To George Winokur

S.H.F. and P.J.C.

To my father, S. Mehdi Fatemi, and to my family, S. Ali Fatemi, M.D., Naheed Fatemi, Parvin Fatemi, S. Mohammad Fatemi, Neelufaar Fatemi, Maryam Jalali-Mousavi, Ph.D., and last but not least, my mother, Fatemeh Parsa Moghaddam, whose love and support have enabled me to complete this work, and to my first teacher in psychiatry, Deborah Gould, M.D.

S.H.F.

To my children, who have tolerated my passion for work and psychiatry: Clarissa Beth Weirick, Matthew Charles Clayton, and Andrew Curtis Clayton, to George and his lovely family and to all those at Washington University Department of Psychiatry who taught me and inspired me.

P.J.C.

Foreword

This fourth edition of a classic American textbook of neuromedically oriented psychiatry continues an important tradition reflected in the first edition of 1986 (599 pp) from WB Saunders Press, edited by the late George Winokur, MD, with Professor Clayton, continued with the second edition of 1994 (603 pp), and the third and fourth editions with Professor S. Hossein Fatemi as co-editor in 2008 (799 pp) from Humana Press, a division of Springer. The orientation of the book grew out of a descriptive neuromedical approach to psychiatry that was characteristic of 19th and early 20th century European psychiatry, and largely lost in psychodynamically dominated mid-20th-century American psychiatry. More specifically, it reflects the interests of a most notable and unusual department of psychiatry at Washington University in St. Louis led by Professor Eli Robins and his colleagues, where Dr. Clayton trained, and where Dr. Winokur worked for many years before becoming chairman of psychiatry at the University of Iowa. The present edition is based at the University of Minnesota and is again edited by Drs. Fatemi and Clayton. Most of the 81 authors of this edition are from Midwestern American institutions.

This fourth edition has 1064 pages, with 43 chapters organized into four parts: I. Adult Syndromes (17 chapters), II. Child Psychiatry (5 chapters), III. Symptom Clusters (6 chapters), and IV. Special Areas (15 chapters). Diagnosis largely follows DSM-5 criteria. For a complex, multiauthored product, there is substantial uniformity of organization and referencing, which is extensive. Topics addressed in considerable detail include those expected of a medically oriented text, such as neuroimaging, genetics, and psychopharmacology, as well as consideration of therapeutic brain stimulation and psychosurgery. An interesting discussion addresses findings from basic neuroscience from the perspective of potential therapeutic innovations, and there are useful summaries of psychometric rating scales and of normal laboratory testing values and typical serum concentrations of psychotropic drugs. Forensic psychiatry is covered, and there is a single chapter on psychological treatments, based heavily on behavioral and cognitive methods. A particularly clinically and educationally useful section considers symptom clusters or syndromes rather than "disorders" in the somewhat narrower DSM tradition. A unique chapter presents brief biographical sketches of noteworthy historical figures in psychiatry and neuroscience—ranging from ancients, through 19th and 20th century leaders, to living neuroscientists and pharmacologists.

Overall, this somewhat enlarged volume very effectively continues the valuable tradition started by Drs. Winokur and Clayton in 1986, and ably continued by Drs. Fatemi and Clayton. The fourth edition continues as a leading and novel textbook of psychiatry with a strong neuromedical orientation. It can be highly recommended for students, trainees, and professionals working in this complex and constantly evolving field.

Harvard Medical School
Boston, Massachusetts

Preface

It has been 8 years since the last edition of *The Medical Basis of Psychiatry* was published. The third edition of the book was quite successful in terms of readership and received overwhelmingly positive reviews from the scientific community. As numerous changes have occurred in the field of psychiatry including advances in neuroscience of the brain, genetics, pharmacology, and etiology of brain disorders, it was deemed necessary to update the book again to collect all of the newest information for clinicians and students. All chapters have been updated and some new topics have also been added such as a discussion of neuromodulation and rating scales in psychiatry. Additionally, details about several new medications introduced since 2008 have been added to the book. We are grateful to all of the chapter authors who have updated the book. We are hopeful that this edition meets with the approval of the readership.

Acknowledgements

We are extremely indebted to Mr. Timothy D. Folsom, who has faithfully and carefully reviewed all chapters for accuracy and worked as a liaison between the editors and the authors of the chapters, and Ms. Jennifer M. Bredemeier for help with various aspects of editing this book. We are also grateful to the authors who have generously given of their time in writing the various chapters as well as to Mr. Richard Lansing, Mr. Brian Halm, Ms. Mary Meritt, Ms. Caitlin Prim, Ms. Amina Ravi, Ms. Ritya Hegde, and Springer Science + Business Media for an excellent job in publishing this book.

The Mental Status Examination

Hagop S. Akiskal, M.D.

Abstract The Mental Status Examination represents a crucial part of the psychiatric interview in that it is devoted to a systematic elicitation of psychopathologic signs and symptoms that are important in diagnosis and differential diagnosis. It is an essential tool for all psychiatrists and mental health professionals, but in abbreviated form, it is an important tool for all physicians.

The present chapter which is derived from the author's teaching experience to medical students, psychiatry residents, and family physicians considers both classical and modern psychopathologic concepts. It is divided into appearance and behavior, psychomotor activity, affect and mood, speech, thinking, perceptual disturbances, orientation, attention and memory, as well as reliability, judgment and insight. Finally, common errors in mental status in clinical evaluation are discussed.

Keywords Mental status · Psychiatric history · Psychiatric interview

This chapter is devoted to the science and art of eliciting the signs and symptoms of mental disorders. The systematic perusal of these manifestations during the psychiatric interview constitutes the mental status examination, which can be viewed as analogous to physical examinations in other branches of medicine (1).

> Consider, as an example of this process, the mental examination of a 26-year-old single, male Caucasian engineering student who was brought to the hospital because of "acute sinus trouble." He had locked himself in his apartment for a week and refused to speak to anyone. When asked about his reasons for this behavior, he stated that he did not wish other people to hear the "noise emanating from my sinuses." The patient looked disheveled and had a frightened facial expression. Despite the psychotic content of his verbalizations, associations were grossly intact. Upon further questioning, he admitted that the "sinus noise" actually consisted of "voices, as if a transistor was installed up there in my head." The voices that were of the greatest concern to him argued in the third person about whether or not he was a "female." He was tremulous and restless during the interview, and on one occasion, he walked to a mirror and began to examine his facial features; with great reluctance, he admitted that he was being "transformed into a female," as the voices implied. At one point he became hostile and threatened to take legal action against a surgeon who, he believed, had "Implanted a device" into his sinuses during an operation for deviated nasal septum 8 months earlier; he added that subsequent to this operation he had intermittently experienced "foul smells" which, like his thoughts, had been "'implanted from outside." All these manifestations occurred in clear consciousness, without evidence of disorientation or memory disturbances.

To arrive at a diagnostic formulation, the examiner considers the signs and symptoms observed during the mental status examination in combination with information obtained from the psychiatric history. In this case, the diagnosis of paranoid schizophrenia was suggested by lifelong traits of seclusiveness, suspiciousness, and litigiousness; the absence of a history of substance abuse; and persistence of this clinical picture for longer than 6 months in the absence of major mood symptoms. Laboratory studies [e.g., negative urinary drug screen for stimulants and a normal sleep-deprived electroencephalogram (EEG)] were used to rule out, respectively, the remote possibility of stimulant-induced psychosis or complex partial (temporal lobe) seizures as the basis for his presenting complaints. Such physical workup to rule out somatic contributions is often a

H.S. Akiskal, M.D. (✉)
Professor and Director of International Mood Center, Department of Psychiatry, and Division of International Health and Cross-Cultural Medicine, University of California at San Diego, La Jolla, CA, USA
e-mail: hakiskal@ucsd.edu

S.H. Fatemi and P.J. Clayton (eds.), *The Medical Basis of Psychiatry*, DOI 10.1007/978-1-4939-2528-5_1

necessary step in psychiatric presentations with complex symptomatology, especially in patients with first psychotic breakdowns (2, 3). The presence of a positive family history for schizophrenia in a paternal cousin provided further support for a schizophrenic diagnosis.

Thus, the diagnostic process in psychiatry is analogous to that used in other branches of medicine: personal history, family history, examination, and laboratory tests constitute the essential steps. Because the raw data of psychopathology are often subjective and may elude precise characterization, the mental examination is of particular importance in psychiatry. Accurate description is difficult to obtain without careful and skillful probing during face-to-face interview. The faithful description of subjective experiences in psychiatry, known as *phenomenology*, was perfected by the German psychiatrist Karl Jaspers (4). His approach differs from that of Freudian psychodynamics, which concerns itself with the unconscious meaning and interpretation of symptoms. In contrast to the Freudians, who focused on the content of psychopathology, hypothesized to arise from early life situations and current interpersonal distortions, Jaspers believed that phenomenology—by its emphasis on the *form* of psychopathologic experiences—would eventually disclose "primary" symptoms, which are closest to the neurophysiologic substrate of the illness and which would therefore carry the greatest diagnostic weight. For instance, in the case of the engineering student, the fact that he heard voices arguing about him in the third person is more important *diagnostically* than what those voices said about him (that he was a female). The latter can variously be interpreted psychodynamically or by some other theoretical frame of reference, which pertains to the *formulation* of the case, not formal diagnosis.

A detailed mental status examination constitutes an area of psychiatric expertise, but in briefer format, it is an essential tool for all physicians. A brief mental status examination should be performed as part of the routine physical examination on all patients. When indicated, this should be followed by a more detailed mental examination.

1.1. The Importance of Signs and Symptoms in Psychiatry

Precision in the use of clinical terms to describe signs and symptoms is essential in all branches of medicine, promoting professional communication and preparing the ground for differential diagnostic workup. Imagine, for instance, what would happen if a patient with hemoptysis was erroneously described as having hematemesis. This would certainly confuse one's colleagues as to the medical status of the patient and could lead to an inappropriate series of diagnostic procedures. One can cite many other examples, such as jaundice versus pallor, ascites versus obesity, a functional versus an aortic stenosis murmur, which can all lead to difficulties in differentiation. In brief, genuine difficulties in eliciting, describing, and differentiating the myriad signs and symptoms that characterize diseases occur in all branches of medicine. Psychiatry is certainly not immune to such difficulties, but the belief—regrettably voiced by some medical educators—that differential diagnosis in psychiatry is haphazard and unproductive is both unfounded and dangerous. It is such attitudes that often lead patients with "functional" complaints to be labeled as "crocks," without the benefit of appropriate diagnostic evaluation. They may be viewed as having "imaginary" somatic complaints that waste the physician's time. The potential dangers of such attitudes can be seen in a study in the *Annals of Internal Medicine* (5), which reported that the majority of a sample of completed suicides in St. Louis were seen by physicians within 6 months before their deaths; not only was the depressive nature of their ailment missed, but sedatives, in lethal quantities, were prescribed for their complaints of disordered sleep.

Although physicians typically spend many years mastering the art and science of physical diagnosis, little attention is given in medical education to the mental status examination. Many physicians are unaware that there exist systematic rules—analogous to those used in physical diagnosis—and which can serve to assess mental status. Moreover, it is seldom recognized that the failure to distinguish, for instance, whether a patient is "sedated" or "depressed" can be as grave as the failure to distinguish between dyspepsia and angina: just as angina can be the prelude to myocardial infarction, unrecognized depression can be the prelude to jumping out the hospital window.

The mental status examination is not just common sense or an expression of humane attitudes that assist the physician in empathizing with the patient while probing his inner experiences. Good judgment in complex human situations (an uncommon form of common sense!) and an approach that considers the patient in his or her totality are not the sole prerogative of psychiatry: they are important in all branches of medicine. These attitudes merely set the stage for the practice of the clinical principles that constitute the body of scientific knowledge in any field. In psychiatry, there are established rules in the use of phenomenologic terms to arrive at diagnostic formulations that are the product of nearly 200 years of systematic clinical observation (6, 7). International consensus and standardization have now been reached on the description and clinical probing of psychopathologic experiences as exemplified in the World Health Organization development of the Schedule for Clinical Assessment in Neuropsychiatry (SCAN) (8). The SCAN covers in depth all facets of psychopathology. The Mini-Mental Status Examination (9), widely used at the bedside, is another more focused interview.

1.2. Special Problems in Psychiatric Phenomenology

Admittedly, there are many difficulties in the application of psychiatric terms and concepts. These fall into several categories.

Many psychiatric phenomena are subjective and do not easily lend themselves to objective description.

> For instance, one of the author's patients described herself as being "transformed into a pig" while looking in the mirror. Here, the patient's verbal report is the only evidence for the occurrence of this experience. It is important to record such symptoms – in the patient's exact words – to decide whether the incident is indicative of incipient schizophrenia (psychotic depersonalization in which the self changes) or primary mood disorder (a depressive delusion that one is as ugly and dirty as a pig). This patient, who had no family or personal history of mental illness, suffered from a psychotic major depressive episode. She also saw herself in a coffin and heard voices commanding her to cut her throat with a butcher knife. She recovered fully with a course of electroconvulsive therapy (ECT).

The concepts used in psychiatry are not readily susceptible to the same kinds of external validation that are used in other branches of medicine (e.g., laboratory data). Psychiatrists often rely on family history, treatment-response, and prospective course in validating diagnostic decisions made during cross-sectional examination. For instance, in the case just described, the response to ECT and the full recovery from the psychotic episode strongly favor the affective diagnosis. There has been considerable momentum in attempting to link psychopathologic events with biologic correlates (10). Although no single biologic finding has yet been accepted universally as an unambiguous marker for a specific psychiatric syndrome, several sleep laboratory and neuroendocrine indices can sometimes now be used—along with more traditional approaches—in elucidating diagnostic dilemmas (11–13). These biologic markers, then, are not meant to substitute for clinical judgment, but to supplement it in difficult differential diagnostic decisions.

These foregoing considerations pertain to the external validation of the so-called functional psychiatric syndromes. Laboratory tests are of course used in differentiating general medical and central and peripheral nervous system diseases which are known to produce psychiatric disorders from those in the absence of such ostensible etiology. Unfortunately, at this writing, despite massive and continued research efforts along the lines of genetic and brain imaging techniques, no specific laboratory tests exist for the diagnosis of common mental syndromes without known organic lesions. Psychiatric diagnosis at the present remains quintessentially a clinical endeavor based on the clinical acumen of the examiner at the bedside or in the clinic.

Mental health professionals themselves have, at times, been imprecise in the use of psychopathologic terms and concepts. This situation, however, has improved with the advent of modern pharmacotherapy and biologic psychiatry, in which syndrome-specific treatments, such as mood stabilizers, SSRIs, antipsychotics, and anxiolytics, dictate precise diagnostic evaluation and the course of illness.

Being awarded a doctorate in medicine does not automatically confer to the recipient the art of communication. Given the life-and-death nature of their endeavor, medical students—perhaps more than any other group of professional students—should endeavor to develop the proper habits of precise expression. I am not referring to literary flair—though that would be admirable—but *clarity* of prose.

1.3. Recording Signs and Symptoms in Psychiatry

Signs refer to the clinician's observations of the patient. Symptoms, on the other hand, represent the subjective complaints of the patient based on his verbal report. For instance, agitation is a sign, based on the observation of motor restlessness, pacing, pulling one's hair, and so on. Auditory hallucination is a symptom typically based on patient report. Signs assume major significance when the patient is mute, stuporous, confused, or reluctant to talk.

Whenever feasible, one should try to corroborate symptoms with other observations. There are several ways to accomplish this:

- *Recording overt behavior that is consistent with the symptom*. For instance, does the patient who reports hearing voices appear preoccupied—perhaps mumbling to himself in an attempt to answer the voices? More gravely, the patient may obey the commands given by voices. Likewise, the presence of a delusion can be inferred from behavior that results from it. For instance, a patient who believes himself to be persecuted by the Mafia may decide to move to another town.
- *Recording historical data consistent with the symptoms*. Often patients' reports suggest corollary data that can be confirmed or refuted by other information obtained from patient or significant others. For instance, in the case of a patient who reports loss of ability to derive pleasure from life (anhedonia), one may question his wife as follows: Does he indulge in his hobbies? Does he engage in sexual activities that he previously enjoyed? For the patient who complains of loss of appetite, one might inquire whether he had lost weight or whether his clothes are large on him.
- *Recording other subjective experiences correlated with the symptom*. In some situations this is indeed the best validation. For instance, the report of homosexual orientation or preoccupation can be assessed in terms of masturbatory fantasies.

In this instance, it is known that homosexual masturbatory fantasies may be more valid indicators of homosexuality than, say, incidental same-sex activity.

- *Physiologic monitoring*. In some situations, a precise physiologic measure can be recorded to substantiate a symptom. The subjective complaint of insomnia, for instance, can be measured with all-night sleep polygraphy (14). This is important because many complaints of insomnia are vague. Neurophysiologic evaluations in sleep laboratories have indeed found that some "insomniacs" actually sleep as long and consistently as people without sleep complaints. Other insomniacs manifest delayed latency to sleep and frequent awakening in the first part of the night (as is characteristic of anxiety disorders). Others manifest early appearance of the first period of rapid eye movement and frequent awakening in the middle and terminal part of sleep (as is characteristic of clinical depression). Finally, other sufferers of insomnia may exhibit specific physiologic changes that characterize specific sleep disorders such as restless leg syndrome and nocturnal myoclonus.

A cardinal rule in recording psychopathologic phenomena is to distinguish clearly those phenomena which are based on history, direct observation, or patient report from inferences that one may derive from such phenomena. For instance, the clinician should avoid describing a patient engaging in "massive projection," when what the patient said was "everyone hates me." The patient's actual report should appear in quotes in the mental status proper, while the inference of "projection" (if made plausible by other evidence) is best reserved for psychodynamic formulation (15). Thus the mental status examination should be free from speculation: it should be a record of the patient's mental condition as described by him and as observed by the clinician.

Aristotle has said that some phenomena, such as colors, can only be defined by pointing at them. This is also true of many manifestations of psychopathology that can be learned only in reference to actual patients. Hence the definitions offered in the following sections are merely a guide for a more intensive patient-based study. Moreover, this is not an exhaustive list of approaches and terms used in mental status examination. The differential diagnoses of signs and symptoms discussed throughout this introductory chapter will selectively focus on those concepts which have special diagnostic significance and which appear to be particularly problematic for trainees.

1.4. Conduct of the Mental Examination

The areas covered in the mental status examination are summarized in Table 1.1. Although flexibility is necessary to allow for special circumstances presented by individual patients, a complete psychiatric examination generally should cover all these areas and is conventionally written up (if not conducted) in the order outlined.

Patients presenting problems generally dictate the types of questions asked and the length and depth of interview. Research clinicians often conduct extensive structured interviews using specific probes for a standardized assessment of individual signs and symptoms. Practicing clinicians have traditionally conducted more or less unstructured interviews that provide for flexibility to tailor questions to the particular situation of the individual patient. Current experience indicates that when major mental illness is suspected, much can be gained by combining the virtues of these two approaches in a semistructured format. This way

TABLE 1.1. Mental status examination outline.

Appearance and behavior
Attire, grooming, appears stated age?, posture, facial expression, eye contact
Attitude toward interviewer
Friendly, cooperative, seductive, ambivalent, hostile
Psychomotor activity
Normal, retarded, accelerated, agitated, catatonic symptoms
Affect and mood (*emotional state*)
Euthymic, irritable, anxious, labile, inappropriate, blunted or flat, depressed, elated
Speech and thinking
Process or form: coherent, circumstantial, pressure of speech, flight of ideas, derailment (loose associations)
Content: phobias, obsessions, compulsions, delusions
Specific speech disorders: echolalia, perseveration, mutism, aphonia, aphasia
Perceptual disturbances
Illusions, hallucinations, depersonalization, derealization
Orientation
Time, place, person, situation
Attention (*concentration*) *and memory*
Digits forward and backward, serial 7, street address, recall of three objects, amnesia
Intelligence
Abstraction, vocabulary, global clinical impression of IQ
Reliability, judgment, and insight

one would conduct a full examination to inquire about areas that an unstructured interview could easily miss while at the same time providing flexibility to follow the patient's leads and to frame the questions as best understood by that patient. When conducting an interview, beginning students should have available for quick reference an outline of the mental status examination, as well as the specific signs and symptoms most relevant to the differential diagnosis at hand. A pocket copy of the "mini-DSM-IV-TR" (16) is useful for this purpose; another useful guide is Goodwin and Guze's *Psychiatric Diagnosis* (17).

It is not necessary to conduct all parts of the interview with the same depth on all patients. For instance, one need not directly check the orientation, vocabulary, and calculating ability of a moderately anxious young university professor who appears to be in good contact. Nor is it necessary to inquire extensively about bizarre psychotic experience when interviewing a diabetic patient who presents with the chief complaint of difficulty in attaining erections. Experience teaches one when such shortcuts can be made. The examiner must at times forego inquiry into a given area out of consideration for the patient, who may be unwilling or too uncomfortable to talk about certain topics; if the omitted area is of major significance for differential diagnosis, one should endeavor to obtain collateral information from significant others or return to questioning the patient at a later time, using a more indirect approach. There are situations in which one should conduct the mental status in multiple brief encounters, as in the case of extremely disturbed, violent, psychotic, or semistuporous patients, attempting to glean the optimal amount of information necessary for a tentative diagnosis.

1.5. Areas of the Mental Status

The mental status typically begins with a statement about the setting in which the examination was conducted (e.g., inpatient or outpatient, private or public institution) and the purpose for which it was done (e.g., initial evaluation for outpatient treatment, disability determination, consultation for another physician). It typically follows a careful review of all existing records and proceeds with the areas described below.

1.5.1. Appearance and Behavior

Although this is the first section of the mental examination, relevant data are gathered throughout the interview process. Attire, posture, facial expression, and the level of grooming are described in such a way that the person reading the narration can visualize the patient's physical appearance at the time of the examination. It is important to note any obvious physical signs or deformities that point toward medical disease. The chronically ill and those experiencing severe depression may look older than stated age; by contrast, hypomanic, histrionic, and hebephrenic individuals may look younger. Poor eye contact may indicate shame, embarrassment, anxiety, social anxiety, or paranoid traits. In some cases, little will be revealed in this section beyond the fact that the patient's physical appearance was unremarkable compared with other individuals of same age, educational level, and socioeconomic status. In other instances, the general observation may provide important clues about the patient's personality, mood, thought, awareness of social conventions, and ability to function adequately within society.

1.5.2. Attitude Toward the Interviewer

The patient's attitude toward the interviewer is often evident without specific inquiry, simply by ongoing observing of the patient throughout the interview. Some patients relate easily, are open and cooperative, and reveal plenty of information without much probing. Others may be reticent, guarded, or even suspicious, too embarrassed, unwilling, or frightened to share personal experiences. Some may be overtly hostile, even attempting to embarrass or humiliate the examiner; in the extreme, the patient may be uncommunicative or openly belligerent. Some patients are obsequious, trying to flatter the examiner, emphasizing how competent he is compared with all previous doctors, who "do not seem to care." Others may display *ambivalence*, a term that refers to the simultaneous presence of "incompatible" emotions (positive and negative). Still others may be overtly seductive. Clinical experience teaches the clinician how to interview these different kinds of patients. The two extremes of aggressive and seductive behavior represent the greatest challenge for clinical interviewers. Faced with such behaviors, the interviewer must set limits and maintain objectivity without losing empathy.

1.5.3. Psychomotor Activity

Psychomotor activity refers to physical activity as it relates to psychological functioning. A patient who displays "psychomotor agitation" moves around constantly, cannot sit still, and often shows pressure to talk. One may observe hand wringing, shuffling of feet, crossing and uncrossing of knees, picking on scabs, scratching, nail biting, hair twisting, and even hair pulling. One

must contrast such purposeless physical restlessness with the more patterned psychomotor acceleration, in which the patient is extremely "busy," engages in many activities, talks incessantly by jumping from topic to topic, and experiences rapid thought progression. In the extreme, both agitation and acceleration may lead to frenzied activity that can be debilitating. In fact, before the availability of electroconvulsive and neuroleptic treatments, some of these patients died of sheer exhaustion. In other patients, one observes psychomotor retardation, in which there is a general slowing of movement, speech, and thought progression. Here, the patient may sit in a slumped, often frozen posture; speech is slow, monosyllabic, and of low pitch, accompanied by few gestures; and facial expression is either sad or blank. For such patients, talking may seem to be an effort, and latency of response to questions is typically prolonged. In some conditions, such as mixed states of affective psychosis, psychomotor agitation and retardation can be present, i.e., physical slowing with racing thoughts simultaneously; these patients are often suicidal (18). Abnormal psychomotor activity on repeated examination is usually indicative of a major psychiatric disorder. Quantitative rating of psychomotor function is now possible through the use of a reliable scale developed by Widlöcher and his team at the Salpetrière Hospital in France (19). Despite proposals to develop physiologic measures of speech pause time and abnormalities of facial expression of emotions (20), this area still very much relies on qualitative judgments made by experienced clinicians. In other words, there is no objective test to determine whether the facial expression of a patient is one of fear, depression, anger, or elation (21). Darwin (22) wrote extensively about the evolutionary significance of emotions. His book, recently reprinted, remains the classic on the topic (22).

Other forms of psychomotor disturbances that occur in psychotic states include "posturing," "stereotyped movements," "mannerisms," "negativism" (doing the opposite of what is requested), *echopraxia* (imitating the movements of another person), and "waxy flexibility" (maintaining certain awkward positions despite apparent discomfort). In the extreme, such manifestations may progress to *stupor*, which represents an extreme degree of psychomotor retardation and mutism combined. The condition is sometimes observed on the battlefront or in civilian catastrophes, where the victim may be "paralyzed by fear." In the absence of such history, organic contributions should be excluded by EEG, various brain imaging techniques, lumbar puncture, and other laboratory tests. Once this is done, intravenous amytal may help in differentiating depressive from schizophrenic stupor; the schizophrenic patient will momentarily come out of his state of inactive *mutism*, and express delusional thoughts, for example, that he dare not move because his weight "would tilt the balance of the earth and bring the end of the world." The two conditions may be further distinguished clinically by the presence of urinary incontinence, catalepsy (increased muscle tension), and expressionless *facies*, all of which are more suggestive of catatonic schizophrenia than of depression.

1.5.4. Affect and Mood

Affect is the prevailing emotional tone during the interview, as observed by the clinician. One must describe whether the patient exhibits an appropriate range of affect, which varies with the theme of the conversation and may include fear, sadness, and joy. In the case of marked disparity between affect and thought content, one speaks of inappropriate or "incongruent affect." Other commonly observed disturbances of affect include tension (or inability to relax), panic (a crescendo increase in fear), anger (a predominantly argumentative or hostile stance), "lability" (rapid shifts from happiness to sadness, often accompanied by giggling, laughing, or, conversely, sobbing and weeping), and "blunting" or flattening (minimal display of emotion, with little variation in facial expression). In addition to the observed disturbances of affect, the clinician also must record the mood, or subjective feeling state, reported by the patient over the preceding several days or weeks. The most common moods reported by patients are depression (i.e., feeling in "low spirits" or "down in the dumps") and anxiety, a feeling of apprehension whose source remains undefined. When irritability is the prevailing mood, the patient may report having a "short fuse." In "euphoria," the mood is one of extreme elation and jubilation that is not justified by objective circumstances. These self-reports will not necessarily coincide with the observed affect. For instance, some patients may have a gloomy, downcast expression, yet vigorously deny experiencing depressed mood; conversely, patients who do not show prominent signs of emotional distress may report a pervasive gloom. Such lack of concordance between subjective report of mood and observable affect and behavior is not uncommon in both normal and psychopathologic states (23). In the absence of specific disturbance in affect or mood, the patient is described as "euthymic."

1.5.5. Speech and Thought

In this section the examiner describes the patient's verbal communication and its disturbances. *Thought form* (or thought process) refers to how ideas (or associations) are put together in an observed sample of speech and in what sequence and speed. A patient exhibiting no abnormality in the formal aspect of thought is said to have intact associations, coherent thought that is clear, logical, and easy to follow and understand. In "circumstantiality," there is a tendency to answer questions in terms of long-winded details. In "pressure of speech," the patient seems to be compelled to talk, while in "flight of ideas," thoughts actu-

ally race ahead of the patient's ability to communicate them; he skips from one idea or theme to another, and ideas may be connected by rhymes or puns ("clang association"), as shown in this address made by a patient to the psychiatrist in chief during the morning round: "Let me part soon … to the moon … moonshine is for lovers … the cure for lovers' heart … the lure of poets … the doors of perception … a magnificent conception … on! on! Let me conquer the moon."

This form of thought is most characteristic of mania and tends to be overinclusive, with difficulty in excluding irrelevant, extraneous details from the association. In the extreme, it may be hard to draw the line between manic flight of ideas and schizophrenic derailment (literally, "off the track"), in which it is impossible for the observer to glean any logical sequence from the patient's speech. Patients with the latter degree of "loosening of associations" sometimes invent new words that have private meanings ("neologisms"). Associative slippage also may manifest in general vagueness of thinking, which is not grossly incoherent but conveys little information, even though many words may have been used. This disturbance, known as "poverty of thought" (24), is a major diagnostic sign of schizophrenia, when known organic mental disorders have been ruled out. Here is a sample from a letter a high school student wrote to the psychiatrist in response to the question why he was in the hospital: "I often contemplate—it is a general stance of the world—it is a tendency which varies from time to time—it defines things more than others—it is in the nature of habit—this is what I would like to say to explain everything."

Bleuler (25) coined the term "autism" to refer to the self-absorption that he believed characterized schizophrenic thought, feeling, and behavior (25). Thinking that is governed by inner drives and a "private logic" is therefore known as autistic thinking; "dereistic thinking" is a synonym for it. Current evidence indicates that such thinking may actually reflect, in some cases, reactive reduction of left cerebral density (26).

"*Echolalia*," most commonly observed in catatonia, is the irrelevant, sometimes playful, repeating of words used by the interviewer (e.g., "What day is today?" "Today"). In "perseveration," also seen in catatonia, as well as in chronic organic mental disorders, the patient adheres to the same concept or words and appears unable to proceed to others. "Thought block" refers to the sudden arrest of thought in the middle of a sentence, often followed, after a momentary pause, with a new and unrelated thought. When mild, this experience may be caused by exhaustion, anxiety, or depression; severer degrees are seen in schizophrenia, where they may be the observable counterpart of the subjective experience of thought withdrawal. *Mutism* consists of the loss of speech and can be intentional in origin (as part of a dramatic cluster personality disorder) and limited to interactions with certain people (elective mutism) or involuntary (as part of catatonia or midline lesions of the brain). In *aphasia*, owing to dominant temporal lobe lesions, the patient has a specific memory disorder for words and language; even when unable to talk, the patient usually attempts to communicate by other methods. In *dysphonia*, the patient loses his voice and cannot raise it beyond a whisper, which, in the extreme, can proceed to aphonia; here, in contrast to mutism, one can observe lip movements or nonverbal attempts to communicate. Unless based on laryngeal pathology or excessive use (i.e., as in teachers) or abuse of vocal cords (as seen in voluble manics), these deficits in phonation are almost always due to a conversion disorder, representing, for example, a compromise in an adolescent who feels conflicted between lying and telling her parents the truth about sexual behavior of which they would strongly disapprove.

Common abnormalities of *thought content* include obsessions (repetitive ideas, images, or impulses that intrude into consciousness unwanted, yet patients are aware that these thoughts are their own), compulsions (irresistible urges to engage in apparently meaningless acts), and phobias (irrational fears unjustified by objective circumstances). Phobias are usually categorized by the circumstances eliciting them, such as social phobia (a common form of which consists of fear of facing a group in a lecture situation), agoraphobia (fear of going out alone in public places), acrophobia (fear of heights), etc.

Two obsessions that commonly torment neurotic patients are the unwanted idea that one might inadvertently harm or kill loved ones and that one could be contaminated by germs, dirt, excreta, or other undesirable elements. The latter obsession is typically associated with cleaning compulsions or rituals to rid oneself of such elements. The unwanted idea (obsession) that one might inadvertently hurt loved ones does not ordinarily lead to taking action; instead, it may be associated with the ritual of hiding away knives, scissors, other sharp objects, etc. Thus obsessions with aggressive content should be distinguished from homicidal ideation or threats, which do carry some likelihood of being carried out. The clinician must likewise distinguish between an obsession with self-injury content and suicidal ideation. The former refers to the tormenting thought that one might, contrary to one's value system, hurt or kill oneself. However, in other patients, the pain of depression can be of such a magnitude that the normal barriers that prevent one from taking one's life do break down, and thus suicidal thoughts can lead to suicidal action; suicidal ideation is a particularly ominous symptom if associated with loss of hope for the future (hopelessness). Such patients should be carefully monitored to prevent suicide (27). Therefore, *the clinician should always inquire about suicidal ideation and suicidal plans (as well as current and past attempts and their outcome)*; the notion that one thereby inadvertently "puts thoughts into the patient's head" is unfounded; on the contrary, patients are typically relieved that the physician is aware of their mental suffering and could provide appropriate measures to terminate it. It is also important to realize that not all depressed patients actively contemplate suicide; instead, this propensity may be expressed more passively as a general feeling that life holds little meaning for them (tedium vitae) and that they would prefer not to wake up in the morning, or that they would welcome a fatal disease or an accident. It is incumbent upon the psychiatric examiner to explore such possibilities with circumspection and sensitivity.

"Delusions" are common abnormalities of thought content among psychotic patients. They are defined as false beliefs that are unshakable and idiosyncratic to the individual. Thus the beliefs of a delusional patient cannot be typically undone by logical arguments to the contrary, as illustrated in the following vignette:

> An African-American female inpatient, admitted to an emergency psychiatric service, believed that she was Jesus Christ. When questioned by a nursing trainee how this was possible, given that Christ was male, white, and Jewish, the patient responded with a smile: "The Bible is wrong." The examiner in this instance was lucky to elicit a mere smile; delusional beliefs are often associated with more vehement affect. Therefore, they should be probed with the requisite tact and sensitivity on the part of the examiner, especially when they involve race, gender, and religion.

It is also important to keep in mind that the idiosyncratic nature of delusional beliefs means that they are *not shared by members of the same culture or subculture*. For instance, the belief that one is sexually "voodooed" and will not regain one's potency until the spell is lifted is not necessarily delusional; neither are beliefs in unusual health practices and folk remedies. The decision of whether one is dealing with a culturally accepted phenomenon must be based on a thorough knowledge of a given culture or subculture. To complicate matters, in cultures where voodoo and witchcraft are part of daily life, delusions may sometimes represent pathologic elaborations of such beliefs. The definitive test is whether an unusual belief is shared by members of the patient's subculture. Delusions also must be differentiated from "overvalued ideas," which are fanatically maintained notions, such as the superiority of one sex, nation, or race over others, and while not necessarily an indication of clinical pathology, such ideas may, in the extreme, suggest the diagnosis of a personality disorder described by the German psychiatrist Kurt Schneider as a "fanatical psychopathy" (28).

Delusions are categorized as "primary" or "secondary." Primary delusions cannot be understood in terms of other psychological processes. The most common examples of these are represented by Schneider's first-rank symptoms (29), which consist of externally imposed influences in the spheres of thought ("thought insertion"), emotion, and somatic function ("passivity feelings"), as well as experiences of "thought withdrawal" and "thought broadcasting"; hence they are also known as delusions of control or delusions of influence. Primary delusions may arise in the setting of what is termed "delusional mood," in which the patient is gradually losing his grasp of reality: neutral percepts may suddenly acquire special personal or revelatory significance of delusional proportion (e.g., a red car being seen as an indicator of imminent invasion by communist forces). This two-stage phenomenon, known as "delusional perception," is also considered a first-rank symptom. Although one or two Schneiderian symptoms may be seen in severely psychotic affective—especially manic—patients (30, 31), the presence of a large number of such symptoms usually points toward schizophrenia (32, 33), provided that stimulant-induced psychosis, complex partial (temporal lobe) seizures, and alcoholic hallucinosis are excluded.

Secondary delusions derive from other psychopathologic experiences and occur in a variety of psychiatric disorders. Delusions may be secondary to:

- Hallucinations—the patient hears the voice of his deceased mother and concludes that he must be dead too.
- Other delusions—the patient believes that he is being persecuted by others, may decide that he must be the messiah.
- Impaired memory—a patient with general paresis of the insane (tertiary syphilis) who, unable to remember where she had placed her purse, repeatedly called the police to report that her neighbors were robbing her.
- Morbid affective states—These are sometimes referred to as *affective delusions* and arise from the prevailing mood—usually depression—and the associated guilt, low self-esteem, and insecurity (33).

Delusions can take the form of delusions of guilt or sinfulness (the belief that one has committed an unpardonable act), delusions of jealousy (false belief in infidelity of spouse or lover), hypochondriacal or somatic delusions (i.e., delusions of ill-health), nihilistic delusions (the belief that parts of one's body are missing), and delusions of poverty (the belief that one has lost all means and family members will starve).

Other delusions secondary to affective states include *delusions of reference* (the idea that one is being observed, talked about, laughed at, etc.), *erotomania* (in which the patient believes that a famous person is in love with him or her), and *grandiose delusions* (belief that one has unusual talents or powers or that one has the identity of a famous person). Although erotomania and grandiose delusions often arise in the setting of expansive mood, one can usually find clinical evidence for underlying low self-esteem or depression. Delusions of reference can occur in affective, schizophrenic, as well as organic psychoses. In what is termed *delusions of assistance*, the patient believes oneself to be the object of benevolence from others or supernatural powers; for example, a manic woman, who had run away from her ex-husband's harassment, stated that chariots were being sent to transport her and her children to heaven. In the more common persecutory delusions, the patient believes oneself to be the target of malevolent action; this may be due to the conviction that one is somehow guilty and deserves punishment, or it may result from a grandiose self-concept; in other cases, the patient may be misattributing his hostile impulses to his presumed persecutors.

1.5.6. Perceptual Disturbances

The simplest form of perceptual aberration is represented by an *illusion*, often in the visual sphere, in which real stimuli are mistaken for something else (e.g., a belt for a snake in a dimly lit room). Such misinterpretation can be secondary to exhaustion, anxiety, altered states of consciousness, delirium, or a functional psychosis.

Hallucination, a more serious perceptual disturbance, consists—in Esquirol's definition—of a perception without external stimulus (34) (e.g., hearing voices when nobody is around, seeing things that are not there, or perceiving unusual odors and tastes). In synesthesia, observed in psychedelic intoxication, the perceptual disturbances are in more than one sensory modality, and the subject "hears" colors, "smells" music, and so on. For example, Baudelaire, the French poet whose drug experimentation was well known, wrote about the color of vowels: "A noir, E blanc, I rouge, U vert, O bleu" (i.e., A = black, E = white, I = red, U = green, and O = blue).

Auditory hallucinations are classified as either elementary (noises) versus complete (voices or words). They are commonly reported by schizophrenic patients, but also occur in organic mental disorders and drug intoxication or withdrawal. Some patients in the initial stages of a psychotic breakdown report hearing their own "thoughts spoken aloud" (*écho de pensée*); at a later stage, voices lose their connection with the person and appear to be coming from outside, making a "running commentary" on the patient's behavior or arguing about him in the third person. These are all special categories of hallucinatory phenomena included in Schneider's list of *first-rank symptoms* (29). They occur in a variety of psychotic disorders, but when they are extremely pronounced or continuous, they suggest schizophrenia. Typically, Schneiderian hallucinations are considered to be "mood-incongruent" in that they have no plausible link to the patient's state of mood. Other hallucinations also can be "mood-congruent"; these are observed in the affective psychoses, in which voices make derogatory statements about the patient, usually in the second person ("You are a jerk") or give self-destructive commands ("Slit your throat"). Perceptual disturbances that occur in affective illness tend to be transient and typically occur at the depth or height of an affective episode or during the unstable neurophysiologic transition (mixed state) from depression to mania. They also can arise from the exhaustion, dehydration, or superimposed drug or alcohol abuse that often complicates affective disorders; these complications explain in part why mood-incongruent psychotic experiences are occasionally seen in otherwise classic affective psychoses (33).

Visual hallucinations are most characteristic of organic mental disorders, especially acute delirious states. Sometimes they are "Lilliputian" (less than life-size); they may coexist with auditory hallucinations and can be frightening. Visual phenomena associated with psychedelic drugs can be pleasant or frightening, depending on mental set. Visual hallucinations, sometimes elicited from manic patients, are not characteristic of schizophrenia but can occur in normal grief (visions of a dead relative), in depressive psychoses (e.g., seeing oneself in one's casket), and in brief reactive psychoses observed in abnormal personalities. "Hypnagogic" and "hypnopompic" hallucinations are visual experiences that occur in twilight state between sleep and wakefulness, occurring, respectively, when falling asleep and waking up. Although their occasional occurrence is normal, repeated experiences, especially when associated with sleep paralysis and sudden loss of muscle tone under emotional arousal (cataplexy), are cardinal manifestations of narcolepsy, representing rapid eye movement intrusions into consciousness. Other circumstances that can provoke visual hallucinosis include sensory deprivation (e.g., after cataract surgery), delirium, and other organic mental disorders (35). Histrionic personalities may give flamboyant accounts of "perceiving" objects or events that fit their fantasies. All these manifestations must be distinguished from perceptual disturbances, in which objects may seem to get larger or closer (macropsia) or smaller and recede into space (micropsia), which are special forms of illusory phenomena that occur in retinal detachment, disorders of accommodation, posterior temporal lesions, and psychedelic drug intoxication. Finally, psychedelic drugs can produce impression of extremely vivid colors with geometric patterns known as "kaleidoscopic hallucinations."

Olfactory hallucinations may be difficult to distinguish from illusions. For example, a woman with low self-esteem might be preoccupied with vaginal odor and might misinterpret neutral gestures made by other people as indicative of olfactory disgust. In complex partial seizures of temporal lobe origin, hallucinations of burning paint or rubber present as auras.

Haptic hallucinations (hallucinations of touch) are usually experienced as insects crawling on one's skin (known as "formication") and characteristically occur in cocaine intoxication, amphetamine psychosis, and delirium tremens owing to alcohol or sedative-hypnotic withdrawal. In schizophrenic disorders, they may take such bizarre forms as orgasms produced by invisible objects or creatures. Tactile hallucinations must be distinguished from extreme tactile sensitivity (hyperesthesia) and diminished sensitivity (hypesthesia), both of which can occur in peripheral nerve disease as well as in conversion disorders.

Vestibular hallucinations (e.g., those of flying) are seen most commonly in organic states, such as delirium tremens and LSD psychosis, and may result in serious injuries when, for example, the subject attempts to fly off a roof. In hallucinations of presence, most commonly reported by schizophrenic, histrionic, or delirious patients, the subject senses the presence of another person or creature who remains invisible. In extracampine hallucinations, the patient sees objects outside the sensory field (e.g., behind his head), whereas in *autoscopy*, the patient visualizes himself projected into space. The latter phenomenon, which can occur in organic, conversion, depressive, and schizophrenic disorders, is also known as "Doppelganger," or seeing one's double, and is skillfully portrayed in Dostoevski's novel, *The Double*.

Other perceptual disturbances that cannot be classified easily into specific sensory modalities include depersonalization (the uncanny feeling that one has changed), derealization (the feeling that the environment has changed), *déjà vu* (a sense of

familiarity with a new perception), and *déjà entendu* (the feeling that a new auditory perception has been experienced before). As isolated findings, these can occur in normal people who are anxious, tired, or sleepy, but repeated experiences along these lines indicate the following differential diagnoses (36): complex partial seizures, panic disorder, schizophreniform psychosis, hysterical dissociation, and psychedelic intoxication.

1.5.7. Orientation

In this section the clinician records whether the patient knows who he or she is (orientation to person), the place of the interview (orientation to place), the purpose for being there and the nature of the interview (orientation to situation), and, finally, what date and time of day it is (orientation to time). One who is orientated in all spheres is considered to have a "clear sensorium." Patients with affective and schizophrenic psychoses are not typically disoriented (although, because of apathy, they may fail to keep track of daily routines), whereas patients who suffer from organic mental disorders are characteristically disoriented in some or all the above areas. In acute brain disease, patients often show remarkable fluctuation in orientation depending on time of day, with worsening disorientation at night. With increasing severity of brain impairment, the patient is totally confused as to orientation, and the sensorium may be clouded at all times to such an extent that in the very extreme he may lapse into an organic stupor.

1.5.8. Attention (Concentration) and Memory

The patient who shows deficits in attention or concentration is often unable to filter relevant from irrelevant stimuli as they pertain to the interview material and thus may be easily distracted by the TV, telephone, and other background stimuli. A patient with milder disorder may be able to achieve the attention required for a successful interview but may complain that his or her mind is "not working." Care must be taken to distinguish between deficits in attention, which are involuntary, and lack of cooperation; an example of the latter would be a patient who whistles instead of answering questions that are being posed. Attention and concentration are usually tested by digits forward and digits backward ("Can you repeat 7248 forward? Can you repeat it backward?"). A related test is serial sevens (i.e., subtracting 7 from 100 and from each successive remainder); in using this test, the observer needs to make some allowance for educational background; thus, one might elect to start with "serial threes."

Deficits in memory are conveniently grouped into four kinds: (1) immediate, when the patient cannot even register things one has just been told, (2) short-term, when one cannot retain information for 5 minutes or so, (3) recent, unable to recall the events of the past months or years, and (4) long-term, or remote, unable to recollect what took place many years ago. Documented deficits in immediate recall suggest serious acute brain impairment or stupor. Less severe brain insults tend to spare registration but can lead to deficits in short-term memory, which can be assessed by asking the patient to remember a street address or three unrelated items (e.g., "17, yellow, chair") in 5–7 minutes, after making sure that the patient fully understands the items to be remembered. Recent memory is most likely to be compromised by chronic organic impairment; its intactness can be tested by asking the patient about verifiable recent events in one's life or current events. Remote memory is usually spared in the early course of dementing diseases, but at later stages, it may be impaired to such an extent that the patient may not recognize his or her own children. This is best tested by asking about several past historical events that someone with the patient's social background and intelligence can reasonably be expected to be familiar with.

Disturbances in attention, concentration, and memory are most characteristic of organic mental disorders, yet schizophreniform and acute affective psychoses also may exhibit *reversible* abnormalities in these functions. Although it is customary to use the term pseudodementia to refer to this phenomenon, it appears that reversible neurophysiologic derangements underlying these psychotic illnesses may well be responsible for the observed cognitive deficits (37). Finally, memory disturbances also can result from a combination of organic insults (e.g., head trauma) and emotional causes (e.g., hysterical dissociation) that could lead to amnesia for events before ("retrograde") or after ("anterograde") the injury. In general, the more psychogenic in origin, the more circumscribed is the amnesia, and the more organic, the more global. Retrograde amnesia for autobiographic events for variable periods can also occur after a course of electroconvulsive therapy.

It is beyond the scope of this chapter to consider more formal neurocognitive testing which neuropsychologists undertake in various localizing and diffuse brain diseases.

1.5.9. Intelligence

Intelligence can be indirectly inferred from the patient's overall intellectual performance during the mental status examination. If deficits are grossly apparent, historical information should be used to decide whether they have always been present (intellectual subnormality) or developed after a certain age (intellectual impairment). Intelligence is commonly assessed by testing for abstracting ability. To accomplish this, one inquires about similarities, going from simpler comparisons ("How are an air-

plane and a car alike?") to more difficult ones ("A painting and a poem?"). The examiner also must pay special attention to the patient's vocabulary. Vocabulary and performance on similarities testing depend not only on the patient's intellectual capacity but also on his age, social background, and educational level. For instance, the presence of a good vocabulary and abstracting ability, despite a third-grade education, indicates above-average intelligence. If vocabulary and abstracting ability are poor, allowance should be made for social deprivation. In the absence of such factors, and especially if the patient has a college education, the examiner must consider the possibility of intellectual impairment owing to an organic mental disorder.

