allowed sexual offenders to continue their sexual offending without experiencing feelings of guilt, anxiety, and shame. The study of cognitive distortions more generally in psychology has led to the conceptualization of schemas as a structured or organized patterns of thinking involving preconceived ideas about oneself and situations that strongly influence the processing and interpretation of information derived from experience. "Schema" is viewed as rooted in both an individual's culture and their own specific experiences. Prominent among schema is the notion of a "self-schema," related to a belief system about oneself and "event schemas" involving belief system about general and specific situations. By virtue of their structure, schemas are seen as both influencing a person's attention and of being resistant to contradictory information; to the degree that schemas are incorrect or maladaptive, they lead to misperceptions and misinterpretations of experience. Ward (2000) suggested that offense-supportive statements by sexual offenders were the products of schemas or as Ward termed them "implicit theories." Gannon (2009) has suggested the importance of the "external" world's role in supporting sexual offender's misperceptions and maladaptive beliefs and attitudes.

During this same period, investigators like Hanson and Thornton (e.g., Hanson et al., 2007; Knight & Thornton, 2007) have identified offense-supportive attitudes as beliefs that justify or excuse sexual offending in general. It was noted that such attitudes showed a small but statistically significant relationship with sex offense recidivism in the most recent meta-analysis (e.g., Hanson & Morton-Bourgon, 2004). More recently, Helmus, Hanson, Babchishin, and Mann (2013) studied 46 samples involving approximately 14,000 persons and found a "small, but reasonably consistent relationship with sexual recidivism," more so for child molesters than for rapists. They concluded that attitudes supportive of sexual offending are PMRF for sexual reoffending. However, as Mann et al. (2010) and Thornton and Knight (2014) have suggested, while this dimension appears to be a propensity, there are clear problems with identifying and measuring such attitudes, particularly in adversarial settings, including supervised release (e.g., Hanson et al., 2007). Offense-supportive attitudes are typically measured with self-report measures; limitations of such methodology are their susceptibility to impression management due to their obvious transparency and the inclusion of items expressing "post hoc" justifications as opposed to actual attitude statements. Consequently, offenders in a forensic, adversarial, or mandated context may not endorse the presence of such attitudes because of implications for their potential disposition. Unfortunately, there is little evidence "that evaluators are able to distinguish between feigned and sincere remorse, particularly in adversarial settings" (Mann et al., 2010, p. 200). Consequently, if such attitudes are endorsed, they most likely represent "true positive" reports on the part of examinee; however, if the individual does not endorse such attitudes, it cannot be concluded that particular maladaptive attitudes are not present.

Self-report obtained by the MMPI-2, MMPI-2RF, MCMI-III, and PAI can provide potentially useful information regarding various attitudes and beliefs that may be related to sexual offending; consequently, these tests of general personality predispositions can be extremely relevant to this domain, even though these tests were not specifically developed to provide "sexual offense"-specific information.

MSI/MSI II/MIDSA

Both the MSI II and the MIDSA provide a means of measuring such cognitions and attitudes.

The MSI II Justifications scale is a measure of the degree and manner in which sexual offenders explain their sexual offending to others. On the MIDSA, the *Child Molester Cognitive Distortions* scale consists of items that endorse attitudes conducive to or supporting sexual behavior with children, including the items that focus on the theme that children are sexual beings and sex with them is like sex with adults and other items that downplay the possibility of any harm to the child. Further, the MIDSA contains a number of scales that speak to distorted attitudes generally and/or related to antisociality and, more specifically, deviant sexuality (e.g., Hostility Toward Women, Negative Masculinity, Molester Cognitive Distortions).

The Accountability scales of the original MSI provide several measures of attitudes that may support sexual offending. The Cognitive Distortions and Immaturity scale measures the extent to which an offender adopts a victim stance in relationship to his present offense and measures levels of accountability accepted for offending behaviors. The Justifications scale taps various potential justifications sexual offenders may use to explain their offenses.

The MSI II also provides a number of scales that serve to provide measures of criminogenic attitudes generally and most specifically regarding past criminal sexual behavior. The Denial (Dn) scale assesses an offender's use of excuses for having engaged in sexual contact with someone who has accused him of sexual impropriety, such as being mixed up, under the influence of alcohol, etc. The Justifications scale identifies a client's lack of ability to take responsibility for his sexual behavior by placing blame onto others and on circumstances beyond his control, such as that his sexual offense occurred because he had too much alcohol or drugs.

Sets of measures used in the MSI II are designed to assess cognitions and attitudes associated with sexual deviance. Based on an empirical scaling procedure, if an offender obtains a score like the group with the known attribute (e.g., child molesters or rapists), it is more likely that the offender will evidence distorted cognitions (thinking errors) and sexual attitudes similar to the criterion sample. Two criterion-oriented scales are reported by the MSI II. The *Molester Comparison scale* is an empirically scaled measure using demographically comparable, but distinctly different samples involving admitting adult male sexual offenders who manipulate, rather than force their victims (criterion group sample) and normal adult males (control group sample). The *Rapist Comparison scale* is also an empirically based measure using demographically comparable but distinctly different samples of admitting adult male sexual offenders who primarily used force during a sexual assault. An offender's score is compared to both the criterion-related and normal group samples, and the results report the degree to which he scored as similar to the criterion group(s). Thus, the interpretation of the self-report of the particular offender is identified by the degree to which the results suggest a level of commonality in thinking and behavior between the client and the reference group of adult male sexual offenders (e.g., not similar, somewhat, moderately, or highly similar).

Other Measures

In addition, the Abel–Becker Cognition scale (ABCS; Abel et al., 1989) was developed to measure distorted attitudes regarding sexual behavior between an adult and child. The ABCS is a questionnaire that asks an individual to indicate his relative agreement on a 5-point scale (from strongly agree to strongly disagree, including neutral) with beliefs about the appropriateness of adult sexual contact with youth. The ABCS includes what might be considered to be rationalizations, justifications, and cognitive distortions used by child molesters to justify their child molestation behavior. The ABCS is a very transparent instrument, with responses denying the appropriateness of sexual contact between adults and youth strongly associated with social desirability. Consequently, any positive response to the items on the ABCS is significant because of the high face validity.

Similarly, the Burt Rape Myths scale was designed to assess cognitions related to rape victims (Burt, 1980). However, beyond the transparency of these scales, Schlank (2011) pointed out other methodological weaknesses (e.g., the Likert scale response option of each scale allowed for a person to assume a "neutral" position on items). Bumby (1996a, 1996b) developed two scales for MOLEST and RAPE on a small "in treatment" sample, which were viewed as less transparent and more free from "social desirability"; they also utilized a Likert scale that eliminated a possible neutral response. Per Schlank 91 % of high-risk sexual offenders endorsed a higher percentage of cognitive distortions on the Bumby scales relative to the Abel–Becker and Burt scales, suggesting that the Bumby scales might be more useful (relative to other such scales) in identifying such need areas and for treatment purposes. However, Arkowitz and Vess (2003), with a similar group of offenders, found that

rapists and child molesters in their sample endorsed markedly fewer cognitive distortions than the sexual offenders in Bumby's original study (Bumby, 1996a, 1996b). They suggested that current self-report measures such as the MOLEST and RAPE scales are too susceptible to a socially desirable response set to provide useful data with high-risk sexual offenders (e.g., those who were involuntarily committed for treatment). Pervan and Hunter (2007) also found issues with the MOLEST and RAPE scales, particularly the latter. They also noted that offenders reporting "higher" self-esteem selected more pro-social or socially desirable attributes than those who endorsed lower self-esteem.

Pemberton and Wakeling (2009) investigated a particular domain of distorted attitudes among sexual offenders, namely, sexual entitlement. In their review of extant research and in their own study, they found evidence for four forms of sexual entitlement: (1) "I can offend because women/children are my possession/property"; (2) "I can offend because it's my right as a husband/partner/ father"; (3) "I can offend because it is my birthright as a man"; and (4) "I can offend because only I matter." In addition, their analyses identified two additional common forms of sexual entitlement: (5) "I can offend because the victim owes me" and (6) "I can offend because I have the power." They noted that the third and fourth form of sexual entitlement were more common among rapists, while the other four were found among both rapists and extra- and intrafamilial child molesters.

Self-Management

Self-regulation has been said to refer to a person's ability to formulate and enact goal-directed behavior without immediate external control or to take responsibility and control one's own thoughts, feelings, and actions. A number of personality issues have been viewed as related to self-regulation, including (1) relative impulsivity and/or recklessness, (2) rapid and intense anger, (3) noncompliance with general social mores or more specifically social regulations that apply to a particular individual (e.g., noncompliance with supervision, the demands of schools, or other social programs), (4) dysfunctional or maladaptive coping, and (5) substance abuse.

Aspects of impulsivity are measured by several of the MDPT. As noted earlier, persons who score relatively high on Scale 4 of the MMPI-2 (e.g., the Psychopathic Deviate scale) are typically very impulsive persons who strive for immediate gratification of impulses, do not plan their behavior very well, act without considering the consequences of their actions, tend to be very impatient, and have a limited frustration tolerance. Their behavior may involve poor judgment and considerable risk-taking, they tend not to profit from experiences, and they find themselves in similar difficulties on repeated occasions. Similar attributes are associated with elevations the RC 4 (antisocial scale) of the MMPI-RF. Further, on the MMPI-2, an elevated score on the PSY-5 scale DISC (for Disconstraint) is associated with high risk-taking and impulsive behavior. Such individuals appear to "be less bound by moral restraints than other people and show callous disregard for others."

On the MCMI-III, elevations on any of the three scales [and more specifically, the Grossman Facet scale (GFS) scores within each of those scales] are associated with heightened impulsivity including the antisocial (GFS: Expressively Impulsive and Acting-Out Mechanism), sadistic (GFS: Temperamentally Hostile, Eruptive Organization), and borderline scale (GFS: Temperamentally Labile).

As indicated, issues with alcohol and drugs are often considered to fall under the risk domain of self-regulation. In addition, studies of both Scale 4 of the MMPI-2 and RC 4 of the MMPI-RF show a particularly strong relationship between elevated scores on RC 4 and both alcohol and drug abuse history (Greene, 20011). In addition, elevated scores on the MacAndrews Alcoholism Scale-Revised (also associated with extraversion and thrill-seeking), the Addiction Potential scale and the Addiction Admission scale (AAS) can all indicate substance abuse and related issues. The MCMI-III includes straightforward scales for persons to endorse drug or alcohol problems. The PAI also includes scales that provide measures of alcohol problems (ALC) and drug problems (DRG). Both provide an index based on the offender's self-report of behaviors, and consequences relate to the use, abuse, and dependence of alcohol and drugs, respectively. Higher scores are associated with abuse and dependence, respectively. Morey and Hopwood (2006) have reported that in true clinical samples, these scales are able to differentiate patients with problems with substance abuse from those without such problems. However, the authors note: "Because the items for ALC and DRG inquire directly about substance use, the scales are susceptible to denial" (p. 102). Unfortunately, most available measures of alcohol or drug abuse are quite transparent; further, they may not capture the propensity to use alcohol or drugs in persons who have been in institutional settings for extended periods of time or who deny or are defensive about their inclination to consume alcohol or drugs.

Relative to self-management, the MIDSA includes four *Pervasive Anger* scales that assess "constant" anger (instances of anger and failure to control one's temper including grouchiness, frequent anger, and temper tantrums), fighting (instances of physically assaultive behavior against both males and females as an adult), aggression toward animals, and nonsexual aggressive fantasies (having fantasies of hurting other people or seeing them hurt).

Diagnoses or Mental Disorders

Several studies have demonstrated that a considerable number of sexual offenders are characterized by elevated rates of psychiatric disorders and other psychopathological conditions (e.g., Kafka & Hennen, 2002; Marsh et al., 2010; Raymond et al., 1999). Långström, Sjöstedt, and Grann (2004) examined psychiatric disorders among a nationwide, representative cohort of sexual offenders. They found that alcohol use disorder was the most frequent diagnosis, followed by drug use disorder, personality disorder, and psychosis; each of these conditions was associated with increased risk for sexual offense recidivism. They noted that their diagnoses were based on only those sexual offenders who had been admitted to psychiatric hospitals as inpatients likely leading to a significant underestimation of the true prevalence of psychiatric disorders in general. More recently, Marshall (2007) has reviewed the extant literature on primary and comorbid mental health conditions among sexual offenders. Among the reports in the literature, the following rates of such conditions were identified, depending on sample and setting: mood disorders (5–95 %), anxiety disorders (3–39 %), ADHD (36 %), substance-related disorders (8–60 %), antisocial personality disorder (35–40 %), and any personality disorder (33–52 %). In addition, Marshall noted the "general inadequacy of DSM to fully cover all those people who seek and need clinical treatment… It often forces clinicians to use the 'not-otherwise-specified' (NOS) category for various types of problems. As it turns, the NSO category is the most common diagnosis appearing in general clinical practice…" (p. 20).

Clearly, each of the MDPT has the potential to offer considerable, reliable, and valid information that can be utilized in ascertaining diagnoses for sexual offenders. As would be expected, each of the broadband test manuals indicates that a diagnosis should never be made directly or exclusively from the finding of any psychological test. That is, the results of psychological testing should be considered as one source of information that supports, does not support, or is equivocal/silent about the degree to which a diagnosis may characterize a sexual offender at the current time and context; again, the most compelling conclusions about current diagnoses are those which rely on and integrate as many sources of information as possible. It is also of particular note that Rogers (2003) has emphasized that a common error among MHPs is the misinterpretation of the so-called Within Normal Limits (WNL) results on tests like the MMPI-2 when they erroneously conclude that the lack of clinical elevations reflects an absence of psychopathology. Rather, as Rogers emphasizes: "The 'WNL' is often found in chronic populations and cannot be interpreted as a 'healthy' profile. The 'WNL' profile is the most common patient profile, occurring in approximately 30 % of referrals" (p. 318, emphasis in original).

Regarding a past history of childhood psychiatric disorders, on the MIDSA, symptoms associated with attention-deficit/hyperactive disorder (ADHD) and oppositional defiant disorder (ODD) during childhood are measured via several scales: *Attention Deficit* (being careless, distractible, and disorganized before the age of 12 years), *Inhibition Difficulties* (indicating that they found it difficult to inhibit verbal and motoric behaviors as children), and *Oppositional Behavior* (reporting that they tended to be hateful, angry, and argumentative and that they often refused to obey rules when they were children).

The determination of the presence of personality disorders can often be supported by the findings of the results of computerized interpretations of the MDPT as well from the analysis and descriptions of the various interpretive books for the MDPT. For sexual offenders, the Pearson and PAR interpretations of the MMPI-2 and the MCMI-III as well as the PAR interpretation of the PAI are often, but not always, sources of identified personality disorders as likely or to rule out diagnoses. The interpretations of the MCMI-III, based on its scoring method, can potentially identify the degree to which maladaptive personality features and traits, as well as "full" personality disorders, characterize an individual (within a larger contextual perspective). More so than the Pearson interpretations, the PAR interpretations of the MMPI-2 and the MCM-III provide more clear statements of the likely presence of personality disorders.

In addition, there are also several additional self-report questionnaires that can also be sources of information about the degree to which a sexual offender views himself as characterized by maladaptive personality traits. The Personality Diagnostic Questionnaire (PDQ-4+; Hyler, 1994, 2008) consists of 99 true–false items, each of which corresponds to the specific personality traits enumerated by DSM-IV. Similarly, the Structured Clinical Interview for DSM-IV-Axis II Questionnaire (SCID-II-Q; Spitzer et al. 1990a, 1990b) is composed of one item per diagnostic criterion. However, the SCID-II-Q, the questions regarding antisocial personality disorder, only includes the items on conduct disorder based on the apparent assumption that individuals are less likely to acknowledge adult antisocial behavior. Consequently, the PDQ-4+ by virtue of including items regarding adult antisocial personality traits may be a better choice for evaluations of sexual offenders. Since the PDQ-4+ is a paper questionnaire (e.g., not a computerized answer sheet), one can also provide permission and encourage an offender to write comments about their responses to questions about particular diagnostic criteria. Guy, Poythress, Douglas, Skeem, and Edens (2008) have shown that the responses on the PDQ-4 by over 1,300 criminal and substance abuse offenders were strongly related to scores (e.g., simple dimensional symptom count) on the PAI ANT scale and interview responses to the SCID-II Antisocial Personality Disorder scale. However, those offenders formally identified as being characterized as

antisocial personality disorder were different among the three measures. This is, in part the result of method variance, the diagnostic concordance of interview, and self-report measures of antisocial behavior were more limited suggesting that while self-report screens may identify a pool of persons with likely ASPD, structured interviews provide more rigor in making such diagnoses.

However, as should be apparent, the specific statements endorsed by an offender via a self-report instrument represent a form of self-representation. Consequently, if the actuarial interpretive comments from the MMPI-2, MCMI-III, or PAI indicate the presence of criteria of antisocial or other personality disorders, that can provide particularly important information about the offender since those endorsements are the product of the offender's own self-report. Again, there appear to be relatively few false positives when offenders endorse items that indicate particular personality disorder diagnoses.

Alternately, evaluators will certainly encounter cases where the offender's criminal and personal history (as evidenced in the available archival records) and/or responses to diagnostic interviews clearly indicate the presence of specific relevant personality disorders, but the results of the standardized personality tests do not indicate the presence of one or more specific personality disorders. In those cases, it can be informative to take the time to examine the set of items that compose the relevant test scales and compare the offender's responses to those items and determine if he has responded to those items in a manner congruent with the existing archival or interview data. In those cases, the evaluator can identify that the records and/or interview responses indicate the presence and severity of the personality disorder of concern and note that the offender's self-report per one or more tests does not indicate such a disorder, suggesting that the maladaptive traits may be ego-syntonic (such that the offender is not aware of or minimizes such traits) or that the offender is denying specific traits or behaviors that are identified in the existing records and/or interview responses.

The structured diagnostic interviews described earlier can also be utilized to acquire information that can provide basic information regarding the existence of potentially relevant traits of personality disorders and in combination the definition of and determination of personality disorders themselves. Thus, the SCID-II, the PDI-IV, the SIDP, etc., provide useful information collected from the offender and interpreted by the evaluator that can provide the foundation for identifying specific maladaptive personality traits and typically multiple personality disorders that may characterize an offender.

Similarly, and perhaps more clearly, the results of the offender's responses to the MSI II scales can provide a basis toward concluding that the offender has the characteristics of a pedophilic, coercive/rape, or exhibitionistic paraphilia. As the developers have noted, the MSI II contains 11, 12, and 4 items placed in the past tense, respectively, in the subscales regarding deviant sexual fantasies related to child molesting, rape, and exhibitionism. In addition, the MSI II contains 12, 8, and 4 items placed in the past tense, respectively, in the subscales regarding urges as measured by pre-assault behaviors (e.g., grooming or "cruising" as methods to find or "obtain" a victim related to child molesting, rape, and exhibitionism). Finally, the MSI II contains two assault subscales for each paraphilia which are summed to reflect behavior related to a specific paraphilia: (1) for child molesting there are 10 and 6 items in the Sexual Assault and Aggravated Assault subscales; (2) for rape there are 12, 4, and 5 items in the Sexual Assault, Rape Sadism, and Violent Assault subscales; and for exhibitionism, there are 8 and 4 items in the Sexual Assault and Advanced Assault subscales. Scores or endorsements in each of these subscales are identified in the report and then summed to provide a Sexual Deviance scale for child molesting, rape, and exhibitionism, which then provides an account of his self-reported behaviors and also helps diagnose recurrent paraphilia behaviors (which then can also be compared to his known record of potentially paraphilic behaviors). Then, that summed Sexual Deviance score is recorded onto the MSI II Profile form, which contains standard T-scale norms. The offender's Sexual Deviance scores are then compared to MSI II scores for the nationally standardized samples including different types of sexual offenders, persons who deny committing an offense, end-of-treatment subjects, and normal (nonsexual offender) males. Taken together, the results from the MSI II Sexual Deviance subscales may provide information that suggests or directs confirmation of one or more paraphilic disorder.

Of note, it seems likely that, in the near future, the field will move to a more dimensional (versus categorical approach) to considering sexual offenders. This seems likely to occur both as a result of the increasing evidence for "crossover" paraphilic behavior among a large subset of sexual offenders and part of the larger movement in the mental health field to shift to a dimensional approach to conceptualizing mental disorders (already reflected in the dual methods of DSM-5 for classifying personality disorders). As Marshall and Kennedy (2003) wrote a decade ago: "…a description of the acts of sexual offenders, along various dimensions would be more useful than an attempt to categorize these offenders…Such dimensional ratings should provide a better guide to assessors, treatment providers, researchers, theoreticians and the courts." (p.15)

Information regarding antisocial personality disorder and/or its traits can be also be provided by the MSI II Antisocial Personality Disorder scale because the scale was developed based on the DSM-III criteria. The Antisocial Behavior (AB) scale of 50 items represents a sum of two 25-item scales: a Conduct Disorder Index and a Sociopathy Index (including

exploitive and aggressive behaviors, stealing behavior, financial irresponsibility, arrests and detentions).