Classically, organic mental disorders have been described as involving changes in orientation, attention, memory, and intelligence. When profound, such changes provide clinical evidence for an underlying somatic disease. However, as indicated, subtle yet measurable deficits in these mental faculties often accompany the so-called functional psychiatric disorders, and such data point to underlying disturbances in cerebral structures involved with these faculties, the precise nature of which continues to elude psychiatric research. The clinician also must keep in mind the not uncommon occurrence of moderate to severe subcortical pathology or disease with relatively intact intellectual function, manifesting instead in profound alterations in perception, mood, and psychomotor behavior; delusions, obsessions, phobias, depersonalization, derealization, and related bizarre psychopathologic disturbances often accompany such disease (3, 38).

1.5.10. Reliability, Judgment, and Insight

Every mental status examination should have a statement regarding the extent to which the patient's report of his or her experiences and behavior is to be considered reliable. This assessment is largely an aggregate based on an estimate of the patient's intellectual ability, honesty, attention to detail, and motivation. Sociopathic and histrionic individuals are notoriously unreliable. "Retrospective falsification," commonly observed in such patients, consists of distortion of real past experiences to conform to present emotional needs; at other times, they may lie to avoid personal responsibilities. A related type of unreliability is "pseudologia fantastica," expansive storytelling such that the individual is unable to discern which of one's statements are true and which are false. Psychotic patients and those with organic mental disorders also tend to be unreliable informants; here one sometimes observes "confabulation," a spontaneous fabrication of responses to fill in memory gaps.

Judgment refers to the patient's ability to evaluate the proper course of action in difficult situations and is traditionally tested by asking what one would do if one were the first to observe smoke in a movie theater. The patient's history will often give clues as to whether he or she generally has good or poor judgment. Disturbances in judgment can be circumscribed to one or more areas (e.g., money, attire, sexual conduct), leaving other areas, such as maternal role, intact. "Insight" pertains to a more complex form of judgment regarding the patient's awareness of his or her emotional state, its causes, its severity, and its impact on significant others. Psychotic patients, especially in mania, notoriously lack insight and are often unaware of the painful consequences of their spending sprees and sexual promiscuity, which explains in part their frequent lack of cooperation with treatment regimens.

1.6. Common Errors in Mental Status Examination

Eugen Bleuler's work on schizophrenia (25) continues to exert a major influence in the description and differential diagnosis of schizophrenic manifestations. Bleuler believed that disturbances in associations, affect, ambivalence, and autism characterized this group of disorders. His ideas were, unfortunately, accepted before being empirically tested, leading to much confusion in mental status evaluations. This is particularly true for disturbance in affect (39) and associations (24).

1.6.1. Disturbances in Affect

The examiner must distinguish between flat and depressed affect, which occur in disorders that seldom intersect (i.e., chronic schizophrenia versus primary mood disorder). Shallow, blunted, and flat affect refer to increasing degrees of emotional impoverishment—often accompanied by a subjective feeling that one cannot experience emotions, a classical disturbance of schizophrenia. By contrast, depression is a painful affect, what William James termed a *psychical neuralgia* (40).

Depressed patients given antipsychotics, particularly classical neuroleptics, usually for agitation, may appear to have flat or blunted affect. This is seldom observed nowadays with the advent of the atypical antipsychotics.

Many depressed patients also experience anhedonia, best described by Shakespeare: "How weary, stale, flat, and unprofitable/Seem to me all the uses of this world" (Hamlet, Act I, Scene 11). Diagnostic difficulties arise in "severe" depression, where the anhedonia may progress to a pervasive sense of emptiness, often accompanied by the inability to feel normal emotions; such patients may feel "dead inside" and see the world around them as lifeless. Differential diagnosis can be accomplished as

follows: First, the facial expression of the chronic schizophrenic individual is typically vacuous, whereas that of the clinically depressed person is typically one of pain, gloom, and dejection. Second, those with schizophrenia tend to produce, in the observer, a cold feeling and an inability to empathize (the so-called praecox feeling), whereas the depressives' dejection and pain are usually communicated in such a way that the interviewer can empathize with them. Admittedly, this is a subjective criterion, but it is quite useful in the hands of experienced clinicians.

Labile affect (which changes quickly, often from one extreme to the other) must be distinguished from incongruent affect (which is inappropriate to the thought content or the context). Labile and incongruent affects should both be differentiated from "affective incontinence," in which the patient laughs or cries for long periods with little or no provocation. Lability is encountered in the dramatic cluster of personality disorders; in mixed states of manic-depressive illness, where there are rapid shifts from elation to irritability to depression; and in acute organic brain disease, where the affect can quickly change from anxiety to terror to panic. Inappropriate affect (e.g., laughing while relating the gory details of a natural disaster) should raise the suspicion of schizophrenia. Emotional incontinence suggests organic states, such as arteriosclerotic dementia and multiple sclerosis.

Euphoria and elation, although characteristic of manic states, also can occur in organic mental disorders, such as general paresis of the insane and multiple sclerosis. The euphoria seen in mania has a warmth that is communicated to the observer (although manic patients especially when crossed, can be irritable, hostile, and obnoxious); the interviewer should avoid direct confrontation with manic patients. A type of euphoria characteristic of chronic schizophrenia and frontal lobe lesions, known as *Witzelsucht*, consists of the patient relating silly jokes; these lack the empathic contagiousness of the humor of bipolar patients.

La belle indifference should be differentiated from apathy. In the former condition—observed in conversion reactions—the patient exhibits lack of concern or even smiles in the face of reported disability. Apathy, on the other hand, seen in many chronic psychiatric patients because of their overall dismal situation, is a feeling akin to or associated with general demoralization.

1.6.2. Disturbances in Thinking

Unfortunately, "thought disorder" is often involved rather loosely to refer to both formal thought disorder and delusional content. For the sake of clarity, the unqualified use of the phrase "thought disorder" should be discarded from psychiatric communication. Even the designation "formal thought disorder" covers too wide a territory. It should always be made clear whether one is referring to derailment or loose associations, flight of ideas, or circumstantiality. The presence of a delusion cannot be considered evidence of underlying formal thought disorder because, as noted previously, delusions can be secondary to affective, perceptual, and memory disturbances. We consider below several of these issues critical for a competent mental status exam.

"Derailment" refers to a disorder in associations whereby different thoughts are dissociated, disconnected, or rambling. If mild, it leaves the impression of "vagueness"; if the patient makes no sense at all, it is referred to as "word salad." The phrase "loose associations" is used for an intermediate degree of severity, wherein one finds fragmented thoughts that do not seem to follow Aristotelian logic but may nevertheless have an inner, private (autistic) logic of their own. The "incoherence" that one observes in the thinking of organic patients is qualitatively distinct from the loose associations of the schizophrenic patient in that it lacks symbolism and autistic quality; however, in severe cases of schizophrenia, this distinction may be difficult to make. *Vorbeireden*, or talking past the point, also should be differentiated from incoherence. In *vorbeireden*, which occurs in the *Ganser syndrome*, the patient gives obvious indication that he has understood the question yet deliberately provides "approximate" answers.

> For instance, a patient examined in 1977, when asked who the president was, replied, "Jerry Carter", and when asked who was president before him, he replied, "Jimmy Ford."

The Ganser syndrome seen among prisoners is best understood in terms of conscious and unconscious reasons for appearing psychotic or demented; hence it is also referred to as "hysterical pseudodementia." To complicate matters, adolescent schizophrenic patients may find approximate answers amusing and may respond to an entire interview with a series of approximate answers; such patients may therefore appear to exhibit hysterical pseudodementia, but in reality, they have a hysterical "pseudopseudodementia."

It is often erroneously assumed that inability to abstract on testing of similarities or proverbs (i.e., "concrete thinking") has major diagnostic importance in schizophrenia. There is little scientific rationale for this belief. Concreteness correlates best with poor intellectual endowment, cultural impoverishment, and organic brain disease. Because all three of these factors not infrequently coexist with schizophrenia, to that extent, schizophrenic patients will have impaired ability in abstraction. The major value of testing abstraction in schizophrenia lies in the patient's tendency to give highly idiosyncratic and bizarre answers to proverb and similarities testing.

"Pressure of speech," usually seen in agitated depression, refers to patients who feel pressured to talk and usually cannot be stopped. "Flight of ideas," a major diagnostic sign of mania, refers to a type of overproductivity wherein the patient rapidly skips from one idea or theme to another, often by resorting to rhyming or punning, but without totally abandoning logic. Pressure of speech and flight of ideas both should be distinguished from loose associations that do not follow Aristotelian logic. "Circumstantiality" is the unnecessary elaboration of detail and is seen in dullards (borderline IQ), pedantic obsessionals, and patients with severe somatization disorder, but in severe degree, it may be difficult to differentiate from schizophrenic looseness.

The clinician must note that in some manic patients examined formally after having been given antimanic drugs, the triad of hyperactivity, flight of ideas, and pressure of speech is not as obvious as their delusional thinking.

The term "paranoid" is often used incorrectly to refer to suspiciousness or persecutory beliefs. Paranoid actually means "delusional" and should be restricted as a generic term for disorders characterized by prominent delusional formation (e.g., paranoid schizophrenia and paranoid states). Paranoid schizophrenia is a schizophrenic subtype in which delusions—not always persecutory in nature—occur in abundance. In paranoid states, usually one delusional theme predominates, with no evidence of schizophrenic formal thought disorder. For example, in conjugal paranoia, a man believes that his wife is having an affair and interprets all her behavior along those lines.

Delusions can be graded on the basis of their plausibility. For instance, the false belief that one's spouse is unfaithful is nevertheless a believable idea. The false belief that one's spouse is having multiple affairs simultaneously, although delusional, is not impossible. However, the belief that one's spouse is having an affair with a creature with green tentacles is patently absurd; such bizarre delusions are the hallmark of schizophrenia, although they also can sometimes be associated with organic mental disorders.

1.7. Summary: Further Reading

The mental status examination represents the portion of the psychiatric interview that is devoted to a systematic elicitation of psychopathologic signs and symptoms that are important in diagnostic formulation. Consequently, it is essential that descriptive terms be used precisely and consistently. This will not only facilitate professional communication, but will also enhance the chances of formulating differential diagnosis in a cogent way, setting the stage for rational therapy.

Further in depth classic psychopathologic evaluation can be found in the work of Frank Fish (6) and German Berrios (41). More relevant to the American scene are Morrison's *DSM-IV Made Easy* (42), Shea's *Psychiatric Interviewing* (43), and the related monograph by MacKinnon and colleagues (44). Informative writing on various rating scales can be found in Sajatovic and Ramirez (45).

Psychologists use various tests of intelligence, personality, and cognitive function. They can be useful in specific situation such as mental retardation, personality (Axis-II) and organic mental disorders. Their discussion is beyond the scope of this chapter. Two recent monographs, the Cummings-Mega *Neuropsychiatry* (46) and the Moore-Jefferson *Medical Psychiatry* (47) provide succinct coverage in relation to organicity.

Syndromes of Brain Dysfunction Presenting with Cognitive Impairment or Behavioral Disturbance: Delirium, Dementia, and Mental Disorders Due to Another Medical Condition

Susan Czapiewski, M.D., M.S. and Victoria Brown-Nyseth, M.D.

Abstract Delirium, dementia and psychiatric syndromes due to medical illness exemplify how brain function influences cognition, emotion, and behavior. For each diagnostic category, this chapter addresses disease prevalence and provides specific terminology to describe brain–behavior relationships. Included are current understandings of pathophysiology, clinical tools for recognition and assessment, and treatment modalities.

Keywords Delirium · Dementia · Cognitive impairment · Behavioral disturbance · Mental disorder

2.1. Introduction

Delirium, dementia and psychiatric syndromes arising from medical illness exist in the domain of brain-behavior relationships. Historically, an arbitrary distinction has been made between "organic" conditions, associated with known brain pathophysiology, and "functional" conditions, presumably caused by a psychiatric disorder divorced from its cerebral substrate. Illness with unexplained medical pathophysiology was considered "psychosomatic." The term was used pejoratively, as if brain-derived physical symptoms were not real. The brain was the territory of neurology; the mind and behavior belonged to psychiatry. Although the specific pathophysiology of many psychiatric disorders has yet to be described, important developments in neuroimaging have allowed us to start visualizing real time connectivity between the brain, mind, and behavior. Functional imaging technology has made the philosophical notion of a divide between body and mind obsolete. The word "functional" is currently used to describe imaging techniques such as positron emission tomography (PET) or functional magnetic resonance imaging (fMRI), but also refers to adaptive performance in social, occupational, and other important areas of life. The term "psychosomatic medicine" is now applied to a subspecialty of psychiatry that provides consultation to medical and surgical patients.

Scientific interpretations of brain–behavior relationships still vary according to the observer's perspective. The situation brings to mind the fable of the Blind Men and the Elephant where a group of blind men touch an elephant, each man describing the tusk, tail, ear, or side as though it were the whole animal, and debating their findings. Neuroscientists and practitioners of psychiatry, psychology, neurology, and pathology may all describe the same phenomena using different terms. Terminology across disciplines is not always clear or consistent. This reflects the growing body of knowledge about the brain, but can be confusing for the student. Over time, knowledge will be synthesized and common cross-disciplinary descriptions of brain-behavior states will be adopted. All the while, we are increasing our understanding of how brain dysfunction due to infection,

trauma, tumor or a neurodegenerative process causes emotional and behavioral symptoms that are traditionally associated with psychiatric disorders such as schizophrenia and affective illness.

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) Neurocognitive Disorders Workgroup has placed delirium and dementia under a new category, *neurocognitive disorders (NCD)*, major and minor (1). The term *delirium* has been maintained from previous manuals and is under the category of *Minor NCD*, along with signs of cognitive decline that are more severe than normal forgetfulness of aging, but do not rise to the level of dementia. Dementia is now considered a *major NCD* with a specific etiology, for example: NCD due to Alzheimer's disease or frontotemporal NCD. The DSM-5 authors take care to say that the term *dementia* is customarily applied to disorders like the degenerative dementias that are usually associated with aging. However, *neurocognitive disorder* is the preferred term for conditions affecting younger individuals such as impairment due to traumatic brain injury or Human Immunodeficiency Virus (HIV) infection.

The DSM-5 authors acknowledge that dementia is the term used more generally by many physicians and patients. This chapter will use the term dementia except in the discussion of HIV related cognitive disorders, when language preferred by the researchers will be applied.

Although patients with delirium and dementia may share mood, psychotic or anxiety symptoms with the other psychiatric disorders, the primary disturbance is that of cognition. Cognitive deficits are present in all mental disorders, but psychosis or mood changes are predominant findings in schizophrenia or mood disorders. Cognition is the ability to think, perceive, communicate, and solve problems. Cognitive domains are attention, memory, language, visuospatial, executive function, and social cognition. Cognition cannot be separated from function. A cognitively intact person can behave and function adaptively in life. Cognitive impairment makes thinking and functioning more difficult, and independent living is threatened.

The terms delirium and dementia are attributable to Celsus, a Roman aristocrat writing in the first century A.D. It was not until the twentieth century that the two disorders, which frequently co-occurred, were consistently identified in the medical literature as separate entities (2). Both represent a change from a person's baseline cognition and function. They are acquired, not developmental disorders. Delirium and dementia can be differentiated from one another by onset (acute or insidious), course (symptom resolution or persistent), and predominant cognitive domain affected (attention or memory, language, visuospatial, executive).

The topics reviewed in this chapter—delirium, dementia, and psychiatric syndromes due to other medical conditions—can all be mistaken for primary psychiatric disease. Knowing the age-associated onset of different psychiatric disorders, and following the patient's course over time and response (or lack thereof) to treatment can help determine if the clinical picture fits with a primary mood, anxiety, or psychotic disorder or is better explained by a cognitive or secondary disorder.

2.2. Syndromes of Brain Dysfunction Presenting with Cognitive Impairment: Delirium

2.2.1. Definition

Delirium is a disturbance of attention and awareness that arises in the context of medical illness and is characterized by acute onset and fluctuating course. It has been described in the medical literature over millennia. Hippocrates (460–366 BC) was aware of the syndrome's origin in the brain and its association with medical illness. The term *delirium is* derived from the Latin *de lira*, meaning "out of the furrow" or off the track. The student with an interest in history of medicine is encouraged to read the vivid historical descriptions of the syndrome in Lipowski's classic 1990 text, *Delirium: Acute Confusional States* (2). Although delirium had been clearly described by the turn of the twentieth century, little was known about its etiology. In 1959, Engel and Romano (3) published the first study to use both descriptive and experimental research methodology, employing the electroencephalogram (EEG), to examine the pathophysiological mechanisms underlying delirium. Their publication named delirium "a syndrome of cerebral insufficiency," similar to syndromes associated with renal, cardiac, hepatic, and pulmonary insufficiency.

Despite longstanding description of delirium signs and symptoms in the medical literature, the syndrome remains underrecognized or mistaken for psychiatric illness (4) and there is significant chaos surrounding terminology. Poorly defined terms like *encephalopathy*, *confusion* or *altered mental status (AMS)* can be seen in medical records. When delirium is taken simply as a phenomenon of illness or aging, and not recognized, the consequences for patients can be dire. In the hospital, where the syndrome is common, the delirious patient is at risk for increased morbidity and mortality. Hospital length of stay is increased and there is a greater chance of being discharged to a skilled nursing facility than to home.

2.2.2. Etiology and Pathogenesis

Understanding delirium involves comprehension of the process of directing, focusing, sustaining, and shifting attention. At any given moment, the brain receives an overwhelming amount of sensory input, from its internal and external environments, and yet, when functioning properly, is able to focus on some things and ignore others in order to create a coherent perspective and

function adaptively in an ever-changing environment. Attention involves the complex cognitive processes by which salient environmental information can be selected and irrelevant information ignored (5). In delirium, selective attention is impaired. Without attention, other cognitive domains cannot be usefully employed and the central nervous system (CNS) as a whole temporarily malfunctions.

Delirium can be triggered by any event or disease process that directly or indirectly disrupts the integrity of CNS function. Although the list of potential etiologies is long, identification of a cause or causes is important to diagnosis and critical to treatment. Detecting and treating the underlying illness or condition contributes to the resolution of CNS dysfunction. The DSM-5 separates conditions responsible for delirium into cases due to substance intoxication or withdrawal; induced by medications; due to another medical condition, multiple etiologies, unspecified or unknown (1). Detective work, using the history, chart, laboratory results, imaging and medication notes, may uncover the factors involved but assigning primacy of cause may not be possible. Often, multiple factors converge to precipitate delirium.

Many medical illnesses can cause delirium. Severity of illness is a risk factor.

Terminal illness regardless of cause can be associated with delirium (6). Failure of other organ systems, such as heart, lungs, liver, and kidney is frequently associated with brain dysfunction, causing changes in cognition and perception. Hepatic encephalopathy, caused by such diverse conditions as viral hepatitis or alcoholic cirrhosis, represents a well-described type of delirium with treatment options that can reverse or minimize the impact of liver failure on brain function. Delirium is more likely to appear with acute organ failure; for example, the brain can adapt over time to chronic hypoxia from emphysema but cannot function adequately in the face of decreased oxygen saturation associated with acute pulmonary failure.

Fluid (e.g., dehydration) and electrolyte (e.g., hyponatremia) disturbances can result in delirium with resolution occurring after homeostasis is restored. Restoration of normal cognitive capacity can lag behind correction of any metabolic disturbance, so a person may appear confused despite normal laboratory values. Various infections can cause delirium, either directly (e.g., septicemia) or indirectly (e.g., hypoxia associated with pneumonia). Delirium can result from intracranial processes even in the absence of focal or lateralizing neurological signs. For example, a seizure can be followed by disorientation and perceptual difficulties. The acute phase of recovery from traumatic brain injury is frequently associated with delirium.

At times the cause of delirium can be iatrogenic, with medical treatments or prescribed medications contributing to the clinical picture. Surgical procedures are associated with an increased risk of delirium. Any patient recovering from anesthesia has a brief interval of impaired cognition. In a small proportion of post-anesthesia patients, this transient episode can be prolonged; and when it is associated with agitation, critical care in post-procedure areas can be difficult and recovery delayed. Delirium can appear hours or days after the operation as the result of overtreatment or undertreatment of pain, or complications such as infection or metabolic abnormalities.

Over the counter, herbal or prescribed medications and other substances are associated with delirium (see Table 2.1). CNS active drugs or toxins are more likely to trigger delirium than drugs that act peripherally. Other causes of delirium, such as those attributable to toxins (lead, ethylene glycol, methanol, carbon monoxide) are rare. Intoxication from drugs of abuse can be associated with delirium; and in the case of alcohol, benzodiazepines, and barbiturates, withdrawal can precipitate delirium. When alcohol withdrawal is complicated by delirium, the term "delirium tremens" is used. Delirium tremens is a serious complication that affects 5–10% of patients admitted to the hospital with alcohol withdrawal (7). Because excessive alcohol use can often be associated with other causes of delirium such as liver failure, seizures, fluid and electrolyte disturbances and trauma, a confused patient with a positive alcohol drug screen needs a thorough and thoughtful medical evaluation.

Drugs with anticholinergic properties, of which there are many, pose an increased risk of delirium. Over-the-counter medications containing diphenhydramine, for treatment of upper respiratory infections, allergies, or insomnia, are highly anticholinergic. Commonly prescribed medications with anticholinergic properties include H2 antagonists (e.g., ranitidine), and oxybutynin. Herbal preparations such as those made from jimsonweed or ma huang are associated with delirium (8).

Abnormal electroencephalographic (EEG) readings are frequently observed during delirium and are consistent with cortical dysfunction. Subcortical structures like the reticular formation and thalamus drive cortical electrical rhythms implicating the involvement of these structures in delirium. Any toxic or metabolic disturbance severe enough to cause delirium, such as acute

Table 2.1. Examples of drugs and other substances associated with delirium.

Alcohol	Benzodiazepines
Anesthetics	Botanicals (e.g., morning glory)
Antiarrhythmics	Corticosteroids
Anticholinergics	Herbal remedies (e.g., ma huang)
Anticonvulsants	Lithium
Antidepressants	Metals and related compounds (e.g., mercury)
Antihistamines	Muscle relaxants
Antihypertensives	Opioid analgesics
Antiparkinsonian agents	Organic solvents (e.g., gasoline)
Barbiturates	Organophosphate insecticides

renal or hepatic failure or drug overdose, will usually result in impaired cortical neuronal function and be evident on the EEG, manifest by diffuse slowing of the background rhythm or the superimposition of generalized slow rhythms (9).

Neurotransmitter and neuroendocrine dysfunction, and inflammation have been implicated in delirium pathogenesis. Pathways that involve the neurotransmitters acetylcholine, serotonin, dopamine and histamine appear vulnerable (10), as are those of the more widespread gamma-aminobutyric acid (GABA) and glutamate. The cholinergic theory of delirium involves a relative inhibition of central cholinergic neurotransmission. Neurohumoral theories are based on the pervasive impact that substances such as corticosteroids have on CNS function. Another theory involves the role of inflammatory responses on the brain. Inflammation can lead to the dysfunction of endothelial cells (including those making up the blood–brain barrier) during critical illnesses. As the blood–brain barrier becomes more permeable, this leads to neuronal inflammation and tissue damage (11).

Further investigations into the mechanisms underlying delirium have prompted functional MRI studies. One small study found that alterations in the reciprocity between the posterior cingulate cortex and the dorsolateral prefrontal cortex could be a partial explanation of impaired attention in delirium (12).

2.2.3. Epidemiology

The prevalence of delirium is difficult to determine, in part because the disorder is transient and generally confined to a medically ill population. Much effort has been devoted to estimating the frequency of delirium in hospitalized patients (13, 14) with insufficient attention paid to other institutional settings like nursing homes. Patients can present to the hospital already delirious or can become delirious during their stay. The prevalence of delirium in general medical-surgical inpatient populations at presentation is conservatively estimated at 10–15% and slightly higher in the elderly (15–20%). Incident cases during hospitalization are estimated to be roughly similar. Although advanced age is a risk factor, delirium can occur at any age. The disorder in children is associated with infection and medication (15). The rate of delirium is higher following medical and surgical procedures, and increases with the more invasive and extensive procedures. Intensive Care Unit patients, who are sicker, frequently experience delirium with rates as high as 80% reported (16). Vision or hearing impairment, preexisting cognitive dysfunction, and polypharmacy also add to the risk of delirium.

2.2.4. Pathology

Description of the neuropathological changes associated with delirium is complicated by the brief duration of the syndrome and comorbid factors, such as dementia. The neuropathology literature focuses mostly on forensic topics such as homicide or iatrogenic disease. There may be subtle, poorly described alterations in brain structure that reflect the deliriogenic agent. For many specific agents (carbon disulfide, organophosphates, *n*-hexane), the brain appears grossly normal. Other toxic agents (lead, ethylene glycol, methanol) may be associated with edema, in some cases (cyclosporine, tin) most prominent in the white matter. Stimulants (cocaine, amphetamines) are associated with infarcts, reflecting the cardiovascular effects of these drugs. Microscopic vascular changes may be striking, including hemorrhage (arsenic, lead) and vasculitis (amphetamines). Neuronal loss may be obvious in the case of excess mercury or lithium with preferential effects on the pallidum in the case of methanol or carbon monoxide, and the cerebellum with ethanol or phenytoin. Gliosis may point to lithium and lead toxicity and demyelination is seen in methotrexate overdose. Sometimes the findings are quite specific, as with ethylene glycol poisoning causing deposition of calcium oxalate crystals (17).

2.2.5. Clinical Picture

Disturbances of attention and awareness are central to the clinical presentation of delirium. Patients with delirium have difficulty staying alert and focused, and appear to be flooded with incoming stimuli, no longer capable of responding adaptively in a given situation. For the clinician, completing a history and examination can prove difficult with a patient who is unable to maintain meaningful engagement. The clinical interview may be brief as the delirious patient "drifts off" or appears to grasp and respond to only fragments of the dialogue. The patient may perseverate on answers to previous questions, unable to shift away from that topic. With the examination finding of an attention deficit, only the history is needed to make the diagnosis. It is useful to take the time to interview collateral sources such as family, friends, and caregivers.

Delirium typically develops over hours to days and fluctuates in severity throughout the day. When a clinician sees a calm, pleasant patient on rounds in the morning and later that day receives notification from caregivers that the patient is confused and agitated, the cause is delirium until proven otherwise. Often, nursing staff are an important source of information leading to accurate diagnosis.

Carefully reviewing risk factors that either predispose patients to developing delirium or precipitate delirium is of utmost importance (18). While reviewing medication lists it is useful to keep in mind the principle of "addition by subtraction." This principle includes the idea that reduction in dosage or removal of nonessential medications (subtraction) can elicit a positive clinical response (addition). Regularly screening hospitalized patients with risk factors for the development of delirium is recommended. Multiple bedside instruments are available for use in assessing patients for delirium, one of the more common tools is the Confusion Assessment Method (CAM) (19).

Because attention is required for any other cognitive domain to function properly, delirious patients will have a transient disturbance in memory and learning, executive function, language or visuospatial perception. More generally, thought is slowed, disorganized and fragmented. Reasoning is defective and problem-solving ability is drastically reduced.

Serial cognitive examinations over time can capture cognitive fluctuations. Unfortunately, "AOX3" (alert, oriented to person, place, time) is often the only cognitive finding documented in the medical record. This is not an adequate examination. It provides information about level of consciousness but little else that is useful. Disorientation is a non-focal finding, which can be found in other cognitive disorders, such as dementia.

Brief but effective cognitive examinations cover attention, short-term memory (recall), and executive function. The Mini-Cog (20, 21) is a well-validated screening tool that takes a brief amount of time to complete. The patient is given three words to remember, a distraction task (draw a clock with hands set at 11:10) and then asked to recall the three words. Inability to recall any of the three words and/or abnormal clock draw (clock appears abnormal and/or hands set incorrectly) suggests need for further cognitive workup.

The physical examination of a delirious patient may reveal nonspecific findings such as a fine to coarse irregular tremor, asterixis, multifocal myoclonus, and various signs of autonomic dysfunction (e.g., nausea, vomiting, flushing, blood pressure changes). Other discrete medical and neurologic signs are comparatively uncommon.

Perceptual abnormalities are the most obviously "psychiatric" aspect of delirium. The patient may experience life as a waking dream. There may be misinterpretations, illusions, and/or hallucinations. Mistaking the unfamiliar for the familiar is a form of misinterpretation. During the examination or as care is delivered, strangers are likely to be misidentified as family members and the hospital room as home. Misperceptions that convert the unknown to the familiar seem adaptive. Less comforting are the propensities to perceive objects as too big, too small, moving or flowing together. Patients are also inclined to mistake common objects: spots for insects, folds in the bedcovers for snakes, or a bedpost for a rifle. Although these illusions are typically visual, they can involve any sensory modality.

Hallucinations, false sensory perceptions, are another disorder of thought content. They are nonspecific findings, requiring further investigation as to their cause. Auditory hallucinations are more likely associated with primary psychiatric disorders such as schizophrenia or depression. Presence of visual hallucinations suggests delirium. Visual perceptual abnormalities can also appear in dementia with Lewy Bodies (DLB), where patients "see" small children or animals. Auditory and tactile hallucinations can occur in delirium, but are less common.

Delusions, false fixed beliefs, are also nonspecific findings in psychiatric and cognitive disorders. Delusions in delirium are transient and, unlike those found in primary psychotic disorders, not very complex. They commonly involve persecution or vague plots against the patient. In dementia, delusions are related to the memory deficit: a wallet is lost, so it must have been stolen, or a spouse is no longer recognized, so he/she must be an imposter. Psychotic symptoms are often troubling to delirious patients and can complicate the delivery of care.

Associated features of delirium can include disturbances in the sleep-wake cycle, psychomotor disturbances and emotional disruption; these are incorporated into the International Classification of Diseases definition (ICD-10) (22). Disturbances in the sleep-wake cycle are common. The delirious patient may nap or sleep during daytime hours and be awake "all night long."

Mood and behavior are frequently disturbed. Patients with delirium can exhibit anxiety, fear, depression, irritability, anger, euphoria, and apathy. Unpredictable shifts in emotions can occur and be accompanied by behaviors such as moaning, screaming, or cursing.

Three motor subtypes of delirium have been recognized (23). A patient with the hyperactive subtype has psychomotor agitation and affective lability; that can cause behavioral dysregulation and lead to an identifiable disturbance on the medical unit. Patients with the hypoactive subtype are quiet, psychomotor retarded, sluggish, and lethargic. Their behavior is rarely a problem on the unit, but prevents them from actively participating in physical or other therapies. The third subtype, mixed, includes patients with impaired attention and awareness with either normal or rapidly fluctuating level of activity.

2.2.6. Clinical Course

Delirium is a transient illness, with acute onset and fluctuating course. Prodromal features can be present, such as vague feelings of uneasiness, irritability, and hypersensitivity to light and sounds. If a hospitalized patient appears short-tempered and belligerent, this may be a personality change brought on by incipient delirium. In general, the onset of delirium tends to be

within minutes to hours and resolves rapidly. Uncomplicated delirium in otherwise healthy patients tends to be short-lived, on the order of a week. Recovery is usually complete unless the underlying disorder cannot be redressed.

Although in the majority of patients cognitive deficits resolve completely within a week, recent investigations have shown that, in vulnerable populations, delirium can be associated with a significantly prolonged cognitive impairment on the order of months to years. One study, examining patients aged 60 years and older after cardiac surgery, revealed that patients who developed postoperative delirium were significantly less likely to have returned to their preoperative level of performance at 6 months than were patients without delirium (24). In an analysis of prospectively collected data on patients with Alzheimer's disease, the development of delirium (affecting 56% of the sample studied) was associated with an increased rate of cognitive decline that was maintained for up to 5 years (25).

Delirium is marked by wide clinical variability, even in the same patient. The severity of symptoms varies over the course of a day, and is greatest over late evening to night, when external orienting stimuli decrease. Lucid intervals are most likely to be observed in the morning. After resolution, the experience of delirium may leave the patient and family puzzled and anxious. Patients are often able to recall only bits and pieces of their experience upon recovery. Families can fear that the patient is developing schizophrenia and benefit from counseling about delirium.

Delirium superimposed on dementia may result in worsening of cognition that does not completely reverse. Delirium increases the risk of institutionalization and death in the months after hospital discharge. When delirium complicates terminal illness, it makes the final days more difficult for the patient and loved ones.

2.2.7. Laboratory Finding

Specific laboratory studies should be ordered based on evidence obtained from the history and physical examination that would suggest a causative drug or physical illness. Since causes can be multiple and the patient's physical examination unrevealing, systematic consideration should be given to studies such as electrolytes, urine drug screen, hepatic and renal function studies, TSH, vitamin B12, folate, drug levels, oxygen saturation, urinalysis, and an electrocardiogram. Central nervous system imaging is usually suggested by focal or lateralizing neurological findings and confirms the location of a lesion or lesions, for example, after a stroke. Sometimes an EEG is helpful. A diffusely slow tracing can suggest the diagnosis although slowing can be observed in other circumstances (e.g., after a seizure). A normal or fast record does not exclude delirium (9). Absence of a diagnosis after a systematic evaluation (including the tests noted above) may warrant head CT or MRI and examination of the cerebrospinal fluid although the yield from these efforts is likely to be low.

2.2.8. Differential Diagnosis

The differential diagnosis for delirium involves other disorders of cognition, primarily dementia. This distinction should center on the acute onset and disordered attention and arousal that characterize delirium; by contrast, both delirium and dementia are associated with memory impairment and perceptual disturbances (26). Fluctuating course is less helpful because patients with delirium and dementia can both experience worsening at night ("sundowning"). In circumstances where the onset of dementia can be defined (after traumatic brain injury, stroke, or resection of a brain tumor), delirium may precede the chronic deficits associated with dementia.

In many cases, delirium is superimposed on dementia. The tip-off can be an acute change in behavior, which is usually associated with illness in a demented person. In other instances, dementia can have prominent features consistent with a persistent and long-lasting delirium. This is most frequently seen with dementia with Lewy Bodies (DLB), although the persistent parkinsonian features and autonomic instability of DLB should aid in the differential diagnosis. In the absence of a good history or convincing examination, the provisional diagnosis should be delirium.

Patients with delirium can have comorbid psychiatric illnesses. While most often disorders such as depression, mania, and schizophrenia can be readily distinguished from delirium, there are a significant number of cases in which symptoms overlap. Attention deficits and fluctuating course can be helpful in separating delirium from schizophrenia and affective disorders. Hypoactive delirium can be mistaken for depression. Catatonia can be difficult to distinguish from hypoactive delirium, especially when the patient is not verbally responsive (27).

Mania and acute psychosis can be confused with the hyperactive form of delirium. Additionally, there are clinical presentations that combine features of delirium, mania, and catatonia. Unfortunately, these cases can be difficult to study partly because, as of yet, no clear consensus criteria have been defined. Names given to these presentations include delirious mania, manic excitement, Bell's mania, lethal catatonia, and malignant catatonia. Delirious mania has been described as a syndrome characterized by the rapid onset of delirium, mania, psychosis, and catatonic features (28, 29). There have been studies that suggest up to 15–20% of acutely manic patients also meet criteria for delirium. Recognition of delirious mania is very important as it can progress rapidly and become life threatening.

2.2.9. Treatment

Prevention is the ideal approach to treatment. Some research has shown that up to 40% of cases of delirium are preventable (30). One well-known delirium prevention protocol, the Hospital Elder Life Program (HELP), was developed by Dr. Sharon K. Inouye and colleagues at the Yale University School of Medicine. This protocol targets six risk factors: cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration. Since 1999 hundreds of hospitals have implemented the HELP protocol, both in academic settings and community hospitals. The delivery of this protocol by special multidisciplinary teams has yielded reductions in rates of delirium and the complications of delirium in a controlled clinical trial (30). In 2010, a multidisciplinary National Institute of Health panel developed a guideline for prevention of delirium comprised of 13 clinical recommendations (31). These recommendations included assessing persons at risk for clinical factors contributing to delirium within 24 hours of hospitalization, assessing and addressing pain, and reviewing all medications. Drugs should be minimized in number and dosage. While these interventions are consistent with exemplary medical care, limitations in resources and difficulty in systematically identifying patients at risk for delirium are barriers to more widespread implementation.

In a given patient, systematic attempts should always be made to treat the cause or causes of delirium. Sometimes this effort involves the physician primarily responsible for patient care working with the psychiatric consultant. This is helpful especially when the symptoms persist despite the lack of physical or laboratory findings or when assistance with behavior management is required. Nevertheless, a systematic approach to diagnosis and treatment can lead to detection of unusual circumstances such as attempted suicide or homicide by poisoning. When delirium is a feature of terminal illness, the underlying condition is obviously not reversible.

Attention to the patient's environment can be critical to effective care. Availability of a constant attendant ("sitter") allows timely monitoring of behavior, frequent reorientation and assurance. The room should be simply and practically arranged to provide consistent environmental cueing and reassurance without excessive stimulation. Restraints are undesirable but can be necessary to prevent the patient from harming self or others and for sustaining essential treatment (32). When restraints are necessary, patients benefit from sedation, since a delirious person, inexplicably unable to move freely, is likely to become frightened and agitated.

Medications for delirium should be considered if non-pharmacological measures have been ineffective or there is considerable distress or risk of danger to self and/or others. Administration of high-potency antipsychotics such as haloperidol at low doses has been considered first line treatment in many protocols. Haloperidol is favorable because it has fewer active metabolites, limited anticholinergic effects and can be given by mouth or by intramuscular injection (IM) (33). The drug is also administered intravenously (IV), particularly in intensive care unit settings, although this is not a Food and Drug Administration (FDA) approved route of administration. Dosing is usually repeated with the frequency of administration dictated by clinical need (e.g., severity of agitation) until the reason for treatment is no longer a crisis, continued at lower doses until the delirium appears to be resolving then tapered to discontinuation.

The elderly typically require more modest doses (usual haloperidol doses, 5–10 mg; in the elderly, 1–2 mg). Haloperidol is associated with dystonic reactions (the involuntary and usually repeated contraction of a muscle or group of muscles), akathisia (restlessness), parkinsonian rigidity, and rarely, cardiac dysrhythmias such as *torsades de pointes*. Newer antipsychotics such as olanzapine and risperidone are of interest because they may have a lower risk of side effects when used for other conditions, but the data supporting the use of these compounds in delirium is not as robust as is the case for haloperidol. There have been few studies looking at the utility of antipsychotic medications in preventing the onset of delirium; one analysis suggested they might reduce the overall risk of postoperative delirium (34).

While antipsychotic medications continue to be a mainstay of treatment, two recent reviews raise questions about the use of these medications in certain populations. The American College of Critical Care Medicine assembled a multidisciplinary task force to review the literature and publish guidelines regarding the management of pain, agitation, and delirium in adults in the intensive care unit (35). This task force concluded there was no published evidence that treatment with haloperidol reduces the duration of delirium in adult patients in the intensive care unit, though there is some evidence for atypical antipsychotics. Another systematic literature review determined that due to severe methodological limitations in the studies included, the use of antipsychotics in the treatment of older hospitalized adults was not supported (36).

Other medications are of uncertain value. The cholinergic theory of delirium pathogenesis suggests that inhibition of cholinesterase, the enzyme responsible for degrading acetylcholine, could have a positive effect. Blinded, randomized clinical trials of the cholinesterase inhibitor donepezil showed little benefit in reducing the risk of postoperative delirium for elderly patients undergoing an elective orthopedic procedure (37, 38). Dexmedetomidine, an alpha$_2$ adrenergic agonist, has shown some promise as a sedating agent in the intensive care unit when compared to alternatives such as the anesthetic propofol or benzodiazepines (39). Further work is necessary to support preliminary observations. Although sedation is undesirable, sometimes use of propofol or a benzodiazepine (e.g., lorazepam) is necessary because haloperidol and related compounds are not sufficient for symptom control.

Complicated alcohol withdrawal, delirium tremens, is one of the most common causes of delirium in hospital settings. Treatment is best accomplished with benzodiazepines such as lorazepam, diazepam, midazolam, and chlordiazepoxide (7). While all of these benzodiazepines can be given orally and intravenously, lorazepam may be the drug of choice because it can also be administered intramuscularly. Lorazepam may also be favorable in some situations, such as in patients with decreased liver function, because it does not have active metabolites. Delirium precipitated by benzodiazepine withdrawal can also be treated with benzodiazepines, with a plan for a gradual taper. Phenobarbital, a barbiturate, is rarely used but may have a role in the treatment of delirium associated with barbiturate withdrawal, benzodiazepine withdrawal or in neonatal abstinence syndrome (40). Finally, haloperidol and other antipsychotics may be used as an adjunct in some patients with delirium tremens, benzodiazepine withdrawal delirium or barbiturate withdrawal delirium because benzodiazepines may provide insufficient symptom control, especially in the case of multifactorial delirium.

2.3. Dementia

2.3.1. Definition

Dementia is a syndrome of acquired, persistent cognitive and behavioral deficits that interfere with the ability to function socially or at work or to perform usual activities (41). The term "dementia" comes from the Latin *dement,* meaning "to be out of one's mind."

Aractaeus, in the second century, associated the global dysfunction characteristic of dementia with aging. Although aging is the greatest risk factor for dementia, disease is not the inevitable result of growing old. Dementia symptoms represent a change from baseline. The person with dementia experiences difficulties with cognition and function that are a departure from a lifetime of thinking, perception, communication, and problem solving. The presence of cognitive impairment transforms emotional experience, personality and behavior. An extrovert can become socially withdrawn and isolative or a formerly thoughtful and conscientious person can show disregard for the feelings of others and engage in antisocial behavior. Performance in work or daily tasks is impaired. A surgeon with early dementia may forget operating room procedure and make an error that puts a patient at risk. A formerly reliable driver may get lost in a familiar place, panic and cause a motor vehicle accident. As these examples show, cognitive and functional decline affects not only the person but also a wider circle of family, friends, colleagues, and society.

Dementia is a clinical diagnosis, based on specific criteria. In the clinic, symptoms of dementia are elicited by a combination of history taking and an objective cognitive assessment. Since the cognitively impaired person may not be aware of any problems, it is essential to obtain corroborative history from a knowledgeable informant. Cognition can readily be assessed through a focused mental status examination (see Sect. 2.3.5). Cognitive domains are attention, memory (the ability to learn and remember), language (receptive and expressive speaking, reading or writing), visuospatial abilities (recognizing faces or objects; the ability to navigate while driving or walking), executive function (planning, organizing, decision making, monitoring, mental flexibility, the ability to use environmental feedback to guide behavior), and personality and behavior (social cognition). According to the NIAA-AAA criteria (41), diagnosing dementia from any cause requires deficits in two or more cognitive domains (see Table 2.2). Symptoms cannot be explained by delirium or a major psychiatric disorder.

There are many causes of dementia. Etiologies can include neurodegeneration (Alzheimer's disease, frontotemporal dementia, Lewy Body disease), stroke, infections (HIV, Creutzfeld Jacob), central nervous system neoplasms, traumatic brain injury, toxins (e.g., alcohol), autosomal dominant mutations (Huntington's Disease), and iatrogenic (radiation or surgery induced). The course of most dementias is progressive. Head injury and vascular disease (a stroke risk factor), which cause static cognitive impairment, increase the likelihood of developing a degenerative dementia as well (42).

TABLE 2.2. Core clinical criteria for dementia, any cause.

Cognitive or behavioral symptoms that interfere with ability to function at work or usual activities and represent a decline from previous levels of functioning and performing
Symptoms are not explained by delirium or major psychiatric disorder
Impairment is detected and diagnosed through history and objective cognitive assessment
Impairment involves a minimum of two of the following:
• Learning and memory
• Executive function
• Visuospatial abilities
• Language
• Changes in personality, behavior, or comportment

Adapted from (41) copyright (2011) with permission from Elsevier.

Over several decades, expert work groups have developed and revised diagnostic criteria for the different dementias according to research findings. In earlier consensus criteria (43), systemic disorders such as thyroid disease or vitamin B12 deficiency were thought to commonly mimic Alzheimer's disease (AD) and should be ruled out prior to the diagnosis being made. This notion of "reversible dementia" is no longer widely held. Clinical and research experience have shown that in the presence of signs and symptoms of AD, thyroid or B12 replacement does not alter the progressive course of the dementia (44).

Dementia syndromes can be subdivided into those involving the cerebral cortex and subcortical brain systems. In the brain, these systems are interconnected and overlapping but the concept of cortical and subcortical dementia may shed light on the mechanisms underlying both cognitive and psychiatric disorders. Previous DSM iterations used only cortical symptoms to define dementia: memory impairment, aphasia, apraxia, and agnosia. Anatomically, these symptoms are localized to the temporal and parietal lobes of the brain. Alzheimer's disease (AD) is the prototypic cortical dementia. Subcortical brain systems are involved in the regulation of a variety of cognitive and emotional processes. Pertinent subcortical regions include the basal ganglia, thalamus, and white matter connections to the frontal lobes (45). Impairments that occur in these systems are often confused with primary psychiatric disorders. Subcortical cognitive impairment can present with emotional dysregulation, apathy, slowed cognitive processing and executive dysfunction. This can look like depression, without the sadness and emotional distress. Subcortical system lesions can occur with frontal axonal shear-strain in traumatic brain injury, lacunar infarcts in the basal ganglia, Parkinson's disease and HIV neurocognitive impairment. With subcortical cognitive dysfunction, cortical domains such as memory, language, and visuospatial function are better preserved (46). There is significant clinical symptom overlap between lesions in the frontal-subcortical circuits underlying motivation, executive function, and personality and cortical lesions involving the frontal lobes. These will be described in more detail in the discussion of frontotemporal dementia.

In short, there are many ways to approach the topic of dementia. This chapter will focus on three broad categories of dementing illness: dementias that are commonly seen in clinical practice and have a strong research base (Alzheimer's, dementia with Lewy Bodies), one that is often mistaken for a primary psychiatric disorder (behavioral variant of frontotemporal dementia) and a subcortical dementia that has influenced the psychiatric nosology in DSM-5 (major neurocognitive disorder due to HIV).

Alzheimer's disease is the most common dementing illness. This fatal neurodegenerative disease was initially described by the psychiatrist Alois Alzheimer (1864–1915) who described "a peculiar disease of the cerebral cortex" (47) involving a 51-year-old woman, Auguste Deter, who was institutionalized and died with impaired memory and language, psychosis, and global functional deficits. Alzheimer's description was facilitated by a new technology. His colleague, the pathologist Franz

TABLE 2.3. Diagnostic criteria for probable Alzheimer's disease dementia.

Meets criteria for dementia (see Table 2.2)
Insidious onset over months–years
Clear cut history of worsening of cognition by report or observation
Initial and most prominent cognitive deficits are evident on history and examination in one of the following:
- Amnestic presentation: impairment in learning and memory (most common)
- Non amnestic presentations: language, visuospatial, executive

Exclusionary criteria: recent stroke temporally related to onset or worsening of cognitive impairment; core features of dementia with Lewy bodies; prominent features of a frontotemporal dementia variant; or evidence of another medical, neurological, or medication-related reason for cognitive decline

TABLE 2.4. Cognitive domains, symptoms/observations, and history/examination findings.