While the available meta-analyses have not identified alcohol or drug abuse dependence as a consistent risk factor for sexual offense recidivism, those conditions are commonly found among sexual offenders. In addition, anecdotally, sexual offenders frequently report that such substance use has been related to their sexual offending. Substance abuse has been identified by some as a criminogenic need related to self-regulation and/or as predisposing factor for sexual offending. In addition, it appears to be a key situational component to nonsexual predisposing conditions to sexual offending (e.g., Abbey, 2011; Hoberman, 2014). All of the broadband PAP tests provide one or more specific scales that tap substance abuse. The MacAndrew's revised scale on the MMPI-2, when elevated, suggests the possibility of a drug or alcohol abuse problem, as does an elevation of the Addiction Potential scale (APS). In addition, it should be noted that the Pd scale, particularly when a high clinical scale, is the MMPI-2 profile configuration most common among alcohol- and drug-abusing populations. The MCMI-III provides both an Alcohol Dependence and Drug Dependence scale, while the PAI contains both Alcohol Problems (ALC) and a Drug Problems (DRG) scales. Each of these scales on the MCMI-III and PAI provides direct measures of self-reported alcohol and drug abuse; however, the items are very transparent and thus subject to impression management.

Treatment Amenability, Planning, and Outcome

The major MDPT provide varied information regarding several areas related to the process and direction of psychosocial treatment. Butcher (1990) wrote that psychological testing can provide information about an individual's motivation, attitudes, defensive style, personality traits, and symptoms, much of which a person may be unaware of or reluctant to admit to directly (particularly in an adversarial context). Thus, psychological testing can provide a normative framework from which treatment motivation and "problems" can be viewed.

SPA can provide important information about an offender's general amenability to treatment. As Butcher, Graham, Kamphuis, and Rouse (2006) noted:

> Unfortunately, the assumption that patients are ready to engage in the treatment process is not always well founded. The MMP-2 validity indicators provide a direct test of patient's readiness for treatment. By directly assessing response attitudes, the therapist can evaluate the patient's level of cooperativeness and encourage or reinforce the willingness toe engage in the task of self-disclosure…patients who produce defensive, uncooperative test patterns, as reflected in the test validity scores, may likewise be relatively inaccessible to the therapist during sessions. (p. 4)

Weiner and Greene (2008) offer similar comments on the application of validity scales generally to amenability to treatment stating:

> Individuals who provide extremely self-favorable descriptions of psychopathology see their problems as less troubling to themselves, and, hence, are less motivated to change. Their problems also may be more chronic, and consequently, more difficult to treat, if they remain in treatment. None of these potential causes of an extremely self-favorable description of psychopathology is a good prognostic sign for any type of psychological intervention. (p. 149)

On the MMPI-2, for example, the Pearson interpretation of the offender's self-report may indicate: "The treatment prognosis is poor. Although he may enter treatment through court referral or at the insistence of a family member, he is not motivated to change, tends to feel that others are to blame for his difficulties, and is likely to terminate therapy when the pressure eases." Similarly, on the PAR interpretation for the MMPI-2, a common comment encountered for sexual offenders is "His prognosis is guarded unless treatment begins early in his life."

The MCMI-III does not always provide specific statements about the amenability of an individual for psychosocial treatment but suggests aspects of treatment that may be more useful given an individual's test responses; by its nature, the test appears to assume that persons taking the test are interested in and/or motivated to participate in treatment. Consequently, it offers perspectives on the types of treatment, therapeutic approaches, and potential treatment issues that a particular set of responses by an individual tend to be associated with.

On the PAI, there is a specific Treatment Rejection (RXR) scale that provides a measure of attributes and attitudes associated with an interest (or disinterest) in personal changes of a psychological or emotional nature. Items tap the relative willingness to participate actively in treatment, acknowledgment of personal problems, and the disposition to accept responsibility for problems in one's life. Elevated scores on RXR indicate little motivation for treatment, whereas low scores indicate that the offender is representing major difficulties in his functioning and perceives a need for help.

Geer et al. (2001) found that the MSI II (in conjunction with the MMPI-2 and the Abel–Becker Sexual Interest Card Sort) was able to identify which sexual offenders were likely to complete a sexual offender treatment program in prison.

Some evidence exists that those individuals who are identified and characterized as antisocial or moderately to highly psychopathic by their scores on the PCL-R may respond poorly to treatment (e.g., Garrido, Esteban, & Molero, 1995) or cannot be treated (Harris & Rice, 2006). Thornton and Blud (2007) noted five domains related to interpersonal effects of psychopathic traits which might interfere with effective treatment: dishonesty about past history and functioning, having "bogus" intentions, disrupting group process,

experiencing treatment as just another opportunity to con or dominate, and, finally, seeing no reason for persona change. In addition, they note that more psychopathic individuals often lack the capacity for empathy, avoid responsibility of their past criminal behavior, and lack an ability to bond meaningfully with therapists. Further they noted that the treatment setting and expectations might be experienced as boring and lead to noncompliance with homework and attendance. Finally, they note that not uncommonly more psychopathic individuals have difficulty complying with rules. Thornton and Blud conclude that "all four facets of psychopathy have a potential to disrupt effective participation in treatment, though the ways in which they affect therapy vary" (p. 511).

Regarding treatment planning, Davis and Archer (2010) pointed out that that objective multiscale personality inventories such as the MMPI-2, MCMI-III, and PAI continue to have utility in individual treatment planning with sexual offender because of these instruments' ability to identify a psychopathological characteristic that may be relevant to treatment. Grady et al. (2011) noted that surveys had identified significant common core treatment targets in adult sexual offender treatment in North America, and these treatment targets are focused on presumed risk factors believed to be related to risk factors for sexual reoffending. Such treatment targets included offense responsibility, victim awareness and empathy, intimacy and/or relationship skills, social skills training, problem-solving, arousal control, emotional regulation, self-monitoring, and offense-supportive attitudes. As noted previously, Grady et al. have provided a review of available specific scales or available instruments that could be utilized to measure such sexual offender treatment targets. However, they concluded "…the psychometric properties of these instruments and their applicability to sexual offenders vary tremendously…there are few valid and reliable instruments available to researchers and clinicians to accurately measure se offender's deficit areas…more research is need to develop specific instruments that can be used with sex offenders to better understand the areas of specific deficits…" (p. 237).

As has been suggested, the results of SPA can be utilized to identify PMRF that can be selected as treatment targets. However, we have also noted that an evaluator must apply special considerations in the "clinical/forensic" context given the strong possibility or even likelihood that individuals are likely to present attenuated presentations of such PMRF. Thus, offenders may begin sexual offender treatment with self-reported lower levels of identified PRF than may actually characterize them.

Regarding treatment outcome, SPA can also have unique and potentially powerful utility in providing a standardized means of measuring whether sexual offenders appear to change as a result of participating in treatment. When Thornton (2002) compared first-time offenders to repeat offenders, he found that repeat offenders who had molested children tended to score more highly in the area of distorted attitudes; they also had lower scores in the areas of socioaffective functioning and self-management than the first-time offenders group. However, again given the "clinical forensic" context of sexual offender treatment, it may be that offenders are simply altering their verbal or written responses to test items as opposed to having changed their cognitions or behaviors. As Grady et al. (2011) have also noted that most measures are relatively transparent and susceptible to response bias, they also note that research has demonstrated that sexual offenders do in fact "fake good" relevant to reported treatment change or gains. Barnett, Wakeling, Mandeville-Norden, and Rakestrow (2012) suggested that treatment participation may create a "demand characteristic" relative to the participants' belief that they are expected to have changed; we would similarly suggest that a similar pressure that may operate is secondary gain where participants believe that they "need" to show that they have changed—or at least report change—to secure some desired outcome (i.e., "successful" treatment completion to secure a reduced period of incarceration or detention). Consequently, it is perhaps no surprise that a number of studies have consistently found that *pretreatment measurements* of psychosocial constructs, including personality traits and aspects of sexual deviance, have been more predictive of sexual offense recidivism. Rice, Quinsey, and Harris (1991) found that despite the appearance of change in measured deviant sexual interests between pre- and posttreatment, pretreatment measures were much more strongly associated with sexual offense recidivism relative to posttreatment assessment. Similarly, albeit with a much larger sample, Barnett et al. (2012), in their study of 3,400 sexual offenders, found that posttreatment scores on various psychometric measures "were less discriminative and predictive of reconviction than pretreatment scores…one explanation is that pretreatment scores are a *purer* measure of dysfunction than post treatment scores" (p. 23). They stated: "…the poor performance of these measures posttreatment suggest that treatment providers should rely less on these scores as a way of assessing risk after treatment. Indeed, for programme evaluators, these findings suggest less emphasis should be placed on post treatments scores on psychometric measure of dynamo risk factors as a way of establishing the efficacy of treatment programmes" (pp. 23–24). In a more recent review of the literature, Wakeling and Barnett (2014) reviewed the relationship between psychometric test scores and reconviction in sexual offenders participating in sex offender treatment in the UK. They concluded:

> We believe that these results suggest that it may be unwise to rely on large batteries of psychometric tests to determine change in treatment and that further research is required before we can be sure of the relationship of psychometric tests to

> recidivism outcome…it is very unfortunate that we are not yet in a position to make reliable estimates of the extent to which such programs have benefited individual participants. The use of psychometric tests may not be so promising as we once thought. Additionally, *the evidence so far suggests that to use change on psychometric test scores for program evaluation (i.e. as a proxy measure of reconviction outcome) is not warranted*." (p. 143; emphasis added)

Consequently, it has been relatively unusual for posttreatment or change scores to be associated with outcomes following participation in sexual offender treatment and, relatedly, relatively little evidence that sex offender treatment outcome can be meaningfully measured or demonstrated by the use of within-program psychological tests and questionnaires.

Risk Assessment

Measuring recidivism is a complex endeavor. First, base rates increase substantially with longer periods of follow-up, certainly for sexual offenders. Second, more serious offenders are often arrested and/or incarcerated for various offenses and "removed" from the "opportunity" to be followed or studied; consequently, only studies utilizing survival analysis should be considered, since they only follow persons who remain in the community with the possibility of committing additional offenses. Without survival analyses, recidivism rates most likely apply to only low- or moderate-risk offenders since high-risk offenders are more likely to be in secure settings, often for extended or repeated periods of time. Finally, the implications of the criterion variable must be carefully understood. As Douglas, Vincent, and Edens (2006) pointed out: "Sole reliance on official records will invariably underestimate actual criminal behavior" (p. 545) and lower base rates of actual recidivism. Thus, Douglas and Ogloff (2003) found that when criminal records were supplemented by other archival sources, the base rate changed from approximately 10 % to 40 %. Similarly, Monahan et al. (2001) found that the inclusion of information from official records, other collateral sources, and self-report increased recidivism rates by a factor of six!

As noted, the PCL-R has historically been regarded as the gold standard for various types of recidivism. The association between dimensional (e.g., continuous scores from 0 to 40) scores on the PCL-R and criminal and violent outcomes is, for the most part, linear; this means that a higher score on the PCL-R is associated with a higher likelihood of future negative outcomes (including criminal or violent behavior (Hart & Hare, 1997)). Via meta-analysis of the PCL-R and its relationship to recidivism was studied across multiple individual studies (Hemphill, Hare, & Wong, 1998; Hemphill, Templeman, Wong, & Hare, 1998; Hemphill, 2007). Results demonstrated that the PCL-R was consistently among the best predictors of recidivism, whether utilized as a continuous or categorical measure. In fact, surprisingly, survival analyses for "medium" and "high" PCL-R groups were not clearly differentiated from one another; both of these groups showed similar recidivism rates and patterns. Thus, a somewhat elevated PCL-R score (i.e., a moderate score) was also associated with a significantly greater likelihood of recidivism than a low score. [Of note, the mean PCL-R score for any prisoner in a state correctional facility is approximately 22, while that for the general population of males is 6 (Hare, 1991).] In addition, as Douglas et al. (2006) demonstrated: "The PCLR was more strongly predictive or added incrementally…to other predictors such as demographics, criminal history variables and personality disorder. …What these studies suggest is that the predictive contribution of psychopathy remains quite robust in the face of competing factors" (p. 542).