Cognitive domain	Symptoms or observations	History/examination findings
Attention	Inability to focus, direct, sustain, and/or shift attention appropriately	Dozing, somnolent, cannot keep eyes on examiner or follow directions, distractable
Memory	Inability to learn and remember	Cannot give accurate historical information, poor recall on Mini-Cog
Language	Trouble with expressive and receptive speaking, reading, writing	Word finding difficulties, paraphasic errors, empty speech
Visuospatial/ perceptual-motor	Inability to recognize faces, objects or navigate in space (driving, walking), apraxia (tools, sewing)	Family has concerns about driving or tool use, wandering, abnormal clock draw on Mini-Cog
Executive function	Inability to plan, organize, make decisions, self-monitor or use environmental feedback to guide behavior; lack of mental flexibility	Cannot effectively manage finances, chronic illness, medications or appointments; trouble shopping or cooking; abnormal clock draw on mini-cog
Personality and behavior, social cognition	Poor social skills; speech or behavior outside socially acceptable norms; inability to read social cues or facial expressions	Personality change, lack of empathy, poor social skills, antisocial behavior; dressed or acts inappropriately, perseverative, impersistent

Nissl had recently developed a method for staining nerve tissue. This technique allowed Alzheimer, at autopsy, to visualize for the first time neurofibrillary tangles that, along with amyloid plaques, are pathognomonic for the disease that would bear his name. This was the first of many technological innovations over the years that have allowed us to connect brain and behavior.

Currently, the diagnosis of AD is made when the patient meets criteria for dementia (see Tables 2.3 and 2.4), with insidious onset and gradually progressive course. Cognitive impairment is most commonly related to memory, plus deficits in executive, visuospatial and/or language function; and/or personality change. Strong historical, clinical, and/or neuroimaging evidence of another dementia precludes the AD diagnosis. There are uncommon variants of AD that present with primary visual or frontal deficits (41).

Dementia with Lewy Bodies (DLB) falls under the broader category of Lewy Body diseases. Persons with DLB have dementia plus the neuropsychiatric, motor, sleep, and autonomic symptoms that are associated with the other Lewy Body diseases: Parkinson's disease and Multiple System Atrophy. They exhibit the parkinsonian tremor, bradykinesia, and gait disturbance as well as repeated falls, syncope, and autonomic dysfunction. Attention and alertness fluctuate throughout the day. Complex, recurrent visual hallucinations can occur, usually of small children or animals. Treatment of the hallucinations is complicated by the fact that patients are very sensitive to antipsychotic side effects (48). REM sleep behavior disorder (RBD) often presents decades before the neurodegenerative disease becomes clinically evident (49). Persons with RBD, usually elderly males, have vivid, often frightening dreams. The accompanying loss of REM atonia results in dream enactment behavior, which can cause injury to the patient and bed partner.

Vascular dementia is defined as dementia that occurs within three months of a cerebrovascular event, is accompanied by focal findings on neurological examination and exhibits cerebral lesions on neuroimaging that correlate with the identified cognitive deficits. Lesions can be the result of ischemic, hemorrhagic, and hypoxic (cardiac arrest, pulmonary failure, CO poisoning) events (50).

Frontotemporal disorders causing dementia can best be understood in the context of the frontal lobes of the brain, which are composed of the prefrontal and motor cortices. Extensive white matter tracts conduct the reciprocal interactions between the frontal cortex and subcortical regions such as the thalamus and limbic system. Unlike more posterior brain regions, the frontal lobes have more white matter and less collateral vascular circulation, leaving them susceptible to traumatic injury, chronic hypoxia, and watershed infarcts. White matter tracts connecting the frontal lobes and subcortical regions form part of the striatum, which is susceptible to hypertensive (lacunar) infarcts (51). A subcortical, striatal lesion in a strategic location can create the same clinical picture as frontal cortical damage.

The neuroanatomic proximity between the prefrontal cortex and the motor strip and extensive reciprocal circuits connecting the frontal lobe to the limbic system predict the complex interaction between emotion, thought, and behavior. Functionally, the frontal lobes take information from throughout the brain, integrate environmental and emotional information, formulate an action plan, initiate motor activity, and ultimately mediate action on the environment (52).

Intact frontal cortical function is crucial to effective social interactions. Frontal lobe damage causes significant changes in personality and behavior. The most famous example of this is the case of Phineas Gage who, in 1848, sustained a traumatic frontal lobe injury in a railroad construction accident. Twenty years later his treating physician, Dr. John Martyn Harlow, described his former patient as:

> *Fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom) manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operations, which are no sooner arranged than they are abandoned in turn for others appearing more feasible. A child in his intellectual capacity and manifestations, he has the animal passions of a strong man…his friends and acquaintances said he was "no longer Gage"* (53). Gage's disinhibition, indifference to others, willfulness, executive dysfunction, inflexibility, perseveration and impersistence at a task are examples of frontal dysfunction.

Frontotemporal dementia (FTD) is a degenerative dementia with three clinical variants: behavioral, language and motor. The behavioral variant (bvFTD) is the most common form and the most likely to be mistaken for psychiatric illness. Persons with bvFTD can act like Phineas Gage, although the behavior begins insidiously. The bvFTD patient will show early symptoms of socially inappropriate behavior, apathy or inertia, loss of sympathy or empathy, stereotyped and perseverative behaviors, hyperorality, and/or dietary changes. Episodic memory and visuospatial skills are well preserved early in the course of the disease. Diagnosis is made by observation or history provided by a knowledgeable informant (54).

Many persons with bvFTD are initially misdiagnosed with psychiatric illness. Apathy can be mistaken as depression. Disinhibition and impulsivity mimic anxiety, bipolar or a personality disorder (55). However, psychiatric hospitalization and treatments are either ineffective or cause worsening of cognitive and motor symptoms (56). Social consequences of bvFTD can be extreme. Acquired sociopathic behavior such as shoplifting, driving violations, inappropriate sexual behavior, and violence can result in incarceration (57).

HIV-associated neurocognitive disorders (HAND) have been classified into three subtypes ranging in severity from asymptomatic to dementia, for which the preferred term is major neurocognitive disorder due to HIV infection (MND-HIV). MND-HIV causes predominantly subcortical dysfunction. Patients show difficulty with sustained attention and concentration, slowed psychomotor processing speed, and executive dysfunction (46).

2.3.2. Etiology and Pathogenesis

Despite the tremendous amount of research on the dementias over the past decade, the complexity of brain function has complicated our understanding of etiology and pathogenesis. Progress, however, has been made in developing better diagnostic criteria and in elucidating genetic and molecular biological determinants of the disease.

Dementia disconnects the complex physical, electrophysiological and neurochemical systems that allow humans to function adaptively in the world. Dementing illness involves selective loss of cortical neurons, disruption of white matter tracts, synaptic degradation, neurotransmitter deficits and desynchronization of neural network activity. This occurs via multiple mechanisms: trauma, cerebral infarction, infection, tumor, post-radiation, or neurodegenerative disease. The majority of dementias are neurodegenerative. Proposed mechanisms of neurodegeneration include toxic protein accumulation, pro-inflammatory responses, mitochondrial dysfunction, oxidative stress, genetic and environmental factors, and apoptosis (42).

Especially in Alzheimer's disease (AD), the lines of demarcation between illness and normal cognitive changes in aging are not clear. Normal cognitive aging involves slowed information processing, impaired vigilance, and inefficient executive function. New memories can be stored long term, although access to those memories may take time and effort (58). Deficits are rarely evident outside of a formal neuropsychological evaluation. However, despite relatively intact cognition and function, brains of non-demented elders may show pathological changes associated with dementia (59).

AD is a multifactorial disorder. A complex association between environmental or lifestyle and polygenetic factors likely plays a crucial role in vulnerability (42). Mediators of AD vulnerability and protection include cerebrovascular disease, genetics, TBI, toxins such as alcohol, smoking, and diabetes. Midlife vascular and metabolic disorders are important risk factors for AD. Hypertension, hypercholesterolemia, cardiovascular disease, and carotid artery stenosis increase the risk of dementia. In genetically susceptible hosts, atherosclerotic lesions and other vascular changes lead to chronic cerebral hypoperfusion and may converge to initiate or accelerate the neurodegenerative processes in an aging brain. Combined cerebrovascular disease and Alzheimer's pathology predicts a more rapid decline in cognition and function (60). Diabetes and impaired glucose tolerance may play a role in dementia pathogenesis. The exact mechanism is unclear but there may be a direct effect of glucose-mediated toxicity and hyperinsulinemia on amyloid metabolism and neurodegeneration (42).

Protective factors for neurodegenerative disease include physical and cognitive activity and maintaining social connections. There is a growing literature showing the neuroprotective benefits of aerobic exercise, especially in middle age. Exercise may even attenuate cognitive decline in persons diagnosed with dementia (61). Light to moderate alcohol consumption, especially wine, may protect against dementia (62).

Although the majority of AD cases are sporadic, there are rare genetic familial forms, which are thought to be autosomal recessive (63). Three genes have been implicated: amyloid precursor protein (APP), presenilin 1 (PSEN1), and presenilin 2 (PSEN2). Persons with Down Syndrome (Trisomy 21), with three APP copies, are very likely to develop AD (42).

Late onset AD, occurring >60 years of age, is a polygenic disease that accounts for nearly 95% of all cases. Although the major risk factor is age, genetic factors like the apoliproprotein E ε4 (APOE4) further increase the chance of developing AD and reduce the average age of disease onset (42).

The acknowledged hallmark of AD is the deposition in brain parenchyma of two abnormal proteins: Aβ as amyloid plaques and tau as neurofibrillary tangles. Amyloid plaque burden is not associated with dementia severity, but greater neurofibrillary tangle density correlates with cognitive dysfunction (42). Accumulation of tau in neurofibrillary tangles is not specific to Alzheimer's disease and has been associated with other dementing illnesses, including FTD.

The sequence of events involved in AD pathophysiology continues to be vigorously debated in the scientific literature. Evidence suggests that the neurodegenerative process of AD begins years, if not decades, before the clinical diagnosis of dementia (64). Synaptic loss in the hippocampus and other cortical regions is widely considered the major pathophysiological correlate of cognitive decline. Defects in synaptic transmission occur early in the disease and progress slowly (42). Deficits in acetylcholine, a neurotransmitter involved with memory, and toxicity from the excitatory neurotransmitter glutamate are involved in the pathogenic process and are the targets of current medications to treat AD.

The amyloid β protein (also known as Aβ) derives from a sequential cleavage of the amyloid precursor protein (APP). It can vary in length, according to the pattern of cleavage of APP. The Aβ1-42 (also known as Aβ42) isoform has hydrophobic properties and aggregates more readily than the Aβ1-40 form, contributing to plaque formation.

In the normally functioning neuron, the protein tau is responsible for the assembly and stability of microtubules, and axoplasmic transport (transporting proteins, neurotransmitters, hormones, and enzymes along the axon toward the cell body or toward an axon terminal). Abnormal phosphorylation of tau causes it to detach from axonal microtubules and aggregate into insoluble neurofibrillary tangles. Subsequent neurofibrillar degeneration may trigger or facilitate multiple pathological changes that affect mitochondrial dysfunction and neuronal damage (42).

The pathogenic sequence of interactions between Aβ and tau proteins has been extensively investigated and still remains a subject of scientific debate. In the rare early onset familial forms of AD, the "amyloid cascade hypothesis" appears to be valid. Excessive formation and deposition of Aβ, with consequent aggregation in plaques, initiates a neurotoxic cascade (including

neurofibrillary tangle formation) and ultimately leads to synaptic and neuronal loss. In the more common age-associated form, the pathogenic trigger remains unidentified (42).

There is a great deal of research interest in the symptomatic pre-dementia stages of Alzheimer's disease, when the characteristic pathological changes, but not dementia, are present. AD begins insidiously, with no fixed events that define its onset. In an attempt to identify transition points, the concept of Mild Cognitive Impairment (MCI) has been developed (65). MCI is a syndrome defined by clinical, cognitive, and functional criteria. Amnestic and non-amnestic subtypes have been described. Amnestic MCI appears most likely to convert to AD over time. Persons with amnestic MCI have memory complaints and preserved independence in functional abilities. However, they show mild difficulty with complex functional tasks they had habitually performed, such as paying bills, preparing a meal, or shopping. They may take more time, be less efficient, and make more errors at performing such activities than in the past. Nevertheless, they generally maintain their independence of function in daily life, with minimal assistance. These patients should be followed longitudinally: cognition and function monitored over time (66). Trials of acetylcholinesterase inhibitor drugs in MCI have not shown any effect in slowing conversion to dementia (65).

Dementia with Lewy Bodies (DLB) is characterized by Alzheimer's pathology and Lewy Bodies, which are pathological cytoplasmic accumulation of α-synuclein. Other synucleinopathies such as Parkinson's disease and Multiple System Atrophy share many clinical features with DLB and can progress to dementia. The presence and onset of visual hallucinations in DLB is associated with loss of neurons in the anterior and inferior temporal lobe and amygdala. These areas of the brain are implicated with generation of complex visual images (48).

Vascular dementia has an abrupt onset and is classically described as having a stepwise course. A single stroke can readily be associated with a specific cognitive deficit, such as a left middle cerebral artery thromboembolism resulting in aphasia; but the broad range of findings that constitute dementia is typically the result of multiple vascular events. The loss of blood supply results in neuronal death; current hypotheses about CNS vascular lesions suggest that other factors, including glutamate toxicity and calcium imbalance, are toxic to neurons.

Neuropathological and imaging studies of early bvFTD suggest that the disease begins in the nondominant anterior cingulate cortex (ACC) and frontoinsula (FI), then spreads to a circumscribed network of anterior brain regions. The ACC and FI contain von Economo neurons, which may be involved with creation of internal representations of the autonomic nervous system (67). One model of ACC and FI functioning proposes that cells in these structures, including the von Economo neurons, anchor the neural representation of emotional awareness and play a role in consciousness (68). As neurodegeneration progresses, patients with bvFTD lose emotional-moral and contextual sensitivity; the loss of which facilitates their uninhibited, socially disadvantageous behavior (67).

In contrast with AD, the cholinergic system in FTD appears to remain intact. The frontal cortex has multiple serotonergic projections from the raphe nuclei (69), and many of the behavioral manifestations of bvFTD can be moderated by serotonergic medications.

FTD has a strong genetic component. Approximately 40% of patients report a positive family history of dementia; of which one-third to one-half follow an autosomal dominant inheritance pattern. Many genes have been identified; the most common of which are: MAPT (microtubule-associated protein tau), PGRN (progranulin), and C90RF72, a recently identified hexanucleotide repeat expansion on chromosome 9. There may be a connection between the specific gene mutations and patterns of brain atrophy (69).

HIV infection can cause MND-HIV (dementia) either as a result of viral effects or because immune suppression predisposes to cancers or opportunistic infections. The exact mechanism of neurodegeneration leading to HIV-associated MND is unclear. There is no in vivo evidence that HIV directly infects neurons. The current, "indirect" model involves virus-bearing peripheral monocytes and lymphocytes. These infected cells migrate across the blood brain barrier and differentiate into macrophages that release proinflammatory cytokines/chemokines and substance P. This process ultimately impairs the neuroprotective activity of astrocytes and contributes to a neurotoxic environment involving increased permeability of the blood brain barrier, the release of excitatory amino acids (eg, the neurotransmitter glutamate), free radical production, oxidative stress, and dopamine dysregulation (70).

This summary gives a glimpse of the recent and remarkable accumulation of scientific knowledge of the dementias, particularly on the descriptive, biochemical and genetic fronts. We know that regular physical exercise, especially in middle age, is neuroprotective. Lifelong learning, managing vascular risk factors, and preventing traumatic brain injury (wearing seatbelts and bike helmets) will decrease disease risk. Nevertheless, much remains to be learned, including the process by which molecular lesions initiate the path to neuronal degeneration and death. How is it that ubiquitous proteins start aggregating within the brain and produce relatively specific syndromes? What is the sequence of events in the transitions from normal aging to "preclinical" to full blown Alzheimer's disease? How do we take advantage of the delay between illness onset and clinical symptoms to halt the neurodegenerative process? Future therapies will be based on improved understanding of dementia etiology and pathogenesis.

2.3.3. Epidemiology

Dementia prevalence rates vary among studies, depending on setting and diagnostic criteria, but it is clear that cognitive impairment and dementia are strongly associated with increasing age. However, it should be emphasized that dementia does not appear to be an inevitable consequence of growing older. Even after age 90, only 37.5% of persons have Alzheimer's disease, the most common dementia (71). Mild cognitive impairment (MCI) has been documented in more than one in ten seniors over age 70, with more than 20% affected after the age of 80 years (72). Over five years, approximately one out of five persons with MCI is likely to progress to AD (72).

AD accounts for 60–90% of all dementias. The older a person is when diagnosed with dementia, the more likely it is to be AD. The incidence of AD is approximately 1% at age 60 and roughly doubles every 5 years afterward. The estimated lifetime risk of AD is 10–11% in men and 14–17% in females. The gender difference is thought to be due to women's longer life expectancy (42).

FTD is considered the third most common dementia overall, after AD and DLB, but is the leading cause of dementia in persons <60 years old. US prevalence in persons aged 45–64 years is estimated to be between 15 and 22 cases per 100,000. Onset is usually in the 50s, but the range can be anywhere between ages 30–90. Men and women are equally affected (69).

Introduction of effective HIV treatment has had a positive impact, making MND (dementia) a less frequent finding (73). Nearly half of all HIV/AIDS patients have milder, more slowly progressing cognitive impairment (74). Of the 80% of IV drug abusers receiving psychiatric care in one methadone maintenance program, one in five was receiving treatment for a neurocognitive disorder, presumably related to HIV infection. Among patients medically hospitalized for complications of HIV/AIDS, 19% were found to have delirium or dementia (75).

2.3.4. Pathology

The diagnosis of a specific dementia is primarily made based on clinical criteria, but pathology provides insights into disease pathogenesis and plays a supporting role in diagnosis (Alzheimer's disease) or contributes to classification based on histopathology (frontotemporal dementia). In Alzheimer's disease (AD) structural changes are often evident on inspection of the brain postmortem (17). Gross findings are prominent cortical sulci and narrowing of gyri with relative preservation of the cerebellum. The atrophy associated with AD usually results in a brain that weighs substantially less than the brain of persons without dementia.

Histopathological hallmarks of AD are the combined presence of two proteinaceous aggregates: extracellular neuritic (Aβ-containing) plaques and intraneuronal neurofibrillary tangles. Neuritic plaques are composed of a central core containing Aβ protein, surrounded by clusters of dystrophic axons, dendrites, and glia. In addition to brain parenchyma deposits, Aβ aggregates can be found on the walls of the leptomeningeal, cerebral cortical, and cerebellar blood vessels. Neurofibrillary tangles consist of paired helical filaments, formed by hyperphosphorylated tau protein. Cerebral amyloid angiopathy is correlated with AD pathogenesis and may lead to vascular rupture and multiple lobar hemorrhages (42).

In vascular dementia, multiple cerebral infarcts are visible upon inspection of the brain. Pathology associated with vascular dementia and AD frequently coexists (76). To diagnose vascular and not Alzheimer's dementia, there needs to be more vascular pathology than tangles and plaques.

Lewy Body disease histopathology shows the characteristic intracellular Lewy Bodies pathological aggregations of α-synuclein in the cerebral cortex and subcortical brain regions. The presence of extensive plaques and tangles signifies "low likelihood" of the disease (48).

In 1892, Arnold Pick, a professor of psychiatry at the University of Prague first described cases of striking frontal and temporal lobe atrophy in the brains of dementia patients without memory impairment. Twenty years later, Alzheimer was able to visualize microscopic silver-sensitive intraneuronal inclusions (Pick Bodies) and ballooned cortical neurons. For much of the 20th century, "Pick's disease" was synonymous with FTD.

The clinical syndrome FTD is caused by frontotemporal lobar degeneration (FTLD). Although distinguished on gross pathology by the selective degeneration of frontal and anterior temporal lobes, FTLD is histopathologically heterogeneous. Pick bodies do not have to be present to make the diagnosis. Specific FTLD subtypes are classified according to one of three abnormal protein inclusions, which are presumed to be pathogenic or most characteristic. These are based on tau (FTLD tau), TAR DNA-binding (FTLD-TDP), or fused in sarcoma protein (FTLD-FUS) (69). As of now, no correlation has been made between the pathological and clinical subtypes.

MND-HIV neuropathology is designated as HIV-encephalitis (HIVE). HIVE is characterized by synaptic loss and dendritic simplification in pyramidal neurons, loss of calbindin-immunoreactive interneurons, focal or diffuse myelin loss, widespread reactive astrogliosis, the accumulation of perivascular macrophages, and, in particular, formation of multinucleated giant cells and microglial nodules in central white matter and deep gray matter. Neuroimaging and pathology show white matter disruption in intercortical and cortico-striatal pathways. Hippocampal damage is also found and may relate to inhibition of neurogenesis in that structure (77).

2.3.5. Clinical Picture

Characteristic of the neurodegenerative dementias, Alzheimer's disease (AD) is a slowly progressive disorder with no fixed events that define its onset (64). Often, clinicians do not recognize dementia until the middle to later stages of disease. The typical AD patient is diagnosed 32 months after symptom onset (78). There are many reasons for missing early signs and symptoms of dementia. Patients' social skills are intact and they lack awareness of cognitive and functional problems. Knowledgeable informants are not always present at medical appointments. It can be a clinical challenge to identify transition points for individual patients from normal to abnormal function. For these reasons, clinicians need to be aware of the increased age-related risk of cognitive impairment and attuned to the subtle clinical signs. Common early medical presentations of cognitive impairment are unexplained weight loss or a previously stable patient who becomes unable to manage a medical illness and to follow advice regarding diet, exercise, keeping appointments, and completing paperwork. Failure to self-administer medications accurately is one of the earliest, most reliable, most culturally independent signs of mild dementia (79).

A Veteran's Administration study showed benefits of brief cognitive screening in veterans aged 70 or older who had not previously been diagnosed with cognitive impairment. Twenty six percent of veterans failed the screen, and of those who received further evaluation, 93% were diagnosed with cognitive impairment, including 75% who met criteria for dementia (80).

Making the diagnosis of dementia is extremely important. With the demographic shift toward an aging population in the USA, the prevalence of dementia will increase over the coming decades. The disease has significant consequences for the individual, families, medical system, and society as a whole. Families are significantly distressed by obvious lapses in performance and personality changes. They may attribute difficult behavior to willfulness, indifference, laziness, and passive aggression. They can be frustrated and angry with the patient but are relieved when an alternative reason is given for the distressing behavior. Caregivers require education and support for the difficulties of caring for a person with cognitive, psychological and behavioral disturbances. Social isolation with associated physical inactivity, boredom, agitation, and depression can be recognized and modified if the diagnosis is made.

Drivers with dementia can threaten public safety. Safe driving capability is questionable when family members refuse to be passengers, there is a history of crashes or traffic citations, presence of aggressive or impulsive personality characteristics, and examination findings of cognitive impairment. A patient will likely insist that he has always been a good driver but self-report is not an accurate predictive factor of safe driving (81). Persons with moderate–severe dementia can inadvertently start cooking fires, take unsafe risks using electrical equipment, firearms or power tools and be prey to predatory financial scams. Dementia can also affect medical decision making capacity and the ability to adhere to treatment recommendations. If dementia is diagnosed early, patients can have the opportunity to participate in financial and legal planning, and complete Advance Directives.

An accurate history of symptom onset and course is critical to diagnosing dementia. Because patients can be unaware of their symptoms, it is essential for the clinician to obtain corroborative history from a knowledgeable informant. An important clinical question is, has he or she always been like this or is this a change? Is the change sudden or has it developed gradually? Are the problems getting better, worse or staying the same? A clinician attuned to executive function can easily note any changes in the patient's ability to manage medical problems and medications. There is reason for concern if a previously well-managed problem such as hypertension becomes hard to manage, a patient cannot keep track of appointments or medications are no longer refilled on time. Other signs of executive dysfunction involve not paying bills, trouble shopping and cooking and difficulty with using tools. With visuospatial dysfunction, the patient may get lost driving in familiar locations or, in later stages of dementia, may wander off and be found by neighbors or police. If new onset perceptual disturbances are present, a description of the visual hallucinations or delusions can assist in diagnosis. Visual hallucinations in dementia with Lewy Bodies occur early and include well-formed and detailed figures of small children or animals. Delusions in AD usually occur in the moderate stage of the disease and are related to memory loss. A patient cannot find his/her wallet and thinks it has been stolen. A spouse is no longer recognized, so he/she must be an imposter.

The clinician can learn a great deal from the mental status examination. Patients with cognitive impairment can have poor hygiene or dress inappropriately for the weather, such as wearing short sleeves and slippers in the middle of a Minnesota winter. Inability to follow social conventions and cues may be a sign of frontal lobe dysfunction. Inappropriately disinhibited patients can stand too close to or attempt to kiss the clinician, or start touching objects around the office. Affect can appear labile or unusually disengaged and apathetic. Pathological affect occurs when the patient appears to laugh or cry without endorsing correspondingly elevated or depressed mood. The clinician can easily evaluate language by listening to how patients talk about things they are experts in, such as their personal history. Does the description of their previous line of work or a lifelong hobby make sense or is it hard to follow? Note the presence of word finding difficulties, paraphasic errors (substitution of one word, sometimes nonsensical, for a correct word), or empty speech (use of many words which communicate little).

Examining other cognitive domains is easy and straightforward. Serial cognitive examinations over time can capture progressive decline. As mentioned in the delirium Sect. 2.2.5 above, documenting a patient as "AOX3" provides little useful information about cognition. Brief but effective cognitive examinations cover attention, short-term memory (recall), and executive function.

Note if the patient is paying attention to you or has a decreased level of consciousness or is distractible. The Mini-Cog (18, 19) is a well-validated screening tool that takes under 2 minutes to complete. The patient is given three words to remember, a distraction task (draw a clock, set hands at 11:10) and is then asked to recall the three words. In the case of difficulty with recall or clock drawing, a more focused functional history and further cognitive assessment is indicated.

A focused neurologic examination will pick up signs associated with parkinsonism or other movement disorders or focal deficits that may indicate a cerebral lesion. "Frontal release signs," such as suck and snout reflexes, are nonspecific and will occur in most dementias late in the disease course.

A good history and examination are necessary and often sufficient to provide the clinician with enough information to diagnose a specific dementia; but early in the disease presentation, the clinical picture can be unclear. It is normal for elderly patients to have trouble remembering names and find it harder to keep track of things to do. Although there may be word-finding difficulties, the cognitively intact elder usually can recall the word with a cue, or after some time has passed. Solving unfamiliar problems and shifting mental gears may take more time and effort. Early Alzheimer's disease often presents with irretrievable word finding difficulties and poor short-term memory. There is trouble with getting lost driving in familiar places. The ability to keep track of finances deteriorates. These early cognitive changes can lead to mood changes, apathy, or anxiety. Symptoms and function gradually worsen over time.

Persons with dementia with Lewy Bodies have cognitive and perceptual problems, and develop motor and autonomic disturbances. Visual hallucinations occur in the early stages of the illness, and memory is initially less affected than attention, executive function, and visuospatial dysfunction (48).

Because of prominent psychological and behavioral changes, the behavioral variant frontotemporal dementia (bvFTD) patient is often brought to a psychiatrist for evaluation. According to diagnostic criteria ((54)—see Table 2.5), bvFTD patients will show early symptoms of at least three of the following changes: behavioral disinhibition (socially inappropriate behavior, loss of manners or decorum, impulsive, rash, or careless actions), apathy or inertia, loss of sympathy or empathy (diminished response to others' needs and feelings and diminished social interest, interrelatedness, or personal warmth), perseverative, stereotyped or compulsive/ritualistic behaviors, hyperorality, and dietary changes (altered food preferences especially sweet craving, binge eating, and increased consumption of alcohol or cigarettes and oral exploration or consumption of inedible items). Neuropsychological testing will show executive deficits with relative sparing of episodic memory and visuospatial skills. Diagnosis is made by observation or history provided by a knowledgeable informant.

2.3.6. Clinical Course

The course of the degenerative dementias is progressive and fatal. Initial presentations have been noted in Sect. 2.3.5, clinical picture. Global cognitive impairment is characteristic of all the dementias in their severe stages.

TABLE 2.5. Diagnostic criteria for possible behavioral variant frontotemporal dementia.

Progressive deterioration of behavior and/or cognition by observation or history
Persistent or recurrent symptoms of three of the following:
A. Early behavioral disinhibition with one of the following:
• Socially inappropriate behavior
• Loss of manners or decorum
• Impulsive, rash, or careless actions
B. Early apathy or inertia
C. Early loss of sympathy or empathy with one of the following:
• Diminished response to other people's needs and feelings
• Diminished social interest, interrelatedness, or personal warmth
D. Early perseverative, stereotyped, or compulsive/ritualistic behavior with one of the following:
• Simple repetitive movements
• Complex, compulsive or ritualistic behaviors
• Stereotypy of speech
E. Hyperorality and dietary changes with one of the following:
• Altered food preferences
• Binge eating, increased consumption of alcohol or cigarettes
• Oral exploration or consumption of inedible objects
F. Neuropsychological profile, with all of the following:
• Deficits in executive tasks
• Relative sparing of episodic memory
• Relative sparing of visuospatial skills

Adapted from Raskovsky et al. (54) copyright (2011) with permission from Oxford University Press.

Alzheimer's disease course progresses gradually, sometimes with brief plateaus, from mild to severe dementia to death. Factors that accelerate the decline are autosomal dominant familial type, presence of APOEε 4 allele, significant vascular disease, other medical comorbidities, presence of behavioral and psychological symptoms, and antipsychotic medications. The mean survival after diagnosis is approximately 10 years, although some individuals live as long as 20 years with the disease (1).

In the middle stages of the disease, patients require more assistance with instrumental activities of daily living such as finances, medication management, driving, and cooking. Behavioral and psychological symptoms are common, affecting up to 90% of patients (82). Sleep disturbances and "sundowning," (symptomatic worsening in afternoon and evening) will occur. Agitation and aggression often result in patients being brought to medical attention. Aggression, sleep–wake cycle disturbances, and delusions cause significant caregiver distress.

Persons with late stage Alzheimer's disease can have difficulty ambulating, dysphagia, myoclonus and seizures. They lose the ability to process information from the environment and may stop recognizing family members. Bowel and bladder control are lost. Most patients will be institutionalized at this point because the mental and physical demands of providing care 24 hours a day, 7 days a week exhausts even the most determined and resourceful families. End stage individuals are eventually mute and bedbound. Death most commonly results from aspiration and infection (1).

The course of DLB is progressive disabling cognitive and motor impairment. Although executive dysfunction and visual hallucinations are prominent early neuropsychiatric symptoms, memory impairment becomes more evident as the disease progresses (48).

Over time, impulsivity wanes and apathy is the main clinical finding in bvFTD. Decline is relatively rapid. In one sample, the mean time between onset and death was 7.8 years, with a standard deviation of 3.9 years. A small subset of patients does not decline clinically over time (54).

2.3.7. Laboratory/Imaging

Although clinical criteria are used to diagnose a specific dementia type, laboratory testing and neuroimaging can rule out potential comorbidities. The 2001 American Academy of Neurology practice parameter for diagnosis of Alzheimer's disease (83) recommends obtaining blood tests and, when clinically indicated, neuroimaging. Blood tests are useful in dementia to exclude treatable medical comorbidities. According to these guidelines, syphilis and HIV serological tests should be considered in high-risk populations and when there are suggestive clinical features. (More recent guidelines from the American College of Physicians endorse universal HIV screening in adults to age 75, i.e., regardless of cognitive status (84).)

Central nervous system imaging is worthwhile with focal neurological symptoms on examination, early onset or atypical presentation. "Generalized atrophy," loss of gray matter or "small vessel ischemic disease" are common findings in cognitively normal seniors and do not necessarily correlate with dementia. Increasingly, structural or functional imaging findings are part of research criteria to define probable as opposed to possible dementia; but clinical use of imaging modalities to diagnose specific dementias remains more limited.

There is considerable research interest in disease biomarkers, including Aβ protein deposition and downstream neuronal injury. Amyloid imaging on brain positron emission tomography (PET) scans and reduced levels of Aβ in the CSF may have diagnostic value (1), but are not yet reliable enough to be used clinically. In the future, biomarker evidence is expected to enhance the pathophysiological specificity of the diagnosis (41).

Genetic testing is recommended for symptomatic patients with early onset AD, individuals with a family history of dementia with one or more cases of early onset AD and individuals with a relative affected by a known mutation of APP, PSEN1, or PSEN2 (42).

Neuroimaging evidence is a criterion for probable bvFTD. Present are frontal and/or anterior temporal atrophy on MRI or CT or frontal and/or anterior temporal hypoperfusion or hypometabolism on PET or SPECT (51).

There are no clear neuroimaging criteria for major neurocognitive disorder due to HIV (MND-HIV). Volumetric and structural magnetic resonance and diffusion tensor imaging demonstrate cortical/subcortical atrophy and white matter abnormalities in HIV-infected individuals. Reduced basal ganglia volume is associated with cognitive impairment on neuropsychological testing. As compared to HIV-seropositive individuals without cognitive impairment, subcortical volume loss can be seen in individuals with MND-HIV. Functional imaging modalities such as MR spectroscopy and positron emission tomography also show white matter abnormalities (77).

2.3.8. Differential Diagnosis

Longitudinal assessment of a patient's cognition and function is important to differentiating dementia from other mental disorders. The decline from baseline function and performance distinguishes dementia from mental retardation. Not uncommonly, cognitive impairment can be a feature of major psychiatric disorders (such as depression or schizophrenia) just as psychiatric

symptoms can be present in dementia. In major psychiatric disorders, cognitive deficits, if noticed, are generally less evident than mood, psychotic or anxiety symptoms. Patients with psychiatric illness have variable performance on cognitive tests, with poor effort and insistence that they cannot do items on which they ultimately perform well.

Patients who present with concerns about memory but have intact function are often depressed or anxious, although MCI should be considered, since as many as one third will go on to develop dementia over 2 years (65). "Pseudodementia" is a condition where a depressive disorder presents with prominent confusion that clears when the depression is treated. These patients should receive regular cognitive assessments. A majority of these develop dementia over 5–7 years (85).

Dementia often presents as depression or anxiety. A family member becomes apathetic and looks depressed but does not endorse sadness and finds pleasure in fun situations. Or, without an anxiety disorder history, he/she appears anxious when in an environment where the cognitive demands of the situation are too overwhelming. Demented patients will have cognitive, behavioral and motor disturbances and respond poorly, if at all, to psychiatric medications or ECT.

Persons with dementia can display pathological laughing and crying, also referred to as pathological affect or pseudobulbar affect. These brief, unprovoked stereotyped affective displays that occur without voluntary control or modulation are often mistaken for primary psychiatric illness (56). Determining the patient's prevailing mood will differentiate the dysregulated affect of dementia from mania or depression. For example, if the person does not appear depressed most of the time and, when redirected, can easily switch from a teary outburst to an expression of joy, the diagnosis is not likely to be depression.

Apathy can be a symptom of depression or a cognitive syndrome commonly associated with dementia. In DSM-5, symptoms of depression that suggest apathy are loss of interest in activities and psychomotor retardation. The apathy frequently associated with AD, vascular dementia, the subcortical dementias and bvFTD (86) is often mistaken for depression by psychiatrists (87) and other clinicians. Apathy syndrome is defined as diminished motivation (88) without the sadness and considerable emotional distress that accompany depression.

To complicate matters, cognitive impairment and depression often coincide in neurodegenerative disease, and in clinical situations, it is often difficult to distinguish between the two. In Parkinson's disease, depression worsens executive function, with poorer mental set shifting and response inhibition evident on neuropsychological testing. Treatment with an SSRI can improve cognitive performance independently of effects on depressive symptoms (89).

Examination of psychiatric comorbidities in bvFTD shows that psychosis is rare (55) and affective lability does not have the pervasive changes in mood and neurovegetative signs characteristic of a mood disorder. Sociopathy or addictive disorders developing in late life may be signs of bvFTD (57).

Patients with dementia are at higher risk for delirium and depression, so care must be undertaken to determine overlap and treat appropriately. Knowing the person's baseline and obtaining corroborative history are essential. An acute change in behavior in a demented person is delirium until proven otherwise.

Persons with dementia with Lewy Bodies (DLB) or delirium can exhibit cognitive fluctuations and attentional deficits. DLB can be differentiated by the presence of Parkinsonism, REM sleep behavior disorder and autonomic instability as well as symptom worsening, not recovery over time. Hallucinations in DLB are usually well formed and detailed. Differentiating DLB from AD involves reviewing the neuropsychiatric symptom profile. The difference between DLB and Parkinson's disease dementia is based on history; cognitive symptoms in DLB occur at least one year before the onset of motor symptoms (48).

Both dementia and schizophrenia are associated with executive dysfunction. In fact, Emil Kraepelin first called schizophrenia by the term *dementia praecox.* Psychosis in dementia usually involves visual hallucinations and delusions related to memory loss (theft, agnosia, unfaithfulness). Psychosis in schizophrenia often involves bizarre, paranoid delusions and auditory hallucinations. Although schizophrenia usually has an onset between the late teens and late 30s, a small proportion of patients will have an onset later in life.

Amnestic disorder is an impairment of only one cognitive domain: memory. Although there are many plausible causes, alcohol is the most important cause via thiamine deficiency and the induction of a delirium (Wernicke's encephalopathy) followed by persistent amnesia (Korsakov's psychosis). Alcoholic dementia is also characterized by memory impairment, with a clear history of alcohol abuse/dependence. Expectation is that memory and function will stabilize after sobriety is achieved.

2.3.9. Treatment

Pharmacological strategies in dementia have focused on neurotransmitter replacement and modulation for the treatment of cognitive, behavioral and other neuropsychiatric symptoms. These therapies are only modestly and often inconsistently effective. The concept of dementia "treatment" must be broadened to include psychosocial interventions. The most effective treatments are those that promote safety, independence and better quality of life (80). The demented patient is no longer able to adapt the environment to meet his needs so the environment itself needs to be adapted. Caregivers can easily become exhausted and depressed. Providing a safe environment and the continuous education and support of caregivers are the most effective ways of managing problematic behaviors and safety issues.

Caregivers need to know that dementia progression means that the symptoms and behaviors change over time and that behavioral and environmental interventions will need to change as well. At any stage of the illness, safety issues involving money, medications, vehicles, home appliances, tools and firearms need to be addressed. Adaptation of facilities at home should be planned to minimize confusion and falls. Patient enrollment in adult day programs can provide physical activity, social interaction, and engagement in mentally stimulating activities; as well as respite for caregivers. Caring for a person with moderate-severe dementia requires consistent attention and the ability to redirect agitated or unsafe behavior. The patient benefits when the caregiver's own need for time away is met. The use of advocacy organizations for education, resources, and support is crucial (90). Because of caregiver stress and patient's memory problems, the clinician may need to repeat essential information over the course of treatment.

For the clinician, an individualized approach to comorbid conditions and simplification of medication regimens is essential. There are a few helpful rules of thumb. Consider dementia the organizing principle of care for patients. Be aware that the keys to good care are to preserve function, maximize quality of life, and help patients identify and meet goals. Effects on patient function and dementia progression should be considered in every care decision, including the treatment of comorbid illnesses (91). Ongoing monitoring and modification of care goals and treatments is necessary as the disease progresses.

The currently available medications used for AD enhance cholinergic or inhibit glutamatergic neurotransmission. They offer symptomatic benefit in cognition, function and behavioral outcomes. Maximum benefit appears to be gained early in treatment, although donepezil, a cholinesterase inhibitor, has been shown to have benefits in moderate-to-severe Alzheimer's disease as well (92).

Cholinesterase inhibitors (donepezil, rivastigmine, galantamine) are the mainstay of cognitive treatment. In clinical trials, they consistently show a modest benefit on cognition global outcome and function when compared to placebo. They do not modify disease progression but appear to stabilize cognition and function for the first 6–12 months of treatment. These medications may have some benefit in treating dementia related apathy and agitation. They are generally well tolerated but can cause side effects such as gastrointestinal disturbance, anorexia and sleep disturbances. Rare, severe side effects include bradycardia and syncope. Cholinesterase inhibitors do not alter the conversion of mild cognitive impairment to AD (93). However, they can be useful in the Lewy Body diseases (DLB and Parkinson's dementia), where visual hallucinations often decrease in frequency and intensity in response to cholinergic treatment.

Memantine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, is FDA approved for moderate-to-severe AD. The proposed mechanism of action is neuronal protection against glutamate-mediated excitotoxicity. It has been shown to have modest benefit in cognitive performance and global function for AD and possibly vascular dementia. It may be useful in preventing and treating agitation, aggression, irritability and psychosis (94). It is usually well tolerated. Side effects can include headache and gastrointestinal disturbance. There may be additive cognitive benefits to combining a cholinesterase inhibitor and memantine, although this is not a consistent finding in the medical literature. In Britain, analysis of data from the National Health Service prompted the recommendation to use a cholinesterase inhibitor but not memantine, unless there is a contraindication or intolerance to a cholinesterase inhibitor (95).

There are many studies underway to find treatments for AD, most targeting Aβ, including drugs that reduce Aβ production and immunotherapy to remove Aβ. Other strategies under investigation include using compounds that reduce tau hyperphosphorylation, as well as enhancing brain-derived nerve growth factor (BDNF) or potentiating the effects of caffeine and exercise (42).

Difficult, distressing, and dangerous behaviors often accompany dementia and effective medical treatment is elusive. Human behavior is complex and difficult to predict. There are reasons why a person with dementia may be agitated, pacing, yelling, weeping, throwing objects, or physically assaultive. But dementia impairs the ability to communicate what is wrong, so it is up to the caregiver to figure out where the problem lies. Treating common problems such as pain and constipation can be very effective at calming behavior. Providing caregiver education, adjusting the environment to meet the patient's needs and offering reassurance and redirection are more effective than using medication. When psychological and environmental approaches are not possible or have proven ineffective and the behaviors are dangerous and distressing, antipsychotic medications are the mainstay of treatment (96). They have modest benefits—18% over placebo (97)—but significant potential side effects, including falls, stroke and death. They are most effective for short-term treatment of psychotic symptoms in dementia. Antipsychotic discontinuation studies in Britain have shown increased socialization, decreased mortality and no significant increase in agitation when the antipsychotic is stopped (98). These drugs should be avoided in Lewy body disease due to worsening motor symptoms and increased fall risk. There is sparse literature supporting the use of other medications for agitation; including SSRIs, trazodone and anticonvulsants. Giving benzodiazepines to demented patients should be avoided, because of potential for disinhibition, falls, and adverse effects on cognition (82).

There is no specific medication for bvFTD. Cholinesterase inhibitors are ineffective and may cause increased agitation and irritability. SSRIs are commonly used for controlling symptoms and modulating behavior, based on the consideration that the depression, aggression and impulsivity seen in bvFTD are examples of serotonergic dysfunction. SSRIs may also be effective in ameliorating disinhibition, depression, compulsions, and carbohydrate craving. Trazodone (a mixed serotonin agonist/antagonist with serotonin reuptake activity) has been found useful to treat distressing behaviors in bvFTD (69).

For treatment of HIV related neurocognitive disorders, psychostimulants have demonstrated efficacy, although concerns for abuse liability may limit use in a population that includes substance abusers (75).

2.4. Mental Disorders Due to Another Medical Condition

A conceptual theme that underlies this chapter is that mood, anxiety, or psychotic symptoms and disordered behavior can be interpreted, depending on the clinician's perspective, as primarily psychiatric or medical. Mental disorders were incorporated into psychiatric nosology in 1972, when the so-called Feighner criteria (99) included "secondary depression" that could arise in the context of a life threatening or incapacitating medical illness. The notion of "organic" illness was operationalized eight years later in DSM III, (100) which designated four organic syndromes: hallucinosis, delusional disorder, affective and personality disorders. Later iterations of the DSM considered psychiatric symptoms arising from a medical condition as "secondary" disorders, than those "due to a general medical condition." The "organic" designation was eliminated in DSM-IV-TR (101). DSM-5 closed the gap between psyche and soma by referring to this category as "mental disorders due to *another* medical condition" (emphasis added), perhaps looking forward to the time when psychiatric pathophysiology is better described.

Descriptions of the different disorders are listed in the DSM under the corresponding psychiatric diagnosis. This chapter section combines these disorders under one heading and reviews the symptoms of psychosis, catatonia, mood and anxiety disorders, and personality change that are caused by other, detectable medical illnesses. Following convention, *secondary* is the term that will be used for the mental disorders due to another medical illness.

2.4.1. Definitions and General Observations

Recognition of mental disorders due to another medical condition requires several judgments on the part of the diagnostician. A specific medical condition needs to be identified, based on the history, physical examination, and/or laboratory finding. As with delirium, there are many possible conditions but some have known physiological mechanisms that are well supported by the medical literature. There are no infallible guidelines for diagnosis (1), but some helpful clues exist. First, there must be no preexisting psychiatric diagnosis. Second, there should be a temporal association between the medical illness and psychiatric symptoms. That is, the psychiatric symptoms should coincide with the onset and course of the medical condition, arising shortly after the onset and remitting near the time that the medical condition is effectively treated. This temporal sequence is not always the case. Mood symptoms often precede the motor disturbances in Parkinson's disease (89). In central nervous system systemic lupus erythematosis, mood and psychotic symptoms can be present months before other manifestations of illness. Alternatively, psychosis has long been known to be a late complication of chronic epilepsy. The latter mechanism may be similar to seizure kindling: psychotic episodes may beget psychotic episodes (102). Associations may be bidirectional: the risk of developing depression appears to be increased in patients who suffer from preexisting migraine headaches and a history of depression appears to increase the risk of developing migraine. Physiological adjustment to and compensation for most illnesses result in systemic changes that cause symptoms associated with depression. For example, changes in the hypothalamic–pituitary–adrenal axis or increased production of pro-inflammatory cytokines causes vegetative symptoms such as fatigue or anergy that are common to being sick or depressed. The mental disorder and medical condition may share common pathophysiology. Catecholamines, platelet abnormalities, impaired immune function, and increased cytokines appear to play a role in both depression and coronary artery disease (103).

A third consideration for detecting a medical etiology is an atypical psychiatric presentation, with either onset outside of the expected norm for age, or symptoms that do not fit the profile for the primary psychiatric illness. For example, onset of schizophrenia and anxiety disorders becomes less common with increasing age. Appearance of psychosis after age 40 should prompt a thorough neurological examination, laboratory and imaging studies. Consideration of substance abuse or medical illness should accompany the workup of new onset of anxiety after the second or third decade. Hallucinations that are visual or olfactory instead of the more common auditory hallucinations in schizophrenia can indicate a secondary cause. Sub-threshold syndromes—several symptoms of depression or an unusually long duration to worsening of panic symptoms, for example—may be a clue to an association between a medical condition and a mental disorder.

Prior episodes of mental illness and a strong family history would suggest caution about attributing symptoms to a particular medical condition, regardless of how plausible the connection might appear. In the presence of a well-defined preexisting mental illness, the medical illness associated with a mental disorder should not be considered the primary cause of the symptoms.

The mental disorders due to another medical condition are relatively rare disorders that occur primarily in a medically ill population. Therefore, it is often difficult to determine population prevalence, with depression a notable exception. To link a medical illness to depression, which has a roughly 10% lifetime prevalence, the rate of depression associated with a particular medical condition should rise above the base rate.

It should be emphasized that depression is not the inevitable outcome of severe medical illness. People have an amazing capacity to show resilience in the face of debilitating disease. There may be an adjustment to the illness, with the stress that comes from the loss of a "normal" life. Persons who are "sick and tired of being sick and tired" may become demoralized; but their mood returns to normal as their medical illness improves. Demoralization does not have the pervasive hopelessness or anhedonia associated with a depressive disorder.

Exclusionary criteria for mental disorders due to another medical illness include a primary psychiatric diagnosis or a neurocognitive disorder, especially delirium. As with all other psychiatric syndromes, the disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

2.4.2. Psychotic Disorder Due to Another Medical Condition

Hallucinations or delusions dominate the clinical picture of psychotic disorder due to another medical condition. The parallel primary psychiatric disorders are schizophrenia and related syndromes. Coincident occurrence of psychotic symptoms with a medical illness, onset after age 40 and atypical features are clues to a secondary psychotic disorder. At any age, prominent visual, tactile or olfactory hallucinations suggest a medical cause. Psychosis in the context of inattention and other cognitive impairments indicates delirium. DSM 5 places medication-induced psychosis, such as that found with high dose steroid use, in its own category.

The known pathophysiology of secondary psychotic disorders includes multiple systems: neurological, endocrine, toxic metabolic, and autoimmune. Psychosis can be present with neoplasms, cerebrovascular disease, Huntington's disease, multiple sclerosis, epilepsy, auditory or visual nerve injury or impairment, deafness, migraine, and central nervous system infections. Temporal lobe seizure activity can produce olfactory hallucinations and religious delusions. Untreated endocrine disorders associated with psychosis involve thyroid, parathyroid and adrenocortical systems. Associated toxic metabolic conditions include hypoxia, hypercarbia, hypoglycemia, fluid or electrolyte imbalances, hepatic or renal disease. The clinical presentation of CNS systemic lupus erythematosis and other vasculitidies can include psychosis. Nervous system dysfunction associated with the acute porphoryias can include hallucinations and agitation.

Symptomatic treatment with antipsychotic medication is recommended if treatment of the medical condition is not sufficient or the delay in response to medical intervention puts the patient/others at risk.

2.4.3. Catatonic Disorder Due to Another Medical Condition

Catatonia is a relatively rare psychiatric condition characterized by stupor (no psychomotor activity; not actively relating to the environment), catalepsy (passive induction of a posture held against gravity), extreme negativism or mutism, peculiarities of movement (posturing, mannerism, stereotypy, grimacing), echopraxia (mimicking another's movements), and echolalia (mimicking another's speech) (1). Sometimes patients show excessive purposeless activity. Catatonia is a serious problem that can become complicated by pneumonia and urinary tract infections, deep vein thrombosis, pulmonary embolism, and death. Although it is more frequently associated with primary psychiatric conditions, catatonia can be seen in neurological (encephalitis, head trauma, cerebrovascular disease, central nervous system neoplasms) and metabolic conditions (hypercalcemia and diabetic ketoacidosis) (104). As with all the secondary disorders, the differential diagnosis includes delirium. Psychosis may be the common symptom that links catatonia and schizophrenia. Unfortunately, treatment with antipsychotics can produce a medication-induced dystonia or cause neuroleptic malignant syndrome, which can mimic catatonia. Benzodiazepines and electroconvulsive therapy (ECT) can effectively treat catatonia, and are the recommended therapies.

2.4.4. Mood Disorders Due to Another Medical Condition

The DSM-5 lists depressive, bipolar and related disorders due to another medical condition under their respective mood syndromes. Clinical features mirror those of mania or depression: a prominent and persistent period of abnormally elevated, expansive or irritable mood, and abnormally increased activity or energy (mania), or depressed mood or markedly diminished interest or pleasure in all or almost all activities (depression). History and longitudinal course help differentiate a primary from a secondary mood disorder. In the latter, the mood disturbance usually appears within a month of the medical condition.

Thyroid disorders, both hypothyroidism and hyperthyroidism can include mood symptoms and complicate affective illness (1). Cushing's disease, traumatic brain injury, and multiple sclerosis can appear with a bipolar or depression presentation. There are clear associations between depression and neurodegenerative illnesses such as Parkinson's disease and Huntington's disease. Stroke-related depression has a prevalence of 29%, some of which represents a recurrence of preexisting illness. The major predictor of new onset depression is stroke related disability; other factors include cognitive impairment, stroke severity, lack of social and family support, and anxiety. The risk of post-stroke depression is not affected by the location of the lesion (105). New onset mania, a very rare consequence of stroke, is associated with right hemisphere lesions. The typical symptoms of mania usually occur within days of the stroke (106).

Substance induced depression has its own category in DSM-5. The depressive symptoms are associated with the ingestion, injection or inhalation of a drug or toxin and persist beyond the direct physiologic effects of the substance, including withdrawal. There are few prospective controlled trials examining the association of depressive symptoms with use of a medication and evidence of causality is difficult to determine. According to the DSM-5, the long list of medications implicated in medication-induced depressive disorder includes: antiviral agents (efavirenz), cardiovascular drugs (clonidine, guanethidine, methyldopa, reserpine), retinoic acid derivatives, antidepressants (107), anticonvulsants, anti-migraine agents (triptans), antipsychotics, hormonal agents (corticosteroids, oral contraceptives, gonadotropin-releasing hormone agonists, tamoxifen), and immunological agents (interferon) (1).

2.4.5. Anxiety Disorder Due to Another Medical Condition

Anxiety disorders due to another medical condition are specified in DSM-5 as being predominantly associated with panic attacks or anxiety and obsessive-compulsive symptoms. These subtypes reflect prominent types of anxiety disorders. In general, primary anxiety disorders tend to arise in childhood to early adulthood and are more frequent in women than in men. Anxiety symptoms that present after age 45 years or include atypical panic symptoms (vertigo, loss of consciousness, loss of bowel or bladkder control, slurred speech, amnesia) are more likely to be related to another illness or medications. In secondary anxiety, gender prevalence is equal. Cardiovascular disease and respiratory conditions, including pulmonary embolus, are commonly associated with anxiety. Symptoms can present in neurologic illness such as neoplasms, vestibular dysfunction, encephalitis, and seizure disorders. Rare conditions such as pheochromocytoma and porphyria have also been associated with anxiety.

Obsessive–compulsive disorder related to another medical condition involves prominent obsessions, compulsions, preoccupation with appearance, hoarding, or body-focused repetitive behaviors (e.g., hair pulling, skin picking). Striatal damage is a known physiological mechanism. PANDAS, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection, is a controversial diagnosis that is characterized by sudden onset of obsessions, compulsions and/or tics in the absence of motor symptoms or arthritis following a Group A streptococcal infection (1).

The association between anxiety and vascular disease is bidirectional. Anxiety symptoms and stress increase both incident coronary heart disease and cerebrovascular disease. The association with coronary heart disease is especially strong in women. The connection between anxiety disorders and hypertension is unclear. Suggested mechanisms involve the effects of sympathetic nervous system and hypothalamic–pituitary axis hyperactivity along with altered sympathovagal control of the heart increasing the risk of cardiovascular disease and decreasing the threshold for cardiac ischemia, arrhythmias and sudden death (102).

Differential diagnosis of anxiety complicating medical illness includes depression (which often has anxiety as a symptom), medication intoxication and withdrawal, and delirium. Other primary psychiatric disorders in the differential include illness anxiety (worry not associated with a diagnosed medical condition) and adjustment disorders, which are merely associated with the stress of being ill (1).

Pending resolution of the medical condition, SSRI's and other antidepressants as well as benzodiazepines can effectively control secondary anxiety disorder symptoms. Benzodiazepines can cause respiratory depression and loss of protective airway reflexes; level of consciousness, ventilatory effort, and respiratory function should be monitored if this class of medications is used.

2.4.6. Personality Change Due to Another Medical Condition

Personality Change due to another medical condition is listed under the Personality Disorder category in DSM-5 but is not as well defined as the other secondary disorders. However, as its name suggests, features of Personality Change represent a new and different pattern of inner experience and behavior as opposed to the enduring patterns required for a primary personality disorder diagnosis. Specific Personality Change subtypes are labile, disinhibited, aggressive, apathetic, and paranoid. With the exception of the paranoid subtype, they show little relationship to primary personality disorders. Common manifestations of Personality Change include affective instability, poor impulse control, outbursts of inappropriate aggression or rage, marked apathy, suspiciousness, or paranoid ideation. The clinical presentation depends on the nature and localization of the lesion or pathological process. Personality change often accompanies traumatic brain injury, of which Phineas Gage, whose friends described him as "no longer Gage," is a prime example. It is associated with neurodegenerative disease, especially involving the frontal lobes. Right hemisphere strokes can trigger personality changes in association with unilateral spatial neglect and motor symptoms. DSM-5 allows the Personality Change designation in addition to a major neurocognitive disorder (dementia) diagnosis, if the personality change is a prominent part of the clinical presentation (1).

Treatment is similar to that of the dementias. A structured safe environment, acknowledgement and redirection, and caregiver education and support are the most effective treatments. SSRIs and antiepileptic drugs can help modulate aggression. Antipsychotics may attenuate paranoia. Lithium, buspirone, antidepressants, benzodiazepines, and β blockers have been used empirically with no clinical trials showing evidence of benefit.

The Amnestic Syndrome

Afshan Anjum, M.D.*

Abstract This chapter focuses on the amnestic syndrome or an impairment in the ability to form new memories. The chapter first describes the history of amnestic disorder and background on memory and memory function. Descriptions of the four amnestic syndromes (Wernicke–Korsakoff syndrome, transient global amnesia, mild cognitive impairment, and hysterical amnesia) are then provided. Finally, the etiology, evaluation, and treatment of amnestic syndrome are described.

Keywords Amnesia · Memory · Transient global amnesia · Wernicke–Korsakoff syndrome · Mild cognitive impairment

3.1. Introduction

3.1.1. History

This chapter will focus on a medical rarity that is far more common in artistic renderings of amnesia than it is in real life. The importance of the amnestic syndrome in research is substantial as it is a single symptom impairment that provides rare views into the function of memory processes. The amnestic syndrome is defined simply by impairment in the ability to form new memories. There are usually other associated features, some of which may be quite striking, e.g., the patient's indifference to their deficit, though these features are secondary in prominence to the overwhelming deficits in memory. There is some disagreement about how much impairment in other domains distinguishes an amnestic disorder from a dementia syndrome. The memory defect is in "new learning" or "short-term" memory though some loss of remote memories is usual. Older memories tend to be protected and resistant to damage. Ribot's law, first articulated by the French psychologist Theódule Ribot in 1882, notes that amnesia affects memories in reverse order of their development—"The dissolution of memory is inversely related to the recency of the event (1)." Memories of recent events are most vulnerable; memories of events long ago are more resilient. The terms *anterograde* and *retrograde* memory are important here. Anterograde memory refers to the ability to lay down new memories and is sometimes called "recent memory" or new learning. Retrograde memory refers to the ability to recall previously learned material or prior experiences. Amnestic disorders are primarily disorders of anterograde memory though some component of retrograde memory loss is invariably present. Some (2) have argued that the retrograde impairment is quite prominent though detection of this deficit requires a more specialized approach to cognitive testing.

Memory disorders can be classified based upon phenomenology, etiology, and nosology. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) introduced a new category, neurocognitive disorders (NCDs) as a substitute for the dementia, delirium, and amnestic disorders in DSM-IV (3). While upholding the term delirium, the very familiar term dementia will not be a diagnostic entity. Neurocognitive disorders include dementias and purported early prodromal stages of dementias. The diagnosis of NCDs requires psychological testing. NCD is further differentiated into major and mild categories with major neurocognitive disorders including dementia and other debilitating conditions and mild neurocognitive disorders (mNCDs)

*This is a revision of a previous chapter written by Dr. H. Grossman.

defined by noticeable decrease in cognitive functioning that goes beyond normal changes seen in aging. The new concept of NCD also allows the diagnosis of etiological-specific prodromal states of cognitive impairments.

3.1.2. Phenomenology of Memory

Memories can be described by their temporal occurrence or by their content.

3.1.2.1. Types of Memory

3.1.2.1.1. Temporal

The terms used to describe memory can be quite confusing and lacking in uniformity of use. For example, how short is the term in "short-term" memory? "Short-term" memory can be used to refer to immediate recall or repetition of a list (registration), to keeping that list in mind while focusing on another task (working memory), to memories of events from minutes prior, hours prior, or days earlier. Memory is most often defined temporally as in immediate, short term or long term or by its content (see Fig. 3.1).

Immediate memory, also known as working memory, attention span or registration, refers to the first grasp of information in its original apperception, e.g., the visualization of a license plate or hearing a telephone number. This information is retained only as long as one is actively attending to it. Once attention is diverted, e.g., when one stops looking at the license plate or hearing the telephone operator, the numbers are lost from recollection. To retain such information it must be passed to short-term memory where it is transformed to a symbol or semantic construct such as a word or number. Immediate memory involves parts of the prefrontal and parietal cortices but does not involve the limbic lobes.

Short-term memory is very much a limbic phenomenon. Here sensory information is encoded and initial consolidation of the sensory material into a symbolic representation begins. Further consolidation comes with rehearsing the new knowledge until the symbolic representation is formed (see Fig. 3.1).

Long-term memory refers to the enduring memory traces formed after consolidation is completed. Consolidation likely reflects a potentiation of neural circuits (see Fig. 3.1).

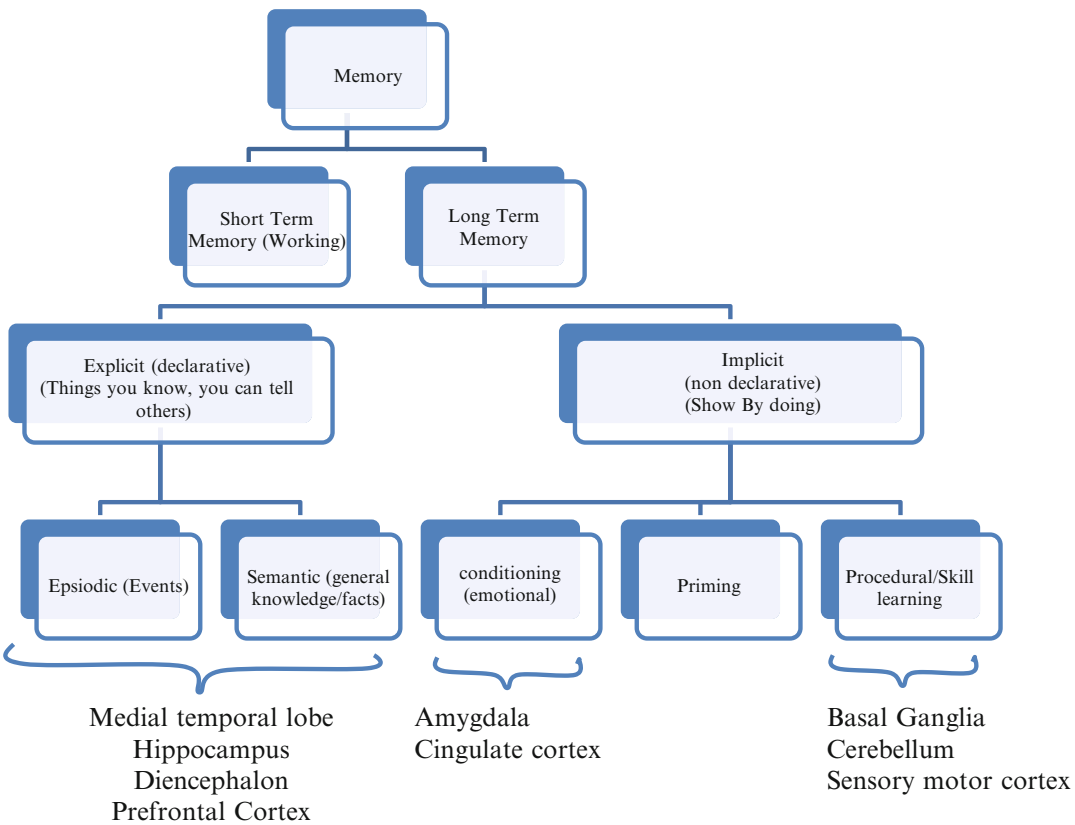

FIGURE 3.1 Classification of types of memory and the relevant brain regions involved.

3.1.2.1.2. Content

Content definitions of memory distinguish between declarative memory which requires a conscious effort (e.g., what is the capital of Idaho?) and non-declarative memories that rely upon unconscious retrieval of information (the association of fire to a burning smell).

Explicit and Implicit Memory

Explicit memory refers to the ability to *consciously* recollect facts and events (see Fig. 3.1). Explicit memory is sometimes known as a declarative memory and can be subdivided into semantic memory, the recollection of facts and rules, and episodic memory, the recollection of past events and circumstances. Implicit memory refers to information that is learned or recollected without conscious effort (see Fig. 3.1). Edouard Claparede (1873–1940), the French neurologist, provided an early description of a patient who illustrates the distinction between implicit and explicit memory. Claparede's patient suffered from a classical Korsakovian amnesia with little ability to learn new semantic information. She was unable to learn the name of the hospital in which she had been residing for many years, could not report the city she was in and could not recall her birthdate. She was able, however, to learn her way about the facility and to find her room from the dining room and other public areas. This demonstrates intact visuospatial learning. Claparede's famous experiment (which would not be approved by a contemporary IRB!) involved introducing himself to the patient with a handshake that disguised a sharp pin in his hand. After a short lapse in time, Claparede reintroduced himself to the patient who demonstrated no recognition of his face and no explicit recollection of having met him before. However, when he extended his hand with a handshake, the patient declined to take it, noting famously, "some people hide pins in their hands." Here we have learning without explicit knowledge of that learning and without semantic details, i.e., only the pain associated with the handshake is learned, not the name or face of the pain-inducing hand shaker.

Procedural memory is the non-conscious recollection of motor activities and skills (see Fig. 3.1). The motor skills of driving a car or hitting a golf ball rely upon procedural memory. These are almost "automatic" activities that do not require conscious effort. As noted above a different neuroanatomical circuit than that of new learning subscribes these memory functions and these memories are more resilient. Not infrequently, caregivers will report that an amnestic patient's driving skills are quite good though the patient cannot functionally drive because they cannot remember where they are going or how to navigate there (a failure of episodic memory) or they cannot recall the rules and etiquette of safe driving (a failure of semantic memory). Similarly, the amnestic golfer might hit true and strong strokes and putt evenly but will have great difficulty remembering whose turn it is, where his ball was resting, or with whom he golfed or even that he has golfed. Here the implicit mechanisms of procedural memory are carrying the amnestic's golf game.

3.2. Anatomy of Memory

3.2.1. Diencepalic vs. Hippocampal Amnesia: Korsakoff, Wernicke, and Milner

Korsakoff and Wernicke worked and wrote in the same decades of the late 19th century but neither they nor any of their contemporaries saw a connection between their descriptions of amnestic conditions. Decades later, there emerged reports of patients who presented with acute Wernicke's encephalopathy and then developed a chronic Korsakovian amnesia, demonstrating that the two syndromes represented different time points of the same condition. Not before the 30s, however, when cases of Wernicke's were described in non-alcoholic patients with gastric malabsorption, it was appreciated that the etiology was related to nutritional deficiency, namely insufficient thiamine or Vitamin B1. Damage to the diencephalon, meaning mammillary bodies and mesial thalamic nuclei, was identified as the underlying neuropathology. Amnestic disorders and Korsakoff's syndrome became virtually synonymous until the 1950s when Brenda Milner and her colleagues described amnestic patients like H.M. who had demonstrable pathology remote from the diencephalon. H.M. had intractable seizures for which he underwent bilateral surgical extirpation of the medial aspect of his temporal lobes, including at least the anterior hippocampi. Seizures were indeed relieved but he was left with a profound deficit in new learning with his other intellectual facilities largely remaining intact (4). In a landmark series of studies of H.M., the integral role of the hippocampi in formation of new memories was clearly demonstrated.

3.2.2. Anatomy and Memory Function

The roles of memory formation and memory storage are carried out in different structures. Memories are initially formed in the limbic memory system. They are temporarily stored in these structures but ultimately long-term storage requires other structures. Amnesia as noted above, is a failure in new learning or in the encoding of new information or the laying down of new memories.

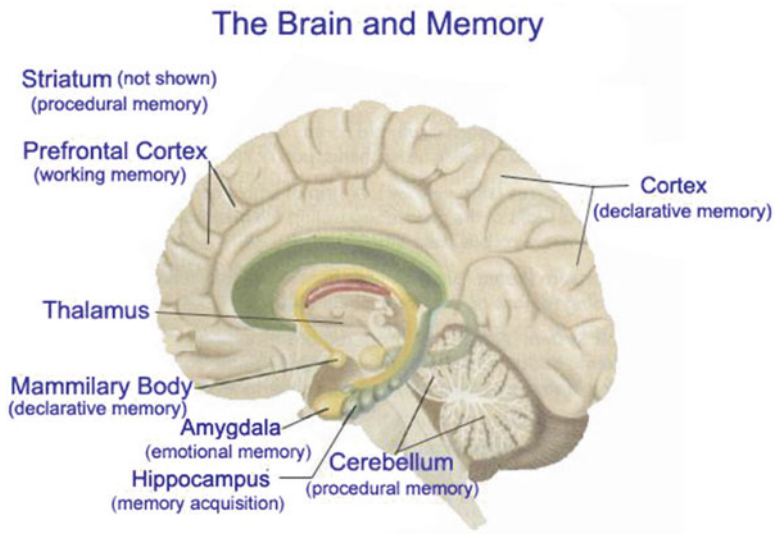

FIGURE 3.2. Anatomy of brain structures involved in memory. Reprinted with permission from Bionews Texas, http://bionews-tx.com/wp-content/uploads/2013/08/memory.jpg.

This is because amnestic syndromes derive from damage to the limbic structures subserving the encoding of new information—the laying down but not the storage of long-term memories (see Fig. 3.2). The structures most commonly involved are the hippocampus and/or the diencephalon as they are highly vulnerable to vascular compromise, anoxic injury, and head trauma.

The hippocampi have major roles in new learning (anterograde memory) but are not involved in long-term storage (retrograde memory) (see Fig. 3.2). The diencephalon includes the mammillary bodies, mammillothalamic tracts, medial dorsal thalamic nuclei, and the internal medullary lamina (see Fig. 3.2). While these structures certainly have a role in new learning that is inferred from the disorders that result from focal damage to these structures, the precise function of these structures in memory has not been determined as yet. Some have suggested that the mammillary bodies store neurotransmitters important for memory processes.

The hippocampi have hemispheric laterality functions akin to the language functions of the cortex. Verbal memory localizes to the left hippocampus and non-verbal memories such as memory for faces, geospatial organization, and musical memories localize to the right hippocampus.

The notion of a *single* anatomic locale for a memory is misleading; memories are formed with contributions from several brain regions, i.e., memories are distributed across brain regions with specific contributing roles. For example, the common memory or knowledge of the dangers connected with the smell of burning draws upon the memory link of the burning smell with fire that resides in olfactory heteromodal cortex while the affective association of fear with the smoky smell would derive from components of the limbic circuitry, most likely the amygdala. Damage to the "storage" areas can result in highly nuanced and subtle deficits or dissociations, e.g., déjà vu phenomena.

As noted above, explicit memory uses the limbic structures, primarily the hippocampal formation, medial temporal lobe and diencephalon. Implicit memories are stored in the host cortical regions for the specific function, e.g., visual memories in parieto-occipital regions and procedural memories in the motor cortex. These memories are distributed in both primary sensory and heteromodal areas.

3.3. The Symptoms of Amnesia

The hallmark of an amnestic disorder is the disruption of *anterograde* memory or the ability to learn and retain new information, and to form new memories. The impairment in new learning is not total: new information can be learned through *implicit* cognitive strategies such as conditioning or priming. These strategies are demonstrable experimentally but do little to mitigate the functional devastation caused by the impairment in explicit memory. Functioning in everyday life requires the ability to continually learn new information (i.e., form new memories) and as well the ability to consciously recall this information as needed. *Retrograde* amnesia is also usually present though it is less prominent and less disabling. It typically follows Ribot's

law with memory for recent events more affected than information learned long ago. The essential elements of all amnestic disorders are:

1. Anterograde amnesia, meaning the patient has severe deficits in learning new ideas, names, or episodes.
2. Retrograde amnesia is also present though to a lesser extent with a temporal gradation such that older memories are more preserved.
3. General cognition is largely intact.
4. Immediate memory, otherwise known as attention, working memory or registration is intact.
5. Procedural memory or the ability to learn new tasks or motor sequences (as opposed to new words or episodes) is largely intact.
6. The ability to learn implicitly is intact though of limited use.

In short, amnestic disorders are disturbances of new learning or short-term memory. Long-term memory is spared. It is explicit memory processes, i.e., memories learned and retrieved through conscious effort that are affected. Implicit memory processes can remain intact.

3.3.1. Anatomy and Symptomatology

The previous discussion of the anatomy of memory is useful in understanding the symptoms of amnestic disorders. New learning is impacted primarily because these are disorders that affect the hippocampi or diencephalon, the primary structures of new learning. Remote memories are largely intact because these memories are consolidated and protected within the lateral temporal lobe or other function-specific regions that remain undamaged in the conditions that cause amnestic disorders. Similarly, implicit memory skills remain intact as they utilize structures other than hippocampi and diencephalon; as such, the amnestic patient can still learn through priming, conditioning, and other implicit means though the utility of such learning, in the absence of an ability to consciously recall is limited.

3.3.1.1. Associated Symptoms

Confabulation is the production of false information in response to a question or stimulus. It is not lying in that the confabulator has no conscious intent to dissimulate and believes what he just said. For example, the amnestic patient with no recollection of where he lives when asked might respond to the effect of "oh I live around here in the neighborhood, not far.... in my own little place." He does not respond, "I don't know" because of a pressure or push to respond that defines confabulation. Some see this as more a failure of executive control than memory: the executive "censor" whose role is to inhibit unreasonable interpretations and responses is allowing "the first thing that popped into my head" to escape into discourse. Confabulation is more common in diencephalic amnesia (e.g., Korsakoff's) suggesting an associated involvement of frontal circuitry in this disorder. Similarly a change in personality that can involve apathy or agitation often is part of the amnestic syndrome and might again be attributable to involvement of these frontal networks.

Motor and sensory symptoms may not be present at all as in Transient Global Amnesia or they may be quite prominent as in the Wernicke–Korsakoff syndrome. In the acute presentation of Wernicke's encephalopathy there is striking opthalmoplegia and gait disturbance. Even after timely treatment with parenteral vitamins there can be residual extra-ocular abnormalities including lateral or even vertical nystagmus. The gait disturbance arising from peripheral neuropathy, muscle weakness, or cerebellar degeneration related to chronic alcoholism can also persist.

3.4. Amnestic Syndromes

3.4.1. Wernicke–Korsakoff Syndrome

Korsakoff (1853–1900), the prodigious Russian neuropsychiatrist, in his lifelong study of the repercussions of alcoholism, described a condition that comprised a polyneuritis and a cognitive disorder in which memory was significantly impaired. He attributed the disorder to an as-yet unidentified toxin (5). Carl Wernicke, the German neuropsychiatrist, was simultaneously describing a condition also seen in chronic alcoholics that presented acutely with opthalmoplegia, gait ataxia, and confusion. He attributed the condition to inflammatory or cerebrovascular processes. Both of these disorders were quickly incorporated into the clinical lexicon and widely recognized in practice (6). However, it was not until the 1930s that it was appreciated that the disorders were similar and that both were attributable to a vitamin deficiency (Vitamin B1 or thiamine) not unique to alcoholics.

Maurice Victor and Raymond Adams subsequently described diencepalic degeneration as the hallmark neuropathological feature (7, 8). They advocated a unitary term, Wernicke–Korsakoff syndrome, which remains in widespread use though with variations. Wernicke's Encephalopathy or Wernicke's Dementia is often used to refer to the acute presentation for the vitamin deficiency and Korsakoff's Dementia or Psychosis is used to refer to the chronic amnestic states that persist after the initial presentation. This amnesia as originally described by Korsakoff is the paradigmatic amnestic syndrome: "at times an almost pure form of acute amnesia where the recent memory is well preserved though the remote past is remembered quite well." Korsakoff's original papers also capture the variability within the syndrome with some patients presenting with greater or lesser degrees of dilapidation in other cognitive domains, as well as behavior and function.

3.4.2. Transient Global Amnesia (TGA)

TGA, first described in 1964, is characterized by a sudden inability to record new memories in previously non-demented patient (9). There are no associated motor or sensory deficits, no impairment in any other cognitive domain, and the sensorium is clear. A frequent presenting feature is repetitive questioning regarding geographic or contextual orientation (e.g., where are we? Where are we going?). It typically occurs in middle age or later and seems to affect men and women equally. The episode can last minutes to hours after which the ability to form new memories gradually returns, the only residual effect is a persistent amnesia for the actual episode and events that occurred during the period of anterograde amnesia. TGA tends not to recur. The etiology is unknown though some advance a vascular spasm hypothesis akin to migraines as a mechanism (10). Others have proposed cerebral venous insufficiency, seizures, and transient arterial ischemia as possible etiologies though none of these occur regularly in studied patients with TGA and do not as yet adequately explain the symptomatic specificity of the syndrome (11, 12).

3.4.3. Mild Cognitive Impairment (MCI)

This is likely the most common type of amnestic syndrome. MCI is defined in most operational criteria by:

- A subjective deficit in memory, preferably corroborated by another informant.
- Objective deficits in performance on memory tests, compared with other people of similar age and educational background. The overall performance might still be within the established range of normal but should be below expectation for this patient considering his/her premorbid intelligence, level of education, or occupational achievement.
- Essentially normal judgment, perception, and reasoning skills.
- Largely normal activities of daily living.
- Absence of dementia.

The above definition refers to the "amnestic type" of MCI. There is also a "non-amnestic" MCI though the definition and predictive value of this entity is not as well established.

Ten to twenty percent of those over the age of 70 have mild cognitive impairment. Of those diagnosed with MCI, 10–15% will progress to an Alzheimer's disease diagnosis in each year following identification of MCI such that at 3 years post-diagnosis with MCI, half will have frank Alzheimer's. What emerges is that MCI can serve as a pre-Alzheimer's diagnosis, though it can be the precursor state for other dementias as well. In addition, there are patients who do not progress or even those who improve. MCI diagnostic criteria will collect a clinically heterogeneous population (13, 14).

3.4.4. Hysterical Amnesia

Amnesia can represent a hysterical response in a vulnerable patient similar to hysterical paralysis or hysterical epilepsy. The so-called dissociative or psychogenic amnesia involves difficulty recalling details or circumstances related to a particular event usually of a traumatic nature. For example, a patient who had been assaulted presented to an emergency room after the assault and provided a detailed accounting of the event. However, 2 days later she presented with no knowledge of the assault and over the next week she became amnestic to earlier traumatic life events and subsequently was unable to recall her address or the names of immediate family members. This sort of non-chronological and situation-specific amnesia is characteristic of hysterical amnesia.

In hysterical amnesia there may be an extensive retrograde amnesia extending over days, weeks, or even years though anterograde memory or new learning is intact. This contrasts sharply with the amnestic syndrome described above in which anterograde memory is densely impaired and retrograde memory follows Ribot's law with most recent memories more vulnerable to loss.

In typical amnesia there can be significant recovery of memory over time whereas in hysterical amnesia the deficits may worsen with time. Hysterical amnesia can include amnesia for person, something that is virtually never seen in the amnestic disorders and is seen in progressive dementia only at the terminal stage (15, 16).

3.5. Etiologies for Amnesia

There are numerous potential etiologies for the amnestic syndrome, listed in Table 3.1. These include head trauma, vitamin deficiencies, hypoxic conditions, cerebrovascular disorders, toxic exposures, specific infections, and the idiopathic transient global amnesia. What is common to all these provocative etiologies is the relatively focal involvement of the limbic or diencephalic circuitry that subserves new learning or "short-term memory."

3.5.1. Hypoxic Conditions

The hippocampi are exquisitely sensitive to oxygen deprivation. Hence any interference with the supply of oxygen to the brain can differentially impact the hippocampi and create the relatively narrow symptoms of the amnestic syndrome. Anoxic injury due to cardiac sudden death or shock can produce discrete infarction of the hippocampi even as the rest of the brain is salvaged with cardiopulmonary resuscitation. Carbon monoxide poisoning, as in failed suicide attempts interferes with the oxygen transport within the red blood cells and can selectively impact the limbic memory structures. Focal necrosis of the hippocampi can be seen at autopsy and at times on imaging.

"Pumphead" or post-perfusion syndrome, in which cardiac surgery patients develop abiding cognitive deficits after surgery involving mechanical perfusion has long been part of clinical lore. A landmark study in 2001 found that over 40% of patients in this series had a performance decline of 20% or more from pre-surgery testing (17). However, large retrospective studies of dementia patients have found they were no more likely to have had cardiac surgery previously than a non-demented control sample. If post-perfusion syndrome is a true phenomenon then it is a subtle change in cognition rather than a full dementia. It is not progressive, as the deficits are related to the insults associated with surgery, presumably micro-emboli, and further decline would not be expected (18, 19).

3.5.2. Infections

Herpes simplex encephalitis causes a focal hemorrhagic necrosis that usually localizes to the temporal and frontal lobes. It is caused by herpes simplex virus type 1 (HSV-1). There is a high mortality rate but survivors often display a focal amnestic disorder due to destruction of mesial temporal structures. General cognition is largely intact.

3.6. Evaluation

The evaluation of an amnestic patient often takes place in an emergency room or inpatient hospital ward as the deficits may be screaming for attention. The single most important aspect on initial evaluation is determining if the patient is presenting with an acute Wernicke's encephalopathy. Extra-ocular movements and gait must be assessed and there should be a low threshold

TABLE 3.1. Common etiologies for the Amnestic Syndrome.

Acute onset	Insidious onset
Transient global amnesia	Korsakoff's dementia/psychosis
Traumatic brain injury	Other vitamin deficiencies due to malabsorption, persistent vomiting, malnutrition
Wernicke's encephalopathy	Post-herpetic encephalopathy
Anoxic encephalopathy as seen post-cardiac or respiratory arrest; thrombotic or embolic events, carbon monoxide poisoning	Mild cognitive impairment (MCI)
Electroconvulsive therapy (ECT)	
Anesthesia	
"Pumphead syndrome"	
Alcohol or sedative–hypnotic intoxication	

for administering intravenous B vitamins: the potential to reverse severe deficits is present only at this early stage. Bedside examination can elucidate the disproportionate devastation of memory that characterizes the amnestic disorder. Casual conversation will appear normal as the patient has intact verbal skills and will often confabulate to fill in a reasonable context. Bedside cognitive testing, however, will quickly demonstrate the deficits. The patient will be wholly disoriented in the absence of a wall calendar, watch or newspaper at hand (though will retain the insight and ability to look over at the calendar or his watch). Asking the patient to register and recall a list of items or words will make manifest the deficits. The amnestic will be able to repeat back the list of words as long as he can keep them in working memory (e.g., by focusing on the words or repeating them to himself). However, after an intervening task such as serial 7 subtractions (which he will be able to do as general cognition and calculating skills are spared) the words will be lost without trace. No hints or cues will bring these words back as they have left no memory trace. Short-term memory or new learning has failed. Neuropsychological testing can further delineate the extent of the impairment in new learning and the relative preservation of other cognitive domains.

Neuroimaging is often unremarkable in the amnestic disorders, in large part because the structures involved, the hippocampi and diencephalon are small and don't always show damage on conventional scanning methods.

The main differential in amnestic presentations is delirium and dementia. Delirium is the great mimicker of psychiatric symptoms and delirious patients can present with disorientation in all spheres and profound inability to retain new knowledge.

Delirium is defined by a disturbance in attention and consciousness, both of which are entirely intact in the amnestic patient. In the delirious patient the EEG reflects this disturbance in sensorium with a diffusely slow background rhythm. In amnestic disorders, the EEG is unremarkable.

Dementias also present with clear consciousness and significant impairment in new learning. Dementias, however, by definition, involve other cognitive domains such as language, calculation, or comportment.

3.7. Treatment

The treatment of amnestic disorders requires careful determination of the etiology and then treatment for that condition. Amnestic disorders can present emergently such as in Wernicke's encephalopathy with a narrow timeframe of hours during which intravenous provision of thiamine might reverse the symptoms and prevent enduring amnesia. Transient Global Amnesia resolves spontaneously though the typical middle aged patients presenting with this sudden onset memory impairment need to be evaluated emergently for stroke, seizures, or a space-occupying brain mass. Hysterical amnesia should be treated, as other hysterical phenomena with the use of suggestion to promote a belief that that memory will recover quickly in its entirety. Hypnosis or controlled narcosis such as that obtained with amobarbital can be used to provide post-hypnotic suggestion that memories will return.

Other amnestic disorders present after the fact, i.e., after the damage to brain tissue is irrevocable as in anoxic brain damage or post-herpetic encephalopathy. In these cases the treatment is nonspecific and aimed at ameliorating symptoms. Case management becomes the more essential intervention. These patients will likely require a guardian of person and effects, supervised housing and a sheltered work environment if they are to work at all.

Nonspecific treatments that can be used for chronic amnestic disorders include cholinesterase inhibitors for enhancement of memory; antipsychotic or anticonvulsant medication for intrusive disinhibition or agitation; and psychostimulants for disabling apathy or abulia. All of these symptomatic interventions are off-label and have minimal quality evidence to support or discourage their use. Cognitive rehabilitation or remediation and memory enhancement programs have theoretical utility here as amnestics can learn through implicit means such as conditioning and priming and still have access to procedural and more remote ("overlearned") semantic memories. However, all these approaches are confounded by the impairment in conscious recall, i.e., even if the amnestic can learn associative mnemonics, if he cannot learn that he knows these mnemonics, they will never be called in to play in a given situation where they may have been useful. Similarly, having access to a rich base of procedural skills such as master carpentry is not helpful if the patient cannot recall where the building materials are stored or if he was to build a house or a rocking chair. A job coach can act as an external conscious memory though this is rarely feasible for extended periods of time.

Attempts to supplement a failed conscious recollection through the use of technological supports such as smart phones, electronic organizers, or personal robotics are again limited by the patient's inability to remember to take the phone with him or inability to learn even the rudimentary operating procedures for the technical innovation.

Bipolar Illness

William Coryell, M.D. and Paula J. Clayton, M.D.

Abstract This chapter records the historical significance of the disorder, mania, a symptom complex that has been recognized since antiquity. It shows the development of the concept of bipolarity and the more recent broadening of the concept. This is followed by etiologic considerations, with emphasis on the genetic components, and its epidemiology, risk factors, clinical picture, course, complications, differential diagnosis, and treatment. Updates in this revision apply to all areas subsequent to the history of the concept. They are particularly extensive in the areas of genetic underpinnings, the onset and course of the illness, those features with prognostic value and the various treatment options. Given the considerable accumulation of new findings since the first edition of this volume there is also a new emphasis on meta-analyses to better allow for tentative conclusions.

Keywords Bipolar I · Bipolar II · Mania · Depression · Hypomania · Rapid cycling · SAD · Secondary mania · Mood stabilizer · Course · Suicide

4.1. History

Numerous terms, usually dichotomous, have been used to classify mood disorders. The separation into unipolar disorder and bipolar mood disorders rests on extensively described genetic and clinical differences and has become the most fundamental and widely used of them. Unipolar mood disorder refers to patients who have depression only. Bipolar mood disorder designates patients who have episodes of mania or hypomania. Hypomania without a history of depressive episodes is not considered a diagnosable disorder (1).

Hippocrates is credited with introducing psychiatric diagnoses into medical nomenclature. Two of the six diagnoses that he proposed were mania, derived from a Greek word "to be mad," and melancholia, from "black bile." In his classification, mania referred to acute mental disorders without fever, and melancholia referred to a wide variety of chronic mental illnesses. In the first century AD, Aretaeus noted that depression and excitement often alternated in the same person and therefore might represent different aspects of the same illness. Although it is difficult to tell from the classification systems how pervasive this idea of cycling became in the centuries thereafter, the term mania remained prominent in all. For hundreds of years the diagnosis of mania has been used primarily for an illness with an acute onset and with a mood of merriment, rage or fury (2).

In 1686, Bonet used the term maniaco-melancholicus to characterize such patients. In the 1850s, Falret adopted the term circular insanity, and Baillarger used that of double-form insanity for similar patients (3). In 1874, Kahlbaum (4) referred to patients with cyclothymia. Kraepelin (5) drew on and synthesized the various approaches to nosology bequeathed to him from the preceding centuries. Beginning in 1883, he published nine editions of his textbook on psychiatry, and it was he who separated dementia praecox from manic-depressive illness using clinical descriptions and the natural history of the illnesses.

If we could assume that names are given to illnesses in an attempt to organize clinical observations, then it must be said, from the long history of the term mania, that the particular symptom cluster and course of mania has been apparent to clinicians throughout history.

Lange (6) may have first suggested the separation of unipolar from bipolar illness. Pederson et al. (7) noted "periodical depression has no manic phases and differs from manic-depressive psychoses with regard to heredity as well as distribution of somatic types and prognosis." They added that manic-depressive patients were more likely chronic and disabled in contradistinction to periodic depressives, who were more likely to be discharged and recovered. Leonhard (8), Perris (9), and Angst (10) solidified this point of view and the first American researchers to place emphasis on this distinction were Winokur and Clayton (11).

Although bipolar illness was separated from unipolar illness on the basis of differences in age of onset, course, family history, and response to treatment, this separation may not, in the end, prove entirely valid. More recently some data has accumulated that suggest, as Kraepelin (5) did, that the two illnesses may be different forms of the same disorder, with bipolar illness being a more severe, earlier-onset form than recurrent major depressive disorder. This unitary approach has been gaining momentum in the last 10 years and is best exemplified by Cassano et al. (12) and Akiskal and Benazzi (13).

4.2. Definition

Manic-depressive disease, or manic-depressive illness, is the old term for bipolar disorders as described in the Diagnostic and Statistical Manual of Mental Disorders (DSM 5). Bipolar I disorder requires a history of manic episodes and bipolar II disorder requires both episodes of depression and hypomania in the absence of any episode of mania. Cyclothymic disorder is characterized by at least 2 years of numerous episodes of hypomanic and depressive symptoms. Other Specified Bipolar and Related Disorders encompass presentations which feature symptoms that are characteristic of bipolar disorder but which do not meet the full criteria.

Bipolar I disorder may manifest with manic or depressed phases and either type may include an admixture of the other syndrome. If three symptoms of mania or major depression coexist with the full alternate syndrome for most days of the episode, it is said to have mixed features. The coexistence of full syndromes of both major depression and mania is considered to be a manic episode with depressive features.

For a diagnosis of a manic episode, DSM-5 requires presence of an irritable or elevated mood as well as increased energy and three or more of seven symptoms that last for 1 week. The symptoms cause social impairment and the episode should not be due to an abuse of a drug or a medical condition or treatment.

Specifiers can be used to identify patients with mood-congruent or mood-incongruent psychotic features. This distinction hinges on whether the content of delusions or hallucinations is, or is not, consistent with typical manic themes. If mood-congruent and mood-incongruent features coexist, the episode is specified as mood-incongruent.

Major depressive or manic episodes that begin during pregnancy or within 4 weeks following delivery are specified as having a peripartum onset. If three or more of 12 listed catatonic features dominates a major depressive or manic episode, that episode is considered catatonic.

Bipolar II disorder requires a history of at least one hypomanic episode and of one or more major depressive episodes. The criteria for a hypomanic episode resemble those for a manic episode except that the minimum duration is 4 days and symptoms must not include psychotic features and do not necessitate hospitalization or result in marked impairment.

4.3. Etiology

Genetic factors play a significant role in the etiology of bipolar affective disorder. No other data concerning etiology are as strong as those in the genetic area, and knowledge of family history appears to have practical value. The development of the genome map and of DNA probes for linkage markers led investigators to anticipate the identification of linkages to specific chromosomal markers. To date, however, only a few reproducible risk alleles have been detected. It may be, instead of using categories to divide individuals as affected, unknown and unaffected, it will be more informative to separate individuals by dimensions.

In addition to the genetic factors, studies have also investigated possible etiological roles for biochemical, neuroendocrine, neurophysiologic, and chronobiological abnormalities. Evidence that particular abnormalities are specific to bipolar illness over MDD has been scant, however. Besides the problem of always including some not-yet-identified bipolar patients in unipolar studies (at least 25–33%, up to 50%) one must always consider if the abnormalities described in any particular report occurred during a unipolar or bipolar depression, during a manic phase, pure or mixed, or in a well state, and under what conditions (i.e., on, or recently on, medications).

4.3.1. Genetics

There is no doubt that bipolar disorder is familial; that is, it runs in families, with close relatives being more likely to be affected than unrelated subjects. Three types of studies show the extent to which this is true: (1) family studies, (2) adoption studies, and (3) twin studies.

4.3.1.1. Family Studies

Family studies were originally anecdotal. Falret in 1854 interviewed the parents of patients with circular insanity and obtained compelling evidence as to the hereditary disposition in the illness (3). He concluded that circular insanity was very heritable, but could not decide whether it was more heritable than any other type of mental illness, although he was inclined to think so.

Many decades later Perris (9), Angst (10), and Winokur and Clayton (11) confirmed the heritability of bipolar illness with a series of family studies. Many others have followed and a review of those that included normal control groups estimated that the first-degree relatives of bipolar patients have a sevenfold increase in risk for bipolar illness over that of control subjects (14).

In addition to providing some support for the role of genes in the etiology of bipolar disorder, the results of family studies also speak to the validity of distinctions between bipolar and unipolar disorder and between bipolar I and bipolar II disorders. Their relevance to boundaries between bipolar I disorder and schizoaffective disorder, bipolar type, is covered in the chapter on schizoaffective disorder.

For the first of these distinctions, nearly all comparisons between the relatives of bipolar patients and those of unipolar patients have found the former to have substantially higher rates of bipolar illness. Some have also found more unipolar illness among the relatives of bipolar probands than among controls but this may be accounted for, in large part, by the substantial proportion of seemingly unipolar patients that eventually develop manic episodes. In fact, a family history of mania is among the most reproducible of the features that predict the development of mania among seemingly unipolar patients (15).

Regarding the distinction between bipolar I and bipolar II conditions, relevant studies appeared later and are fewer in number. The largest of these used data from the NIMH Collaborative Depression Study (CDS) (16). In a comparison of non-bipolar, bipolar II, and bipolar I probands grouped according to Research Diagnostic Criteria (RDC) (17), bipolar II disorder was most often diagnosed in the relatives of bipolar II probands and bipolar I disorder in the relatives of bipolar I probands (18). Other studies have observed a similar pattern (19).

More recent support for the separation of bipolar I and bipolar II conditions derives from an analysis of risk factors for diagnostic stability over a lengthy observation period (15). Probands who began follow-up with a diagnosis of non-bipolar disorder were more likely to switch to bipolar II disorder if their interviewed relatives had bipolar II disorder. Those who switched to bipolar I disorder were more likely to have had relatives with bipolar I disorder.

The diagnostic reliability of bipolar II disorder is problematic for several reasons. First, because patients rarely seek help for a hypomanic episode, clinicians usually diagnose on the basis of episodes that occurred in the sometimes distant past. Second, because hypomania, by definition, does not result in serious impairment and, in contrast to most mental disorders, need not involve impairment at all, such features as increased mood and energy may shade imperceptibly into correlates of normal mood fluctuations.