In their two meta-analyses, Hanson and Bussière (1998) and Hanson and Morton-Bourgon (2004) identified a number of clusters of variables and specific psychosocial characteristics that demonstrated a particular association with sexual offense recidivism. Both reviews found that the two primary predictors of sexual offense recidivism for both adult and adolescent sexual offenders were deviant sexual interests and antisocial orientation. Hanson and Morton-Bourgon (2004) found that "Sexual recidivism was significantly predicted by almost all indicators of antisocial orientation (antisocial personality, antisocial traits and history of rule violation). Specifically, sexual recidivism was predicted by the *Hare Psychopathy Checklist… the MMPI Psychopathic deviate scale [Scale 4]*…and by other measures of antisocial personality (e.g., psychiatric diagnoses, responses to questionnaires…" (emphasis added, p. 9). They also found that the general category of "any personality disorder" was also significantly related to sexual offense recidivism. In a study of rapists and child molesters, Quinsey et al. (1995) found that within 6 years of release from prison, more than 80 % of psychopaths (versus 20 % of non-psychopaths) had violently recidivated and that many of their offenses were sexual in nature; it should be noted that psychopathy was defined by a score of 25 or greater on the PCL-R. Rice and Harris (1997) found that violent recidivism rates for 5 years after release were 85 % for persons classified as psychopaths by record review (i.e., cutoff score of 25 or more) based upon survival analysis; this rate was approximately 50 % above that of non-psychopaths.

On the PAI, Morey and Hopwood (2006) noted that elevations on the PAI Aggression, Antisocial, Borderline, and Manic scales elevate the risk of behavioral acting out and recidivism, particularly higher scores on ANT and ANT-E. Morey (1996) developed a Violence Potential Index (VPI; available via the computerized interpretation of the PAI from Psychological Assessment Resources, this index samples 20

indicators of violence potential based on PAI scale elevations or configurations). Per Morey and Hopwood (2006) studies have shown the BP as demonstrating an anticipated pattern of correlations. However, as noted, Boccaccini et al. (2010) examined the ability of scores from the PAI to predict post-release rearrests over a 5-year follow-up in a sample of over 1,400 sexual offenders. ANT, AGG, DOM, and the VPI were predictive of violent and nonviolent recidivism, and AFF scores demonstrated incremental validity over both age at release and total number of prerelease arrests for both types of recidivism. However, none of the scales predicted sexual offense recidivism. The authors concluded that "the small size of the predictive effect suggest that PAI scores may be of only limited practical value for improving risk assessments… it does not appear that PAI scores are predictive of arrest for offenses that are clearly sexual in nature" (p.146).

As noted, the combination of deviant sexual interests and psychopathy has been demonstrated to greatly increase the amount and rate of sexual offense recidivism. Rice and Harris (1997) found that the combination of higher PCL-R scores (e.g., 25 and above) and deviant sexual arousal resulted in substantially faster and higher rates of sexual reoffending; sexual recidivism per survival analysis was approximately 60 % for this group. More recently, this research group again confirmed this finding [Harris et al. (2003)]. Other investigators (e.g., Doren, 2002; Hildebrand, de Ruiter, & de Vogel, 2004; Serin, Mailloux, & Malcolm, 2001) demonstrated that this "dynamic duo" of both elevated antisocial characteristics for offenders with deviant sexual interests was associated with higher rates of sexual offending. Most recently, in a meta-analysis, Hawes et al. (2013) confirmed that across studies the combination of different measures of the presence of sexual deviance and higher PCL-R scores were strong predictors of future sexual offense recidivism.

Even more broadly, Thornton and Beech (2002) examined the interaction between "psychological deviance" and Static-99 scores to sexual offense recidivism. They found that simply the number of dysfunctional domains (e.g., the number areas of psychosocial and psychosexual deviance, similar to the domains of criminogenic needs discussed previously) that characterized sexual offenders obtained moderate predictive accuracy in predicting sexual offense recidivism in two samples (AUCs ranging from .83 to .85). The number of dysfunctional psychological domains also showed significant independent contribution to prediction over and above the Static-99 risk category, indicating incremental validity.

Using the original MSI, Craig et al. (2007) found that sexual offenders who committed subsequent offenses produced higher scores on several scales: social desirability, cognitive distortions/immaturity, attitudes toward treatment, and rape interests. They also found good predictive accuracy for several scales of the MSI, including Sexual Obsessions (AUC=.85), Child Molest (AUC=.74), Rape (AUC=.74), and Paraphilia (SUC=.74). In contrast, self-report on the "Normal" factor was a poor predictor of sexual offense recidivism. Further, after a factor analysis, Craig et al. found that a "Sexual Deviance" factor made a statistically significant contribution *independent* of the Static-99 at both 2- and 5-year follow-up.

Craig et al. (2007) studied the effectiveness of psychological markers of risk, in effect by selecting test scale scores to approximate PMRF. Mean scores on deviancy domain scales were compared between recidivists and non-recidivists. Craig et al. found that recidivists obtained significantly higher scores on the MSI: Sexual Obsession and MSI: Cognitive Distortions and Immaturity scales than did non-recidivists. There was a trend for recidivists to obtain higher scores on measures of hostility, depression, and the Psychopathic Deviate scale of the MMPI. Further when measures of psychosocial deviance were statistically combined to create a "psychological deviance index" (PDI), Craig et al. too found that the number of dysfunctional psychosocial domains had a linear relationship to sexual offense recidivism. When PDI was grouped into low, moderate, and high domains (defined as deviance in three or more domains), the results showed that the degree of PDI and the rates of sexual offense reconviction were linear at 3 %, 18 %, and 40 % respectively. A logistic regression analysis indicated that the PDI made a statistically significant contribution to production in addiction of sexual offense recidivism reconviction that was independent of the Static-99 at 5-year follow-up.

Wakeling, Freemantle, Beech, and Elliott (2011) reported findings that tentatively suggested that some psychometric scores, particularly those gathered pretreatment and relating to socioaffective functioning, were associated with subsequent sexual and/or violent reconviction in sexual offenders. They concluded that such measures of PRF might be able to add to the predictive power of static risk assessment. However, more recently, Wakeling and Barnett (2014) reviewed the relationship between psychometric test scores and reconviction in sexual offenders participating in sex offender treatment in the UK. They concluded:

> We believe that these results suggest that it may be unwise to rely on large batteries of psychometric tests to determine change in treatment and that further research is required before we can be sure of the relationship of psychometric tests to recidivism outcome…it is very unfortunate that we are not yet in a position to make reliable estimates of the extent to which such programs have benefited individual participants. The use of psychometric tests may not be so promising as we once thought. Additionally, the evidence so far suggests that to use change on psychometric test scores for program evaluation (i.e. as a proxy measure of reconviction outcome) is not warranted." (p. 22)

Wakeling and Barnett suggested that rather than using specific tests to measure particular risk factors for the purpose of treatment outcome, efforts should be made to develop measures to reliably quantify "domains of risk."

However, while pre- and post-scores on certain specific psychological tests or scales may not be useful in measuring treatment outcome, they may still be useful in risk appraisal. Craig and Beech (2009) in their review of psychometric assessment of sexual offenders concluded that the use of psychometric measures to approximate dynamic deviancy domains in predicting sexual reconviction challenges existing risk assessment procedures by demonstrating that psychological trait factors provide unique information not captured by actuarial methods. Trait or psychological dispositional factors assessed at prerelease and also help to identify individuals exhibiting characteristics of psychological deviance may require greater supervision. It has been demonstrated that psychometrically assessed information can have a significant contribution to the assessment of recidivism independent of actuarial systems. There appears to be a relationship between psychological and actuarial risk markers. It may be that actuarial scales are best understood as being composed of historical markers for the past expression of the psychological risk factors (p. 103).

Summary

The comprehensive evaluation of sexual offenders represents the cornerstone of almost all disposition and treatment planning—all management-related matters—for sexual offenders. Given that almost all such evaluations occur related to or within some existing or potential legal context, it is our contention, as that of Hoberman and Jackson (2015), that most evaluations of sexual offenders are effectively forensic ones. Consequently, *Structured Psychological Assessment*, constituting standardized, typically norm-referenced methods of collecting and organizing self-report or professional ratings, is essential as a central component of all evaluations of persons facing allegations of or convicted of committing a sexual offense. Perhaps even more than in most clinical and forensic evaluations for psycholegal settings or purposes, *Structured Psychological Assessment* has particularly unique and significant value in any assessment of sexual offenders. To a large degree, this has to do with the limitations of unstructured self-report by sexual offenders and issues with unstructured judgments by varied MHP. The combination of self-report by a sexual offender (in the context of standardized, actuarial test administration/interpretation and validity (self-presentation) assessment) and structured professional judgment provides a critical and highly useful adjunct to the available records regarding a sexual offender and their particular version of their history and current psychosocial status. SPA is particularly effective when results are considered in the context of available comprehensive records and other collateral sources of information regarding the individual under consideration. The use of SPA is virtually ubiquitous for all significant clinical and forensic evaluations generally and, in effect, represents the standard of practice relating to formal comprehensive psychosocial evaluations.

Currently, a variety of broadband, multidimensional measures of personality and psychosexual characteristics as well as structured professional interviews and rating measures are available to provide useful, critical information about impression management and psychologically meaningful psychosocial characteristics of sexual offenders across key domains of so-called criminogenic needs, including general personality characteristics, social functioning, self-management, psychiatric status and history (e.g., the existence of mental disorders), treatment amenability and/or planning, and risk assessment. Such norm-referenced, standardized methods of collecting and appraising information also provide a particularly useful evidence-based means of addressing psycholegal issues. The use of SPA greatly enriches the ability for evaluators to obtain current information from sexual offenders themselves in a uniform, reliable manner and then to organize and compare that information to normative data and even past administration of the same or similar tests. Such information by virtue of combining the individual self-report in relation to normative data and structured professional judgment provides a unique substantive platform for understanding a particular sexual offender and offering unique and valuable information for decision-making about such offenders. Further, as seems likely, if the field of sexual offender research moves toward a dimensional model for the consideration of predisposing conditions for sexual offending from both a theoretical and an applied [e.g., risk assessment (e.g., Doren, 2010; treatment planning) approach, then SPA will likely serve as a primary means of best identifying and quantifying those dimensions.