The CDS findings of Rice et al. (20) are pertinent to this problem. First-degree relatives of probands with MDD or bipolar disorder were reinterviewed blindly after a 6-year interval. A history of hypomania obtained at the first interview was recalled in the second interview in only 1 of 10 cases. Of the seven given a diagnosis of bipolar II disorder in one but not the other interview, all were related to probands who had a bipolar disorder. This suggests that if at least one of repeated screenings for past hypomania is positive, then the true diagnosis is most likely to be bipolar II disorder, even if some of those screenings were negative.

4.3.1.2. Adoption Studies

In contrast to family studies, adoption studies offer a means to separate familial transmission attributable to being raised by a parent with bipolar disorder from that due to being genetically related. Adoption studies are understandably difficult to accomplish and only two exist for bipolar disorder. One of these found that the adopted-away offspring of bipolar biological parents were four times more likely to have bipolar disorder than were adopted-away offspring of parents without bipolar disorder (21). Another found a twofold difference (22).

4.3.1.3. Twin Studies

Comparisons of monozygotic and dizygotic twins with and without bipolar disorder are another way to separate nature and nurture. The systematic review of six of these yielded median concordance rates of 39 and 5% for monozygotic and dizygotic

twin pairs, respectively (23). The heritability of bipolar I disorder is approximately 80% (24, 25), more than twice the 35% for unipolar major depression as derived from a weighted mean across seven studies (26). The heritabilities of bipolar II disorder and cyclothymia have been estimated at 58% and 68%, respectively.

4.3.1.4. Genetic Studies

Many linkage studies of bipolar disorder have sought to identify rare gene variants that carry high disease risk. The lack of clearly replicable findings has led to the conclusion that very few cases of bipolar disorder result from such genes. Rapid advances in the efficacy of genome mapping have made possible studies of unrelated subjects in order to detect population-level associations between disease and genes of smaller effect. Further progress in the relevant technology then allowed genome-wide association studies (27), an approach that has had some success. Currently, a small number of polymorphisms have shown associations that are strong and replicable (28).

Perhaps the most notable of these is CACNA1C (29). This gene encodes major L-type alpha subunits in the brain and is thus of particular interest given the apparent efficacy of L-type calcium channel blockers in mood disorders (30). However, this and other polymorphisms within the calcium channel subunit have also been associated with MDD and schizophrenia (31). Such findings have revived controversies over the Kraepelinian distinction between schizophrenia and mood disorders and have supported a greater emphasis on the study of spectrum variables rather than diagnostic categories (32).

4.3.2. Biochemical and Neuroendocrine Parameters

The depressant effect of reserpine when given for hypertension, and the antidepressant effects of a monoamine oxidase inhibitor when given for tuberculosis, led to the development of the biogenic amine hypothesis for the etiology of depression. The classic amine hypothesis held that depressive illness arises from a functional deficit of either norepinephrine or serotonin at critical synapses in the central nervous system. Conversely, an excess of such amines is associated with mania. It is evident that the third biogenic amine, dopamine, is also important and that other neurotransmitters or neuromodulators, such as those of the cholinergic, GABAergic, and endorphin systems, play roles in bipolar disorder. Janowsky et al. (33) suggested that an affective state may represent a balance between central cholinergic and adrenergic neurotransmitters and that depression may be a disorder of cholinergic predominance and mania, the opposite. In keeping with this, pilocarpine has been shown to rapidly decrease manic symptoms (34). More recently glutamatergic modulators have attracted particular interest in the search for additional new stabilizers (35).

Early observations of the affective state of patients with excesses or deficiencies of corticosteroids (Cushing's syndrome and Addison's disease) led to the measurement of corticosteroids in the plasma and urine of patients with depression. Some depressed patients had elevated levels of corticosteroids that returned to normal with recovery (36). Capitalizing on an endocrine challenge test for the diagnosis of Cushing's disease, Carroll et al. (37) began to systematically evaluate the dexamethasone suppression test (DST) in depressed patients. They reported that 67% of depressed melancholic inpatients and outpatients given 1 mg of dexamethasone at 11:00 p.m. failed to suppress cortisol at 8:00 a.m., 4:00 p.m., or 11:00 p.m. the next day (37).

The prospect of a long awaited diagnostic laboratory test in psychiatry together with the pathophysiologic implications of the findings and the ease with which the DST could be conducted, resulted in a profusion of studies. A recent review of published comparisons between samples with depressive disorders and comparison samples included those from 361 studies (38). The preponderance of findings indicated substantially higher rates of HPA axis hyperactivity in the depressed groups with an effect size of $d = 0.70$ for results of the DST. Effect sizes were higher in groups with older mean ages or with greater overall severity and were therefore larger in groups comprised of inpatients or of patients with melancholic or psychotic depression. Despite some findings to the contrary, most studies of bipolar disorder found HPA hyperactivity to be more likely in depressed and mixed manic phases than in purely manic phases.

4.3.3. Chronobiology

Numerous lines of evidence link bipolar disorder to disturbances in biological circadian rhythms. These include observations of phase advances in patients with bipolar disorder (39), the therapeutic benefits of induced phase advances (40), of sleep deprivation (41), and of morning light exposure, whether administered intentionally (42) or not (43). Also relevant is the seasonality that many with bipolar disorder experience (44) and the tendency for travel across time zones to provoke mania or depression, depending on the direction of travel (45, 46). Accordingly, refinements of therapeutic interventions that affect these rhythms have evolved to include serial sleep deprivation (47) and sleep deprivation combined with light therapy (48), lithium (49, 50), or antidepressants (51–53).

4.3.4. Brain Imaging

Numerous structural imaging studies exist and have generated highly variable results, perhaps because typical sample sizes have not been large enough for the number of regions tested (54). Among the more consistent observations are that, in comparisons to well controls, bipolar patients have larger lateral ventricles and smaller cross-sectional areas of the corpus callosum. Hyperintensities, particularly those that are manifest in deep white matter, are substantially more prevalent in patients with bipolar disorder than in well controls or in subjects with unipolar disorder (54). Relative to those with MDD, individuals with bipolar disorder have smaller corpus callosum cross-sectional areas and larger hippocampal volumes (55). Because bipolar patients taking lithium have larger hippocampal grey matter volumes than do those taking other mood stabilizers (56), the much greater use of lithium in bipolar disorder than in unipolar disorders may account for the observed differences between them in hippocampal volumes.

Functional neuroimaging studies have also been numerous and have generated a variety of findings. In a recent meta-analysis of functional neuroimaging in bipolar disorder that identified 55 studies (57), subjects with bipolar disorder had limbic hyperactivity and frontal hypoactivity in comparison to control subjects. This pattern was present in euthymic and depressed states but was most prominent in manic states.

4.3.5. Secondary Mania

Krauthammer and Klerman (58) thoroughly reviewed the literature on secondary mania, and required specific criteria for mania. The majority of reported causes were neurologic conditions such as neoplasm, epilepsy, head injury, cerebrovascular lesions, drugs, metabolic or endocrine disturbances, infections, or other systemic conditions.

Reviews of differences between organic and non-organic mania (59–61) have shown that patients with induced mania are frequently older at illness onset, their mood is more often irritable than manic, and they are less frequently psychotic. Their family histories are also more frequently negative, and they respond preferentially to anticonvulsants.

Mania may develop after a closed head injury (62–64). In a comparison of a large number of patients with bipolar disorder to well controls, those with a history of head injury were clearly overrepresented in the former (65). This relationship only existed for those whose injuries had occurred within 5 years of their admission for mania and was most prominent for admissions that had occurred within 1 year.

The relationship between stroke and the onset of mood disorders has also been well studied (66, 67). In a meta-analysis of 49 reports, the typical patient that developed mania following a stroke was a male with a right-sided infarction and without a personal or family history of psychiatric disorder (68).

4.4. Epidemiology

Because of the inclusion of BP II, estimates of the prevalence of bipolar disorder have increased since those reported by Boyd and Weissman (69) and by the ECA studies (70). Lifetime prevalence rates for DSM IV bipolar disorders (I and II) from the National Comorbidity Survey Replication were 3.9% (71). Rates varied inversely by age. Although prevalence rates for schizophrenia were not measured in these studies, bipolar illness is clearly the more common illness. Moreover, the cited rates did not include all of the cases of MDD that would later switch to bipolar disorder. Some authors contend that Major Depression and Bipolar Disorders may be nearer to equal in prevalence, mainly because of the BP II individuals embedded in the MDD group (72, 73). In most studies the distribution of males to females is balanced in BP I but is 2:1 female to male in BP II.

There are no racial differences in the incidence or prevalence of this illness. Evidence exists that both Hispanics and blacks with bipolar affective disorder are more likely to be misdiagnosed as having schizophrenia (74–76). In the ECA study (70), there were no differences in the lifetime prevalence of mania by race and mania was equally prevalent in urban or rural residents.

A relationship between bipolar disorder and creativity has long been appreciated (77). Studies of probands and relatives in the past several decades have likewise associated bipolar disorder with high educational and occupational achievement, but this appears to be true of the relatives of bipolar probands, rather than the probands themselves (78–80). The advantage in bipolar family members was particularly strong in the relatives who themselves had bipolar disorder, however. This suggests that, though the diathesis toward bipolar illness carries with it traits that promote higher achievement, the disability associated with those cases of bipolar disorder that necessitate treatment at tertiary care centers may overwhelm this advantage.

4.5. Diagnostic Stability

A recent review of follow-up studies that used structured interview at baseline showed a median conversion rate to bipolar I or bipolar II diagnoses of 15% (15). Follow-up studies that derived baseline diagnoses of MDD from chart review often reported considerably higher conversion rates than did those based on structured diagnostic interviews. This illustrates the frequent failure to appreciate past episodes of mania or hypomania that occurs in typical clinical settings. In the study that combined a high-surveillance intensity with a particularly lengthy follow-up of up to 31 years, the conversion rate was 1 in 5 (19.6%). For switches specifically to bipolar II disorder and to bipolar I disorder, rates were 12.2% and 7.5%, respectively (15). Patients with an early age of onset, with psychotic features, or with a family history of bipolar disorder have higher rates of switching (15, 81). Any admixture of manic symptoms with a depressive syndrome, particularly those of decreased need for sleep or increases in energy or activity, substantially raises the risk of an eventual bipolar diagnosis (15).

It should also be remembered that individuals who appear to have bipolar disorder are at risk for an eventual diagnosis of schizophrenia. In a carefully executed study of diagnostic stability over 10 years, Bromet et al. (82) found that a change in diagnosis of bipolar disorder to schizophrenia (14/95 = 14.7%) was more than three times more likely than a diagnostic change in the opposite direction (5/126 = 4.0%, $p < 0.005$).

4.6. Course

Though numerous reports have described tendencies for adverse life events to precede both manic and depressive episodes (83), most that have taken care to focus only on those adverse events that were likely to be independent of symptoms have found adverse events to be no more common before than after manic episodes (84). On the other hand, life events that disrupt social rhythms, particularly those resulting in sleep loss, do appear to trigger manic episodes (85, 86). This observation has led to efforts to stabilize social rhythms as a part of the long-term management of bipolar disorders (87).

Parturition is clearly a trigger. All studies have confirmed the postpartum period as a risk period for mania in known bipolar patients (88–90), and in patients with serious previous depression (81). Women who experience post-partum episodes are likely to develop them again following one or more subsequent deliveries.

Numerous studies have indicated that, in the teenage years, bipolar illness can be seen as schizophrenia, antisocial personality, or borderline personality disorder. Akiskal (81) indicated that the clinical presentation of adolescents with bipolar disorders are, in decreasing frequency, psychosis, alcohol and drug problems, moodiness, suicidal ideation or attempt, academic failure, philosophic brooding, obsessional brooding, somatic complaints, school phobia, "hyperactivity," stupor, and flagrant antisocial behavior.

The literature on late-onset (more than 50 years of age) bipolar illness is confusing because some of the patients discussed had episodes of depression before the age of 50 but did not become manic until after age 50. A study of manic episodes in older people indicated that a mean of 10 years had elapsed between the first depressive episode and the first manic episode (91). Late onsets should trigger a search for an underlying medical condition but there are onsets after 50 that are not associated with organic pathology (92–95). Since this age group is enlarging we should see more.

Periodicity of this illness exists for some patients, with fall/winter depression and spring/summer mania being most frequently described. Sayer et al. (96) confirmed in the southern hemisphere what had been reported in the northern hemisphere (97), that hospital admissions for mania have a spring/summer peak. A lengthy study of week-to-week mood ratings similarly found a peak for depressive symptoms in winter, but also a peak for hypomanic symptoms near the fall equinox (44).

Such observations have led to the concept of seasonal affective disorder (SAD) (98, 99), and many with this condition have bipolar disorder. Indeed, a community study concluded that bipolar patients experience greater seasonality than those with depression or healthy controls (100). The recognition of such patterns may be important for the management of certain patients.

4.7. Clinical Picture

4.7.1. Onset

More than one-third of patients first develop symptoms consistent with bipolar disorder in the teenage years (88, 101). Although there are conflicting reports (102), most researchers agree that the majority of patients, particularly women, begin with depressive episodes (103–106). Bipolar disorder most often starts with an episode of pure depression. Angst (103) reported that the ratio of depression to mania in the first episode was 3:1 for women and 3:2 for men.

It is well established that the mean age of onset for bipolar disorder is earlier than that for unipolar disorder. Moreover, many age-of-onset admixture analyses have been done to refine groups for genetics studies and most have identified three groups.

Early, middle, and late onset groups usually fall in the ranges of 20 or less, 21–29, and 30 or greater, respectively (101). An early age of onset is, according to substantial evidence, indicative of poorer outcomes. Such patients have longer index episodes (107), more depressive morbidity over time (102, 108, 109), a higher likelihood of psychotic features, lesser responses to treatment (110), and a greater likelihood of rapid cycling (111–113). They also make more suicide attempts (102, 111–113) and are more likely to abuse substances (114). Aging itself, when tracked within subjects, seems to bring more time in depressive episodes but not more manic or hypomanic morbidity (115).

The type of initial phase with cycling episodes also has prognostic value. In comparison with patients who began with a depressive phase, those with mania as their first phase tend to show better responses to lithium (116–120) and to have shorter episodes generally (121).

4.7.2. Symptoms

Mania can begin suddenly with the development of a full-blown syndrome over hours, or it may appear more gradually, and develop over days. It seldom takes weeks to develop. A history of a change in the patient's behavior is usual although, unless the onset is sudden, close relatives may miss the first indications. Early in the course of illness, mania can be preceded by life events, including bereavement, but later episodes do not appear to follow life events as often (122). There are no data to suggest that unipolar mania differs from the bipolar mania. Kraepelin (5) originally reported that 17% of his 900 manic-depressive patients were exclusively manic. In the Jorvi Bipolar Study (JoBS) only 4.4% of these recently diagnosed inpatients and outpatients reported having mania only (106). In the CDS, 14 (8.6%) of 163 bipolar I patients who had at least 15 years of follow-up gave a history of only manic episodes at their intake evaluation (123) but this number dwindled to 7 (4.3%) over the course of follow-up.

The picture can vary from an excited, talkative, loud, over-reactive, somewhat amusing individual to a completely disorganized, intrusive, and psychotic one. The mood is, by definition, elated, angry, or irritable. Patients often appear overly confident, bragging, self-aggrandizing, and happy but become irritable when their ideas are not enthusiastically endorsed. Frequently they become most angry at those who are closest to them, particularly their spouses. They interrupt conversations but dislike being interrupted themselves. They are distractible, and racing thoughts, pressured speech, circumstantiality, irrelevancies, and flight of ideas characterize their thoughts and language. Decreased need for sleep, an increase in sexual thoughts, and an increase in alcohol intake are all common in the manic patient. During the full-blown syndrome, there may be periods of depression lasting from minutes to hours. Grandiose ideas and delusions are common and are often the basis for the symptoms of excessive telephone calls, extravagances, and excessive writing. One or two themes usually predominate and may be religious, political, financial, sexual, or persecutory. Catatonic features during manic episodes have been well documented (124, 125).

All varieties of psychotic symptoms have been reported in the manic patient (126, 127). One of the better descriptions of this is the Carlson and Goodwin study on the evolution of manic episodes (128). They described patients admitted to research units at the NIMH, where, because of participation in various protocols, manic episodes were often allowed to evolve fully before treatment began. At the height of manic episodes, patients exhibited unusual psychomotor activities, incoherent thought processes, and delusions and hallucinations that were bizarre and idiosyncratic. They found symptoms of hyperactivity, extreme verbosity, pressured speech, grandiosity, irritability, euphoria, mood lability, hypersexuality, and flight of ideas. Seventy-five percent had delusions that were either of control or had sexual, persecutory, or religious themes; 75% exhibited assaultive or threatening behavior; 60% were intrusive; 55% had some delusions; 45% had regressive behavior (urinating or defecating inappropriately and exposing themselves); 40% had auditory and visual hallucinations; and 35% were confused. Confusion is, in fact, a well-documented symptom of acute mania. In one chart review, 58% of 31 manic patients were reported either to be disoriented or to have memory lapses (126). Kraepelin (5) used the term delirious mania for this condition.

Pope and Lipinski (129) emphasized that between 20 and 50% of well-validated bipolar patients have psychotic symptoms, including hallucinations, delusions, catatonia symptoms, and Schneiderian first-rank symptoms. The presence of formal thought disorder either during a manic episode, or more especially, at some time outside of a manic episode, is a predictor of persistent delusional thinking after 5 years of follow-up (130).

Andreasen (131–133) studied thought disorder in mania and found that, besides being over-inclusive, manic patients were tangential and had derailment, incoherence, and illogicality that was as prominent as it was in schizophrenic patients. Manic patients were more likely to have pressured speech, distractibility, and circumstantiality, while the schizophrenics more frequently had poverty of both speech and content of speech. Some have found that at follow-up, though it is in partial remission, many continue to have thought pathology (134, 135).

Many studies have compared bipolar depression to unipolar depression by symptoms. Differences have been inconsistent (136) but an excess in bipolar depression of psychomotor retardation (137, 138) and psychotic features have been among the most replicable (139–141). Other distinctions that have distinguished the depression of bipolar II patients from that of bipolar I patients include more anxiety (137, 142) and a greater likelihood of rapid cycling (143, 144) in the former.

4.7.3. Course

It should be remembered that nearly all descriptions of course in bipolar illness have used samples recruited from inpatient settings and that little is known of the typical outcome of bipolar I and bipolar II patients who might be sampled in outpatient settings. Individuals with relatively severe or refractory illnesses are more likely to be found in inpatient settings and, of course, such patients would be expected to follow on average a more malignant course. The body of follow-up studies nevertheless allows the use of a number of features in making useful prognostic estimates.

The most consistently reported difference in course between bipolar and unipolar disorders, other than in the likelihood of manic or hypomanic episodes, is the shorter time to relapse and shorter cycle lengths in the former (122, 145–149). Follow-up studies published over the past 50 years show single episode cases of bipolar disorder to be quite rare (1, 148–151).

Bipolar I and bipolar II disorders differ markedly in the likelihood of future manic episodes (152). In comparison to patients with bipolar I, those with bipolar II disorder experience more weeks with depressive symptoms, both above and below the threshold for a major depressive episode (153). This observation is in harmony with the tendency of bipolar II patients to exhibit higher levels of borderline, histrionic, and schizotypal traits (154).

Evolution in cycle length has been a topic of conflicting reports. A number have described a shortening of cycle length as episodes accumulate (148, 155) and this has spurred speculation that episodes themselves produce brain changes that result in an increased propensity to new episodes (the kindling hypothesis) (156). Nearly all of these studies were entirely, or at least largely, retrospective in design and therefore shaped by the tendency to remember more recent episodes and to forget those in the distant past. Other descriptions that were entirely prospective in their tracking of episodes have revealed no evidence that cycles decrease in length (121, 157, 158).

The presence of psychotic features, whether in depressive or manic phases, portends greater symptom morbidity and psychosocial impairment in the long term (159–161). Psychotic features that are mood-incongruent appear to predict even greater psychosocial impairment (162–164).

Anxiety symptoms during bipolar depressive phases comprise another feature with sustained prognostic import. It is not clear which types of anxiety symptoms are most important, but their presence in general is associated with a higher likelihood of switching (165, 166), shorter euthymic periods (160), poorer treatment response (163, 167), more suicide attempts (160), and a longer time to remission (168). A high level of anxiety appears to mark a type of depressive illness rather than to simply characterize a given episode. The degree of difference in morbidity over time between anxious and non-anxious individuals does not lessen over decades of follow-up (115).

Cycling within a given episode indicates a longer time to remission (169, 170), a greater likelihood of subsequent rapid cycling (143) and more morbidity in the ensuing years (121, 171). Cycling (121) and mixed episodes (172) also increase the likelihood of such episodes in the future. Those who tend to present with single phases of mania have, on average, much better long-term outcomes (173, 174).

Rapid cycling is the more extreme form of cycling and its poor prognostic implications are well appreciated (175–177). Some patients exhibit this pattern chronically but the majority with a prospectively observed onset of rapid cycling ceased to have rapid cycling within 1–2 years of its development (143, 175).

The reported frequency of mixed states varies with the number of symptoms of the other pole that are required to define it. Some reports combine mixed and cycling episodes, which elevates the percentage identified as having a mixed state (174, 178–181). In any event, those with mixed onsets are more likely to develop rapid cycling (182).

Patients with mixed mania also have poorer responses to acute treatment (178, 179) and worse outcomes on follow-up (161, 183, 184). Depressive episodes with mixed features last longer on average, feature more intense dysphoria and both carry a higher likelihood of suicidal thinking and behavior and feature dysphoria that is more intense (185, 186).

Two early studies (88, 187), with follow-ups averaging 2 years and 6 years, respectively found that nearly 30% in both never achieved full remission. Welner et al. (188) later reviewed a large number of studies of bipolar illness and indicated that chronicity, if defined as presence of symptoms, social decline, or both, occurred in at least one-third of the bipolar patients. Chronic mania, however, is uncommon.

An analysis of the weekly status of bipolar I and II patients, most of whom who were hospitalized at the beginning of a lengthy follow-up, showed that the average patient with bipolar I disorder was ill for 47% of weeks (189) while those with bipolar II disorder were in episodes for 54% of weeks (190, 191). Sub-syndromal residual symptoms are an important problem for bipolar patients (191). Disability resulting from both depressive and manic symptoms increase steadily with increases in symptom number (192) and relapse into a full syndrome is much more likely in the presence of even mild subthreshold symptoms (193).

There are several more favorable outcome studies. One was Petterson (194) who observed the clinical, social, and genetic aspects of 123 patients in Sweden for approximately 5 years. At the end of the study, a large number of patients showed more satisfactory work capacity and better social adaptation. This was a group treated by a single investigator. Similarly, Miller et al. (195) also reported that their carefully treated patients were asymptomatic 59% of the time in a 23.7 month follow-up. So perhaps with complete and vigorous treatment in a stable clinical setting, the course is more favorable.

4.7.4. Consequences

4.7.4.1. Psychosocial Impairment

Bipolar disorder may cost twice as much in lost productivity as major depression disorder (196). It is estimated that each US worker with bipolar disorder averaged 66 lost workdays in a year compared to 27 for major depression.

Some have indicated that the marriage of bipolar patients end in divorce more frequently than those of unipolar patients or appropriate controls (197). In the CDS, patients with bipolar disorders were twice as likely to be divorced as were unipolar patients (198). Bipolar patients who were married, however, were only half as likely as were married unipolar patients to rate the relationship with their spouse as poor or very poor. Well spouses may have a different view though. In one report, 53% of well spouses compared with 5% of the bipolar patients indicated that they would not have married the spouse, and 47% of the well spouses, compared with 5% of the patients, would not have had children had they known about the bipolar illness before making these decisions (199). Thus, the illness has an impact on marriage, job, child rearing, and all aspects of life (200).

4.7.4.2. Suicide

A review of 27 studies of bipolar disorder showed a median suicide rate of 0.4 per 100 person-years (201). The 13 reports that included standardized mortality ratios had a median value of 22, indicating that individuals with bipolar disorder have a 22-fold greater likelihood of eventual suicide than do age- and sex-matched individuals from the general population.

In a 40–44 year follow-up of patients hospitalized for a mood disorder, 10.2% of those with bipolar disorder died by suicide (202, 203). Even though it was the more seriously ill patients who got treatment, the suicide rate was much reduced in those who were treated compared to those who were not. Outpatients have lower suicide rates in most studies (194, 204, 205).

Bipolar patients die by suicide in the depressed phase of their illness. One of the first psychological autopsy studies showed that although the most frequent diagnosis was one of a mood disorder, no patient was manic at the time of the suicide (206).

Findings have been uneven regarding whether risks for completed suicide are higher for patients with bipolar disorder than for those with MDD. In many reports, and particularly in retrospective studies, bipolar patients were more likely to have made suicide attempts (137, 169, 207). In prospective studies bipolar patients appear to have the same risk factors for suicide attempts and completions, as do MDD patients (208).

4.7.4.3. Cardiovascular Morbidity and Mortality

There are also links between bipolar disorder and excess cardiovascular mortality (209, 210). The increase in risk appears to be higher in bipolar illness than in MDD (211–213) and may be especially strong when the illness is not treated (202, 214, 215). The few studies that have compared bipolar I and bipolar II groups found significantly higher risks for cardiovascular morbidity in the former (208). The cumulative time already spent in manic or hypomanic episodes appeared to drive this risk (216).

4.7.4.4. Other Morbidity

Bipolar illness is associated with increased risk for dementia (217) as is MDD. Some of this association can be attributed to mood symptoms that are a prodrome of dementia, but a number of reports have described robust associations with mood disorders with onsets that have preceded the onset of dementia by many years.

Most mental disorders increase risks for alcohol use disorders, but the risk is highest in bipolar I and bipolar II disorders (218), and, relative to the general population, is much greater for women than men (219). Alcoholism may develop before or after bipolar illness first appears, and this order has some prognostic significance. Bipolar disorder which develops after alcoholism is established has a later onset and entails less affective morbidity over time (220, 221) The outcome for the alcoholism is poorer, however (220). This suggests that, when the onset of either bipolar disorder or alcoholism is facilitated by the presence of the other disorder, the course of the illness with later onset may be less malignant. Ongoing alcoholism or substance abuse, however, appears to predispose to mixed bipolar episodes (222, 223).

Some researchers have concluded that, in remission, manics evaluate themselves in a positive way (199, 224, 225). Others have emphasized the achievement-oriented personality of the bipolar patients (226, 227) and still others have found that bipolar patients who are well or stabilized on lithium have personalities similar to those of controls (228, 229). Some have suggested rather that lithium mutes underlying cyclothymia and causes bipolar patients to test more like unipolar patients (230).

A more recent look at distinct temperaments in 98 bipolar I, 64 bipolar II, and 251 unipolar major depressive disorder patients found that bipolar I patients described themselves as near normal whereas bipolar II patients emerged as mood labile, energetic, and assertive yet sensitive and brooding (231). Bipolar I patients were low on neuroticism and bipolar II patients were high,

mostly because of their mood lability. Angst and Clayton (232) compared premorbid personality traits in young men who went on to develop bipolar illness with those who remained well, and found no differences. Unfortunately, the personality test did not measure obsessionality—the trait, as reported by Klein and Depue (233), that may be associated with risk for bipolar disorder in the offspring of bipolar probands.

Rates of comorbidity in general are probably higher in bipolar disorders than in any other prevalent DSM IV disorder and this certainly extends to the personality disorders. Bipolar II disorder is more likely to be accompanied by personality disorders than is bipolar I disorder. Many patients with bipolar illness have high levels of impulsivity, a trait that worsens during episodes but then appears to remain higher than those of normal controls, even between episodes (221, 234).

With regard to criminality, Petterson's (194) patients had fewer convictions than expected in comparison with the general population, a finding replicated in other studies. An interesting set of studies (235), however, indicates that symptoms of mania are more common in forensic settings than was generally thought. Among patients admitted to St. Elizabeth's Hospital in Washington, DC, 11 of the 13 attempted crimes against the presidents of the USA, so-called White House cases, were perpetrated by people diagnosed as having an affective disorder, and the majority of them were bipolar.

There is also an association between pathologic gambling and a bipolar diagnosis (236). Pathologic gamblers have high rates of comorbidity, especially with bipolar disorder (237). In a large family study, the relatives of pathological gamblers were more likely to have bipolar disorder than were the relatives of control probands. This remained true when the effect of bipolar illness in the proband was controlled (238).

4.8. Differential Diagnosis

As indicated, there are other disorders that share many features with bipolar disorder. The distinction between bipolar disorder and some of these disorders is particularly problematic.

4.8.1. Schizophrenia

Schizophrenia and mania are alike in many ways. The symptoms of a current episode can be similar in mania and schizophrenia. There is not one symptom that is pathognomonic for either, although the mood of merriment, elation, ecstasy, or even irritability is much more likely to occur in mania than in schizophrenia. A study of diagnostic criteria for mania indicated that the triad of symptoms—manic mood, rapid or pressured speech, and hyperactivity—is relatively specific for mania (239). Thus, the presence of this triad should heavily tilt a differential diagnosis toward mania. In patients partially treated with lithium or other anti-manic drugs, these symptoms may be muted, and the prominent symptoms may only be psychotic symptoms.

Mania, for the most part, should have a relatively sudden onset, with the only extended prodromal symptoms being a depressive syndrome, and should be characterized as a clear change from the person's premorbid self. Schizophrenia is usually more insidious in onset, but it, too, can begin with depression or anxiety. Again, the other indications of a manic syndrome, such as increases in activity and decreased need for sleep, previous episodes, an acute onset, and family history, should help to differentiate patients. Prominent delusional thinking or hallucinations may overshadow manic symptoms in an acutely psychotic individual. In these cases a careful questioning of family members may reveal that manic symptoms were apparent in the lead up to fulminant psychosis.

The course of the illnesses can be similar. At least one-third of bipolar patients have either social disabilities or symptoms that may be more than just low-grade depressive symptoms. Still, all studies show significantly better follow-up outcome in manic individuals than in schizophrenics. Both have high suicide rates, with 10–15% dying by suicide. An important difference in these two illnesses is the family history. Although both are hereditable, at least 50% of manic patients have some family history of an affective disorder (mania or depression). Studies of schizophrenics show a significant but less striking increase in schizophrenia in their families but no increase in affective disorder over the population prevalence.

4.8.2. Catatonic Schizophrenia

Patients who present with catatonic symptoms are more likely to have bipolar disorder than any other diagnosis. All patients in whom the diagnosis of catatonic schizophrenia is entertained should be evaluated carefully for depressive and manic symptoms in the period preceding the onset of catatonic symptoms, for previous episodes, and for family history. Some manics become mute when their thoughts go so fast that they cannot speak. The amytal interview may still be useful in uncovering depressive delusions, disjointed manic thoughts, or disorientation (organicity) (240).

4.8.3. Schizoaffective Disorder

As is discussed in the chapter on schizoaffective disorder, this term has been given many definitions and its boundaries have varied accordingly as has its prognostic position between mood disorders and schizophrenia. Probably the most important component of the criteria in DSM-IV and DSM-5 is the requirement that, at some point, psychotic features have been manifest for at least 2 weeks in the absence of a mood episode. Many clinicians disregard this when they assign a schizoaffective disorder diagnosis.

4.8.4. Organic Mental Disorders

Because at least one-third of manic patients have either disorientation or some memory deficits during an episode, it might be easy to think of mania as a toxic state. Although certain drugs can precipitate manic episodes, usually even these syndromes are treated with neuroleptics or lithium, or both. A first episode in an elderly patient can be quite problematic and it is most difficult in a catatonic stupor. Previous history and family history should be useful in confirming a diagnosis. In younger patients it is important not to be sidetracked by the confusion of mania and to delay treatment for a long time while completing extensive organic workups.

4.8.5. Personality Disorders (Antisocial, Borderline) and Alcohol and Drug Abuse

There are many presentations of bipolar disorder. In the teenage years, a change in behavior would be the key to distinguishing the manic from the typical sociopath. It is easy if the sociopathic behavior is manic—that is, stealing with some grandiose plan in mind—but less easy if it is typical of all adolescent antisocial acts. The same can be said of alcohol or drug problems, school phobia, and borderline personality diagnoses. Here again, this should be a clear change in behavior that could not have been expected or anticipated. Depressive symptoms or, less commonly, previous manic symptoms should be present if inquired about. These things, coupled with a family history of affective disorder, should help in making the proper diagnosis.

Bipolar disorder shares the trait of impulsivity in particular with borderline personality disorder. Many other features overlap as well, including rapid mood shifts, propensity to substance abuse, frequently unstable interpersonal relationships, periods of striking irritability, a high risk for suicide attempts, and an often chronic course with early onset. As a consequence many patients with borderline personality disorder are misdiagnosed as having bipolar disorder and treated accordingly (241, 242). The relationship between borderline personality disorder and bipolar disorder is controversial and some believe they exist on a continuum (243).

4.8.6. Attention Deficit Hyperactivity Disorder in Children and Adolescents

The debate over the comorbidity of bipolar disorder and attention deficit disorder continues (244). Children who meet criteria for bipolar disorder are very likely to do so for ADHD as well (245). The two disorders share the symptoms of irritable mood, accelerated speech, distractibility, and high energy level (246). Symptoms that are relatively specific to bipolar disorder are grandiosity, elation, decreased need for sleep, and hypersexuality (247). Individuals who are comorbid for those disorders are more likely to have anxiety and substance use disorder and to have a criminal history (248). Notably, family studies have shown either bipolar disorder or ADHD to raise the risk of having the other disorder in relatives (249, 250). This opens the possibility that their coexistence represents a subtype of bipolar disorder.

4.9. Treatment

4.9.1. Acute Mania and Mixed Episodes

Little psychosocial management can be accomplished with a patient in the manic state. The patient is talkative, both irritable and irritating, sexually aroused, confident, expansive, and completely lacking in insight or good judgment. Because of the uplifted mood, the patient feels no need of treatment and refuses with vehemence offers of assistance. Hospitalization is necessary and frequently entails commitment. The patient must be protected against the serious social and medical consequences of this state. Because of the manic patient's intrusiveness and potential for creating conflict, it is almost always possible to think of that person as being dangerous to himself or herself. If there are other illnesses, such as hypertension, that are controlled by medication, these get out of control as the manic individual neglects medications, creating another reason for hospitalization.

When manic patients are hospitalized, their excessive energy is easy to handle if they are given space to roam and are not confined to a locked room. This does not mean that they can be on an unlocked unit, since they are capable of excessive spending even while in the hospital. Manic patients are also intrusive and speak in an uncensored way, so they can provoke arguments anywhere, including the hospital. In addition, enormous bills and bad feelings can result if telephone use is not restricted. The relatives, who are worn down and exasperated by the manic patient's behavior and relieved to know that he or she is being protected in the hospital, also often welcome hospitalization. The patient may also be super alert such that they hear and overinterpret everything they see and hear. It is best to maintain them in an environment with as little stimulation as possible; groups, occupational therapy, and television should be minimized until the illness is remitting.

In treating manic patients, physicians should always remember that certain interpersonal traits are part of the manic illness. Janowsky et al. (251, 252) outlined a series of interpersonal behaviors that they had originally thought were part of the manic's premorbid personality but that were later discovered to be symptoms of the manic episode. In addition to the classic manic symptoms of hyperactivity, push of speech, flight of ideas, irritability, distractibility, poor judgment, and increased social contact, they found that manic behavior included such things as the testing of limits, flattery, shifting responsibility for their actions to others, exploiting other's soft spots, dividing the staff, and provoking anger. These traits may lead to marked interpersonal, marital, and ward conflict. Therefore, in treating the manic patient, one must take into consideration these symptoms and behaviors and respond to them as if they were part of the illness. Setting limits in an unambivalent, firm, arbitrary way best does this.

The efficacy of lithium for acute mania is well accepted. With this in mind, the following choices are available, although the order may be debatable and may depend on the severity of the presenting symptoms: (1) lithium, (2) atypical antipsychotics or older antipsychotics (3) anticonvulsants such as valproate or carbamazepine alone or in combination with lithium, or (4) electroconvulsive therapy (ECT). Early studies comparing lithium with chlorpromazine or lithium, chlorpromazine, and haloperidol indicated that lithium was superior to the others in terms of earlier discharge. These studies, however, indicated that chlorpromazine, haloperidol, and other such neuroleptics control the hyperactivity/excitement of the acutely manic patient more quickly than does lithium. Some maintained that, clinically, the end result was superior with lithium alone, whereas others felt that haloperidol alone was sufficient for the acute illness. Because there have been some reports that the combination of haloperidol and lithium can produce adverse side effects (253–255), and because bipolar illness may increase risks for tardive dyskinesia (256–258), the newer second generation of antipsychotics, such as olanzapine, risperidone, quetiapine, ziprasidone, and aripiperazole, may be preferable for the treatment of acute mania.

Before beginning treatment with lithium, the patient's evaluation should include a physical examination, tests for thyroid and renal function (blood urea nitrogen and creatinine), a white blood cell count, and electrocardiography. Other medications should be recorded, particularly the use of diuretics. While the proper dose is being determined inpatients should be monitored daily for symptoms of toxicity, such as tremor, nausea, vomiting, diarrhea, and confusion. In general, if the dose is raised gradually, toxicity can be avoided. Skin rash, usually acneiform, is another potential problem.

The usual starting dose of lithium in acute mania is 300 mg three times a day, which is gradually raised until a blood level of 1.0–1.2 mEq/L is achieved. Lithium's half-life requires an unchanging dose for 5 days before measurement of steady state concentrations. Changes made on the basis of shorter intervals may overestimate doses and result in toxicity. Lower starting dose and smaller dose increments are appropriate for those over 50 years old (259). Once the patient has shown the ability to tolerate the lithium, the regimen should be switched to a single evening dose. That may be better for the kidneys. Improvement typically occurs in 8–10 days.

Unfortunately, patients are often discharged from the hospital long before a manic episode has sufficiently resolved only to be followed by readmission shortly afterward. Before discharge the manic patient should have a marked decrease in symptoms and some insight into the illness and show a willingness to continue lithium (260). In addition, the patient's family should be educated to have an understanding of the illness and the importance of maintenance therapy.

4.9.2. Other Treatment Therapies

All the second-generation antipsychotics except lurasidone have FDA indications for the treatment of mania. It is desirable to weigh the patient, measure waistline and obtain a metabolic panel before these medicines are started. The doses recommended are as follows: risperidone, 2–6 mg/day, olanzapine 10–20 mg/day, quetiapine 400–800 mg in divided doses, ziprasidone 80–160 mg/day, again in divided doses, asenapine 100 mg twice daily, and aripiprazole 30 mg/day. The side effect profiles of each are different, as are the presumed modes of action. The major drawback to some of them is weight gain, metabolic syndrome, and the onset of diabetes, but as we have already noted, there seems to be some relationship between bipolar illness and diabetes, independent of medications.

Double-blind, placebo-controlled studies (261–264) have also shown valproic acid to be effective in the treatment of acute mania. Before beginning, a complete blood count and liver function tests are recommended. Depakote (enteric coated divalproex sodium) is a delayed-release tablet that causes less nausea. The goal is to achieve a blood level between 60 and 120 ng/mL (265).

Giving 20–30 mg/kg from the outset can approximate the dose necessary for therapeutic plasma levels. Beginning at this dose apparently results in a shorter time to improvement than does a conventional tapering regimen and entails no greater side effect burden (266). Poorer responses have been demonstrated for plasma levels below 60 ng/mL and, because protein binding begins to become saturated at doses exceeding 100 ng/mL, concentrations of the unbound portion may rise much more rapidly with increasing plasma levels beyond that point (267). Doses should be adjusted if used with other mood stabilizers like lamotrigine.

Carbamazepine XR as well is useful in the treatment of acute mania (268–272) and placebo-controlled studies have shown it to be an effective antidepressant (273, 274). The average daily dose varies across studies from 200 to 800 mg bid, and the average blood level to be achieved varies between 6 and 12 ng/mL. The use of loading doses is not recommended. Before beginning, a complete blood count and liver function tests are desirable because carbamazepine too can produce elevations of liver function tests and reductions in white blood cell and platelet counts in a dose-related fashion. Dose, however, does not predict the rarely seen aplastic anemia or agranulocytosis. Carbamazepine induces its own metabolism, causing the blood concentrations to drop after several weeks so that an upward adjustment of medication is often necessary. Because it induces liver enzymes, carbamazepine may lower valproate levels and these may, in turn, increase if carbamazepine is discontinued. Other drugs also may have their concentrations reduced during treatment with carbamazepine, notably birth control pills and many of the antipsychotics.

The broad efficacy of valproate and carbamazepine does not extend to other anticonvulsants. There is no published evidence that lamotrigine is effective in acute mania and placebo-controlled studies provide no support for gabapentin (275) or topiramate (276).

Although it is said that the anticonvulsants are particularly useful for mixed or dysphoric mania (277–280), one study that compared lithium to valproate did not find this (281). These drugs should be used when a patient is nonresponsive to lithium or when the side effects of lithium are disturbing, particularly in the face of polyuria, weight gain, or acne. Psoriasis can make the use of lithium quite difficult.

McCabe (282, 283) found that both ECT and chlorpromazine were far superior to no treatment in acute mania, when measured by duration of hospitalization, condition at discharge, and social recovery. There were no significant differences between the two treatments, however. He did not have a comparison group of patients treated with lithium, but Black et al. (284) retrospectively compared ECT and lithium and found that patients treated with ECT (unilateral or bilateral) were significantly more likely to show marked improvement, especially in cases of schizoaffective disorder, manic type. A randomized comparison (285) of lithium and bilateral ECT found ECT outcomes to be better in the first 8 weeks but not in the later outcomes. Finally, Mukherjee and Debsikdar (286) reported a very favorable outcome in India in 30 manic patients treated with unmodified ECT. It seemed particularly good for dysphoric mania, severe cases and those featuring catatonia.

4.9.3. Treatment of the Depressive Episode

Various meta-analyses on this topic have reached conflicting conclusions. The controlled trials at this point most strongly support fluoxetine and quetiapine as monotherapy, and combinations of lamotrigine with lithium and of fluoxetine with olanzapine (OFC) (287). Viewed in terms of a ratio of number needed to treat (remission) to number needed to harm (adverse events), a meta-analysis has shown a value of 9 for aripiprazole, for quetiapine and for risperidone. It showed a value of 19 for OFC (288).

Second generation antidepressant monotherapy may be sufficient for bipolar II patients (289–292). For bipolar I patients, antidepressants should be accompanied by a mood stabilizer.

Controlled trials have shown little evidence that the use of SSRI antidepressants with mood stabilizers increase risks for switching (293, 294). On the other hand, evidence from such trials for the efficacy of antidepressants in bipolar disorder is thin (295) though it is present (296). A consensus is developing, that TCA's and SNRI's pose a greater risk for switching than do SSRI's (294, 297, 298).

4.9.4. Maintenance Therapy

Lithium is clearly an effective prophylactic agent and is the "gold standard for maintenance therapy" (299, 300). Not only does it significantly decrease the number of manic episodes, but it also decreases the number of depressive episodes and the likelihood of suicide. This may occur because lithium decreases the number of manic episodes and, since the illness is frequently biphasic or triphasic, it automatically decreases the potential for depressive episodes. Also, the quality of the episodes that do occur is changed (shorter, less severe), and hospitalization is more often avoided. Because mood swings still occur, however, patients on maintenance lithium need to be followed regularly so that the physician can add antipsychotics, an antidepressant, or other drugs if necessary. Lithium can be given in a single bedtime dose that can be either lithium carbonate or a sustained-release lithium. There is some evidence that this reduces lithium's impact on the kidney (301) and it is likely to improve compliance.

The preventative effects of lithium for mania appear to increase steadily at least up to a level of 1.2 mEq/L (302). Prophylaxis against depressive episodes requires a minimum of 0.6 mEq/L.

When manic symptoms reappear during lithium treatment the treating physician should attempt to determine whether they occur despite adequate plasma levels. This may be difficult with an acute admission for mania since symptom breakthrough may have occurred with adequate levels but then resulted in noncompliance. In any event, a single breakthrough does not necessarily signify lithium's ineffectiveness. Mirror image studies have shown that episodes are less severe and frequent after lithium is started than during a period of similar length before it is started (303).

Carbamazepine and valproic acid are also good maintenance therapies, and here, too, the dose for maintenance is the same as that necessary to treat the acute attack. Lamotrigine is more effective against depressive than against manic occurrences and is therefore complimentary to lithium which is more protective against manic than against depressive episodes (304, 305). The side effect profiles of lithium and lamotrigine do not overlap so their use in combination has unique benefits.

The previous course of illness has bearing on prophylactic treatment selection. As anticonvulsants may be more effective than lithium for acute mixed mania, this selectivity may extend to prophylaxis (306). A family history of mania has been associated with better lithium prophylaxis (307–309).

Patients with a rapid cycling pattern are more likely to experience recurrences during prophylaxis than are those with sustained periods between episodes. Because early studies were focused on lithium as the sole prophylactic agent, rapid cycling has come to be regarded as a predictor of poor response to lithium per se (307, 310). However, most comparisons of prophylaxis success rates between those for lithium and those for anticonvulsants have not found a difference (311–313).

All data show that there is a high risk of recurring episodes if lithium maintenance is discontinued, particularly if it is done abruptly, so a sudden cessation of lithium is hazardous (314, 315). As might be expected, those who had been without episodes for the longest period before lithium discontinuation were the least likely to experience relapse. Even with a pregnancy, lithium should be discontinued gradually and the patient followed very closely.

On maintenance lithium, thyroid and renal functions need to be monitored. With carbamazepine and valproate, blood counts and liver function should be monitored. Blood levels should be done one to two times a year.

Jamison and Goodwin (316) have outlined the therapeutic issues surrounding maintenance therapy with lithium, including patient and physician compliance. O'Connell et al. (317) also discussed the relevance of family and psychosocial factors in the outcome of lithium-maintained bipolar patients, as did Clarkin et al. (318). It is important to address these issues when the literature on maintenance therapy is reviewed, there are far more relapses in collaborative treatment studies of multiple investigators than in studies reported by individual therapists treating a cohort of patients. It is definitely a disorder in which the quality of therapy and management make a difference.

It should be noted that stereotactic tractotomy is still being used for the most resistant cases (319–321). Increasing knowledge of the neurocircuitry underlying mood disorder has resulted in a variety of targets for both tractotomy and deep brain stimulation (321).

4.9.5. Side Effects of Antimanic Drugs

The side effects of lithium may be numerous and disturbing to the patient but seldom deleterious to his or her health. Many complain of tremor while on lithium, and this can be treated with 30–80 mg of propranolol in divided doses (322). Improvement, if it occurs, can be seen in 24 hours. Plasma levels correlate with degree of tremor so dosage adjustments may be helpful. Weight gain is also a frequent problem. Almost 50% of patients gain some weight, and weight gains of up to 30 kg have been reported. Patients who develop hypothyroidism, edema, polydipsia, or an increased appetite are more likely to experience weight gain, but it is less likely with plasma levels below 0.8 mEq/L. Patients should be warned not to treat an increased thirst with calorie-laden drinks. Nausea is more likely with rapid increases in plasma levels and may be improved with divided doses taken with meals or with a delayed release preparation. The latter choice may result in diarrhea.

Polyuria and polydipsia are common and concomitant use of SSRI antidepressants raises the risk of these problems (323, 324). The avoidance of multiple dosing may be helpful for this (301, 325). Likewise, polyuria may improve with amiloride at 5 mg twice daily (326). In the long term, usually after 10 years of lithium treatment, tubulointerstitial fibrosis may develop. Risks for this do not appear to be dose related. It is reversible in early stages and these can be detected from increasing creatinine levels. This adds to the importance of at least annual monitoring.