Psychophysiological Assessment of Sexual Offenders: A Practitioner's Perspective

Wesley B. Maram

Psychophysiological assessment measures have been used in the assessment and management of sexual offenders for over half a century. Despite the large body of research as well as their extensive use in treatment programs (both residential and community-based) and the supervision for sexual offenders, critics continue to raise various issues about the nature of the findings and their application in clinical, forensic, and broader management settings for offenders. However, among those who use physiological assessment there is a recognized family of procedures with common aims that offer general guidance to effectively collect and interpret the results that provides a reasonable justification for the continued use of such measures (O'Donohue & Letourneau, 1992). Thus, the Association for the Treatment of Sexual Aggressive Abusers (ATSA, 2001, 2013) included several psychophysiological assessment measures in their Practice Standards. ATSA notes that it is recognized that psychophysiological assessment methods such as phallometry, viewing time, and polygraphy may have particular usefulness to (a) obtain objective behavioral data about an individual that may not be readily established through other assessment means, (b) explore the reliability of individual self-report, and (c) explore potential changes, progress, and/or compliance relative to treatment and other case management goals and objectives.

This chapter represents an effort to gather and organize the available literature on the procedural steps of administrating the Penile Plethysmograph along with other psychophysiological measures. However, this author departs from some practitioners regarding how to interpret findings in both clinical settings (in which the goal is to identify appropriate treatment targets for therapy) and forensic settings (when the purpose is to elicit information regarding the presences or absence of sexual deviance). It is posited that in clinical practice it is of greater importance to identify the potential presence of sexual deviance among known child molesters than it is to adhere to rigid interpretative guidelines. Having just one positive indicator or evidence of significant arousal to a sexually deviant stimulus provides valuable, clinically important information that should not be ignored even when the individual shows greater arousal to nondeviant stimuli. Important clinical information can be obtained about an individual who was aroused by a single image or deviant story about sex with a child, sexual violence, or nonsexual violence. This chapter includes discussions about and suggestions on how to apply viewing time measures and polygraph examinations as well as Penile Plethysmograph results in clinical and evaluating settings to increase and accelerate client disclosure of sexual deviance. Issues and concerns related to admissibility of this information in the courtroom are also discussed.

It is a formidable but critical process to attempt to determine what factors motivate a person to sexually molest a child, or rape a child, adolescent, or adult and then develop an effective intervention strategy to prevent future sexual abuse from occurring. The effort is complicated by the fact that there is a lack of uniform consensus on how to define the diagnostic criteria for sexual offending against children or nonconsenting individuals. Some even question the wisdom of classifying people with a Pedophilia, a Paraphilic Disorder-Not Otherwise Specified (NOS) (e.g., Coercive Paraphilic Disorder), or Sexual Sadism as mental conditions at all because historically sexual behavior with children and nonconsenting persons has been common (Green, 2002; Quinsey, 2010). Even if we settle on the diagnostic definition provided by the Diagnostic and Statistical Manual, Fourth Edition, Text Revision (DSM-IV-TR, 2000) which reads, "The paraphilic focus of Pedophilia involves sexual activity with a prepubescent child generally age 13 years or younger (p. 571)," different evaluators too often do not come to the same diagnostic conclusion (e.g., Levenson, 2004; O'Donohue, Regev, & Hagstrom, 2000; Wollert, 2007). The DSM-5 does not provide any additional clarity since the diagnostic criteria of Pedophilia remains the same. The only revision made was to change the name of the disorder from Pedophilia to Pedophilic Disorder. Also, efforts to establish

a new diagnosis of Paraphilia Coercive Sexual Disorder (to replace and improve upon the Paraphilia NOS nonconsenting partner diagnosis), referring to males who are sexually aroused by the coercive elements of rape, were debated and subsequently not included as specific disorder in the DSM-5 (DSM-5 Development, 2013; Knight, 2009). However, paraphilic disorders relating to sexual arousal, urges, and/or behavior to nonconsenting persons can still be categorized under DSM-5 as a Paraphilic Disorder-Not Otherwise Specified (NOS) (e.g., Coercive Paraphilic Disorder) or under the expanded definition of Sexual Sadism.

Problems with diagnostic reliability are likely to continue. Reliability is weakened when the evaluator who frequently only has at hand criminal records and the individual's self-report (where the former is too often a superficial behavioral description completely lacking details about internal motivation, and the latter is overly influenced by the desire for self-preservation). There is a common expectation that the accused individual will not be forthright about dimensions of their sexual deviance. Relying on the offender's self-report alone is problematic. This point was recognized by the DSM-V Paraphilia Workgroup (2013). They wrote, "…the fact that a substantial proportion—perhaps a majority—of patients referred for assessment for paraphilias is referred after committing a criminal sexual offense. Such patients are not reliable historians, and they are typically not candid about their sexual urges and fantasies." (pg. 1)

Official records list detected criminal events and may also include behavioral descriptions of criminal incidents. Information regarding the individual's fantasies and urges is generally discovered through clinical interview. Because of the negative societal repercussions associated with child molestation or sexual violence, there is a natural reluctance by the sexual offender to engage honestly in public self-examination of deviant fantasies and urges toward children to evaluators who are going to include this information in reports to the courts and other elements of a the legal system that will make decisions about their freedom.

A variety of strategies have been developed and employed to elicit the psychological factors of an individual related to his sexual offending, including using positive interview techniques that support the individual and avoid "shaming" the person for what they have done. In addition, standardized sex history questionnaires can extract information that might not otherwise be directly disclosed in a face-to-face interview. For example, questionnaires such as the Psychosexual History Questionnaire© (Nichols & Molinder, 1999) pose questions about the person's sexual experiences, fantasies, and urges in the context of gathering background information about the individual in a manner that has the potential to be objective, clinical, and less threatening than having to respond to a clinician who is asking specific questions to the person about their deviant sexual behaviors, fantasies, and urges. Even with the aid of structured questionnaires and skillful interviewing, an evaluator can rarely have confidence that the sex offender has made a full disclosure. Issues associated with subjective offender self-report and clinical judgment in making reliable and valid diagnosis suggest that objective measures might offer potential utility as another source of information (Bradford, Kingston, Ahmed, & Fedoroff, 2010). Sexual arousal testing can help by offering one means of identifying the possible presence of deviant sexual interests. Underscoring the importance of this information, meta-analysis studies (Hanson & Bussière, 1998; Hanson & Morton-Bourgon, 2005; Mann, Hanson, & Thornton, 2010) demonstrated that deviant sexual interest in children is among the strongest predictors of sexual recidivism.

PPG, VRT, and Polygraph

Psychophysiological procedures have been developed that offer the advantage of providing a standardized and often more objective measure to help differentiate the situational offender from the persistent offender with preferential deviant sexual interests. These psychophysiological measures to be discussed in this chapter include the Polygraph in conjunction with Viewing Time, also referred to as Visual Reaction Time (VRT) assessments, and the Penile Plethysmograph (PPG), often referred to as phallometric assessment.

The Polygraph Sexual History Exam attempts to gain an individual's full disclosure of the extent and variety of their criminal, deviant, and nondeviant sexual behaviors using skillful interviewing in combination with measures of involuntary physiological reactions to stress, by monitoring patterns of blood pressure, heart rate, respiration, and galvanic skin response. VRT assessment [such as the *Abel Assessment for Sexual Interest*™ (AASI)] combines measures of self-reported sexual arousal with standard measures of how long the individual looks at slide images of persons of different age and gender categories (e.g., viewing time) along with a self-report sexual history questionnaire (Abel, Huffman, Warberg, & Holland, 1998). The PPG measures sexual arousal by changes in penile engorgement or tumescence (e.g., relative blood flow into the penis) while the individual is viewing clothed or nude images of children, adolescents, and adults; listening to audio recorded sexual stories involving children and sexual and nonsexual violence; or viewing and listening to these stimulus presentations. When these psychophysiological tools are used in tandem with other measures related to potential deviant sexual interests, the evaluator/clinician often obtains a more clear and comprehensive overview of the individual's sexual interests,

arousals, and behavioral history (Maram & Koetting, 2004). The availability of this information from these particular procedures can be used to create an opportunity for the individual to become more willing to disclose their inner motivation for deviant behavior.

Drawbacks and Advantages

As with any measurement approach, each of these psychophysiological measures has relative limitations as well as relative advantages. For example, those critical of the polygraph point to studies that suggest the polygraph lacks scientific validity (e.g., U.S. Congress Office of Technology Assessment, 1983). In contrast, polygraph supporters point to the polygraph's empirically demonstrated utility in post-conviction assessment of sex offenders (English, Jones, Pasini-Hill, Patrick, & Cooley-Towell, 2000; Grubin & Madson, 2006; Kokish, Levenson, & Blasingame, 2005; Raskin, 1988; Raskin, Barland, & Podlesny, 1976). The AASI has been criticized as being inaccurate in distinguishing child molesters from non-molesters (e.g., Fischer & Smith, 1999). Others have reported that the AASI results provide good discrimination between child molesters and non-child molesters (Card & Dibble, 1995; Letourneau, 2002).

Critics have also raised questions about the methodology and value of the PPG. These range from its lack of standardization and potential ethical concerns to questions as to whether penile engorgement is a reliable indicator of sexual arousal (Konopasky & Konopasky, 2000; Schouten & Simon, 1992). Alternately, a number of authorities advocate that the most well-established method for assessing positive evidence of sexual interest or arousal remains the Penile Plethysmograph (O'Donohue & Letourneau, 1992; Rosen & Keith, 1978; Zuckerman, 1971). Penile Plethysmograph responses to slide images and audio stimuli have been reported to provide relatively accurate information to classify child molesters and men who commit sexually coercive acts, such as rape, into more refined, delimited diagnostic groups and/or differentiate them from normals or other sex offender and non-sex offender groups (Barbaree & Marshall, 1984; Fedora et al., 1992; Lalumière, Quinsey, Harris, Rice, & Trautrimas, 2003; Quinsey, Steinman, Bergersen, & Holmes, 1975; Wormith, 1986).

Given the varied points of view and, to some extent, court rulings regarding the potential utility of the PPG, AASI, and polygraph, some forensic evaluators and clinical practitioners may be unclear about the value of such physiological assessment methods. The aim of this chapter is help lower the "noise level" and guide the evaluator in understanding, administering, interpreting, and then applying the PPG, AASI, and the polygraph in the forensic and clinical settings for optimal utility relative to exploring potentially useful additional sources of information about a particular individual related to sexual offending.

Before launching into a discussion on first how to use the PPG in applied settings, we need to be better grounded in its history, empirical support, and ethical concerns.

The Development of Penile Plethysmography

Sexual offenders are not the only category of individuals that might be motivated to deny their sexual interests or preference. In response to the Czechoslovakian government's concern about recruits attempting to evade military service by falsely claiming to be homosexual, Kurt Freund was commissioned to develop a procedure to differentiate sexual preference. In 1957, he employed a device, the volumetric method, to measure blood flow into the penis. He called this method the Penile Plethysmograph (commonly abbreviated as PPG). From this beginning, Freund's research evolved to focus on detection and diagnosis of sex offenders, particularly pedophiles (Wilson & Mathon, 2006).

The popularity of the PPG should be understandable, considering the unreliability of an offender's self-report and the fact that through such an evaluation, there is confidence that a meaningful erectile response to a sexual stimulus presentation of an adult or child is a psychogenic arousal and not simply a random erection (Bradford et al., 2010; DSM-5 Proposed Revision, 2010; Heilbrun, 2003; Janssen, Everaerd, van Lunsen, & Oerlemans, 1994). An offender's reluctance to be fully disclosing about both his current level of deviant arousal and his history of sexual offending is not difficult to understand, considering his fear of societal disapproval and the painful consequences that might follow an accurate accounting of past deeds and current deviant sexual interests. It is common for therapists working with recidivist, i.e., repeat sexual abusers of children and adults, even those with multiple detected victims spanning years, to hear from the sexual perpetrator denial or minimization of their offense history and/or denial of past or current deviant arousal. Abel, Mittelman, and Becker (1985) found that among 411 outpatient volunteers, the subjects initially provided very low reports of their past incidents of sexual crimes. However, when confronted with PPG results demonstrating erectile responses to sexually deviant stimuli, a large majority of those same sexual abusers in their study subsequently admitted that they had committed many more sexual offenses than they had previously disclosed. In a similar manner, Abel et al. (1988) discovered that among 561 nonincarcerated paraphiliacs, when provided assurance of confidentiality (e.g., a Federal Certificate of Confidentitality), most disclosed having engaged in as many as ten different types of sexually deviant behaviors that were previously unknown. This was

evidence of "crossover," with a significant number of sexual offenders reporting multiple types of atypical sexual behaviors as opposed to just one type, such as "rape" or "child molesting." Similar reports of previously non-disclosed victims and a history of varied sexual offending (e.g., crossover offending) have been reported by other researchers relying on polygraph examinations of sex offenders (English et al., 2000; Grubin, Madsen, Parsons, Susnowski, & Warberg, 2004).

Early Beginnings to Present

Contemporary Penile Plethysmography has generally changed from early Volumetric Plethysmograph measurement in which the blood flow into the penis is measured by the air displacement from a glass or rigid cylinder that is placed over the penis with an inflatable cuff. The cylinder is generally held in place with a leather harness that the technician places on the individual. This cumbersome process was first simplified by Bancroft, Jones, and Pullan in 1966 and later by Barlow, Becker, Leitenberg, and Argus in 1970 (Coric et al., 2005) to the method commonly used today, a circumference gauge. The gauge typically used today is a simple, thin mercury-filled elastic strain gauge that is placed on the midshaft or base of the penis. The gauge stretches as the penis circumstance expands with penile engorgement.

From its early beginning in the 1950s, the measurement of erectile responding became a central component and standard in the evaluation and treatment in the field (Marshall, 2006a, 2006b; McGrath, Cumming, & Burchard, 2003). The Penile Plethysmography equipment one is most likely to find in labs today consists of a computer with plethysmography software that includes sexual stimuli presentations and an attached wire leading from a circumferential mercury strain gauge (an elastic mercury band designed to measure electrical impedance to detect blood volume changes) that is calibrated on a calibrating rod prior to testing. The subject places the wire around the midshaft or base of the penis, and audio, video, or audio/video equipment is used for the examinee to listen to and view the stimuli. Some labs continue to use Volumetric Plethysmography, most notably the Centre for Addiction and Mental Health, which was described earlier. Volumetric Plethysmography requires placement of a cylinder over the penis and measures air displacement caused by erectile engorgement during stimulus presentations. Volumetric measurement is reported to be more accurate than mercury strain gauge circumference measurement for erectile response that is less than 10 % (2.5 mm) of full erection. However, both volumetric and strain gauge results were highly correlated for 10 % (2.5 mm) and greater of penile circumference increase (Barbaree, Blanchard, & Kuban, 1999).

Pros and Cons of Penile Plethysmography (PPG)

Proponents of Plethysmography hold that if it has been established that "Pedophilia" is a term that describes a sexual interest in largely prepubescent children, then the PPG is the most effective method for assessing such a sexual interest. Further, it is claimed that the PPG is useful in tracking erectile changes and it is the most well-established available method for assessing sexual interests (O'Donohue & Letourneau, 1992; Rosen & Keith, 1978; Zuckerman, 1971). PPG responses to slide images have been reported to be reasonably accurate in classifying child molesters into diagnostic groups and/or differentiating child molesters from normals or other sex offender and non-sex offender groups. Using the combined method of presenting erotic slides of nude children and adults and audio stimuli together with a self-report card sort (written scenarios of 13 categories of attractiveness to various description of sexual interest) (Laws, 1996) measures to differentiate boy-object and girl-object child molesters provides classification accuracy of 91.7 %, which is greater than any single measure (Barbaree & Marshall, 1984; Baxter, Marshall, Barbaree, Davidson, & Malcolm, 1984; Fedora et al., 1992; Freund, Watson, Dickey, & Rienzo, 1991; Laws, Gulayets, & Frenzel, 1995; Laws, Hanson, Osborn, & Greenbaum, 2000; Quinsey et al., 1975; Quinsey & Carrigan, 1978; Quinsey, Chaplin, & Carrigan, 1979; Wormith, 1986). This finding supports the notion that "more is better" in that using the PPG along with other measures of sexual interest is likely to give you the most comprehensive and accurate picture of the individual's sexual interests.

The primary focus of this chapter is on the assessment of child molesters and rapists in evaluation and treatment settings. Most sex offenders, including rapists are eventually released into the community. Some suggest that the results of PPG studies for rapists are a bit muddier than those for child molesters. A number of researchers have argued that PPG reliability with rapists is too low for its valid application in assessment (Eccles, Marshall, & Barbaree, 1994; Fernandez & Marshall, 2003). Barbaree, Baxter, and Marshall (1989) reported test–retest reliability of the rape index was extremely low ($r = 0.44$). However, Lalumière et al. (2003) revisited and updated quantitative reviews of studies that examined phallometric responses of rapists and other men. They discussed many laboratories assessing rapists have reported that approximately 60 % of rapists (perhaps a modest but still significant detection level) show rape indices that are larger than the rape indices of about 90 % of non-rapists. This 60/90 benchmark is a cut-point that can produce a score that determines interest for rape. In other words, good group discrimination between rapists and non-rapists is suggested

by these results. Lalumière et al. (2003) suggested that future research would be valuable in distinguishing among three potentially different sexual arousal patterns of profiles as these apply to rapists' phallometric responses: biastophilia (sexual arousal involving nonconsenting, struggling, resisting, but not necessarily to injury or cause physical suffering of the victim); sexual sadism (sexual arousal to pain, suffering, and injury); and the general antisocial or indifferent rapist (indifference to the interests, feelings and desires of others).

In a study of 586 male sex offenders convicted of contact sexual offenses assessed between 1982 and 1992 whose recidivism was studied over a 20-year follow-up, Kingston, Seto, Firestone, and Bradford (2010) investigated the predictive validity of sexual sadism, as indicated by psychiatric diagnosis, level of violence during the most recent sexual offense, the intrusiveness of the sexual activity, and phallometrically assessed sexual arousal to depictions of sexual or nonsexual violence. They found that the three behavioral operationalized indications (level of violence, sexual intrusiveness, and phallometrically assessed sexual arousal to sexual and nonsexual violence) were better predictors of sexual recidivism among sex offenders than the psychiatric diagnosis of Sexual Sadism. Of special interest here are the phallometric results of the study.

Kingston et al. calculated the *Pedophilia Assault Index* by dividing the highest response to an assault stimulus involving a child victim (nonphysical coercions of child, physical coercion of child, sadistic sex with child, or nonsexual assault of child) by the highest response to a child stimulus with no overt form of coercion. Similarly, they calculated the *Rape Index* by dividing the highest response to the rape stimulus by the highest response to the adult-consenting stimulus. The *Adult Assault Index* was calculated by dividing the highest response to a nonsexual assault stimulus against an adult by the highest response to a consenting adult. They then created a new index of sexual arousal of sexual and nonsexual violence, irrespective of victim age, that was simply the highest score from any of the three indices (Pedophilia Assault, Rape, and Adult Assault indexes). They found that phallometrically assessed sexual arousal to violence added to the prediction of violence (including sexual) recidivism after actuarially estimated risk to reoffense was controlled. This study's findings suggest that behaviorally operationalized measures, including the results of phallometric assessment, are preferred over psychiatric diagnosis because the phallometrically assessed deviant arousal to violence, including sexual violence, was associated with recidivism; whereas, in contrast, psychiatric diagnosis of sexual sadism was not associated with recidivism. This is yet another argument in support of the use of the PPG for assessment of sexual deviance for violent sexual offenders.

From the perspective of the evaluator and treatment provider, the available research provides sufficient support that the results of a PPG examination of an individual can produce findings that could be useful when discussing with the client that responds strongly to sexual and nonsexual violence. Some writers have suggested that since PPG testing with rapists may not be as discriminating as that for pedophilia, it may be less useful for clinical or forensic purposes. However, in addition to the available research that does support the utility of PPG evaluations with persons accused of or convicted of sexual assaults of adolescents and adults, it has also been long established that a significant proportion of sex offenders tend not to be specialists and some rapists also have sexual interest in children (Abel, Becker, Mittleman, et al., 1988; Marshall, 2006a, 2006b). Therefore, the PPG can still useful to rule out the possible presence of pedophilic interests in persons who assault adult females and is, therefore, also recommended to be used in settings assessing the sexually violent rapist as well as the child molester.

Several studies have assessed PPG sensitivity and specificity for diagnosing pedophilia (Camilleri & Quinsey, 2008). Sensitivity is defined as the probability that the test says a person has the "disease" or condition such as Pedophilia when in fact they do have the disease or condition. Specificity is defined as the probability that the test says a person does not have the "disease" (Pedophilia) when in fact they are "disease free" (Sensitivity and Specificity, 2013). "Sensitivity" is calculated by dividing the number of men identified as pedophiles by PPG assessment out of the total number of true pedophiles in the sample. For child molesters with multiple child victims, sensitivity was reported to range from 61 % to 88.6 %. Offenders with male victims had higher sensitivity scores. "Specificity" is calculated by dividing the number of men identified as gynephiles (men who prefer adult women) by PPG assessment out of the total number of true gynephiles in the sample. The specificity range was 80–96.9 %. For samples among adolescent sex offenders, sensitivity was lower but still acceptable at 42 % (Camilleri & Quinsey, 2008). In summary, the findings reflect moderate to robust sensitivity and robust or strong specificity, meaning we can have greater confidence in PPG findings that indicate the presence of pedophilia rather than in the absence.