Hypothyroidism is more likely in females, in older patients, in those with early weight gain or with a family history of thyroid disease. Cognitive impairment is more highly correlated with TSH values than with lithium concentrations. Moreover thyroid functioning in the hypothyroid half of the normal range is associated with more affective morbidity (327–330).

Some patients complain of effects on cognitive performance. A meta-analysis has shown that lithium results in small but significant impairment in immediate verbal learning and memory (331). The effects of long-term lithium treatment on psychomotor performance appear to be larger difficulties.

Valproate causes at least as much weight gain as does lithium (304). If this threatens compliance, the alternatives of lamotrigine or carbamazepine are typically weight neutral. Nausea is not infrequent and a histamine-2 blocker may be helpful (332). Increases in ammonia levels are also common (333, 334) and may result in fatigue, cognitive slowing, or sedation. This may progress to an encephalopathy regardless of plasma levels (335–337) so ammonia levels should be checked if such complaints are prominent after therapeutic plasma levels are established.

Women may experience menstrual disturbances (338) and possibly polycystic ovary disease (339) though there has been some controversy over this. Use of valproate during pregnancy carries a much higher risk for congenital malformation than does the use of lithium. Hair loss is also more frequent than with other anticonvulsants. Stevens-Johnson syndrome is no less common than with lamotrigine if recommendations for lamotrigine dose tapering are closely followed (340).

Leukopenia is more likely with carbamazepine than with valproate or lamotrigine (341). Notably, concomitant lithium treatment may serve to correct this (342). Hyponatremia is also more frequently seen with carbamazepine (343).

The metabolic side effects of the atypical antipsychotics are well recognized and a metabolic panel at the onset of treatment is now a standard of care. Aripiprazole and ziprasidone appear to carry the least risks for significant weight gain, followed by risperidone, quetiapine, olanzapine, and clozapine, in that order.

4.9.6. Psychosocial Treatment

Pharmacotherapy has been the principle focus of the research into the management of bipolar disorders. Recognition of the extent to which residual symptoms and psychosocial impairment persist despite the use of mood stabilizers has increased interest in psychotherapeutic approaches. Such therapies have sought principally to stabilize day-to-day activities and to improve coping skills, medication compliance, and the recognition of prodromal symptoms.

The largest number of randomized controlled trials has tested cognitive-behavioral therapy (CBT) modified for application to the bipolar disorders. A recent meta-analysis showed low to moderate effect sizes for clinical symptoms ($d=0.44$), quality of life ($d=0.36$), and treatment adherence ($d=.53$) at the end of treatment (344). Effect sizes for clinical symptoms remained at 6–12 months for treatment ($d=0.43$) but were nonsignificant for the other four clinical outcome categories listed. At no point did CBT significantly increase or decrease treatment costs.

4.9.7. Advantages of Lithium

A recent meta-analysis of 31 studies conclusively showed that the risks of completed and attempted suicide were consistently lower, by approximately 80%, during treatment of bipolar and other major affective disorder patients with lithium compared to those not treated with lithium (345). A significant advantage for lithium treatment persisted when trials were limited to those that were randomized and controlled. Moreover, the ratio of attempted to completed suicide was 2.5 times higher than in lithium treated patients indicating that, when suicide attempts occurred, they had lower lethality in patients who were taking lithium. A randomized, placebo-controlled trial undertaken to assess the anti-suicidal effects of lithium found a strong trend in the expected direction for suicide attempts and a significant difference for completed suicide (346).

Major Depressive Disorder

Barry R. Rittberg, M.D.*

Abstract Major depressive disorder or "unipolar depression" is a common condition likely related to several etiologies. Recent research has focused on the biological underpinnings of major depressive disorder as well as treatment advances, involving both pharmacotherapy and psychotherapy. In this chapter, the epidemiology, clinical picture, biological theories regarding etiology, clinical presentation in primary care and mental health settings, and treatment of major depressive disorder are reviewed. Advances in genetic approaches to understanding the pathogenesis of major depressive disorder will likely result in better and more precise treatments in the future.

The term "unipolar depression" evolved from the concept of a primary affective disorder. Primary affective disorder referred to patients whose first psychiatric disorder was depression and who did not evidence manic or bipolar symptoms. Support for the classification of primary affective disorder derived from the classic study of Cassidy et al (1), and symptoms differentiating depressed patients from controls formed the basis of the disorder. Symptoms which occurred in more than 50% of depressed patients included reduced energy, impaired concentration, anorexia, initial insomnia, loss of interest, difficulty starting activities, worrying, subjective agitation, slowed thinking, difficulty making decisions, terminal insomnia, suicidal ideation or plans, weight loss, tearfulness, slowed movements, irritability, and feeling one will never get well (2). These symptoms continue to form the basis for the diagnosis of depressive states.

Keywords Major depressive disorder · Pharmacotherapy · Psychotherapy · Biology of depression · Epidemiology · Genetic studies

5.1. Definition

The term "unipolar" has been dropped from the official nomenclature of DSM-IV TR and DSM-5 and replaced by "major depressive disorder" (MDD). MDD is characterized by one or more major depressive episodes—2 week or greater periods characterized by a grouping of symptoms including depressed mood, anhedonia, sleep, appetite and psychomotor changes, loss of energy, difficulty concentrating, feelings of worthlessness/guilt and suicidal ideation. Furthermore, MDD is diagnosed if there is no history of mania or hypomania (Bipolar I or Bipolar II) disorder, schizophrenia (schizoaffective disorder), medical cause of the symptoms (i.e., hypothyroidism), and depression due to substances that may cause this syndrome (some antihypertensives or stimulants). A brief depression of less than 2 weeks' duration after a life event is also excluded from MDD (adjustment disorder with depressed mood). Impairment in functioning related to the disorder is required. In the United States DSM 5 is the current standard for classification. Worldwide, the ICD system is used. Persistent depressive disorder (formerly dysthymia) can be a low-grade depression that does not meet symptom criteria for Major Depression. It must be present for more days than not for at least 2 years. A Major Depression may be superimposed on Dysthymia. This is often referred to as a "double depression." Chronic MDD of at least a 2-year duration also falls under the Persistent Depressive Disorder classification.

*This is a revision of a previous chapter authored by Dr. D.L. Dunner.

DSM-5 lists several subtypes and course modifies for MDD. "With melancholic features" includes subjects who have a lack of mood reactivity, loss of pleasure from usual activities, distinct quality of the depressed mood, depression worse in the morning, weight loss, excessive guilt, and psychomotor retardation. "With atypical symptoms" is diagnosed if subjects have mood reactivity, over-sleeping, over-eating, rejection sensitivity, and a feeling of leaden paralysis. "With seasonal pattern" is diagnosed if subjects have multiple depressive episodes which usually begin and end at the same time per year. The typical pattern is a winter depression beginning in the fall and ending in the spring. "With psychotic features" is diagnosed if delusions and or hallucinations complicate the mood disorder. These symptoms can be mood congruent or mood incongruent. "With catatonic features" is diagnosed if there are pronounced movement disorders associated with the depression. "With peripartum onset" refers to depression onset during pregnancy or after delivery. Lastly, there is a descriptor of "with anxious distress."

Depression severity can be characterized as mild, moderate, or severe. Determination of severity can be made clinically or by the use of rating scales which had been standardized to determine levels of severity of depressive symptoms over the past week (3–7). Lastly, modifiers also include "in partial remission," in full remission, and unspecified.

5.2. Epidemiology

Two important epidemiologic studies suggest that MDD is quite common and also occurs with high rates of comorbidity (complicated by the presence of other psychiatric disorders) (8, 9). The national comorbidity survey reported lifetime prevalence of MDD of 12.7% in males, 21.3% in females and overall 17.1%. The national comorbidity survey replication study showed similar data. Thus MDD is a common condition and occurs in women twice as frequently as men. In contrast, bipolar mood disorders are estimated to have a lifetime prevalence of 6–8% including the "bipolar spectrum" disorders. MDD occurs in all cultures and affects all age groups. Childhood and late adult onsets are common, and the mean age of onset is generally in the 30s.

5.3. Clinical Picture

Although the criteria for a major depressive episode is 2 weeks or greater, most episodes last much longer and the mean duration of an episode of MDD is generally 6–9 months. Individuals who have one episode are 50% likely to have a recurrence. Individuals who have three or more episodes are 90% likely to have further episodes. Chronic MDD is 2 years or greater of depression and about 20% of MDD patients have chronic MDD. Another type of chronic depression is dysthymic disorder. Most patients with dysthymic disorder ultimately experience one or more major depressive episodes. This condition has been termed "double depression" (10), and most individuals with dysthymic disorder will ultimately experience one or more major depressive episodes. These are diagnosed as persistent major depression with persistent major depressive episode or with pure dysthymia syndrome, respectively.

As mentioned above MDD is quite commonly complicated by other psychiatric conditions. These include panic disorder and other anxiety disorders, substance use disorders including alcoholism, eating disorders, and other major psychiatric conditions (Axis I disorders). Axis II conditions or personality disorders also frequently complicate MDD. The general rule is that individuals with comorbid disorders are more severely ill and more difficult to treat than those who do not have comorbidity.

Suicide and suicide attempts are unfortunate complications of MDD. The exact rate of suicidal behavior among MDD patients is unknown. Some estimates cite about 15% of patients who experience severe depression will ultimately die by suicide. The rate of suicide in the United States is approximately 10–12 per 100,000 individuals per year and at least half of the approximate 30,000 suicides in the United States annually are related to depression. In contrast to concerns in the lay press, research studies suggest that suicide rates in adults are decreased with treatment with modern antidepressants (11, 12).

Depression can complicate medical conditions and if one has a medical condition the depression is frequently worse. Again it is important to rule out possible medical causes of depression, especially in the instance of a patient who has a depressive syndrome and an ongoing medical condition that may be associated with a mood disorder.

Depression in the elderly is of particular relevance in individuals who may be experiencing cognitive effects. The differential diagnosis of depression in a patient who is suspected to have Alzheimer's disease needs to be carefully considered.

Depression can also occur in children and adolescents. Bipolar disorders frequently have earlier ages of onset, and the differential diagnosis of depression in younger individuals should include consideration of bipolar disorder.

5.4. Depressive Subtypes

As noted above, there are several subtypes of depression. About 20% of patients with MDD will have chronic depression and about 25% will meet criteria for a diagnosis of depression with atypical features.

Some of these conditions have treatment implications. For example, chronic depression is more difficult to treat than acute single episode depression and takes longer to respond and higher antidepressant doses to affect a response. Recurrent depression requires maintenance therapy in order to reduce the likelihood of recurrence. Melancholic features suggest that the patient will not likely respond to placebo and will require aggressive treatment. Patients with depression with psychotic features are best treated with electroconvulsive treatment or combination of an antidepressant and antipsychotic medication. Patients with atypical features do not respond well to tricyclic antidepressants and respond better to monoamine oxidase (MAO) inhibitors and also to treatment with selective serotonin reuptake inhibitors (SSRIs).

There is no one characteristic of major depressive disorder. In fact, MDD is a collection of patients who likely have different etiologies to their condition, different clinical courses, and different symptom profiles. One patient may be anxious and agitated and sleepless and another patient may have psychomotor retardation and be over sleeping. Suicidal behavior may be overt in some patients and hidden in others. Some patients have profound comorbidity and some patients only have depressive symptoms. Thus it is impossible to characterize a single type of presentation or symptomatology.

5.5. Etiology

The etiology of major depressive disorder is still unknown. Factors that are thought to play a role in the genesis of MDD include genetic and familial factors as well as negative life experiences. Evidence for both environment and genetics as having a role in the etiology of depression is supported by various studies in the literature (13). The advent of the human genome project will likely go a long way in clarifying the relationship of genetic factors to at least some depressive disorders. Recent genetic research has looked at the role of epigenetics. This refers to the "heritable changes in gene expression that are not encoded by the DNA itself" (14). A recent paper (15) found abnormalities in promoter DNA methylation in the brains of suicide victims. Methylation is a mechanism which helps to turn off and on gene expression. It is likely that both environmental and genetic factors combine to play a role in subjects to produce clinical depression. Thus one might view some individuals as being genetically prone to having depression and who will then develop this depression if confronted with serious negative life events. It is also clear that individuals who have ongoing depression do not tolerate negative life events well and often worsen in the aftermath of the negative life event.

5.6. Biological Theories of Depression

Early theories of the biology of depression were based on the fact that effective antidepressants blocked the presynaptic neuronal reuptake, of the monoamines norepinephrine and serotonin. This led to the speculation that one or more monoamines were responsible for depression by their relative deficit. The advent of SSRIs led to the theory that serotonin dysregulation was involved in the pathogenesis of depression. This theory was based on the notion that low levels of serotonin in the brain might be the cause of depression, since the effect of SSRIs was to increase serotonin neurotransmission in the brain (16).

Recent theories of depression have looked at abnormalities in the HPA axis, which includes the hypothalamus, the pituitary gland, the adrenal gland, and elevated levels of cortisol. In depression-prone persons, there seems to be an overactive HPA axis. This may be the result of early life negative events. The cortisol feedback loop is insensitive, and hence there is less inhibition of cortisol release. The high levels of cortisol are toxic to pyramidal cells in the hippocampus and result in cell death and atrophy of the hippocampus. Evidence to support this theory comes from studies in animals that were subject to parental deprivation as infants and demonstrate dysregulation of the HPA axis (16). Furthermore, patients with severe depression have elevated cortisol levels and have smaller hippocampus than controls (17, 18). Genetic linkage studies in MDD have failed to identify reliable gene candidates. Polymorphisms have been identified for the serotonin transporter gene, monoamine oxidase type A, tryptophan hydroxylase, noradrenaline transporter, adrenaline, and noradrenaline receptors, as well as dopamine receptors and transporters. These are being studied as candiates for association with depression (19).

Recent reports of ketamine (a partial NMDA receptor antagonist) causing a rapid decrease in depression symptoms have focussed research on the NMDA receptor. Ketamine is an anesthetic that, in this case, is used far below the anesthetic dose to treat depression (20, 21).

Mitochondrial dysfunction and inflammation-induced neural degeneration are all active theories in the etiology of depression (22).

5.7. Laboratory Studies

There are no definitive laboratory tests that reliably demonstrate that one group of depressed patients differs from another group of depressed patients or that depressed individuals can be reliably differentiated from normals or from nondepressed individuals (23). Laboratory tests studied throughout the years include the dexamethasone suppression test which showed elevations

of cortisol response after dexamethasone administration in a greater number of depressed patients than controls. However, this test failed to reliably demonstrate differences between patients and controls and is no longer widely used, even in research settings. Other tests reported to be abnormal are a blunted TSH response to TRH. This test is also not currently in clinical use.

Depressed patients frequently have sleep abnormalities and a striking sleep abnormality among depressed patients is shortened REM latency. This finding has been replicated but is of little diagnostic utility

One of the problems with laboratory testing in depressed patients is that major depression itself is likely a very heterogeneous disorder. This makes the likelihood of finding a test that is reliable and can differentiate depressed patients from nondepressed individuals or subtypes of depressed patients from each other difficult.

5.8. Presentation of Depression in the Primary Care Setting

Most patients with depression have their initial medical encounter in a primary care setting. Unfortunately the data regarding recognition of depression in primary care settings has been stable and disappointing over the past several decades. The "50% rule" applies: that is, 50% of individuals with depression are diagnosed in primary care settings and 50% are not. Of the 50% who are diagnosed only 50% are treated. Of the 50% who are treated only 50% are adequately treated (24). It is quite likely that depression would be ascertained more reliably in primary care settings if rating scales to detect major depression such as the Beck Depression Inventory (3), the PHQ-9 (5), or the Quick Inventory of Depressive Symptoms (7)—patient self-rating scales—were applied uniformly to patients presenting in primary care settings, just as a blood pressure and weight are uniformly assessed in such patients.

Depression can present in primary care settings in a multitude of ways. The patient may have seen an advertisement regarding depression in the news or television and presents with a clear complaint and self-diagnosis of depression. Many patients will present with a psychic complaint of anxiety rather than depression. However, many more patients will present with indefinite physical complaints such as fatigue and loss of energy or aches and pains in various organ systems (25). The primary care physician needs to be well attuned to these various presentations of depression so that a proper diagnosis can be made, a proper workup for these patients performed, and a proper treatment plan implemented. Mental illnesses still carry a great deal of stigma regarding their diagnosis. Thus it is important for the primary care physician to present the diagnosis firmly but cautiously as well as optimistically regarding treatment outcome.

The workup for patients suspected of having depression should include a careful history to determine if previous episodes have occurred, a family history to determine if individuals in the family also suffered from depression or bipolar disorder, a physical exam, and a series of laboratory tests, especially a TSH or thyroid assessment. There are many medical causes of a depressive syndrome and many types of depressive disorders. Thus, the clinician needs to carefully consider the differential diagnosis before implementing treatment.

Important conditions to rule out before a diagnosis of MDD is made include the common medical conditions that are associated with MDD, bipolar disorders, anxiety disorders, and substance use and alcohol disorders. The common medical conditions can be simply ruled out with simple laboratory testing—complete blood count to rule out anemia and thyroid screen to rule out hypo- or hyperthyroidism. Other laboratory tests may be indicated if there are particular symptoms or signs that suggest the need for such testing. Since some medications may cause depression, a review of medication changes in the patient in relation to depressive onset is important. Bipolar disorders can be ruled out by asking about hypomanic or manic symptoms occurring prior to or after depressive episodes. About 5% of patients who are experiencing their first depressive episode are bipolar, and this diagnosis usually cannot be made until the patient exhibits hypomania (26). Factors that suggest a patient may be bipolar include frequent and multiple depressive episodes, a family history of bipolar disorder, and an early age of onset. A screening tool, the "Mood Disorders Questionnaire," may also be useful (27). Anxiety disorders frequently complicate mood disorders and depression frequently complicates anxiety disorders. Asking about panic attacks, level of anxiety and its duration in relation to the depressive symptoms, and obsessive compulsive behavior is useful. Substance use disorders and alcohol abuse/dependence are not always correctly identified through history taking as patients frequently deny these conditions. A substance use and alcohol history is important to ascertain, and urine toxicology testing may be helpful if substance use is suspected.

5.9. Presentation of Depression in a Mental Health Setting

In contrast to the situation in primary care, most individuals who are seen in mental health settings for depression have already been diagnosed or are undergoing treatment which is not successful (treatment resistance). In such cases the diagnosis of depression is clearer than in primary care settings. However, the differential diagnosis still needs to be applied and the depression carefully delineated as a major depressive disorder versus a bipolar disorder or a medical disorder with depression. Careful alliance between the mental health practitioner and the patient's primary care physician is important to ensure that the differential diagnosis of the depression from a medical perspective has been satisfactorily determined.

5.10. Principles of Treatment

The principles of treatment of major depressive disorder have been well established over the past two decades. The goal of treatment is to achieve remission and also recovery. Remission is defined as a sufficient absence of depressive symptoms so as to generate a rating of seven points or less on the 17 item Hamilton Depression Rating Scale (4). The Hamilton Depression Rating Scale is a clinician rated, standardized scale for assessing depression severity. Recovery currently is defined by at least two months of a remitted state. The rating scales noted above [Beck Depression Inventory-BDI (3), Quick Inventory of Depressive Symptoms –QIDS (7), and the Patient Health Questionnaire-PHQ-9 (5)] are self-rating scales and are also useful for the patient and clinician to determine the clinical state of the ongoing depression. Remission on the BDI is 9 points or less, on the PHQ-9 is 4 points or less, and on the QIDS is 5 points or less. Depression needs to be considered a lifelong disorder since it is often chronic and frequently recurrent. In situations when patients can monitor their mood with a rating scale, the degree of depression can be easily ascertained by the clinician from the patient self-ratings.

The next principle of treatment is to effectively treat the presenting episode so that it does not relapse. In order to do this patients need to be treated through an acute treatment phase, usually of about 12 weeks' duration and achieve at least a response to treatment in that period of time. Many studies support the notion that if antidepressant treatment is stopped at the end of the acute treatment phase there will be a higher relapse rate than if treatment is continued for 6–9 months longer. Thus, the initial episode of depression should be treated to remission and should have the treatment continued for approximately a year (28, 29). In instances of recurrent depression or chronic depression, current recommendations are for maintenance treatment for at least several years if not for a lifetime. Recall that if individuals have recurrent depression they are highly likely to have further episodes of recurrence. In instances of chronic depression the depression may relapse if long-term treatment is not applied. When treatment is to be terminated it is always best to taper treatment and have patients keep a mood calendar to determine if they are having a recurrence of symptoms during the taper of the treatment. If symptoms recur then the treatment needs to be resumed at the previous dose. Interestingly, studies of both pharmacotherapy and psychotherapy support the notion of the need for continuation and maintenance treatment for depression (30, 31).

Treatment must be given for an adequate duration of time and also at an adequate dose. There is no consensus definition of adequate duration, but 8–12 weeks of treatment is usually recommended. The STAR*D study involved several thousand patients with major depression who were treated mostly in primary care settings (32, 33). Most of the patients were being treated in their first episode of depression. This study involved "guided" treatment in that the treating clinician was advised by the study monitor regarding dose adjustment if the patient failed to achieve remission during the ongoing acute treatment phase. Assessment was made by use of the QIDS and remission of symptoms was the goal of treatment. About 28–33% of patients achieved remission with treatment from an SSRI in the acute treatment phase. Subsequent treatments for this population increased the remission rate overall to approximately 60% after a number of treatments were administered. This study differs from current clinical practice in a number of ways. First of all subjects were assessed via rating scales and clinicians were notified to increase the dose if the optimal treatment outcome was not achieved. Patients had a second treatment trial if the first treatment did not produce remission, and if that treatment did not produce remission then subsequent treatments were applied. In typical clinical practice subjects do not have monitoring of their moods through rating scales nor is there someone to guide the dosage for the clinician. However, these principles of treatment should be applied to clinical practice in order to achieve an optimal outcome for depressed patients.

5.11. Treatments for Depression

Treatment of depression can be separated into three major categories: psychotherapy, pharmacotherapy, and physical therapies. Although logic dictates that combined psychotherapy and pharmacotherapy might provide an optimal outcome, data to support this notion are generally not found in research studies.

5.11.1. Psychotherapy

Psychotherapies that have been studied for major depression and shown to be effective include cognitive behavioral psychotherapy (CBT), interpersonal psychotherapy (IPT), and behavioral activation (BA). The modern trend is to have clinicians administering these therapies trained and certified in the therapies they are administering. The therapies noted above are brief—on the order of 20 weeks—and administered according to a "treatment manual." These three types of psychotherapies have been shown to be as effective as antidepressants in mild to moderate outpatient depression (34–36). CBT, IPT, and BA have all been shown to be effective in reducing relapse and recurrence in depressed patients (37–40).

5.11.2. Pharmacotherapy

We recommend pharmacotherapy if the presenting depression is of moderate or greater severity. Pharmacotherapy is also a logical choice if the patient has a history of recurrent depression or chronic depression. If the patient has a severe depression, treatment with pharmacotherapy or electroconvulsive therapy may be the best treatment. If the patient has psychotic depression the combination of an antidepressant and antipsychotic medication is helpful, although electroconvulsive therapy is the optimal treatment for this condition.

There are several types of pharmacotherapies. The older antidepressants tend to be less safe than the newer antidepressants and therefore the newer antidepressants are preferable as starting treatments (see Table 5.1). The newer antidepressants include the selective serotonin reuptake inhibitors or SSRIs (see Table 5.2). These compounds replaced the tricyclic antidepressants as first choice treatments for depression in the 1990s. Because of their overall safety they remain the treatment of choice for the initial treatment of a depressed patient.

As a general rule all antidepressants have equal efficacy and classes of antidepressants or medications within a class differ only in their side effect profiles. The classes of antidepressants include the SSRIs (fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram). Serotonin reuptake inhibitors that also have serotonin receptor effects include trazodone, nefazodone, vilazodone, and vortioxetine. Mirtazapine is not a reuptake inhibitor, but has direct receptor effects on serotonin and norepinephrine subtypes. The serotonin and norepinephrine reuptake inhibitors include venlafaxine, desvenlafaxine, and levomilnacipram. The older tricyclic antidepressants are also serotonin and norepinephrine reuptake inhibitors. The tricyclics include amitriptyline, imipramine, doxepin, nortriptyline, protriptyline, trimipramine, and desipramine. Tranylcypromine, phenelzine, isocarboxazide, and selegiline are monamine oxidase inhibitors.

TABLE 5.1. Common antidepressants and their usual doses.

Drug	Dosage	Comments
Amitriptyline	50–300 mg	Converted to nortriptyline
Imipramine	50–300 mg	Converted to desipramine
Doxepin	50–300 mg	
Nortriptyline	50–200 mg	
Desipramine	50–200 mg	
Protriptyline	10–40 mg	
The above are tricyclic antidepressants and share common side effects such as dry mouth, constipation, tachycardia, orthostatic hypotension, sedation, weight gain, and blurring of vision. These medications can also be lethal in overdose and have numerous cardiac effects. Blood level monitoring may be useful.		
Isocarboxazide	20–60 mg	
Tranylcypromine	20–60 mg	
Phenelzine	45–90 mg	
Selegiline transdermal system	6–12 mg/24 h	Administered as a patch
The above are monoamine oxidase inhibitors and have several food and medication prohibitions in order to prevent severe hypertensive episodes.		

TABLE 5.2. Newer antidepressants and their doses.

Drug	Doses (mg)	
Fluoxetine	20–60	
Sertraline	50–200	
Paroxetine	20–60	
Citalopram	20–40	
Escitalopram	10–20	
Venlafaxine	75–375	Hypertension can occur at doses above 300 mg
Duloxetine	60–120	
Mirtazapine	15–60	
Nefazodone	300–600	
Bupropion	150–450	Seizures can occur at doses above 450 mg
Trazodone	100–600	Priapism can occur in male patients
Vilazodone	40	
Vortioxetine	10–20	
Levomilnacipran	40–120	
Desvenlafaxine	50–100	

Within the SSRI class the most common side effects are GI disturbances, especially nausea, on initiation of the treatment. In anxious depressives, anxiety may temporarily worsen and starting with lower than usual doses in anxious depressives is recommended. About 15% of patients treated with SSRIs develop insomnia and about 15% experience sedation. Weight gain is usually not a problem with the SSRIs with the exception of paroxetine, and a small percentage of patients will gain a significant amount of weight with this compound. A common late appearing side effect associated with the SSRIs is sexual dysfunction. This side effect occurs in up to 50% of women and perhaps 25% of men and is the most common reason for discontinuation of this class of medication during long-term treatment. The SSRIs are safe in overdose and reduce suicidal behavior in adult depressed patients. Only one SSRI, fluoxetine, has been shown to be effective in the treatment of children with depression. All of the SSRIs are frequently used in the elderly. The SSRIs commonly have drug interactions involving the P450 2D6 enzyme system. All SSRIs with the exception of fluoxetine are associated with a flu-like syndrome on rapid discontinuation and paroxetine has the most marked discontinuation syndrome. As a class, SSRIs show efficacy in a number of anxiety disorders and many are FDA approved for treatment of panic disorder, social phobia, generalized anxiety disorder, post-traumatic stress disorder, and obsessive compulsive disorder. Because of the simplicity associated with their use, overall safety and broad spectrum efficacy, these antidepressants have become the first-line choice for treatment of depression.

The newer antidepressants listed above do not have similar side effects. Venlafaxine, desvenlafaxine, levomilnacipran, and duloxetine are serotonin and norepinephrine reuptake inhibitors. Their common side effects include nausea on initiation of treatment. Sexual dysfunction appears to be less in women with duloxetine than with venlafaxine but venlafaxine has less inhibitory effect on the P450 2D6 enzyme system than does duloxetine. The discontinuation syndrome associated with venlafaxine is much more marked than that for duloxetine and tapering of these compounds is recommended if they are to be stopped. Sustained hypertension is associated with high dose treatment with venlafaxine but has not been associated with treatment with duloxetine, even though duloxetine may have a more potent effect on the norepinephrine transporter system than venlafaxine. Venlafaxine is FDA approved for major depression, generalized anxiety disorder, and panic disorder. Duloxetine is FDA approved for major depression and diabetic peripheral neuropathic pain, and is approved in some European countries for stress induced urinary incontinence. Desvenlafaxine, the active metabolite of venlafaxine, is marketed as a separate agent. It has an FDA indication for depression only. It is a timed release product with an effective dose of 50–100 mg per day. Desvenlafaxine can also have an unpleasant withdrawal syndrome.

Levomilnacipran is also a norepinephrine and serotonin reuptake inhibitor. It has greater effect on norepinephrine than serotonin reuptake. It also has greater effect on norepinephrine than venlafaxine and desvenlafaxine including the risk of hypertension. It is not associated with weight change (41). Levomilnacipran has a wide dose range of efficacy with a dose range of 40–120 mg per day all showing greater efficacy than placebo. The usual starting dose is 20 mg per day with dose increases every two days until desired dose is reached.

The mechanism of action of bupropion is not clearly understood, although it is thought to have a role in dopamine metabolism and is clearly not a serotonin reuptake inhibitor. Bupropion is not associated with weight gain, sexual dysfunction, or a discontinuation syndrome. It is one of the most activating of the antidepressants currently approved and should not be given close to bedtime as it can cause insomnia. Seizures have been reported with higher dose treatment with bupropion and there is a dosage limit of 450 mg with this compound. It is not a particularly effective drug in treatment of comorbid anxiety disorders, although the anxiety associated with depression responds well to treatment with bupropion. Bupropion is FDA approved for major depression and for smoking cessation.

Mirtazapine is one of the most sedating of the newer antidepressants. Mirtazapine has a complicated mechanism of action and affects both serotonin and norepinephrine systems. Its effects on histamine receptors result in sedation, particularly at low doses, and weight gain has also been reported with mirtazapine. Mirtazapine has a low rate of sexual dysfunction and mild effects on the P450 2D6 isoenzyme system. It is unclear if mirtazapine has a discontinuation syndrome. This compound is only approved for major depression by the FDA.

Trazodone is moderately sedating and the major clinical use of trazodone is to combat insomnia associated with SSRI treatment. At higher doses trazodone is an effective antidepressant. Reports of priapism in male patients have resulted in our not recommending the use of trazodone in men. Trazodone is FDA approved for treatment of major depression.

Nefazodone also has a complicated mechanism of action and affects the serotonin postsynaptic receptor with mild serotonin and norepinephrine reuptake inhibition. Nefazodone affects the 3A4 liver isoenzyme system. Its major side effects are sedation and there is a need for complicated dose titration to achieve a therapeutic dose range. Nefazodone does not appear to cause weight gain, sexual dysfunction, or a discontinuation syndrome. Cases of liver toxicity have been reported with nefazodone and the use of this the drug is infrequent in clinical practice. Nefazodone is approved by the FDA for treatment of major depression.

Vilazodone is a serotonin reuptake inhibitor and a 5-HT_{1A} partial agonist. It is reported to have low sexual side effects and does not cause sedation and weight gain (42). The usual dose of vilazodone is 40 mg per day. It needs to be started at 10 mg and titrated up to prevent gastrointestinal side effects. Absorption is improved when taken with food (43).

Vortioxetine is a serotonin reuptake inhibitor that also has effects on specific serotonin receptors (5-HT_{1A}, 5-HT_{1B}, 5-HT_3, and 5-HT_7). It is also purported to have low incidence of sexual side effects and no effect on weight (44). The starting dose is 10 mg, which is increased to 20 mg. It has a very long half-life of 66 hours, therefore needing a 3-week washout before using an MAOI.

The tricyclic antidepressants have a myriad of side effects because of their multiple receptor affinities. They not only affect serotonin and norepinephrine reuptake systems but also have effects on histamine, anticholinergic, and muscarinic receptors. These receptor effects result in side effects such as dry mouth, blurry vision, dizziness, constipation, orthostatic hypotension, increased heart rate, weight gain, and sedation. The tricyclic antidepressants are not safe in overdose and 1.5 g or greater of a tricyclic antidepressant taken in a single overdose can be lethal. These drugs are FDA approved for major depression but also are frequently used off label in pain situations and also have effects in panic disorder. Prior to the advent of the SSRIs in United States the tricyclic antidepressants were first-line treatments. However, their multiple side effects and the lethality in overdose have resulted in a considerable diminution of their use.

The MAO inhibitors were among the first antidepressants introduced in the United States. These drugs inhibit the enzyme that degrades monoamines. Their early clinical use was associated with notable side effects of acute hypertensive crisis and stroke resulting from ingestion of tyramine containing foods or certain medications. MAO inhibitors not only inhibit monoamine oxidase in brain but also in the GI tract where tyramine in foods is normally detoxified by the digestive system. Blockage of this detoxification results in tyramine entering the bloodstream, releasing norepinephrine and causing acute hypertension. Thus tyramine containing foods and certain medications need to be avoided when being treated with MAO inhibitors. MAO inhibitors are approved by the FDA for treatment of major depression. Phenelzine has also been shown to be effective for the treatment of panic disorder and tranylcypromine for the treatment of bipolar depression. Recently selegiline has been formulated to be administered in a transdermal patch. The use of this patch avoids the GI system inhibition of monoamine oxidase and therefore low doses of the patch permit the dietary intake of tyramine containing foods. Oral selegiline is FDA approved for the treatment of Parkinson's disease. Antidepressants and other medications are prohibited during treatment with MAO inhibitors because of the risk of causing a hypertensive crisis or a serotonin syndrome.

5.11.3. Physical Treatments for Depression

Several physical treatments are important in the treatment of depression. These include bright light therapy, electroconvulsive therapy (ECT), vagus nerve stimulation treatment (VNS), repetitive transcranial magnetic stimulation (rTMS), magnetic seizure therapy (MST), and deep brain stimulation (DBS). Of these treatments only ECT, VNS, and rTMS are currently approved treatments in United States and bright light therapy is widely used. MST and DBS are currently experimental (45, 46).

Bright light therapy was developed to treat seasonal mood disorder, particularly winter depression. This depression, which can occur in patients with major depression or bipolar depression, is frequently characterized by oversleeping. Research studies support the use of bright light therapy, usually given in the morning, for improvement of depressive symptoms in these subjects (47). Whether subjects with recurrent winter depression might also be treated with a maintenance therapy is an important consideration. Light boxes and dawn simulator devices are available through several commercial outlets and usually do not require a prescription.

ECT was developed in the 1930s as a treatment for schizophrenia under the mistaken assumption that patients with epilepsy did not develop schizophrenia. Early use of this treatment resulted in the finding that ECT was much more effective for individuals with severe depression than for patients with schizophrenia and the treatment has remained in use as an effective treatment for individuals with severe and treatment resistant depression, and is the treatment of choice for patients with psychotic depression and mood disorders complicated by catatonic features. The modern use of ECT involves administration of anesthesia. The patient is usually sedated with a brief acting anesthetic and then given succinylcholine in order to temporarily paralyze muscles so there is no pronounced physical movement during the convulsion. The treatments are usually administered 3 days a week and an average of 8–10 treatments is typical to improve a severe depressive state. Some patients relapse quickly after ECT is stopped and may require ECT be given on a long-term basis for maintenance treatment. Antidepressant medication should be started after a series of ECT has been administered in order to reduce the likelihood of relapse (48). Side effects of ECT include confusion which usually clears after each treatment and permanent memory loss for some of the days when the treatments have been administered.

VNS was approved by the FDA for treatment of resistant depression. VNS had previously been approved for treatment resistant epilepsy and its use over the years in epileptic patients has resulted in a good deal of knowledge regarding the side effects of VNS treatment. VNS involves the surgical implantation of a pulse generator into the chest wall and attachment of the wire leads from this pulse generator to the vagus nerve. The pulse generator produces a current which is transmitted into the brain and affects a number of brain areas that are thought to be important in relation to mood disorders. As VNS involves a surgical procedure, there is a small- about 1%- risk of surgical complications including pain or infections at the surgical site and care needs to be taken that the recurrent laryngeal nerve is not severed during the surgical procedure. When the device is activated

(usually on for 30 seconds every 5 minutes), the patient may experience voice alteration, cough, shortness of breath, or neck pain. The effect of VNS is not immediate and it often takes 6 months to a year to demonstrate improvement in depression (49). Patients undergoing VNS treatment are ones who have failed at least four antidepressant treatments and are among the most severely treatment resistant patients. A study of patients who were not implanted with VNS but had similar treatment failure histories revealed that only about 10% of such patients improved after 1 year of usual treatment in the community and the improvement in these patients was usually not sustained (50). In contrast, with VNS therapy about a third of the patients markedly improved, about a third of the patients improved somewhat, and about a third of the patients did not change after 1 year and the improvement noted in patients tended to be sustained once it occurred (49).

The FDA has approved tTMS for those patients with major depression who have failed one adequate trial of an antidepressant. rTMS involves the placement of an electromagnet on the outside of the head near the left frontal area of the brain. This magnet generates a current in the superficial layer of the cerebral cortex. Depending on the frequency of the magnetic pulses, it can stimulate or inhibit neuronal activity in that area of the brain. rTMS has been employed experimentally for patients with treatment resistant depression and the results of these research studies show that about a third of the patients will respond in a 3-week period compared to about 10% of patients who are treated with a "sham" treatment (51, 52). rTMS is administered five days a week for about 45 minutes per session. Data suggests that rTMS is ineffective in those patients who have failed ECT or who have psychotic symptoms with their depression.

The other treatments listed above—MST and DBS—are experimental at this time. Magnetic seizure therapy was developed as an alternative to ECT. High-frequency electromagnetic pulses are delivered to the brain to induce a seizure. It causes less cognitive impairment than ECT, but still requires muscle relaxation and general anesthesia (46).

Deep brain stimulation (DBS) is experimental. It involves implanting electrodes into specific brain areas. Stimulation with a pacemaker-like device has shown promise when the electrodes have been placed in the subgenual cingulate, ventral anterior internal capsule, and the nucleus accumbens. Open, unblinded studies have shown promise. Double-blind placebo controlled trials need to be completed (46).

5.11.4. Treatment-Resistant Depression

About 70% of patients who undergo treatment for a depressive episode respond, and about 30% have a remission of symptoms during the acute treatment phase. Patients who do not respond or remit might be considered treatment resistant. There is no uniformly agreed upon definition of treatment resistant depression, but the more treatment trials a subject fails the less likely they are to respond to a subsequent treatment trial. As noted above, ECT and VNS are usually reserved for patients who have failed multiple treatments because they are more invasive than other treatments.

Failure to respond to treatment may be due to many factors, including incorrect diagnosis, too short a treatment trial, or treatments being applied at too low a dose to be effective. Diagnostic issues involve whether the patient is bipolar or has major depression, or whether there is an underlying undiagnosed medical cause for the depression (thyroid disease, tumor, stroke — to name a few). Generally, treatments should be given at higher than starting doses and for at least 8 weeks before the lack of response is considered treatment resistance. Some patients are not truly treatment resistant but cannot tolerate effective treatment doses because of side effects—the "treatment intolerant" patient.

The strategies for approaching a treatment resistant patient involve assessing the patient's history and medical evaluation in order to clarify diagnostic issues and to review the treatment history for type of medication, duration and dose of treatment. The next step is to apply a treatment from another class—presumably a different mechanism of action might be more effective. Augmentation involves addition of a treatment to an ineffective treatment. Common augmentation strategies involve the addition of lithium carbonate or thyroid hormone to medications that have not been effective. Recent research suggests that the addition of an atypical neuroleptic to patients who are not responding to treatment with an SSRI produces a rapid response in the majority of patients (52, 53) Both aripiprazole and quetiapine have been FDA approved as augmenting agents*.

Switch strategies involve selecting a treatment which may have a different mechanism of action than the treatment which has failed—such as switching from an SSRI to an SNRI or to an MAOI.

5.11.5. Other Treatments

Depression often occurs as an episode and has a beginning and an end. Thus, depressed patients may respond to time. The finding that a treatment is effective for depression is therefore quite dependent on placebo controlled studies. Many "treatments" for depression have not been found to be effective when studied in a controlled manner. For example, St. John's Wort was in wide

*Editor's note: Brexpiprazole is an atypical antipsychotic that was approved by the FDA in 2015 as an adjunct for treatment of major depression.

popular use several years ago, but a controlled study later demonstrated that it was not effective in moderately depressed patients (54). Exercise and diet are important for general medical health and likely have positive effects in depression but are not likely to be effective for more moderate depressive states. Psychotherapies need to be further studied to demonstrate their efficacy, and many have passed the test. Whether other psychotherapeutic modalities are effective remains for future evaluation

5.12. Summary

Major depression is a common condition which is likely determined by several etiologies. In clinical practice, depression is underdiagnosed and undertreated. However, several treatments have been shown to be effective for alleviating depressive symptoms. Further research in the genetic basis and molecular determination of some depression may well lead to more effective treatments for this condition. Until that time, however, patients with depression should be encouraged to monitor their clinical condition with self-rating scales and contact their clinician for changes in their treatment should their condition change.

Schizophrenia

S. Hossein Fatemi, M.D., Ph.D., FACPsych and Timothy D. Folsom, M.S.

Abstract In this chapter, we discuss history, current diagnostic criteria, epidemiology, genetics, etiology, clinical signs and symptoms, laboratory investigations, differential diagnosis, pharmacological and behavioral treatment modalities, prognosis and course of illness for schizophrenia. The emphasis in this chapter is the etiopathogenesis and relevant biological treatments for this disorder.

Keywords Schizophrenia • Etiology • Treatment

6.1. History

Schizophrenia is a debilitating disease of the brain which has been described by various physicians for centuries (1). Hippocrates referred to paranoia as a potential antecedent of present day psychosis (1). Aretaeus of Cappadocia referred to a form of mental illness he called insanity (1). Benedict Morel referred to one of the earliest descriptions of schizophrenia as démence précoce (precocious dementia) or deterioration of cognition in the adolescents (1, 2). Karl Ludwig Kahlbaum described catatonic symptoms as early as 1874 (3). Ewald Hecker was the first psychiatrist to refer to disorganized symptoms of schizophrenia as hebephrenia (4).

However, the greatest and most methodological and comprehensive description of schizophrenia was heralded by the German psychiatrist Emil Kraepelin who referred to this disease as dementia praecox and separated it from manic depressive psychosis (5). Indeed Kraepelin's predecessor Wilhelm Griesinger (6) of Berlin's Charité Hospital had already considered psychiatric disorders such as schizophrenia as brain disorders and influenced later psychiatrists on the importance of the organicity of schizophrenia (1) and other psychiatric diseases. Kraepelin's distinction between bipolar psychosis and dementia praecox with the latter disease, being an early onset psychosis which affected cognition permanently and had a poor outcome, opened the way for a true diagnosis of schizophrenia (1, 7).

Eugen Bleuler, another leading figure in the 20th century psychiatry, coined the term schizophrenia to describe the affective disturbance, the ambivalence and sense of isolation (autism), and associative (cognitive) disturbances observed in patients with dementia praecox (8). Bleuler also described schizophrenia as less of a dementing illness with more optimistic prognosis than Kraepelin had suggested (7, 8). Finally, Kurt Schneider, provided the concept of first and second rank symptoms (Table 6.1), to describe schizophrenia. It is now clear that while these symptoms are helpful in diagnosis of schizophrenia, that they are not specific to this disorder.

TABLE 6.1 Schneider's Symptoms.

First rank	Second rank
Audible thoughts	Depressive or euphoric mood changes
Voices heard arguing	Emotional blunting
Voices heard commenting on one's actions	Perplexity
The experience of influences playing on the body	Sudden delusional ideas
Thought withdrawal and other interferences with thought	
Diffusion of thought	
Delusional perception	
Feelings, impulses and volitional acts experienced as the work or influence of others	

6.2. Current Diagnostic Criteria

The current diagnostic criteria for schizophrenia (9) require presence of two of five active-phase symptoms of delusions, hallucinations, disorganized speech, catatonic behavior, or negative symptoms for at least one month. The symptoms of schizophrenia must last for a minimum of six months and cause impairment of social and occupational functioning. Finally, one needs to rule out the presence of other diagnoses including schizoaffective disorder, bipolar disorder with psychotic features, medical or neurologic disorders or whether it is due to side effects of a medication or an illegal substance (9). A detailed account of these criteria can be reviewed in the recently published version of DSM-5 (9).

6.3. Epidemiology

Schizophrenia affects 1% of the adult population in the world (9). The point prevalence of schizophrenia is about 5/1000 population (10) and the incidence is about 0.2/1000 per year (10). This incidence rate was reported to be comparable in most societies (11); however, recent studies suggest greater variability (10). Schizophrenia has an earlier onset in males with mean ages of onset of 20 and 25 in males and females respectively (7, 10). Risk factors other than a familial history of schizophrenia include obstetric complications, parental age, prenatal infections, ethnicity, cannabis use, urbanicity and modernization (trends toward a faster-paced and more technological society) (10).

6.4. Genetics

Emerging evidence points to schizophrenia as a familial disorder with a complex mode of inheritance and variable expression (7, 12–14). While single-gene disorders like Huntington's disease have homogeneous etiologies, complex-trait disorders like schizophrenia have heterogeneous etiologies emanating from interactions between multiple genes and various environmental insults (12). Twin studies of schizophrenia suggest concordance rates of 45% for MZ twins and 14% for DZ twins (7, 15). Consistent with this, a metaanalytic study showed a heritability of 81% for schizophrenia (15). Despite this high genetic predisposition, an 11% point estimate was suggested for the effects of environmental factors on liability to schizophrenia (12, 15). Additionally, adoption studies show a lifetime prevalence of 9.4% in the adopted-away offspring of schizophrenic parents vs. 1.2% in control adoptees (16). The adoption studies also clearly show that postnatal environmental factors do not play a major role in etiology of schizophrenia (12).

The mode of transmission in schizophrenia is unknown and most likely complex and non-Mendelian (7, 12). Chromosomal abnormalities show evidence for involvement of a balanced reciprocal translocation between chromosomes 1q42 and 11q14.3, with disruption of DISC1 (disrupted in schizophrenia) and DISC2 genes on 1q42, being associated with schizophrenia (12, 17). Additionally, an association between a deletion on 22q11, schizophrenia and velocardiofacial syndrome has been reported (18). Mice with similar deletions exhibit sensorimotor gating abnormalities (19).

Linkage and association studies (12, 20, 21) show 12 chromosomal regions containing 2181 known genes (20) and 9 specific genes (12) as being involved in etiology of schizophrenia (12). Variations/polymorphisms in 9 genes including neuregulin 1 (NRG1), dystrobrevin-binding protein 1 (DTNBP1), G72 and G30, regulator of G-protein signaling (RGS4), catechol-O-methyltransferase (COMT), proline dehydrogenase (PRODH), disrupted in schizophrenia 1 and 2 (DISC 1 and DISC 2), serotonin 2A receptor (HTR2A) and dopamine 3 receptor (DRD3) have been associated with schizophrenia (Table 6.2).

More recently, genome-wide association study (GWAS) arrays have identified approximately 30 schizophrenia-associated loci including calcium channel, voltage dependent, L-type, alpha 1-C subunit (CACNA1C), serologically defined colon cancer

TABLE 6.2 Risk genes for schizophrenia.

Gene	Abbreviation	Locus
Neuregulin	NRG1	8p12-p21
Dysbindin	DTNBP1	6p22
G72	G72	13q34
D-amino acid oxidase	DAAO	12q24
RGS4	RGS4	1q21-22
Catechol-O-methyl transferase	COMT	22q11
Proline dehydrogenase	PRODH	22q11
Calcium channel, voltage dependent, L-type, alpha 1-C subunit	CACNA1C	12p13.33
Calcium channel, voltage-dependent beta 2 subunit	CACNB2	10p12.33-p12.31
N-deacetylase/N-sulfotransferse 3	NDST3	4q26-q27
Ankyrin 3	ANK3	10q21.2
Vaccinia-related kinase 2	VRK2	2p16.1
Transcription factor 4	TCF4	18q21.2
Dopamine receptor D2	DRD2	11q23.2
Metabotropic glutamate receptor 3	GRM3	7q21.11-q21.12
Ionotropic glutamate receptor AMPA 1	GRIA1	5q33.2
Ionotropic glutamate receptor NMDA subunit 2A	GRIN2A	16p13.2
Inter-alpha-trypsin inhibitor heavy chain 3	ITIH3	3p21.1
Inter-alpha-trypsin inhibitor heavy chain 4	ITIH4	3p21.1
Serologically defined colon cancer antigen 8	SDCCAG8	1q43

List compiled from (12, 22–26).

antigen 8 (SDCCAG8), inter-alpha-trypsin inhibitor heavy chain 3 and 4 (ITIH3, ITIH4), N-deacetylase/N-sulfotransferse 3 (NDST3), MIR137, ankyrin 3 (ANK3), vaccinia-related kinase 2 (VRK2), and transcription factor 4 (TCF4) (22–25). Furthermore, and very recently, a GWAS involving a large cohort of schizophrenic patients (n=36,989) compared to healthy controls (n=113,075) identified 108 loci that were associated with schizophrenia including DRD2, genes involved in glutamatergic transmission [e.g., metabotropic glutamate receptor 3 (GRM3), ionotropic glutamate receptor AMPA 1 (GRIA1), and ionotropic glutamate receptor NMDA subunit 2A (GRIN2A)]; and voltage gated calcium channels [CACNA1C, calcium channel, voltage-dependent beta 2 subunit (CACNB2)] (26).

Another means of studying the genetic basis of schizophrenia uses the technique of DNA microarray (14, 27). These studies are based on discovering genes either repressed or stimulated significantly in well-characterized postmortem brain tissues from subjects with schizophrenia and matched healthy controls; peripheral lymphocytes obtained from schizophrenic and matched healthy controls and antipsychotic-treated brains of rodents and relevant animal models of schizophrenia (Table 6.3). Genes involved in drug response, or in etiopathogenesis of schizophrenia can be compared and studied to better understand the mechanisms responsible for this illness. Lastly, a new study has reported identification of eight distinct groups of clinical entities based on genotypic networks that indicate schizophrenia is a heterogeneous group of disorders just as predicted by Bleuler nearly a century ago (258). However, this study clearly needs to be replicated further to confirm its veracity.

6.5. Etiology

The concept of schizophrenia as a neurodevelopmental disease dates back to the period of Kraepelin and Bleuler (7). Early manifestations of disease as exemplified by premorbid signs, and deficits in social interaction, were observed by Kraepelin and Bleuler (28) in children who later developed schizophrenia. Later Southard (Fig. 6.1) reported on the presence of neuropathological signs in brains of subjects with schizophrenia which further pointed to maldevelopmental origins of this disorder (29).

6.5.1. Neurochemistry of Schizophrenia

6.5.1.1. The Dopamine Hypothesis

Dopaminergic tracts are composed of four branches: 1) nigrostriatal tract, originating from the substantia nigra and ending in the dorsal striatum, deals with initiation of movement, motor control, sensorimotor coordination, cognitive integration and habituation (7, 30); 2) mesolimbic tract, originating from the ventral tegmental area and ending in hippocampus, amygdala and ventral striatum,

TABLE 6.3 Candidate genes: postmortem studies and animal models.

Gene	Abbreviation	Postmortem	Animal model
Adenosine A2A receptor	ADORA2A	+	+
Apolipoprotein D	APOD	+	+
CDC42 guanine nucleotide exchange factor 9	ARHGEF9	+	
Cholinergic receptor, muscarinic 1	CHRM1	+	+

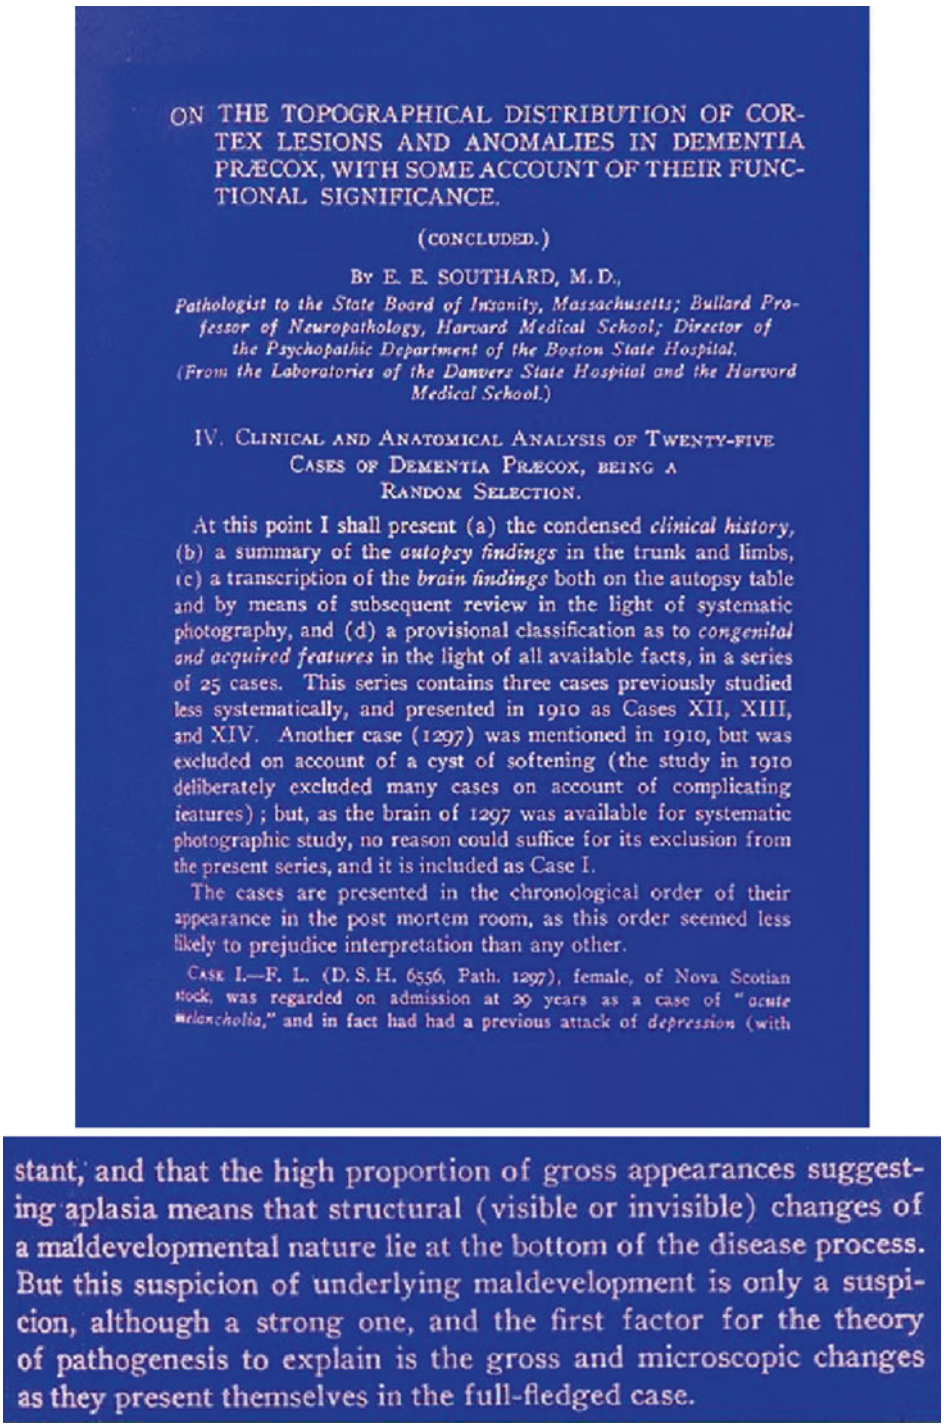
Serotonin 5-HT-2A receptor	5HTR2A	+	
Short stature homeobox 2	SHOX2	+	
Synapsin 2	SYN2	+	

List compiled from (14, 62–64, 115–121) and Papaleo F, Lipska BK, Weinberger DR. Mouse models of genetic effects on cognition: relevance to schizophrenia. Neuropharmacology 2012;62:1204–1220.

deals with cognitive/attentional, motivational and reward systems (7, 30); 3) mesocortical tract, originating from the ventral tegmental area and ending in the cortical structures, deals with attention, motivation and reward systems; and 4) the tuberoinfundibular tract, the cell bodies originating from the arcuate nucleus and periventricular hypothalamic areas and ending in the infundibulum and anterior pituitary, dealing with control of prolactin release (31–33). The dopamine (DA) receptors are classified into two distinct families of D1-like (D1 and D5) and D2-like (D2, D3, D4) receptors (30). The D1 receptors are localized to prefrontal cortex (PFC) and striatum. The D2 receptors are localized mostly to striatum but with lower concentrations in hippocampus, amygdala and entorhinal cortex. The D3 receptors are localized to ventral striatum. The D4 receptors are present in hippocampus and PFC. Finally the D5 receptors are found in hippocampus and entorhinal cortex (7, 30). Presynaptic DA receptors like D2 and D3 are localized to cell bodies or axon terminals of neurons (7). Dopamine helps in modulating glutamatergic inputs and pyramidal cell excitability (30).

The dopamine hypothesis of schizophrenia is based on the assumption that DA hyperactivity causes psychotic symptoms and that DA antagonists like chlorpromazine treat the psychotic symptoms (7). Additionally, administration of D-amphetamine to healthy volunteers leads to production of psychotic symptoms and worsens psychosis in schizophrenic subjects (7). One limitation of this hypothesis is that hallucinogens like LSD or psilocybin (acting on serotonin system) or dissociative anesthetics like ketamine or phencyclidine (acting on glutamate system) also cause psychotic symptoms (7, 30). A further limitation of this hypothesis is that consistent abnormalities have not been found in DA receptors or DA metabolites in subjects with schizophrenia (7, 30, 34). The two consistent postmortem findings include an increase in D2-like receptors in striatum of schizophrenics and lack of changes in striatal densities of D1 receptors or DA transporters (30). However, a recent finding of upregulated D1 receptor binding in dorsolateral PFC of schizophrenic subjects has been associated with impaired working memory performance (30).



ON THE TOPOGRAPHICAL DISTRIBUTION OF CORTEX LESIONS AND ANOMALIES IN DEMENTIA PRÆCOX, WITH SOME ACCOUNT OF THEIR FUNCTIONAL SIGNIFICANCE.

(CONCLUDED.)

By E. E. SOUTHARD, M.D.,

Pathologist to the State Board of Insanity, Massachusetts; Bullard Professor of Neuropathology, Harvard Medical School; Director of the Psychopathic Department of the Boston State Hospital.

(From the Laboratories of the Danvers State Hospital and the Harvard Medical School.)

IV. Clinical and Anatomical Analysis of Twenty-five Cases of Dementia Præcox, being a Random Selection.

At this point I shall present (a) the condensed *clinical history*, (b) a summary of the *autopsy findings* in the trunk and limbs, (c) a transcription of the *brain findings* both on the autopsy table and by means of subsequent review in the light of systematic photography, and (d) a provisional classification as to *congenital and acquired features* in the light of all available facts, in a series of 25 cases. This series contains three cases previously studied less systematically, and presented in 1910 as Cases XII, XIII, and XIV. Another case (1297) was mentioned in 1910, but was excluded on account of a cyst of softening (the study in 1910 deliberately excluded many cases on account of complicating features); but, as the brain of 1297 was available for systematic photographic study, no reason could suffice for its exclusion from the present series, and it is included as Case I.

The cases are presented in the chronological order of their appearance in the post mortem room, as this order seemed less likely to prejudice interpretation than any other.

Case I.—F. L. (D. S. H. 6556, Path. 1297), female, of Nova Scotian stock, was regarded on admission at 29 years as a case of "acute melancholia," and in fact had had a previous attack of *depression* (with

stant, and that the high proportion of gross appearances suggesting aplasia means that structural (visible or invisible) changes of a maldevelopmental nature lie at the bottom of the disease process. But this suspicion of underlying maldevelopment is only a suspicion, although a strong one, and the first factor for the theory of pathogenesis to explain is the gross and microscopic changes as they present themselves in the full-fledged case.

Figure 6.1 Article by E. E. Southard demonstrating neuropathological signs in the brains of subjects with schizophrenia being of neurodevelopmental origin.

6.5.1.2. The Serotonin Hypothesis

The serotonin (5HT) neurons emanate from the midbrain dorsal and median raphe nuclei and project to several sites including hippocampus, striatum and cortex (7, 35–37). The number of various 5HT receptor types in the brain exceed 15 with the most important receptors being 5HT1, 5HT2, 5HT3, 5HT6 and 5HT7 (7). Inhibitory somatodendritic 5HT autoreceptors (5HT1A) are localized to raphe serotonergic neurons which upon activation lead to decreased firing of the neurons (7, 38). In contrast, terminal autorecceptors modulate synthesis and release of serotonin (7). 5HT3 receptors help to stimulate dopamine release (7). Additionally, pyramidal cells in the mesocortical areas bear post-synaptic 5HT2A receptors which subserve 5HT-DA interaction in various brain areas.

While LSD and other serotonergic agonists can lead to psychotic symptoms in healthy individuals, the latter symptoms consist mostly of visual hallucinations, which are less frequently seen in schizophrenic patients. Despite the shortcomings of the serotonin hypothesis of schizophrenia, the atypical antipsychotic agents used extensively today, are potent antagonists of the 5HT2 receptors which may help in treating negative symptoms of schizophrenia and reduce extrapyramidal side effects (EPS). A recent systematic review of the literature based mostly on postmortem studies indicates significant elevation in prefrontal 5HT1A and significant reduction in 5HT2A receptors in patients with schizophrenia (39). Evidence in support of other serotonin receptors has been limited (39).

6.5.1.3. The Glutamate Hypothesis

Glutamate is the main excitatory neurotransmitter in the CNS (7, 30). Approximately 60% of neurons and 40% of synapses of the brain are glutamatergic in nature respectively (30). The glutamate receptors consist of ionotropic and metabotropic families. The ionotropic glutamate receptors (those working through Ca^{++} channels) include N-methyl-D-aspartic acid (NMDA), alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic (AMPA), and kainate receptors (5). The metabotropic family (receptors which indirectly regulate electrical signaling by activation of various second messengers) consists of groups I, II and III receptors (30). The glutamatergic hypothesis of schizophrenia is based on deceased levels of glutamate in the CSF of schizophrenic subjects (7, 31) and decreased expression of NMDA and AMPA receptors in hippocampus and thalamus of schizophrenic subjects (30, 40–43). A recent report indicates that altered glutamatergic function in the anterior cingulate is associated with more severe symptoms in subjects with schizophrenia (48). Changes in expression for various glutamate receptor types including NMDA receptors, AMPA receptors, kainate receptors, and metabotropic glutamate receptors in subjects with schizophrenia have been observed in multiple brain regions, however, a lack of consistent changes has also been noted (49). Mice with alterations in NMDA receptors, show hyperactivity and schizophrenic-like behaviors (44–47). Furthermore, altered N-glycosylation of NMDA, kainate, and AMPA receptors have been reported, suggesting that posttranslational modifications may lead to abnormal trafficking and expression of these receptors in subjects with schizophrenia (50, 51). Additionally, use of noncompetitive and competitive antagonists of NMDA receptors can lead to production of positive, negative and cognitive symptoms of schizophrenia (34). However, administration of clozapine, can block the NMDA antagonistic effects of PCP (34). Several compounds such as glycine, D-serine, and D-cycloserine have been reported to reduce positive and negative symptoms in subjects with schizophrenia (30, 34). Finally, genetic evidence also points to involvement of several genes (DAAO, G72, neuregulin, dysbindin, RGS4) which impact on glutamate system in schizophrenia (30).

6.5.1.4. The GABAergic Hypothesis

Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the mammalian brain. Postmortem evidence suggests involvement of glutamic acid decarboxylase 65 and 67 kDa proteins (GAD65 and 67), the rate limiting enzymes that convert glutamate to GABA, in the cerebellum (52, 53) of schizophrenic subjects. Supportive data (54, 55) also point to decreases in GAD67 species in brains of subjects with schizophrenia.

Investigation of GABA receptors has shown altered expression in brains from subjects with schizophrenia (60–67). $GABA_A$ receptor alpha 2 (GABRα2) and $GABA_A$ receptor epsilon (GABRε) display upregulated protein expression in lateral cerebella of subjects with schizophrenia (63, 64). Protein levels of $GABA_A$ receptor beta 1 (GABRB1) and $GABA_A$ receptor theta (GABRθ) were found to be reduced in lateral cerebella of subjects with schizophrenia (63, 64). Additionally, protein levels of GABAB receptors 1 and 2 (GABBR1 and GABBR2) were found to be significantly reduced in lateral cerebella of subjects with schizophrenia (62). In BA9, protein level of GABRθ was found to be downregulated in subjects with schizophrenia (60, 61, 64–67). These reports provide further evidence of GABAergic dysfunction in brains of subjects with schizophrenia. Lastly, Reelin, an important factor involved in synaptic plasticity which colocalizes to GABergic interneurons is reduced in brains of subjects with schizophrenia (52, 56, 57, 59) (Fig. 6.2a).

6.5.2. Neurodevelopmental Theories of Schizophrenia

The accumulation of a large body of evidence over the last century points to involvement of pathologic processes that occur in utero and lead to development of schizophrenia in adolescence (5, 68, 69). These neurodevelopmental abnormalities, beginning in utero, as early as late first or early second trimester (68, 70) have been suggested to lead to activation of pathologic neural circuits during adolescence (7) which may underlie development of psychotic symptoms in the susceptible individual.

Theodor Meynert (70) referred to frontal lobe pathology as a cause for psychosis. Later, Alzheimer reported on disorientation of pyramidal cells and neuronal loss in frontal lobes of subjects with schizophrenia (71, 72). Elmer E. Southard, an American

(M), dentate inner molecular layer, (GC), granular cell layer, 40 X magnification. 2b: SNAP-25 immunostaining is localized to various layers of ventral hippocampus in subjects with bipolar disorder (a), major depression (b) and schizophrenia (d) compared with a normal control (c). Note the diminution in SNAP-25 specific immunostaining in strata oriens and moleculare of patients with bipolar disorder (a) and schizophrenia (d) *vs* depressed (b) and control (c) subjects. 2a republished from (57), copyright (2000) with permission of Springer Science+Business Media. 2b republished from (58) (2001) with permission from Wolters Kluwer Health.

neuropathologist (73) who worked under Carl Weigert, visited Kraepelin's clinic and Franz Nissl's laboratory and produced the first convincing neuropathological study of schizophrenia (29, 73) that pointed to the maldevelopmental nature of schizophrenia. Southard also inferred that the cause for these maldevelopmental lesions may have been due to insults that interfered with brain cell growth and development (29). Resurgence of biological psychiatric research in the last four decades has strengthened Southard's pathological findings that schizophrenia is likely a neurodevelopmental brain disorder with significant genetic and environmental etiologies based on several lines of evidence which will be discussed in the following sections.

6.5.2.1. Obstetric and Perinatal Complications

There is a large body of epidemiologic research showing an increased frequency of obstetric and perinatal complications in schizophrenic patients (28). The complications observed include periventicular hemorrhages, hypoxia, and ischemic injuries (7, 74).

6.5.2.2. Brain Structural Studies

A consistent observation in schizophrenia is the enlargement of the cerebroventricular system. The abnormalities are present at onset of disease, progress very slowly, and are unrelated to the duration of illness or treatment regimen (7). Additionally, cerebroventicular enlargement distinguishes affected from unaffected discordant monozygotic twins. Furthermore, gross brain abnormalities have been identified in dorsolateral prefrontal cortex, hippocampus, cingulate cortex and superior temporal gyrus (7, 34). Some reports also indicate presence of brain structural abnormalities in individuals at high risk for development of schizophrenia and in unaffected first-degree relatives of subjects with schizophrenia (75). Additionally, studies of white matter tracts show evidence of disorganization and lack of alignment in white fiber bundles in frontal and temporoparietal brain regions in schizophrenia (76).

6.5.2.3. Histologic and Neuroimaging Studies

Numerous reports have documented the presence of various neuropathologic findings in postmortem brains of patients with schizophrenia (29, 77–80). These findings consist of cortical atrophy, ventricular enlargement, reduced volumes of hippocampus, amygdala and parahippocampal gyrus, disturbed cytoarchitecture in hippocampus, cell loss and volume reduction in thalamus, abnormal translocation of NADPH-diaphorase positive cells in frontal and hippocampal areas, reduced cell size in Purkinje cells of the cerebellum, and reduced synaptic spine density (77–79, 81). However, by far the greatest abnormalities have been found in prefrontal, ventral hippocampal and cerebellar cortices of schizophrenic brains (80). Collectively, these data reflect abnormal corticogenesis during the mid-gestation period in schizophrenic patients. Additionally, several various reports using MRI and diffusion tensor imaging (DTI) techniques have shown reduced white matter diffusion anisotropy (diffusion of water molecules in white matter) in subjects with schizophrenia (82–84). In brain white matter, water diffusion is highly anisotropic, with greater diffusion in the direction parallel to the axonal tracts. Thus, reduced anisotropy of water diffusion has been proposed to reflect compromised white matter integrity in schizophrenia (82). Furthermore, reductions in white matter anisotropy reflect disrupted white matter connections, which supports the disconnection model of schizophrenia (85). Reduced white matter diffusion anisotrophy has been observed in prefrontal, parieto-occipital, splenium of corpus callosum, arcuate and uncinate fasciculus, parahippocampal gyri and deep frontal perigenual regions of brain in schizophrenic patients (82, 86–90). There are also negative findings showing no white matter abnormalities in schizophrenia (91, 92). It is conceivable that downregulation of genes affecting production of myelin-related proteins as well as other components of axons may lay the foundation for white matter abnormalities which develop later in life in subjects who develop schizophrenia (93, 94).

Several reports indicate that glial cells are either dysfunctional (96–99) or unaffected in schizophrenia (100). Thus, absence of gliosis in brains of schizophrenic subjects may no longer imply direct support for initiation of early insults in utero in these patients (7). Furthermore, microglial activation has also been identified from several studies (101–104), suggesting dysfunctional immune activity in the brains and peripheral blood lymphocytes of subjects with schizophrenia.

6.5.2.4. Biochemical Brain Marker Anomalies and Microarray Studies of Schizophrenia

Biological markers consistent with prenatal occurrence of neurodevelopmental insults in schizophrenia include changes in the normal expression of proteins that are involved in early migration of neurons and glia, cell proliferation, axonal outgrowth, synaptogenesis and apoptosis (Table 6.4). Some of these markers have been investigated in studies of various prenatal insults in potential animal models for schizophrenia thus helping in deciphering the molecular mechanisms for genesis of schizophrenia (Table 6.3).

Multiple reports implicate various gene families as being involved in pathology of schizophrenia using microarray technology (95), i.e., genes involved in presynaptic function (95), signal transduction (94, 105–113), cell growth and migration (106), myelination (93, 94), regulation of presynaptic membrane function (107, 108), and GABAergic function (94, 109). By far the most well studied and replicated data deal with genes involved in oligodendrocyte and myelin-related functions. Hakak et al. (94) using mostly elderly schizophrenic and matched control dorsolateral prefrontal cortex homogenates showed downregulation of 5 genes whose expression is enriched in myelin-forming oligodendrocytes, which have been implicated in the formation and maintenance of myelin sheaths. Later, Tkachev et al. (93) using area 9 homogenates from Stanley Brain collection showed significant downregulation in several myelin and oligodendrocyte related genes such as proteolipid protein 1 (111), myelin

TABLE 6.4 Neurodevelopmental markers and schizophrenia.

Neurodevelopmental event	Molecule	Findings in schizophrenia
Cell migration	PSA-NCAM	↓ in dentate hilar area
	Reelin	↓ in mRNA and protein of neocortex, hippocampus and cerebellum
Synaptogenesis and axonal growth	SNAP-25	↓ in hippocampus and frontal cortex
	GAP-43	↑ in prefrontal and inferior temporal cortex; ↓ dentate gyrus
	Synaptophysin	↓ in prefrontal cortex and hippocampus
	Synapsin	↓ in hippocampus
Survival of connections	BDNF	↓ in hippocampus
Neuronal cytoskeletal proteins	MAP-2	↓ in subiculum and entorhinal cortex
	MAP-5	↓ in subiculum
Synaptic plasticity	NRG1	Nrg1 type I ↑ significantly in dorsolateral prefrontal cortex
Regulation of neurotransmitter signaling	RGS4	↓ in prefrontal cortex, motor cortex and visual cortex
Glutamatergic transmission	G72	Association of polymorphisms with early onset and male schizophrenia
	DAAO	4 intronic SNPs associated with schizophrenia in a French Canadian sample
	DTNBP1	Family association studies in Germany and Israel; DTNBP1 haplotype associated with schizophrenia in Chinese and Swedish samples
	GAD67	↓ in lateral cerebellum, PFC, and temporal neocortex
Cognition	COMT	Location in region 22q11 deleted in VCFS; variations in COMT associated with schizophrenia
Production of glutamate and GABA	PRODH	Location in region 22q11.2 deleted in VCFS; complex pattern of association with schizophrenia
	GAD1	↓ in lateral cerebellum
	GAD2	↓ in lateral cerebellum
GABAergic transmission	GABRα2	↑ in lateral cerebellum
	GABRβ1	↓ in lateral cerebellum
	GABRε	↑ in lateral cerebellum
	GABRθ	↓ in lateral cerebellum and PFC
	GABBR1	↓ in lateral cerebellum
	GABBR2	↓ in lateral cerebellum

associated glycoprotein (MAG), claudin 11 (CLDN11), myelin oligodendrocyte glycoprotein (MOG), myelin basic protein (MBP), neuroregulin receptor ERBB3, transferrin, olig 1, olig 2, and Sry Box10 (SOX-10) (93).

Mirnics et al. (107) showed downregulation of genes involved in presynaptic function in the prefrontal cortex such as methylmaleimide sensitive factor, synapsin II, synaptojanin 1 and synaptotagmin 5. Another important family of genes involved in schizophrenia are genes involved in glutamate and GABAergic function. Hakak et al. (94) showed upregulation of several genes involved in GABA transmission, such as, glutamic acid decarboxylase 65 and 67 kDa protein genes. However, several reports have shown decreases in these proteins in schizophrenia (54, 112, 113). Hashimoto et al. (109) showed downregulation of Parvalbumin gene, and Vawter et al. (108) showed downregulation of glutamate receptor AMPA 2. For additional details on expression of glutamate and GABA receptors, please see Sections 6.5.1.3 and 6.5.1.4.

Another gene family of import in schizophrenia deals with signal transduction. Hakak et al. (94) showed upregulation of several postsynaptic signal transduction pathways known to be regulated by dopamine, consistent with the dopamine hypothesis of schizophrenia (110, 114) such as cAMP dependent protein kinase II-regulatory subunit and NT-related protein 2. Moreover, qRT-PCR studies have identified increased expression of dopamine and cAMP regulated phosphoprotein 32 kDa (DARPP-32), in PFC and DLPFC of subjects with schizophrenia (115, 116). Mirnics et al. (105) also showed downregulation of RGS4 gene in PFC of schizophrenia. Moreover, COMT, which degrades dopamine, shows altered expression, and is inversely correlated with expression of RGS4 (117). The cholinergic muscarinic receptor 1 (CHRM1) has been shown to be reduced in cortical and subcortical areas in brains of subjects with schizophrenia (118, 119). Furthermore, CHRNA7 mRNA expression has been shown to be reduced in blood from subjects with schizophrenia (120, 121).

6.5.2.5. Effects of Adverse Environmental Events on Brain Development In Utero

There is ample evidence to indicate that the greatest risk factor for development of schizophrenia is being related to a person with schizophrenia, i.e., in some subgroups, heredity can explain more than 80% of the liability to schizophrenia (122–124).

However, there is also a robust collection of reports indicating that environmental factors, especially viral infections, can increase the risk for development of schizophrenia (125, 126, 253, 254). Emil Kraepelin (127) referred to potential for infections causing some forms of dementia praecox (schizophrenia) during early stages of brain development. Meninger (128) described 67 cases of schizophrenia in a large cohort of patients who contracted influenza during the pandemic of 1919. Later, Hare et al. (129) and Machon et al. (130) reported on excess of schizophrenic patients being born during late winter and spring as indicators of potential influenza infections being responsible for these cases. Indeed, the majority of nearly 50 studies performed in the intervening years indicate that 5–15% excess schizophrenic births in the Northern Hemisphere occur during the months of January and March (124, 131, 132). This excess winter birth has not been shown to be due to unusual patterns of conception in mothers or to a methodological artifact (124, 133). Machon et al. (130) and Mednick et al. (134) showed that the risk of schizophrenia was increased by 50% in Finnish individuals whose mothers had been exposed to the 1957 A2 influenza during the second trimester of pregnancy. Later, nine out of fifteen studies performed replicated Mednick's findings of a positive association between prenatal influenza exposure and schizophrenia (68). These association studies showed that exposure during the 4th–7th months of gestation affords a window of opportunity for influenza virus to cause its teratogenic effects on the embryonic brain (135). Additionally, three out of five cohort and case control studies support a positive association between schizophrenia and maternal exposure to influenza prenatally (136–138). Subsequent studies have now shown that other viruses such as rubella (139) may also increase the risk for development of schizophrenia in the affected progeny of exposed mothers (124, 139). An interesting report linking viral exposure to development of schizophrenia was published by Karlsson et al. (126), who provided data suggestive of a possible role for retroviruses in the pathogenesis of schizophrenia (125). Karlsson and colleagues (126) identified nucleotide sequences homologous to retroviral polymerase genes in the cerebrospinal fluid (CSF) of 28.6% of subjects with schizophrenia of recent origin and in 5% of subjects with chronic schizophrenia. In contrast, such retroviral sequences were not found in any individuals with noninflammatory neurological illnesses or in normal subjects (124, 125). The upshot of these studies and previous epidemiological reports is that schizophrenia may represent the shared phenotype of a group of disorders whose etiopathogenesis involves the interaction between genetic influences and environmental risks, such as viruses operating on brain maturational processes (125). Moreover, identification of potential environmental risk factors, such as influenza virus or retroviruses such as endogenous retroviral-9 family and the human endogenous retrovirus-W species observed by Karlsson et al. (126), will help in targeting early interventions at repressing the expression of these transcripts. An alternate approach would be to vaccinate against influenza, thus influencing the course and outcome of schizophrenia in the susceptible individuals (125).

There are at least two mechanisms that may be responsible for transmission of viral effects from the mother to the fetus: I) Via direct viral infection. There are clinical, as well as direct experimental reports (140–143) showing that human influenza A viral infection of a pregnant mother may cause transplacental passage of viral load to the fetus. In a series of reports, Aronsson and colleagues used human influenza virus (A/WSN/33, a neurotropic strain of influenza A virus) on day 14 of pregnancy, to infect pregnant C57BL/6 mice intranasally. Viral RNA and nucleoprotein were detected in fetal brains and viral RNA persisted in the brains of exposed offspring for at least 90 days of postnatal life thus showing evidence for transplacental passage of influenza virus in mice and the persistence of viral components in the brains of progeny into young adulthood (142). Additionally, Aronsson et al. (142), have demonstrated that ten to 17 months after injection of the human influenza A virus into olfactory bulbs of TAP1 mutant mice, viral RNA encoding the nonstructural NS1 protein was detected in midbrain of the exposed mice. The product of NS1 gene is known to play a regulatory role in the host-cell metabolism (144). Several in vitro studies have also shown the ability of human influenza A virus to infect Schwann cells (145), astrocytes, microglial cells and neurons (109), and hippocampal GABergic cells (146, 147), selectively causing persistent infection of target cells in the brain. II) Via induction of cytokine production. Multiple clinical and experimental reports show the ability of human influenza infection to induce production of systemic cytokines by the maternal immune system, the placenta, or even the fetus itself (148–152). Indeed, work by Brown et al. (69) show presence of serologic evidence of maternal exposure to influenza as causing increased risk of schizophrenia in offspring (69). Offspring of mothers with elevated IgG and IgM levels, as well as antibodies to herpes simplex virus type 2 during pregnancy have an increased risk for schizophrenia. Cytokines such as Interleukin-1β, (IL-1β), IL-6 and tumor necrosis factor α (TNFα) are elevated in the pregnant mothers after maternal infection (148, 149, 152) and after infection in animal models (150, 151). All of these cytokines are known to regulate normal brain development and have been implicated in abnormal corticogenesis (153–155). Additionally, expression of mRNA's for cytokines in the CNS is developmentally regulated both in man and in mouse (156–160), emphasizing the significant role that cytokines play during neurodevelopment. IL-1β, IL-6 and TNFα cross the placenta and are synthesized by mother (161), by the placenta (162), and by the fetus (152). Maternal levels of TNFα and IL-8 have been shown to be elevated in human pregnancies in which the offspring goes on to develop schizophrenia (69, 163). A more relevant series of studies in different animal models for schizophrenia show that maternal infection with human influenza mimic poly I:C, a synthetic double stranded RNA that stimulates a cytokine response in mice, can cause abnormalities in prepulse inhibition (164), or after maternal exposure to E. coli cell wall endotoxin lipopolysaccharide, cause disruption of sensorimotor gating in the offspring (165). Finally, maternal exposure to poly I:C also causes

Anosognosia
Apraxia
Sympathetic arousal

disrupted latent inhibition in rat (166). All of these models suggest that direct stimulation of cytokine production by infections or immunogenic agents cause disruptions in various brain structural or behavioral indices of relevance to schizophrenia. Other factors associated with increased schizophrenic births include famine during pregnancy (124, 163) obstetric complications (167), Rh factor incompatibility (168) and autoimmunity due to infectious agents (169).

6.5.2.6. Congenital Anomalies and Developmental Dysfunction

Multiple markers of congenital anomalies indicative of neurodevelopmental insults have been found in schizophrenia (7). Such anomalies include agenesis of corpus callosum, stenosis of sylvian aqueduct, cerebral hamartomas, and cavum septum pellucidum. Presence of low-set ears, epicanthal eye folds, and wide spaces between the first and second toes, are suggestive of first trimester anomalies (7). There is, however, support for abnormal dermatoglyphics (Fig. 6.3) in patients with schizophrenia indicating a second trimester event (170). Multiple reports indicate the presence of premorbid neurologic soft signs (Table 6.5) in children who later develop schizophrenia (171, 172). Slight posturing of hands and transient choeoathetoid movements have been observed during the first two years of life in children who later developed schizophrenia (172, 173). Additionally, poor performance on tests of attention and neuromotor performance, mood and social impairment, and excessive anxiety have been reported to occur more frequently in high-risk children with a schizophrenic parent (174, 175). All of these findings are consistent with schizophrenia as a syndrome of abnormal brain development (255).

6.6. Clinical Findings

6.6.1. Clinical Signs and Symptoms of Schizophrenia

The current diagnostic criteria adopted by DSM-5 is based on extensive research dating back to initial findings of Kraepelin, Bleuler and Schneider (5, 8, 176). Unlike other medical conditions, no one sign is diagnostic of schizophrenia (7). Thus it is absolutely important to obtain as much clinical history about the patient to help establish a correct diagnosis.

As mentioned earlier, The DMS-5 criteria require presence of two or more of the following symptoms during a 1 month period: 1) delusions, 2) hallucinations, 3) disorganized speech, 4) grossly disorganized or catatonic behavior, 5) negative symptoms (flat affect, alogia or avolition). Alternatively, the diagnosis of schizophrenia may be based on presence of bizarre delusions alone, auditory hallucinations of a voice keeping a running commentary one one's daily activities, or two or more voices conversing with each other (7, 34). Delusions are fixed false beliefs not congruent with one's cultural or religious background. Schizophrenic patients may exhibit delusions that correspond to themes of persecution, grandiosity, outside control, guilt, thought broadcasting, thought withdrawal/insertion or ideas of reference (7). Bizarre delusions are highly implausible false beliefs (34). Hallucinations are abnormal perceptions of sensory experiences which occur in the absence of external stimuli. Hallucinations can be based on various types of sensory modalities such as auditory, visual, gustatory, olfactory, tactile or cenesthetic (change in the normal quality of feeling tone in a part of the body) (7, 177). Auditory hallucinations are more common in schizophrenic subjects, and occurrence of other types of hallucinations should be considered as potential signs of other medical/organic etiologies (7, 34). Command auditory hallucinations may lead the patient to act upon the command to harm self or others. Disorganized speech and behavior reflect underlying thought disorder or impairment (7, 34). Examples of abnormal speech include circumstantiality, tangentiality, derailment, illogicality, incoherence, concrete speech, clanging, neologims, echolalia, thought blocking, perseverations and poverty of content (7, 34). Disorganized behavior includes bizarre postures, stereotyped behavior, echopraxia, negativism, catatonic stupor/excitation, waxy flexibility, unprovoked outbursts of laughter or violent behavior, severe neglect of hygiene, poor self-care and grooming, grimacing, athetosis, and mutism. Grossly disorganized or catatonic behavior may also include verbigeration, primitive reflexes, autonomic hyperactivity, staring and rigidity. Finally, negative symptoms reflect deficits of normal functions and examples include affective flattening, avolition, alogia, anhedonia, social withdrawal, and diminished capacity to feel close to others (7, 34). These negative symptoms reflect endogenous markers of schizophrenia and are thus called primary negative symptoms (34). Negative symptoms such as depression or demoralization which may be due to side effects of medications, are called secondary negative symptoms.

Finally, as discussed earlier, social and occupational dysfunction, continuous presence of illness for six months and the ruling out of other illnesses or substance-related symptoms are required before a diagnosis of schizophrenia can be firmly established (9).

6.6.2. Mental Status Examination in a Subject with Schizophrenia

6.6.2.1. Appearance

Upon examination, a patient with possible diagnosis of schizophrenia may appear disheveled, exhibit evidence of poor self-care or grooming. Patient may appear suspicious, relate poorly to the examiner and exhibit bizarre postures, stereotypies, grimacing, athetosis, mutism or catatonic agitation or stupor (7). The clinician must look for presence of abnormal extra pyramidal signs (EPS) such as dystonia, tardive dyskinesia, rabbit syndrome or akathisia.

6.6.2.2. Affect

The subject may exhibit an affect which is incongruent with patient's state of mind and is described as inappropriate. Affect may also appear blunted, constricted or flat. However, absence of a sad affect does not rule out presence of a depressed mood. Flat affect may be secondary to drug induced parkinsonism or EPS.

6.6.2.3. Mood

Mood may be depressed or variable. As depression occurs frequently in schizophrenic subjects and causes a high rate of suicide, it is essential for clinicians to evaluate for presence of depression and to treat it promptly.

6.6.2.4. Speech

Evaluation of patient's speech may identify presence of loose, illogical or bizarre thought patterns. Additionally, patient may exhibit various abnormalities of speech such as tangentiality, circumstantiality, neologisms, clang association (speech directed by sound of a word rather than by its meaning) (177), perseveration and poverty of content (7). Patients may also express echolalia or thought blocking. Evidence of TD or dystonia affecting patient's speech should be investigated.

6.6.2.5. Thought Form and Content

Thought form can be ascertained while listening to patient's speech. Thus, presence of loose and illogical thought pattern is tantamount to evidence of formal thought disorder. Also, answering questions inappropriately (for example tangential responses: Q: What color is the sky? A: It rained yesterday) indicates formal thought disorder. Alternatively, thought content may be replete with evidence for delusions, ideas of reference, thought broadcasting, thought insertion or withdrawal, ideas of persecution or grandiosity or outside control. It is imperative to evaluate for presence of depression, mania, anxiety, panic, racing thoughts, irritability, suicidal and homicidal ideations or plans or past histories of suicide or violence towards others. Presence of obsessive-compulsive symptoms, past or recent histories of traumatic events and signs of PTSD should be evaluated.

6.6.2.6. Perceptual Abnormalities

Presence of hallucinations, illusions, Déja vu, depersonalization, and derealization should be determined. Intensity, frequency and past or present occurrence of various types of hallucinations should be determined. For example, specifics of gender of voices heard, loudness, origin of voices emanating from inside or outside one's head should be investigated. Presence of command auditory hallucinations which may order patient to harm himself/herself or others should be ascertained. The form and color of visual hallucinations should be evaluated. Visual hallucinations occurring during sleep, prior to or immediately after sleep are not necessarily indicative of a pathological process.

6.6.2.7. Cognition/Sensorium

Subjects with schizophrenia generally present with an intact sensorium i.e. they are alert and oriented to place, person and time. Evaluation of immediate, short and long term memory and attention should be performed. Other cognitive domains may display major abnormalities either through bedside examination or by performance of a neuropsychological battery of tests. Insight and judgement are generally evaluated by questioning patient's awareness of their illness or their ability to interact normally with others respectively. These mental abilities are more likely to be impaired in a patient with schizophrenia. Use of proverb analysis and similarities may shed light on patient's degree of abstraction or concreteness of thought. Most schizophrenic patients exhibit IQ scores 10 points lower than general public and exhibit impairments in attention, working memory, visual spatial memory, semantic memory, recall memory, and executive functions (7). Presence of cognitive abnormalities in schizophrenia appears to be independent of positive, negative or disorganization symptoms (7).

6.6.2.8. Physical Examination

As in all other fields of medicine, every psychiatrist must be able to do a focused physical examination to identify presence of any general medical or neurologic abnormalities. However, because of potential boundary issues, presence of a nurse or a chaperone in the examination room is warranted. Patients with schizophrenia have a higher burden of medical comorbidities and thus should be evaluated fully. Review of systems should cover neurologic, cardiovascular, ear, nose and throat, gastrointestinal, genitourinary, dermatologic, and endocrine systems. Presence of neurological soft signs (Table 6.5) such as abnormal gait, abnormal reflexes, changed muscle tone, abnormal rapid eye movements (saccades), frequent blinking, dysdiadochokinesia, astereognosis, poor right-left discrimination, anosognosia, apraxia, sympathetic arousal, choreoathetosis, mannerisms, grimacing, stereotypies and abnormal body movements are indicators of the neurodevelopmental origins of schizophrenia (7). Because of increased risk for diabetes and metabolic syndrome due to atypical antipsychotics, it would be judicious to obtain baseline and follow-up weight, vital signs and waist circumference (Body Mass Index) for every patient examined (178).

6.6.2.9. Neuropsychological Testing

Formal objective tests such as the Halstead-Reitan Battery, the Luria-Nebraska Battery, the Wechsler Adult Intelligence Scale, the Wechsler Intelligence Scale for Children, the Wisconsin Card Sorting Test (WCST), and the Brief Assessment of Cognition in Schizophrenia (BACS) (179) and the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) (180) can identify various brain abnormalities and should be performed in all initial evaluations.

6.6.2.10. Laboratory Investigations

6.6.2.10.1. Blood, Urine and Cerebrospinal Fluid

While no specific blood, urine or CSF tests are available to demonstrate presence of schizophrenia unequivocally, performance of certain blood and urine tests to rule out presence of nonpsychiatric causes for psychotic symptoms is warranted in all initial examinations. Tests such as thyroid function (TSH, T3, T4), RPR, HIV, fasting lipid panel, CBC with differential, metabolic panel (electrolytes, liver enzymes, BUN, glucose, creatinine) ESR, ANA, RF, B12, folate, prolactin, urinalysis, urine tox screen, blood alcohol level and baseline ECG should be performed during the initial evaluation as warranted by clinical judgment of the examining psychiatrists. Evaluation of hemoglobin A1C to rule out presence of diabetes mellitus at baseline and after institution of atypical antipsychotics is warranted. In certain cases, when suspicion of infectious etiologies is present, referral of patient to a neurologist and consultation with an infectious disease specialist for performance of a lumbar puncture is warranted.

6.6.2.10.2. Brain Imaging

Ventricular enlargement and increased brain sulcal prominence can be identified in CT or MRI views. While the findings are supportive of brain abnormality they are not specific to schizophrenia. Additionally, despite identification of a number of other brain abnormalities such as smaller cerebral and cranial size, smaller medial temporal structures (hippocampus), enlargement of lenticular nucleus, cerebellar vermal dysplasia and smaller thalamus in subjects with schizohprenia, none are diagnostic of schizophrenia (7). Shepherd et al. (181) in a meta-review of 32 publications, identified increased volumes of the ventricles and cavus septum pellucidum and reduced volumes for frontal lobe, post-central gyrus, temporal lobe, anterior cingulate, hippocampus, amygdala, thalamus, and insula in subjects with schizophrenia. Changes in volumes for fusiform gyrus, amygdala, parahippocampus, and posterior cingulate cortex/precuneus were only identified in subjects with chronic schizophrenia, suggesting an impact of the duration of illness (181).

More recently diffusion tensor imaging (DTI), has shown presence of white matter tract abnormalities in schizophrenic patients (182). While DTI abnormalities may be due to disease process itself, antipsychotic medications can impact white matter volume, cell density, and oligodendrocyte and astrocyte counts (183, 184), and thus affect DTI studies. Recent DTI studies have focused on white matter changes in drug naïve patients. These studies found white matter abnormalities in the corpus callosum (185), reduced fractional anisotropy in the left inferior longitudinal fasciculus (186), and the right superior longitudinal fasciculus II, the right fornix, the right internal capsule, and the right external capsule (187).

6.6.2.10.3. Functional Brain Imaging

Use of functional MRI (fMRI), SPECT and PET imaging has provided a wealth of information about various brain function abnormalities in schizophrenia (188–191). These abnormalities include dysfunction of information storage and retrieval by dorsolateral prefrontal cortex (DLPFC), abnormal inhibitory response to sensory stimuli by anterior cingulate cortex, abnormal encoding and retrieval of memory by hippocampus, abnormal reception and integration of sensory information by thalamic nuclei, primary sensory cortices and the multimodal cortices and impaired performance of cognitive tasks by basal ganglia, thalamus and cerebellum (34, 192–195, 203). During auditory and visual hallucinations, PET and fMRI studies have demonstrated increased activity in the auditory cortex, visual cortex, as well as the right middle temporal gyrus and/or right superior temporal cortex (196–198). Imaging during cognitive function tasks has shown altered activity in the frontal cortex of subjects with schizophrenia (199–202).

6.6.3. Differential Diagnosis

Psychotic symptoms are present in a number of conditions and must be ruled out before entertaining the diagnosis of schizophrenia.

6.6.3.1. Mood Disorders

Psychotic symptoms such as mood congruent hallucinations or delusions may occur in severe depression or mania. Acquisition of detailed history and correlative clinical data should guide the clinician as to whether these symptoms occur due to mood abnormalities. Exclusive co-occurrence of psychotic symptoms with mood symptoms should denote presence of mood disorder with psychotic features (7). Alternatively, an uninterrupted period of illness during which, at some time, there is either a major depressive episode, a manic episode, or a mixed episode concurrent with symptoms that meet criterion A for schizophrenia should point to possibility of schizoaffective disorder (9).