Although the PPG has been around for over 40 years and there is a large body of research supporting its use as the best-validated tool for assessing pedophilia, a single standardized way of administering the test and published norms are lacking (Camilleri & Quinsey, 2008). Marshall (2006a, 2006b), an early proponent of the PPG, has more recently raised questions about the clinical usefulness of the PPG. He wrote:

> "… clinicians who rely on phallometrics must offer compelling arguments for doing so. The evidence of the reliability and validity of phallometrics presently available in the literature certainly offers little support for its use … some may find justification in the present review for abandoning the use of phallometric assessments altogether (p. 21)."

Similarly, at one point, Laws (2003) opined the PPG should be viewed as more an art than a science because of a perceived lack of universally agreed-upon standards and procedures. He reported on a national effort in the United Kingdom to develop standardization guidelines in 2007 (Thornton & Laws, 2009). There were also earlier attempts in North America to standardize the age and gender assessment of PPG administration for child molesters in 1987. However, of the five sites in the United States and three in Canada, only one Canadian site completed the study. Laws expressed disappointment about lack of plans to standardize the PPG and noted that the PPG is intrusive, invasive of privacy, and time-consuming. He expressed frustration that it had taken too long for the emergence of standardized procedures and explicit protocols (Laws, 2009). However, more recently, Laws (2009) has taken a less negative view on the utility of the PPG. He has retracted some of his earlier criticism because of improvements in the field. He has also acknowledged that PPG works well if implemented in a relatively consistent fashion. Laws acknowledged that many clinicians and researchers believe the PPG is a valid measure of deviant sexual interest, reporting that PPG measures correctly classified 82 % of the offenders by sex of victim and 74 % by both victim gender and use of force. Further, he reported encouragement based upon the implementation of a multisite study in the United Kingdom and the detailed procedure manuals that have been developed as a result. He concluded these results may, at least partially, solve many of the problems that have existed previously.

Similarly, O'Donohue and Letourneau (1992) have opined that although there does not appear to be a single standardized penile plethysmography assessment protocol, recognized procedures do exist and have shared aims. The British Psychological Society has, in fact, published Penile Plethysmography Guidance for Psychologists (British Psychological Society, 2008). The Association for the Treatment of Sexual Aggressors (ATSA, 2001, 2013) has long supported the use of PPG by experienced professionals using one of the more standardized procedures. Marshall and Fernandez (2003a, 2003b) have also supported the PPG's value. The authors stated that the psychometric data for assessments from tools such as card sorts (self-rating of 13 categories of attractiveness to various descriptive paraphilic sexual interests) (Laws, 2009), self-report measures, viewing time, and clinical interview results are less satisfactory than phallometry and that these alternative measures cannot yet be considered as a viable replacement for PPG testing. They opined phallometry would continue to have a role in effective clinical assessment of sexual offenders, but cautioned the role should be restricted to (1) determining which offenders need treatment, (2) targeting its application at modifying deviant interests, (3) estimating whether or not treatment intervention has reduced deviant tendencies, and (4) estimating the likelihood that an individual will reoffend. They indicated PPG evidence of deviant arousal for any sexual offender is an indication of problems that need to be addressed in all the decisions made about the offender, including treatment choices.

Justification for using a considered or qualified approach in interpreting PPG findings can be found in studies measuring PPG sensitivity (44–86 %) and specificity (approximately 95 %). The test sensitivity (accuracy of correctly categorizing individuals with sexual deviance) and specificity (accuracy of correctly categorizing nondeviant individuals as not being sexually deviant) findings tell us PPG test results are most informative when some signs of sexual deviance are revealed However, when no sexual deviance is revealed with PPG testing, it *cannot* be concluded that the person is not aroused by children because PPG false-negative rate can range from 14 % to 56 % (Freund & Blanchard, 1989; Freund & Watson, 1991; Hall, Hirschman, & Oliver, 1995). Consequently, PPG results indicating "nondeviance" do not confirm the absence of pedophilia or absence of arousal to coercive or violent sexual stimuli. In contrast, we can be fairly confident an individual was correctly classified as sexual deviant if their PPG results indicate the positive evidence of sexual deviance.

Further, relative to the value of the PPG assessment for sexual offenders, the Hanson and Bussière's (1998) meta-analysis of 61 scientific reports on the prediction of sexual reoffending involved approximately 40,000 sexual offenders. They found that PPG measure of deviant sexual arousal to male children was the single most distinguishing marker for sexual recidivism. In a second meta-analysis of 91 studies of 31,000 sexual offenders, Hanson and Morton-Bourgon (2005) found further justification for PPG results related to child stimuli in relation to sexual offense recidivism. They reported that phallometric measures of any deviant sexual interest and sexual interest in children were significantly related to sexual recidivism. Most recently, in an updated meta-analysis, Mann et al. (2010) found that measured sexual interest in violence was itself a significant risk factor for sexual recidivism.

PPG and the Polygraph

Laws (2009) described a personal communications with Thornton (5 April 2007), who has integrated the PPG and the Polygraph procedures for assessment and treatment. In Thornton's procedure, the client is instructed during PPG testing to allow himself to become sexually aroused with no attempt to control his response. The second phase is called the "enhanced non-suppression PPG." The procedural instructions are the same, except the client is asked a series of questions about the sexual stimulus 30 s after it has terminated.

The purpose is to encourage the client to process more deeply. Later, after the PPG, the client undergoes a polygraph examination focusing upon his compliance with PPG pretest instructions; he is asked more generally whether he deliberately tried to distort the results.

Clearly, while issues regarding PPG use have been raised and considered, it remains a primary method for the assessment of sexually deviant interests. The popularity of the PPG is irrefutable given its widespread use throughout North America. In a survey of North American treatment programs, out of 330 community-based programs for adult male sex offenders in the United States (U.S.) and 19 in Canada, 27.9 % of the U.S. programs and 36.8 % of the Canadian programs measure sexual interest reported using the PPG. Residential programs' use of the PPG is even higher. Of 85 U.S. residential programs participating in the 2009 North American Survey, 36.5 % were using PPG assessments, and of 8 Canadian programs, 87.5 % were using it (McGrath, Cumming, Burchard, Zeoli, & Ellerby, 2009). Hecker, King, and Scoular (2009), in their investigation of alternative approaches to the measurement of sexual interest, referred to the PPG as the "gold standard" for measuring sexual interest because of the extensive research literature of phallometric testing and the strengths and limitations of plethysmography are well know.

Some of the drawbacks to PPG that exist are simply logistical ones, For instance, equipment, laboratory space, and time required in setting up a lab and prepping for a test are expensive. Also, staff training can be both expensive and time-consuming. This likely means that the smaller program providing sex offender treatment is at a disadvantage without cooperative arrangements to refer clients to other facilities for PPG assessment.

Ethical Concerns with PPG Use

Few topics in North American culture draw as much attention and controversy as the subject of sex. Therefore, it should not be surprising PPG examination of sex offenders causes many to worry about ethics regarding its use with adolescent and adult offenders. The ethical challenges related to the fact that PPG stimuli are designed to evoke deviant sexual arousal and that the testing is intrusive. Examples of related concerns mentioned in the PPG literature should be considered (Association for the Treatment of Sexual Abusers, 2001; British Psychological Society, 2008; Marshall, 1996):

- Explicitly deviant stimuli can be seen as providing tacit approval for the material.
- Exposing impressionable juveniles and adults to explicit deviant stimuli material might shape future sexual interest patterns.
- Stimuli are inherently degrading to women and children.
- Exposure to explicit sexually deviant stimuli can produce anxiety, nervousness, depression, and other emotional upset.
- Lab procedures that require the subject to self-stimulate to achieve maximum arousal can increase subject embarrassment and humiliation, and may be contrary to religious beliefs.

These concerns have dampened research enthusiasm as well as "caused" the reluctance of human research ethics committees or Institutional Review Boards (IRB) to permit PPG studies has made it even more difficult to address the empirical limitations identified by some writers (Marshall, 1996; McAnulty & Adams, 1991; Murphy & Barbaree, 1994).

Here are some of the "Do not's" associated with PPG testing recommended by Marshall (1996) and British Psychological Society (2008):

1. Do not use PPG testing results as the sole criterion for determining deviant sexual interests.
2. Do not use PPG testing alone for estimating risk for engaging in future sexually abusive behavior.
3. Do not use PPG testing results exclusively regarding recommendations to release clients to the community.
4. Do not use PPG testing to determine that clients have completed a treatment program.
5. Do not use PPG test results to draw conclusions about whether an individual has or has not committed a specific sexual crime.
6. Do not test an individual with sexually transmittable diseases until their symptoms are in remission.
7. Do not interpret PPG results in absence of other relevant information to determine risk and treatment needs.

Yet some of these recommended prohibitions have been refuted. Regarding risk assessment, the available data (e.g., Hanson & Bussière, 1998, 2004; Marshall & Fernandez, 2000; Mann et al., 2010) from three meta-analysis studies clearly demonstrated that PPG results regarding deviant sexual arousal are significantly associated with future sexually abusive behavior.

Caution is recommended when using PPG results with clients who are developmentally disabled or have acute major mental illness based upon the paucity of normative data for these populations and the invasiveness of the techniques (National Clearinghouse on Family Violence, 1998). Also, the developmentally disabled population may, for example, have difficulty accurately perceiving the stimuli because of limited ability to discriminate the age and gender in each of the presentations in the assessment, and they might have problems associated with understanding the self-report

procedure (Haaven & Schlank, 2001). Also, it is clear that PPG results must be interpreted and applied in conjunction with other relevant information to determine the risk and treatment needs of a particular sexual offender.

How *Should* the PPG be Used

Lalumière and Harris (1998) offer a list of best practices for optimal discrimination using phallometric testing. They recommend the testing involves:

- Use of images that best discriminate age and gender preference.
- Use of graphic and violent audio narratives that best discriminate preference for coercive sex.
- Use of more than one stimulus per category (2–5 stimuli recommended by Lalumière & Quinsey, 1994).
- Collection of data tracing after the stimulus presentation has ended (recommended at least 30 s).
- Computation of a "deviance differential" index of relative preference between deviant (child or coercive sex) and nondeviant (adult or consenting sex).
- Using *Z*-score transformation to address individual differences in responding (high vs. low responders) to improve discriminate validity, or percent of full erection (PFE). Both methods are believed to provide good validity values.
- When auditory stimuli are used, the employment of anti-countermeasure procedures are recommended for use (such as semantic tracking tasks) to detect faking and encourage subject compliance.

The British Penile Plethysmography Guidance for Psychologists' (British Psychological Society, 2008) instructions on good practice indicate the clinical purpose of the PPG is to provide physiological evidence of patterns in sexual arousal, facilitate participant acknowledgement of their sexual arousal/interests and their engagement in treatment, develop formulation of problematic or offense-related sexual behavior, assist treatment and risk management planning, assist in measurement of changes in sexual arousal/interest, and again emphasize that PPG should not be used to establish guilt or innocence regarding offense behavior. It further indicates responsibility for correct administration, interpretation, and supervision of the PPG assessment should rest with a supervising psychologist who has substantial up-to-date knowledge of the relevant literature, practice, legal and ethical issues surrounding PPG assessment, and substantial experience working with men who have committed sexual offenses.

Establishing and Administering a PPG Lab

It is best to standardize PPG laboratory facility and operating procedures with other PPG labs to obtain greater confidence that assessments are done correctly. Jensen and Laws (1994) provided helpful videotape instruction on the "How-To" of phallometry where the viewer is walked through the physical layout of the lab facility. This author has also inspected a number of labs in California, Washington State, and Toronto. The common theme found in each of these labs is that the physical facility maximizes privacy and minimizes distraction. Typically, the subject is placed in a separate room from the lab technician with a window that permits the technician to both observe and communicate with the subject. Some labs are including audio/video equipment. It can be prudent to video record the administration of the PPG session to discourage false claims that the subject was embarrassed by being required to be exposed to the examiner. Also, the recorded session can be viewed afterward to look for so-called countermeasures (T. Buttle, personal communications, February 8, 2010). The need for countermeasure detection is underscored by the discovery that some males are able to bias or invalidate results by suppressing their arousal, and in some cases they are able to increase their arousal (Abel, Blanchard, & Barlow, 1981; Adams, Motsinger, McAnulty, & Moore, 1992; McAnulty & Adams, 1991). A well-trained technician pays close attention to potential cues suggesting deception such as furtive hand and arm movement, breathing rhythm changes, and unusual erectile tracing patterns displayed on the computer monitor.

The subject's room should have a comfortable, washable chair. Covering the chair with disposable paper medical drape sheets ensures good hygiene and conveys a message that the testing is conducted in a professional environment. The visual stimuli used today are usually displayed using a full-size television or computer monitor that is sufficiently large to dominate the subject's visual field. The room lighting should be dim and the subject should not be distracted by other objects or noises. When using audio presentations alone, you may use small computer speakers, or an audio headset that can be cleaned after each testing. Additional equipment connected to the computer includes the following:

- Mercury strain gauge, which the subject places on his penis in private outside of the view of the technician
- Visual and semantic tracking device such as a keypad, which is used to track the subject's attentiveness, provide self-report of erectile response, and encourage compliance with testing procedures

- Pressure sensor seat pad to detect artifact movement
- Respiration measuring device to monitor breathing pattern

The subject can cover his lap with a medical drape or put on a medical gown to avoid exposure when placing the gauge on the penis and during test administration.

The technician's room is designed to monitor and communicate with the subject during testing. Although a great deal of technological advancement has occurred since Kurt Freund developed the PPG device in 1957, fundamentally little has changed in the actual measurement of penile tumescence. Blood flow is still measured by change in the size of the penis. Most labs use an elastic circumference mercury strain gauge such as D. M. Davis, Inc., HgPC, which is durable and reusable when washed and soaked in a 10 % mixture of chlorine and water. The gauge is connected to a computer, which records electrical impedance that occurs as the penis expands, stretching the strain gauge placed around the circumference of the penis. Typically, software programs specifically designed for PPG testing transmit video, audio/video, or audio stimuli to the monitor and speakers.

The goal is to administer stimuli that will elicit erectile responses sufficient to discriminate between deviant and nondeviant interests. Problems can occur with stimuli such as the Auditory Stimuli for Penile Plethysmography (1993) that include vague audio stimulus descriptions such as, "You are with a young girl…the age you like the most." The subject may visualize that the "young girl" in his mind is a 6-year-old child and become sexually aroused, but then report he imaged the "young girl" to mean an 18- or 19-year-old female. To avoid this type of deception or confusion when using such audio stimuli that doesn't clearly state the age of the sexual partner, the technician or the stimuli materials should give clear and specific instructions stating what the age category will be on each stimulus prior to beginning the assessment, and reinforcing the instructions periodically throughout the testing session.

A variety of types of stimuli have been produced over the years (film, videotapes, slides, audio recordings), but not all stimulus sets generate discriminating responses from the subject. For example, Abel and Blanchard found that videos generated the greatest levels of arousal, but that the strong arousal obscured differential responding, that is, the video overstimulated the subjects causing undifferentiated arousal to deviant and nondeviant stimuli (Marshall, 2006a, 2006b). Conversely, other stimuli sets may not be sufficiently arousing to generate meaningful erectile responses. Further, the duration of stimulus time matters. In a study of 31 child sex offenders aged 21–44, Avery-Clark and Laws (1984) reported that there was a significant difference in the arousal levels achieved between 2 and 4 min of stimulus presentations, suggesting the need for stimuli presentation longer than 2 min; a recommended stimulus time is 3 min. Another important consideration is at what point should the sexually significant event identifying the deviant or nondeviant theme occurs during the sexual vignette in the audio stimulus (Marshall, 2006a, 2006b). If the audiotaped stimulus provides over a 2-min description of sexually arousing behavior and then only toward the end reveals that the sexual partner is a prepubescent child, it is difficult to discern to what the subject is responding. Marshall's finding suggests the introduction of the sexually deviant stimuli aspect of the vignette should occur early on in the stimulus presentation to remove doubt about what is arousing the subject.

Laws and Court Decisions Impacting PPG Use

The stimuli used in PPG testing of sex offenders have not been without controversy. The government of Canada allows the use of what might be termed pornography for scientific or clinical purposes (Howe, 1995), whereas this is not the case in the United States. Concern over distribution of child pornography and legal sanctions against transporting child pornography across state lines, even for evaluation or research purposes, have made it difficult to standardize PPG procedures across evaluation sites (Howe, 1995). In the United States, federal statutes and state laws exist prohibiting the use of nude images of children for the purpose of sexual arousal (e.g., Federal Law, 18 U.S.C. § 1466A (2008) § 1466A. Obscene Visual Representation of the Sexual Abuse of Children; California Penal Code 311.3 & 311.11, Obscene Matter of a Minor). Legal prohibition of images of children construed to be sexually abusive or obscene have encouraged the development of clothed slide images of children and audio stimuli depiction of deviant sexual behavior described above for use in PPG testing. However, research shows that audio stimuli is reasonably accurate when compared to the nude stimuli (Barbaree & Marshall, 1984; Fedora et al., 1992; Lalumière et al., 2003; Quinsey et al., 1975; Wormith, 1986), suggesting valid PPG testing has not been significantly diminished by governmental restrictions.

PPG Stimuli

There are a number of sources for standardized stimuli that can accurately classify deviant and nondeviant subjects and which have demonstrated reliability and validity. Some stimuli are encrypted and are only commercially available through the software manufacturers, so it may be necessary to purchase the hardware equipment and software products from commercial distributors such as Limestone Technology, Inc. and Behavioral Technology, Inc. in order to obtain the stimulus set. The apparent reason for this is to encourage

potential users to purchase their product. This competitive spirit may make good business sense, but it is unfortunate for professionals in the field who seek improved standardization because it limits ready accessibility, thereby discouraging published reports on the same standardized stimuli.

One recently standardized audio/video stimulus, Real Children Voices (RCV) (T. Buttle, personal communications, August 8, 2010), is more creative than many of the older stimuli versions found and may prove to better capture an individual's unique arousal profile. The RCV aural portion of the stimuli includes the voices of the sexual partners. In other words, the subject hears both the adult male talking about the sexual behavior and the voice of the child sexual partner responding as the sexual scene is enacted.

American Psychological Association Ethical Principles 9.03 (2010) requires informed consent be obtained for PPG testing. The subject must agree to volunteer for the testing. Otherwise his resistance is likely to sabotage the testing. It is important to recognize that few individuals find much enjoyment sitting in a chair in a monitored room for over an hour with a gauge on their penis and being directed to pay attention to a variety of deviant and nondeviant sexual stimuli. Preparation of the individual for PPG testing starts with helping the individual client reduce his anxiety by explaining the testing protocol and familiarizing him with the lab before he begins testing. An examinee needs to be trained on how to correctly put the gauge on and how to use the keypad or other devices that encourage his cooperation. He must sign his informed consent to the test and be reassured that the facility and gauge are clean and his privacy is respected.

The test instructions should be standardized. The easiest way to do this is by reading a prepared script describing the protocol, or as with the RCV, the protocol may be described on the subject's monitor to get him ready for the stimulus presentation (T. Buttle, personal communications February 8, 2010). This automatic protocol assures greater standardization. The instructions walk the subject through the testing, starting with how to put the gauge on. The RCV stimulus set begins with the subject in the chair reading instructions on the monitor that inform him about what to expect in each stimulus presentation, then inform him how to respond to the visual and audio attention cues, and how to rate his level of sexual arousal on the keypad. Then the examination begins.

The subject should be instructed before the examination date not to masturbate to ejaculation 48 h before the examination because the sexual refractory period can last from a few minutes to days, depending on age, frequency of sexual activity, and other factors (Crooks & Baur, 2008). To ensure subjects' compliance subsequent to PPG testing, he can be administered a polygraph test and asked if he engaged in dissimulation behaviors to bias the PPG results. Just prior to testing, it should be suggested that he take a restroom break. Also, he should be discouraged from consuming liquids such as coffee or soda beforehand because he will be sitting in a chair for over an hour with no restroom opportunity.

Administration of the PPG

Once the subject is in his seat and the testing has begun, the technician observes both the subject and the computer screen tracings displayed on the monitor. The technician monitors the subject's compliance with the testing protocol and may need to remind the subject how to correctly follow the anti-countermeasure cues. For example, with the RCV stimuli the subject is required to press the OK button on the response pad when the picture shows a different person from the one shown in the previous photo.

The technician watches for a subject attempting to "beat the test" by moving, tensing his muscles, not paying attention, holding his breath, or breathing rapidly. Keen alertness to countermeasures is necessary because research has shown that the phallometric test is easy to fake (Laws, 2003; Wilson, 1998). Indications of faking may also include a wavy arousal pattern viewed on the technician's computer monitor. This pattern suggests the subject is attempting to control his arousal. Similarly, a flat tracing pattern during the presentation followed by arousal after the presentation and continuing beyond 30 s also suggests the subject may be suppressing his arousal. It has also been reported that high responses to neutral stimuli may be another sign of faking (Freund, Watson, & Rienzo, 1988).

Interpreting the Data

Many labs use cutoff scores for low response levels. This author is aware of labs that use cutoff scores ranging between 10 % and 20 % of full erectile response. A full erectile response has been determined by various means, such as requiring the subject to masturbate to full erection and then stop before ejaculation, displaying highly erotic stimuli during a pretest examination designed to measure full erectile responses, and estimating average erectile circumference.

The masturbatory procedure is viewed as problematic. Many subjects are uncomfortable being monitored while masturbating and when full arousal is achieved it might influence tumescent response to subsequent stimuli. Others object to the masturbation procedure because of religious reasons. Viewing highly erotic stimuli before testing might also exaggerate sexual responsiveness during the test administration.

An estimated range of full erection, a preferred procedure in this author's opinion, was reported to vary from between 25 mm to 30 mm, until the results of Howe's (2003) study of