6.6.3.2. Psychotic Disorders Due to Medical, Neurologic or Substance-Induced Conditions

The chronology of psychotic symptoms occurring in relation to an inciting condition or in association with physical or laboratory signs indicative of a medical or neurologic disorder is helpful in distinguishing non schizophrenic psychosis. Many substances can cause psychosis such as amphetamines, substituted amphetamines such as ecstasy, hallucinogens, alcohol, barbiturates, cocaine, ketamine, PCP and belladonna alkaloids (7). Examples of medical or neurologic conditions that induce psychosis include infectious causes (herpes encephalitis, neurosyphilis, AIDS), metabolic events (acute intermittent porphyria, vitamin B12 deficiency, carbon monoxide poisoning, homocystinuria, heavy metal poisoning), neurologic events (temporal lobe epilepsy, frontal or limbic trauma, cerebrovascular accidents, Huntington's disease, metachromatic leukodystrophy, normal pressure hydrocephalus, Wernicke-Korsakoff syndrome, Wilson's disease, Jakob-Creutzfeldt's disease) and various conditions such as neoplasms, Fabry's disease, Fahr's disease, Hallervorden-Spatz disease and systemic lupus erythematosus. Clearly, obtaining historical details on clinical course, performing physical examination and doing pertinent laboratory examination will help the psychiatrist in identifying the cause of psychotic symptoms and ruling out schizophrenia (7).

6.6.3.3. Other Psychotic Disorders

Psychotic symptoms may occur during a period of mood abnormality such as depression, mania or mixed episode with mood symptoms present for a substantial portion of the total period of illness denoting schizoaffective disorder. In brief psychotic disorder, schizophrenic symptoms occur for at least 1 day but less than 4 weeks and these may occur in presence or absence of a marked stressor or with onset within 4 weeks postpartum (9). In schizophreniform disorder, prodromal, residual or active schizophrenic symptoms occur for at least 1 month but less than six months in duration. Delusional disorder refers to nonbizarre delusions in the absence of hallucinations, disorganized speech or behavior or negative symptoms or mood disorder. Finally, psychotic disorder not otherwise specified deals with disorders that do not meet the criteria for any of the above-mentioned diseases and for which adequate information is not available.

6.6.3.4. Other Axis I Disorders

Symptoms which may resemble hallucinations or paranoia may be observed in PTSD patients but these ensue following a traumatic event. Severe intrusive thoughts in OCD patients neither reach the level of delusionality seen in schizophrenia or if they occur in absence of insight do not accompany functional incapacity seen in psychotic patients. Finally, in subjects with hypochondriasis or body dysmorphic disorder no hallucinations or delusions are present (34).

6.6.3.5. Personality Disorders

Symptoms of schizotypal, schizoid, paranoid, and borderline personality disorders lack an exact onset of disease, are present throughout patient's life and are mild (7). However, these do not reach a level meeting criterion A for schizophrenia, and do develop as early as adolescence or early adulthood.

6.7. Pharmacological Treatments of Schizophrenia

6.7.1. Clozapine

Clozapine is a dibenzodiazepine and the prototype for most of atypical antipsychotics [agents which may treat positive, negative or cognitive symptoms of schizophrenia, have decreased liability for EPS and tardive dyskinesia, may be effective for a proportion of treatment nonresponsive patients and exhibit greater 5HT2 over D2 receptor antagonism and do not cause hyperprolactinema

(204, 205)]. It has a complex pharmacologic profile encompassing affinities for 5HT2A, 5HT2C, 5HT6, 5HT7, α1, α2 adrenergic, M1 muscarinic and histaminergic receptors (7). Clozapine exhibits inverse agonist activity at 5H2A and 5HT2C receptors blocking constitutive activity of these receptors (34). The ratio of 5HT2A to D2 receptor affinities may signal clozapine's low EPS profile (7).

Clozapine has been shown to be effective in treatment resistant schizophrenia (206). This important study compared the efficacy of clozapine to chlorpromazine in 268 subjects with treatment resistant schizophrenia (defined as having failed to respond to at least three prior antipsychotics). By 6 weeks, 30% of the clozapine-treated group but only 4% of the chlorpromazine-treated group responded to the respective medications (206, 17). Thus, clozapine remains the only antipsychotic agent to date that is FDA-approved for treatment-resistant schizophrenia (206). Additionally, other studies have shown superiority of clozapine vs. typical agents in treatment of total psychopathology, EPS and TD and categorical response to treatment (206). Clozapine reduces positive, negative and cognitive symptoms of schizophrenia without causation of EPS, TD or hyperprolactinemia (34). Furthermore, clozapine has been shown to reduce depression and suicidality (7, 34).

The dose range of clozapine varies from 150–450 mg/day for most patients (259). The initial dose of 25 mg/day must be titrated upwards slowly (increments of 25 mg/3 days) due to hypotensive and tachycardic side effects (7). The average dose is about 400–500 mg/day as a twice daily regimen (7). Plasma levels of 350–400 ng/ml have been associated with good clinical response (7, 256).

Despite clozapine's important clinical efficacy, several side effects must be considered as potentially significant and life threatening. Agranulocytosis occurs within the initial 4–18 weeks of treatment, necessiting monitoring of while blood cell (WBC) and neutrophil count every week, for the first 6 months (34), every 2 weeks for the next 6 months and once monthly thereafter (7). If the WBC count falls below 3000 cells per mm^3 or the absolute neutrophil count below 1500 cells per mm^3, clozapine administration must be stopped. Upon diagnosis of agranulocytosis, administration of granulocyte colony stimulating factor (G-CSF) and hospitalization, is warranted. The death rate from agranulocytosis is ≈ 1 per 10,000 patients (34). Other side effects of clozapine include sedation, weight gain, seizures, OCD symptoms, hypersalivation, tachycardia, hypotension, hypertension, stuttering, neuroleptic malignant syndrome, urinary incontinence, myocarditis, constipation, hyperglycemia, eosinophilia and fever (7). Seizures can be treated with valproic acid or lamotrigine supplementation (207–209).

6.7.2. Risperidone

Risperidone is a member of the benzisoxazole family of atypical agents and the second FDA approved antipsychotic agent classified as atypical to be marketed in USA. Several studies suggest that risperidone may be more effective than typical antipsychotics in acute and maintenance treatment of schizophrenic subjects (207). While risperidone may be superior to typical agents in treatment-resistant patients, it is not considered as effective as clozapine in this vulnerable group of schizophrenic patients (210).

The recommended dosage of risperidone is 2–8 mg/day (9). Risperidone causes higher occupancy of D2 receptors than does clozapine and may cause mild EPS even at 2–4 mg/day dosage range (7). Additionally, risperidone causes hyperprolactinemia. Other side effects include akathisia, weight gain, sexual dysfunction, decreased libido and galactorrhea (7). Risperidone is available in depot form for injection.

6.7.3. Olanzapine

Olanzapine is a thienobenzodiazepine agent and the third FDA approved atypical agent marketed in the USA in late 1990's. This novel agent exhibits nanomolar affinity at several receptor sites including D1–D4, 5HT2, 3, 6, muscarinic M1–5, α1 adrenergic and H1 histaminergic sites (7). Additional novel findings show that olanzapine causes modulation of several important brain genes like Reelin, insulin, regulator of G-protein signaling (RGS2), pyruvate kinase, calbinden and homer 1 after chronic administration in rats (211). Furthermore, olanzapine was shown to increase glucogenesis in brain via multiple pathways potentially linking its ability to produce glucose for energy consumption in brain to its metabolic side effect profile in the treated subjects (212). Olanzapine also downregulates the soluble isoform of COMT in frontal cortex of rats helping in upregulating the levels of dopamine in this important brain area (213).

Olanzapine has several characteristics of an atypical agent such as low EPS propensity, chemical structural similarity to clozapine, lack of hyperprolactinemic side effect, broad efficacy and ability to treat negative symptoms of schizophrenia (7). Multiple studies have shown olanzapine to have some efficacy over typical agents in the acute and maintenance treatment of schizophrenia (210) and in treatment of refractory patients. The dose range for olanzapine is 5–20 mg/day (259). Despite olanzapine's beneficial effects, several side effects including weight gain, metabolic disturbances, sedation, dizziness and transient liver transaminase elevations should be watched for (7).

6.7.4. Quetiapine

Quetiapine is a member of dibenzothiazepine family of atypical agents with high affinity for 5HT2A, α1 adrenergic and H1 histaminergic receptors (7). Quetiapine also exhibits moderate affinity for D2 and low affinity for M1 muscarinic receptors (7). Quetiapine dose range is 300–600 mg/day with similar efficacy as typical agents and is associated with low EPS propensity and prolactin elevation (207). The most common side effects include sedation, dry mouth, agitation, constipation and orthostatic hypotension (7). Quetiapine can cause QT prolongation (257) and has the potential to cause torsade de pointes and has a warning label based on FDA recommendations.

6.7.5. Ziprasidone

Ziprasidone is a benzothiazolyl piperazine with high affinity for serotonergic (5HT1A, 5HT2A, 5HT2C, 5HT1D) and dopaminergic (more D3, less D2) receptors. It has weak affinities for muscarinic and histaminergic receptors (7). Recent data indicate that ziprasidone has similar antipsychotic efficacy to haloperidol, is associated with minimal weight gain, sedation or prolactin elevation (207). The dose range is 80–160 mg/day. Despite initial concerns for ziprasidone causing QT-interval changes, such as torsade de pointes, FDA does not require ECG acquisition prior to treatment and no published reports indicate any cardiotoxic effects (207).

6.7.6. Aripiprazole

Aripiprazole is the first FDA approved partial dopamine D2 agonist, marketed in 2002, with partial agonist activity at 5HT1A receptor and 5HT2A antagonism (34, 207). Aripiprazole has low EPS propensity, low liability for hyperprolactinemia and weight gain (207). The dose range is 10–20 mg/day (34). Aripiprazole is effective in short and long term treatment of schizophrenia (207). Side effects may include activation and nausea (34).

6.7.7. Paliperidone

Paliperidone was approved for the treatment of schizophrenia in 2006 and schizoaffective disorder in 2009 (214). Paliperidone, a metabolite of risperidone (9-hydroxyrisperidone), is a dopamine D2 receptor antagonist (215). The approved range of doses for paliperidone is 6–12 mg/day (216–219, 259). Clinical data from short-term treatment trials of paliperidone have demonstrated superior efficacy to placebo on several psychometric tests (216–218). Results from a long-term study also found that paliperidone was superior to placebo in preventing relapse [25% for paliperidone vs. 53% of placebo (220)]. Pooled data from three 52-week studies found that paliperidone treatment resulted in maintenance of clinical improvements and was well-tolerated (221). Meltzer et al. (219) using data from three six week studies (216–218) found that subjects treated with paliperidone showed no significant differences in weight gain or for a number of metabolic measurements including fasting glucose, triglycerides, lipoproteins, or cholesterol levels when compared with controls.

6.7.8. Iloperidone

Iloperidone was approved for the treatment of schizophrenia in 2009. Unlike other antipsychotic medications, iloperidone has relatively high affinity for noradrenergic alpha 1 receptors rather than serotonin 5HT2A and dopamine D2 receptors (222). Iloperidone needs to be titrated to its target dose of 12–24 mg/day, and is generally administered twice daily (222). There have been four short-term double-blind, placebo- and active controlled studies of iloperidone's efficacy (223–225). A meta-analysis of pooled patient data found that iloperidone was significantly more effective than placebo in reducing PANSS total score, PANSS positive subscale, PANSS negative subscale, and BPRS-derived total scores (226). Data from three, pooled long-term studies of iloperidone vs. haloperidol found that iloperidone had similar efficacy as haloperidol and a favorable long-term safety profile (227). More recently, Cutler et al. (228) similarly found that iloperidone was safe and tolerable long-term with regard to weight gain and metabolism, however, there was no improvement in total PANSS scores over baseline. Iloperidone is known to increase corrected QT interval (QTc), however, there have not been any reports of serious cardiac dysfunction associated with increased QTc (229).

6.7.9. Asenapine

Asenapine was approved for use in 2009 and is used for the treatment of schizophrenia and for acute treatment of manic or mixed episodes of bipolar I disorder (222). Asenapine is absorbed through the oral mucosa as its bioavailability is less than 2%

if swallowed (230–232). Asenapine has high affinity for multiple serotonin receptors (5-HT2A, 5-HT2B, 5-HT2C, 5-HT6, 5-HT7) and the dopamine D3 receptor (222). Asenapine does not need to be titrated and is dosed at 5 mg/day bid for acute schizophrenia and 10 mg/day bid for maintenance (222). A meta-analysis of four short-term studies of asenapine's efficacy (230, 233, 234) found that asenapine was more effective than placebo with regard to change in PANSS total score (235). Longer-term studies employing olanzapine as an active control found that olanzapine was more effective than asenapine in reducing PANSS scores at the end of 52 weeks (236) and the 16 item negative system assessment (NSA-16) at the end of 26 weeks (237). However, Buchanan et al. (237) found that during the extension study, that asenapine was superior to olanzapine in changing NSA-16 scores at 52 weeks. When compared with placebo, asenapine does not appear to have any effect on weight gain, fasting serum glucose, total cholesterol, or triglyceride levels (230, 238).

6.7.10. Lurasidone

Lurasidone was approved for use in 2010 and is used to treat schizophrenia and depressive episodes associated with bipolar I disorder (222). Lurasidone is a full D2 dopamine and 5-HT2A receptor antagonist (222). Unlike iloperidone or asenapine, lurasidone is taken once a day and has a target dose of 40–80 mg/day for the treatment of schizophrenia (222, 259). A number of short-term, six-week trials have shown that lurasidone, at a variety of doses, is superior to placebo for the treatment of acute schizophrenia as determined by reduction in PANSS scores (239–243). A long term extension by Loebel et al. (244) found that lurasidone produced higher rates of remission than quetiapine. A second long-term study found improvement in mean PANSS total scores, mean Clinical Global Impression Schizophrenia (CGI-S) score, and mean Calgary Depression Scale for Schizophrenia (CDSS) score (245). Lurasidone does not appear to cause increased weight or changes in metabolic values, nor does it impact QT interval (222).

6.7.11. Typical Antipsychotics

Results of CATIE trials (210) have indicated that there may not be significant differences between several atypical agents (clozapine, olanzapine, ziprasidone, aripiprazole and risperidone) and a typical agent (perphenazine) with regards to efficacy in treatment of schizophrenic positive symptoms. Indeed, introduction of chlorpromazine and later antipsychotic agents like haloperidol in the 1950's revolutionized the treatment of schizophrenia (7). These agents clearly treated positive symptoms in 60–70% of patients and enabled many patients to leave hospitals for the first time in decades. The early hypotheses suggested that action of typical antipsychotics in ameliorating the positive symptoms of schizophrenia were due to their dopaminergic antagonism (7). Recent genetic and microarray studies have revealed that most if not all antipsychotic agents probably treat schizophrenic symptoms by modulating a large number of brain genes whose upregulation or repression chronically, may lead to stabilization of positive, negative and cognitive deficits in schizophrenia (246–248). Thus, it appears that modulation of major neurotransmitters like dopamine, serotonin, glutamate, GABA and acetylcholine by various antipsychotic agents may only be part of a larger array of brain genes and proteins that may be involved in treatment of schizophrenia.

6.7.12. Multiple Phases of Pharmacologic Treatment

In acute phase treatment, patients with florid psychotic symptoms are generally admitted to a hospital setting and given short acting antipsychotic agents (ziproasidone, olanzapine or haloperidol) alone or in combination with benzodiazepines and/or anticholingerics. The clinical decision to begin antipsychotic treatment is dependent on several factors including side effect profile, past history of response to medications and patient preference (Table 6.6). The order of antipsychotic agents of choice based on decreased propensity for metabolic side effects/EPS/TD may be aripiprazole, quetiapine, risperidone/paliperidone, ziprasidone, olanzapine, haloperidol. In cases of noncompliance, depot medications such as long acting risperidone, haloperidol or fluphenazine may be administered (34).

In continuation phase treatment, patient's response to antipsychotic agent, side effect profile, tolerability and compliance will be monitored carefully (34). It is generally expected to achieve optimal response to most agents by 4–6 weeks, however, longer periods of therapy may be necessary in certain individuals. In some patients, residual constellation of positive, negative or cognitive symptoms may remain. In some cases, one antipsychotic agent may be switched with another medication. Alternatively and specifically in treatment nonresponsive patients, clozapine alone or in combination with other agents such as valproate, benzodiazepines, antidepressants or lithium may be necessary to treat various symptoms.

Table 6.6 Commonly used antipsychotic drugs.

Class and drug name	Dosage range (mg)	Clorpromazine equivalents (mg/day)	Parenteral dosage (mg)	Galenic forms
Typical drugs				
Chlorpromazine	200–600	100	25–75	O, L, I, S
Fluphenazine	2–20	2.5	5–10	O, L, I
Fluphenazine decanoate	–	–	25–50 every 1–4 weeks	–
Fluphenazine enanthate	–	–	25–50 every 1–4 weeks	–
Haloperidol	4–20	2.5	5–10	O, L, I
Haloperidol decanoate	–	–	50–150 every 1–4 weeks	–
Loxapine*	60–100	10	25–50	O, L, I, OH
Mesoridazine	75–300	83	25–50	O, L, I
Molindone	30–100	10	NA	O, L
Perphenazine	8–32	8	6–12	O, L, I
Pimozide	2–6	1	NA	O
Thioridazine	150–600	100	NA	O, L
Thiothixene	5–30	5	2–4	O, L, I
Trifluoperazine	5–20	5	4–9	O, L, I
Atypical drugs				
Aripiprazole	10–20	7	NA	O, L, I
Asenapine	10–20	5	NA	OD
Clozapine	150–450	67	NA	O
Iloperidone	12–24	6	NA	O
Lurasidone	40–80	20	NA	O
Olanzapine	5–20	5	10–15	O, I, OD
Paliperidone	6–12	2	234 mg on day 1; 156 mg one week later; and 117 mg monthly for maintenance	O, I
Quetiapine	300–600	167	NA	O
Risperidone	6–8	1.3	NA	O, L, I, OD
Risperidone microspheres	–	–	25–50 every 2 weeks	I
Ziprasidone	80–160	40	20–40	O, L, I

O, oral; L, liquid; I, Injection; OH, oral inhalation; S, suppository. OD, oral disintegrating form.
*Loxapine is now FDA approved as the first inhalational-based antipsychotic.

In maintenance phase treatment, patients who have responded well to various agents should be treated indefinitely to prevent relapse and worsening of disease process. In treatment refractory cases, clozapine appears to be the only drug with proven efficacy (34).

6.8. Antipsychotic Related Side Effects

One of the major reasons for choice of new second generation antipsychotics relates to high frequency of several side effects which are more prevalent with typical agents. For example, extrapyramidal side effects (EPS) such as dystonias (repetitive involuntary skeletal muscle contractions, (Fig. 6.4), dyskinesias [slow or tardive dyskinesias (TD) or severe involuntary choreiform, athetoid, or rhythmic muscular contractions which may involve face, neck, tongue, hands, trunk, legs], pseudoparkinsonism, rabbit syndrome, akathesias occur secondary to use of high potency typical antipsychotics. All of these side effects except for TD can be treated by judicious use of anticholinergics, benzodiazepines or propranolol or reduction in dose of antipsychotic agents or by changing to an atypical agent. There are no proven treatments for TD. Non-neurologic side effects may include hyperprolactinemia, gynecomastia, impotence, amenorrhea, weight gain, hematologic effects, jaundice and cardiac effects (7).

6.9. Electroconvulsive Treatment of Schizophrenia

ECT treatment (6–12 treatments) may be an adjunct in treatment-refractory patients and when required in rapid control of excited catatonia and severe agitation. Long term use of ECT in treatment of schizophrenia is not supported by current literature (7).

6.10. Psychosocial Treatment

There are several psychosocial treatment modalities like cognitive-behavioral therapy, personal therapy, compliance therapy, acceptance and commitment therapy as well as supportive psychotherapy which have been found to help patients and their families to deal with the disease process, noncompliance issues and improvement of patients' living and work functioning (34). Application of case management, token economy, reduction of expressed emotion by patients' family and assertive community treatment, social skills training and cognitive rehabilitation strategies can all help patients with schizophrenia to have a better outlook on life and to improve their compliance with medication regimen (34).

6.11. Time Course of Schizophrenia

Disease onset is quite variable. The prodromal phase consists of a period during which patient may experience social withdrawal, decreased motivation, poor cognition, increasing odd behavior and restricted affective range (34). During the active phase (first psychotic break), patient exhibits florid psychotic symptoms either in response to life stressors or following substance abuse (34). In residual phase, there remains some schizophrenic symptoms which persist despite treatment.

6.12. Prognosis and Course of Illness

The modern concept of the prognosis of schizophrenia is based on multiple outcome measures. Four types of outcome measures have been identified: psychopathology, work function, social function, and rehospitalization. These measures could vary independently in schizophrenia, and although they are central to evaluating outcome in schizophrenia, other measures such as cognitive function, general health, and suicide are also important.

Outcome in schizophrenia can be predicted partially by age at onset and by the nature of the prodrome and first episode (Table 6.7). Early age at onset (e.g., 14–18 years) is often associated with a worse outcome than is later age at onset. An insidious rather than an abrupt onset is also associated with a poor outcome. If the initial clinical presentation is characterized mainly by negative symptoms, outcome is likely to be poor, both in the short and long term. Conversely, florid psychosis and an abrupt onset are both likely to be associated with a good prognosis because antipsychotic drugs are much more effective against positive symptoms and disorganization than they are against negative symptoms and cognitive disturbance.

TABLE 6.7 Predictors of course and outcome in schizophrenia.

Factor	Good outcome	Poor outcome
Age at onset[1]	About 20–25	Below 20
CT/MRI studies[1]	Normal morphology	Dilated ventricles, brain atrophy
Initial clinical symptoms[1,2]	Catatonia, paranoia, depression, schizoaffective diagnosis, atypical symptoms, confusion	Negative symptoms (e.g., flat affect, poverty of thought, apathy, asociality); obsessive-compulsive symptoms
Occupational record[1]	Stable	Irregular
Onset[1]	Acute, late	Insidious
Rate of progression[1]	Rapid	Slow
Sex[1]	Possibly females	Possibly males
Length of episode prior to assessment[2]	Months or less	Years
Being in a developing country[3]	Present	Absent
Cannabis use[3]	Absent	Present
Optimal prenatal care[3]	Present	Absent
Precipitating factors[3]	Present	Absent
Socioeconomic status[3]	Middle, high	Low
Substance abuse[3]	Absent	Present
Stressful life[3]	Absent	Present
Early treatment with medications[4]	Present	Absent
Long term drug maintenance[4]	Present	Absent
Response to medications initially[4]	Present	Absent
Family history of mental illness[5]	Affective	Schizophrenia
Other adverse social factors[5]	Absent	Present
Prenatal adverse events[5]	None	Present
Presence of certain gene polymorphism e.g., COMT. NMDA2A[5]	Absent	Present

1 = Clinical; 2 = Diagnosis; 3 = Environment; 4 = Treatment; 5 = Genetic; adapted from Meltzer et al. 2008 (218); Perkins et al. 2006 (249).

Results from several long term reports studying outcome in schizophrenia show that over a 15 year period several disease courses may emerge: 1) 9–38% of patients will have a sustained recovery (249); 2) 10% of the patients will have a persistent unremitting course (249–252); 3) 67% of patients will have a good outcome (249, 250); 4) 32% of patients will have a poor outcome (249, 250); and 5) 10% will die by suicide (249). Generally, the overall prognosis of schizophrenia is more favorable now than before neuroleptics were introduced, mostly because of improvements in pharmacologic therapies and, to some degree, changes in psychosocial treatment strategies. The increased mortality in patients with schizophrenia today is the result of suicide, accidents, and diseases (e.g., infections, type II diabetes, heart disease, and in females, breast cancer) (249).

Schizoaffective and Schizophreniform Disorders

William Coryell, M.D.

Abstract The term "Schizoaffective Disorder" has been variously defined but has been generally applied to individuals in whom features of schizophrenia and a mood disorder coexist. Studies of phenomenology, clinical course, and heritability, have, when taken together, yielded results consistent with the view that a majority of individuals who meet criteria for schizoaffective disorder, in fact, have either schizophrenia or a mood disorder with psychotic features and that a minority suffer from a geneotypic concurrence of both illnesses. The treatment of individuals with schizoaffective disorder should initially assume the presence of a psychotic mood disorder, however.

Keywords Schizoaffective · Schizophrenia · Mood disorder · Family study · Follow-up study

7.1. Definition

Nosological ambiguity is a well-recognized impediment to progress in psychiatry and has been particularly so for the concept of schizoaffective disorder. This is due in part to the conceptual difficulty inherent in any intermediate or boundary category and in part to a series of shifts in the term's definition since operational criteria were introduced.

The Research Diagnostic Criteria (RDC) (1) provided the first definition that was both widely used and operational. These relatively inclusive criteria differed according to whether a manic or depressive syndrome was present but, in essence, required a full affective syndrome accompanied either by Schneiderian first-rank symptoms, by a history of mood-incongruent psychotic features "in the absence of" or "to the relative exclusion of" affective symptoms or by a history of delusions or hallucinations at a time when prominent manic or depressive symptoms were absent. The RDC definition has been used in more studies of schizoaffective disorder than any other single, definition. Yet it was supplanted, at least in the official American nomenclature, when the DSM-III assigned this term to a residual category for those who did not meet criteria for schizophrenia or a mood disorder but who appeared to have features of both. Moreover, the boundaries for major mood disorders were expanded so that many patients with RDC schizoaffective disorder met criteria in the DSM-III for major depression or mania with mood-incongruent psychotic features (2). The DSM-III-R provided operational criteria for the term but applied it only to patients who had had delusions or hallucinations without "prominent mood symptoms" for at least 2 weeks in the index episode. This definition survived largely intact in DSM-IV. The DSM-5 was modified to clarify the distinction between schizoaffective disorder and schizophrenia with the requirement that a major mood syndrome has been present for the majority of the total duration of the active and residual portions of the illness.

These circumstances recommend a generic use of the term *schizoaffective disorder* in any broad overview of the topic. Thus, the following will apply the term to any condition in which there is a coincidence of schizophrenic and affective symptoms or in which there is the occurrence of an affective syndrome at one point and a schizophrenic syndrome at another. At the same time, the full interpretation of any particular study's results requires attention to the definition of schizoaffective disorder used.

7.2. Etiology

Many medical conditions can produce symptoms that suggest schizoaffective disorder. Identification of a cause, however, precludes the diagnosis and, in the DSM-5, the diagnosis becomes one of a psychotic or mood disorder "due to the effects of a substance or another medical condition." The etiology of schizoaffective disorder is, by definition, unknown.

The question then becomes, does schizoaffective disorder share its unknown etiology with schizophrenia, with affective disorder, with both, or with neither? Or does schizoaffective disorder simply label a genotypically mixed group made up partly of mood disorder patients and partly of schizophrenic patients? Because both schizophrenia and the mood disorders are heritable, family studies offer one approach to weighing these alternatives. The relevant hypotheses can be tested in the following ways: (1) if schizoaffective disorder is simply a variant of affective disorder (3, 4), then schizoaffective probands will have no more familial loading for schizophrenia than do mood disorder probands; (2) if schizoaffective probands simply have a variant of schizophrenia, as is implied by the listing of schizoaffective disorder under schizophrenia spectrum disorders in both ICD-10 and DSM-5, their families will contain no more mood disorder than the families of schizophrenic probands; (3) if schizophrenia, schizoaffective disorder, and mood disorder all share a common etiology and form a spectrum, patients in any of these three categories will have relatives at increased risk for disorders in the other two categories; and (4) if schizoaffective disorder is a separate disorder, the first and second predictions listed above should apply and the families of schizoaffective probands will be loaded for schizoaffective disorder, provided this condition is, likewise, familial.

Table 7.1 summarizes informative studies published in English over the past 40 years. Because schizophrenia-like symptoms may have different implications when they coexist with depressive syndromes than when they coexist with manic ones (5–8), this review summarizes these studies in three groups: those that isolated probands with schizoaffective mania, those that isolated probands with schizoaffective depression, and those that did neither. This display serves to reveal overall patterns in group relationships. Many pairwise comparisons were statistically significant, but this information is omitted because statistical significance depends on sample sizes and these varied greatly across studies. For studies using DSM-III and DSM-IIIR systems, the schizoaffective proband group is comprised of patients who met the corresponding criteria for major depression or mania with mood-incongruent psychotic features or, more rarely, for schizoaffective disorder. The mood disorder proband groups consist of those with mood disorder with or without mood-congruent psychotic features.

Those studies that did not separate schizoaffective manic patients from schizoaffective depressed patients consistently failed to support the first hypothesis. In 11 of 11 studies, relatives of schizoaffective probands were more likely to have schizophrenia than were relatives of mood disorder probands. The same was true in 5 of the 6 studies that considered schizoaffective depression apart. Some earlier reports concerning schizoaffective mania supported the first hypothesis (4, 20, 21, 30), but later ones (16, 23, 31) showed patterns in line with those found in studies of schizoaffective depression.

Of those that included schizophrenia cohorts for comparison, all fourteen reported higher rates of mood disorder in the families of schizoaffective probands than in the families of schizophrenic probands. Thus the second of the hypotheses—that schizoaffective disorder is altogether a variant of schizophrenia—can be rejected.

The consistency with which schizophrenia was overrepresented in the families of schizophrenia probands, together with the regular predominance of mood disorder in the families of mood disorder probands, argues against a spectrum hypothesis. Moreover, those few studies which have included normal control probands have generally shown no increase in mood disorder within families of schizophrenic probands (28, 29, 32) nor any increase in schizophrenia within the families of mood disorder probands (28, 29, 32).

Studies of twins and of sib-pairs offer another way to investigate schizoaffective disorder. If most schizoaffective cases result from a "third psychosis" there should be few affected twins or sib-pairs in which one member has schizoaffective and the other has schizophrenia or mood disorder. An early study, in fact, did find a 100% concordance for schizoaffective disorder (33). The same raters assessed members of both twin- pairs, though, and were, therefore, subject to bias. In contrast, Tsuang (34) conducted blind assessments of sib-pair members and, of the 35 pairs concordant for any psychosis, only 4 (11.4%) were concordant for schizoaffective disorder. Of 17 siblings with schizoaffective disorder, 5 (29.4%) had a co-sibling with schizophrenia, 8 (47.1%) had a co-sibling with a mood disorder, and only 4 (23.5%) had a co-sibling with schizoaffective disorder. Moreover, those schizoaffective siblings with mood disorder co-siblings were significantly older at onset of illness than were the schizoaffective siblings with schizophrenic co-siblings. These findings are quite consistent with a fifth hypothesis, that some schizoaffective patients are genotypically schizophrenic while others comprise genotypes for mood disorder.

Similarly, Cardno et al (35) described twin-pairs of individuals with schizophrenia, schizoaffective or manic disorder. Of the 32 in which one of the pair had schizoaffective disorder, the co-twin had mania in 13 (40.6%) of the cases, schizophrenia in 10 (31.2%), and schizoaffective in 9 (28.1%). Model fitting indicated the genetic liability to the schizoaffective syndrome was "entirely shared in common with the other two syndromes." Another analysis of this cohort showed a high heritability (71%) of a lifetime history of one or more Schneiderian first-rank symptoms (36).

Finally, Laursen et al. (37) conducted a register-based cohort of 2.4 million Danes and found that the existence of a first-degree relative ever admitted with a diagnosis of ICD-8 or ICD-10 schizoaffective disorder increased an individual's risk

[b]% Family history (FH) positive = no. of probands with a family history of a disorder/total number of probands.

of being admitted for schizoaffective disorder by a factor of 1.8. A family history of schizoaffective disorder, however, also increased risks for admissions with bipolar disorder or schizophrenia by factors of 2.9 and 3.6, respectively.

Efforts to weigh the relative merits of the first four hypotheses are complicated by the growing consensus that schizophrenia and bipolar disorder probably share some predisposing alleles (38, 39). Indeed, the results of the multiple family studies, together with those of twins and sib-pairs yield no clear support for any of them. Instead, the fifth "heterogeneity" or "diagnostic uncertainty" hypothesis appears to afford the best fit. Patients with this label may, for practical purposes, be viewed in terms of the likelihood that they suffer from either schizophrenia or mood disorder. There are undoubtedly also patients with this label who are suffering from both illnesses. The prevalence figures for psychotic mood disorder and for schizophrenia indicate that such coincidences are rare and probably account for a small proportion of patients with schizoaffective disorder. This rarity, and the lack of any clear means with which to identify such a subgroup, limits the practical significance of its existence.

TABLE 7.2. Rates of illness among relatives of probands with RDC schizoaffective disorder divided by subtype.

	Proband diagnosis	
	Mainly schizophrenic	**Mainly affective or other**
Baron et al., 1982 (15)

MR% for schizophrenia	4.1	0
MR% for mood disorder	10.9	28.1
Kendler et al., 1986 (40)		
No. of probands	19	28
MR% for schizophrenia	8.2	3.8
MR% for mood disorder	7.3	14.5

On the other hand, the likelihood that most schizoaffective patients have schizophrenia or mood disorder gives considerable importance to subdivisions within schizoaffective disorder. Within the mood disorders, the bipolar/unipolar distinction is well supported by family and outcome studies and is widely accepted. Its application to a group that is substantially comprised of individuals with mood disorder thus seems reasonable. Another intuitively compelling subdivision is based on the relative predominance of schizophrenic or affective features. In the RDC, schizoaffective patients who exhibit mood-incongruent psychotic features for at least 1 week without manic or depressive symptoms, or who have premorbid features suggesting schizophrenia, have the "mainly schizophrenic" subtype. The results of at least two family studies clearly support this distinction (see Table 7.2).

The DSM-IV definition of schizoaffective disorder closely resembles the RDC mainly schizophrenic subtype in that it requires a period of delusions or hallucinations without prominent mood symptoms. DSM-IV major affective disorder with mood-incongruent psychotic features, in turn, closely approximates the RDC mainly affective subtype. Not surprisingly, the only family study of DSM-IIIR schizoaffective disorder available as of this writing (29) replicates the patterns displayed in Table 7.2. The relatives of schizoaffective probands had twice the rate of schizophrenia as the relatives of probands with major depression and mood-incongruent psychotic features (morbid risk was 8.7% and 3.8%, respectively) and one-half the rate of major mood disorders (morbid risk was 2.4% and 6.5%, respectively). Notably, both Kendler et al. (40) and Maj et al. (29) provided values for normal controls.

In comparison with those controls, RDC mainly schizophrenic probands (40) and DSM-IIIR schizoaffective probands (29) had no increase in familial loading for affective disorder. Pending further replications of these patterns, we may conclude that the large majority of patients who meet these narrow definitions of schizoaffective disorder, in fact, have schizophrenia. Groups with RDC mainly affective schizoaffective disorder or with DSM-IIIR major depression and mood-incongruent psychotic features apparently retain substantial heterogeneity; familial rates of schizophrenia were substantially higher in both studies (29, 40), though not significantly so, than the rates for normal controls.

7.3. Epidemiology

Most community surveys have not described rates of schizoaffective disorder. Given the many definitions in use and the low concordance across these definitions (41), such rates would have been widely disparate. The National Institute of Mental Health (NIMH) Epidemiologic Catchment Program (42) encompassed a very broad base, but published results have used DSM-III, and as noted above, this system leaves schizoaffective disorder as a residual, non-operationalized category. Of two community surveys that used the RDC, Weissman and Myers (43) found a 0.4% lifetime prevalence for RDC schizoaffective disorder, whereas Vernon and Roberts (44) found 0.8%. These figures were based on only three and four cases, respectively, however, and the individuals were not ill when interviewed.

Brockington and Leff (41) found 10 patients who met at least three of eight definitions for schizoaffective disorder from approximately 222 consecutive admissions; 6 (2.7%) met RDC for schizoaffective disorder (1 manic and 5 depressed). These figures are similar to those derived from all consecutive admissions seen over a several year period at the University of Iowa; of 388 patients, 11 (2.8%) met RDC for schizoaffective disorder (Coryell, unpublished data). In a subsequent series of 97 consecutively admitted non-manic psychotic patients, 48.4% had RDC schizoaffective disorder, depressed type (45). In the same series, only 21 met RDC for schizophrenia. Thus, while conditions meeting one or more definitions for schizoaffective disorder may be rare in the community, they comprise a large portion of psychotic patients who come to treatment.

Some have used prevalence data to address an additional epidemiologic hypothesis—that schizoaffective disorder represents the chance coexistence of schizophrenia and affective disorder. According to Brockington and Leff (41), this chance coexistence should occur only once in a year in Great Britain, yet they found 10 in 1 year in only three hospitals.

7.4. Clinical Picture

A description of the clinical picture seen in schizoaffective disorder is necessarily circular. Most definitions of schizoaffective disorder depend entirely on the clinical picture, and since these definitions vary so markedly (41), the associated clinical picture also will vary depending on the label. By definition, then, patients with RDC schizoaffective disorder, and those with DSM-III or DSM-IIIR mood disorder and mood-incongruent psychotic features, can exhibit in cross section any symptom characteristic of mood disorder. Such a patient may report low mood, anorexia, insomnia, fatigue, and thoughts of suicide, as well as thought broadcasting, delusions of passivity, and hallucinations in any sphere. He or she may also exhibit euphoria, hyperactivity, recklessness, and grandiosity, as well as a blunted affect, bizarre behavior, catatonia, and loose associations. By definition, schizoaffective disorder differs from mood disorder because of the presence of schizophrenic features. In turn, the presence of affective symptoms distinguishes schizoaffective disorder from schizophrenia.

Phenomenological differences may extend further, however. In one study, patients with RDC schizophrenia had delusions that were significantly more bizarre than those reported by schizoaffective patients. Schizophrenic patients also were more likely to exhibit loosening of associations and a blunted or inappropriate affect (45). Moreover, when compared with patients with psychotic major depression, schizoaffective patients reported a lesser severity of 12 depressive symptoms, and these were largely confined to endogenous rather than nonendogenous depressive symptoms. This difference in endogenous symptom severity emerged in another sample as well (46). Thus, broadly defined, *schizoaffective depression* designates patients who have depressive syndromes that are less typical than those of patients with psychotic depression and schizophrenic symptoms that are less typical than those of schizophrenic patients. These patterns support a "heterogeneity" hypothesis.

Because these patients suffer from a psychosis, an associated loss of insight, and often, a psychomotor disturbance, many are poor historians. This deserves special emphasis because, at the time of admission, affective symptoms may be altogether overshadowed by the patient's delusional preoccupation, hallucinations, or bizarre behavior. Indeed, at this point such patients often deny mood symptoms that they later recall and that other informants describe when questioned carefully. The distinction between affective, schizoaffective, and schizophrenic psychosis, therefore, must not depend on the patient interview alone. In all cases the clinician must seek knowledgeable informants to learn whether affective symptoms preceded the psychotic ones. Serial interviews of the patient are also more useful than is generally appreciated (47).

7.5. Clinical Course

The prognosis for schizoaffective disorder appears to be worse than that for mood disorder (see Table 7.3), although a small number of studies have yielded results to the contrary. Proportions with good outcomes vary widely across studies, and this reflects such methodological particulars as the length of follow-up and the definitions of good outcome. The prognostic differences between schizoaffective and mood disorders also vary and appear to reflect important differences in how schizoaffective disorder is defined. Specifically, schizoaffective patients so identified because of the persistence of schizophrenia-like symptoms between affective episodes, as in DSM-IV, may constitute a different group from those defined solely by the presence of first-rank symptoms in the midst of an affective syndrome. The studies finding the largest outcome differences between mood disorder and schizoaffective disorder were those which defined the latter disorder by the persistence of schizophrenia-like symptoms between affective episodes (48–52). In contrast, one of the few studies finding a superior outcome for schizoaffective disorder explicitly excluded subjects with "long periods of psychosis in the absence of an affective syndrome" (21).

As the occurrence of psychotic features outside of affective episodes portends the eventual chronicity of psychotic features, so does the presence of psychotic features within the affective syndrome appear to predict the persistence of affective symptoms. This seems to be equally so whether psychotic features accompany manic or depressive syndromes (8). Among affectively ill individuals with psychotic features the quality of those features has added prognostic importance. A review of thirteen studies that compared mood-congruent and mood-incongruent psychotic features consistently showed at least a somewhat poorer outcome for patients with mood-incongruent features (72).

The heterogeneity that remains among patients with affective illness plus mood-incongruent psychotic features has rarely been explored but may have prognostic relevance. Conus et al (73) showed this when they described 12-month outcomes among patients with psychotic mania. After adjustment for age, sex, age-of-onset, and duration of psychotic symptoms, the presence of first-rank symptoms was predictive of a poorer quality of life scores and greater negative symptoms while the presence of mood-incongruent psychotic features per se failed to predict any of the five outcome measures.

Because lithium is generally thought to be effective in mania and much less so in schizophrenia, acute and prophylactic response to this drug affords another view of the variability within schizoaffective disorder. With one exception, lithium studies that have described five or more patients with schizoaffective mania have reported poorer responses in that group than in more typically manic groups (see Table 7.4). Subdivisions within schizoaffective groups are probably very meaningful to response

prediction, but few studies have considered them. Maj (74) did find that the RDC subtyping strongly predicted prophylactic response to lithium. Those with the mainly affective subtype, but not those with the mainly schizophrenic subtype, showed a significant reduction in number of episodes with lithium therapy.

Such comparisons serve to summarize the literature but their simplicity can be misleading since there are many shades of "response," "improved," and "recovered." In light of the most tenable hypothesis on etiology, some schizoaffective patients should have a course typical of psychotic affective disorder; the psychosis may be profound, but eventual recovery is complete.

TABLE 7.4. Outcome with lithium therapy in patients with schizoaffective (or equivalent) mania: comparisons to patients with manic disorder.

Others may display a waxing and waning of symptoms, which might be perceived initially as recovery and relapse but which eventually evolves into the chronicity and avolition characteristic of narrowly defined schizophrenia. Patients, as well as families and physicians, need to know which course is more likely for a given individual.

Findings from the National Institute of Mental Health Collaborative Program on the Psychobiology of Depression bear directly on this issue (6, 7). These analyses sought to predict the presence or absence of a persistent psychosis 5 years in the future for patients who presented with psychotic affective or schizoaffective disorders. Overall, such outcomes emerged in 24 individuals, or 14 percent of the sample. For patients who were depressed at intake, only a history of mood-incongruent psychotic features to the relative exclusion of depressive symptoms significantly and independently predicted persistent psychosis (6). Among those who were manic at intake, significant and independent predictors consisted of a history of any formal thought disorder in the absence of prominent manic symptoms, loosening of associations, and greater global severity at intake. When manic and depressed patients were pooled (7), a stepwise regression analysis revealed the following independent predictors of a sustained psychotic outcome, in order of robustness: longer duration of index episode, history of psychotic features that had occurred at some point in the absence of (or to the exclusion of) affective symptoms, poor adolescent friendship patterns, having never been married, and the absence of a history of mania. Few other reports have attempted to predict schizophrenia-like outcomes in such a sample, but the most important of these yielded very similar results. Brockington et al. (68) selected as the single most valuable predictor of such an outcome "the presence of schizophrenic symptoms in the absence of affective symptoms."

Early work with the dexamethasone suppression test (DST) suggested a high level of specificity for psychotic depression and it appeared to hold promise as a clinically useful diagnostic tool. Subsequent research showed that nonsuppression rates among schizophrenics, while consistently lower than those for patients with psychotic depression, are nevertheless higher than those for normal controls (80). It now appears that nonsuppression among individuals with narrowly defined schizophrenia has a different meaning from nonsuppression among patients with psychotic depression or mania. In particular, nonsuppression among

schizophrenic patients appears to be associated with relatively prominent negative features (81–84). Nonsuppression may nevertheless have prognostic significance among other patients with depression and psychotic features, i.e., those with psychotic major depression or schizoaffective depression. Two studies (85, 86) have found that among such patients, nonsuppressors are substantially more likely to be free of psychotic features at the end of follow-up (1 and 8 years, respectively). Another reported that nonsupression occurred in four of five individuals with baseline diagnosis of schizophrenia but with a follow-up diagnosis of schizoaffective disorder. Nonsuppression occurred in only two of the seven of those whose diagnosis shifted from psychotic major depression to schizoaffective disorder (87). The DST was not predictive in another follow-up study of schizoaffective disorder (88) but this sample included only four nonsuppressors and the analysis did not use persistent psychosis as an outcome measure.

7.6. Differential Diagnosis

As with other conditions seen by psychiatrists, the differential diagnosis when affective and psychotic symptoms coexist should begin with the distinction between conditions that arise from demonstrable lesions (due to medical conditions) and those that do not. Depressive, manic, and schizophrenic syndromes can be produced by a variety of identifiable insults, and the differential diagnosis for each of these conditions is provided in more detail in the corresponding chapters. With those other possibilities in mind, there are several general features that should increase the suspicion that psychiatric symptoms are arising from a medical condition. "Depression" with only two or three of the possible eight criteria symptoms should raise such suspicions, as should the appearance of affective or psychotic symptoms in an elderly individual with no prior psychiatric history. Confusion that is out of proportion to the depressive symptoms and that features approximate answers rather than refusal or reluctance to answer also increases the possibility of medical illness as etiology. Likewise, "catatonia" in an individual with no recent or remote history of affective disorder or schizophrenia should be considered undiagnosed until a full syndrome can be identified.

Several conditions are of particular note in the differential diagnosis of schizoaffective syndromes. High doses of exogenous steroids may produce conditions in which symptoms of mood disorder, schizophrenia, and delirium alternate rapidly. Liability to this condition is dose-related, and symptoms typically resolve within 3 weeks, rarely lasting longer than 6 weeks (89). The crucial feature here is the history of high doses of steroids preceding the onset of the symptoms. Because this history is almost always apparent, diagnosis is usually not a problem. Patients with persistent symptoms, particularly those with a prior history of similar symptoms not preceded by steroid ingestion, may, however, have a purely functional condition (89).

Amphetamines and other sympathomimetics may produce hyperactivity, euphoria, racing thoughts, and pressured speech typical of mania shortly after ingestion. A "crash" may occur after several days of continuous amphetamine ingestion and often features dysphoria, hyperphagia, hypersomnia, and irritability—a picture that may resemble depression. These conditions rarely, of themselves, lead individuals to seek psychiatric help. Between these two phases of amphetamine intoxication, however, a psychosis may emerge that is indistinguishable from paranoid schizophrenia in cross section. Delusions typically resolve within several days to 1 or 2 weeks, and simple observation over this period usually clarifies the diagnosis.

Phencyclidine (PCP) intoxication may be more difficult to recognize. The diagnosis is frequently missed, even by those who are familiar with its presentation (90). This may be due in part to the protean nature of the symptoms; paranoid delusions with a clear sensorium may alternate with marked depressive symptoms, or these syndromes may coexist with or without evidence of delirium. However, this condition often involves certain physical symptoms that may help to distinguish it from functional psychosis—slurred speech, ataxia and nystagmus, ptosis, hypertension, analgesia, and hyperreflexia. The level of suspicion also should depend in large part on the patient's demographic features and the pattern of drug use in the patient's subculture.

Temporal lobe epilepsy also may produce affective psychosis, schizophrenia-like psychosis, or a mixture of the two (91), and the syndromes can closely resemble their functional counterparts (92). In only 3 of the 69 cases described by Slater and Beard (92) did the psychosis and epilepsy begin in the same year; in all other cases the psychosis followed the epilepsy, usually by many years. Thus the likelihood that epilepsy lies at the base of a new case of psychosis is greatly reduced when there is no history of clinically manifest seizures.

7.7. Treatment

Clinicians should consider the hypotheses described previously when selecting treatment. The most efficient approach, the one most consistent with follow-up and family history data, assumes that a schizoaffective patient has either schizophrenia or mood disorder. The clinician must weigh the probability of one of these illnesses over the other using all available data—demographics, present and past psychopathology, premorbid or prodromal features, and family history.

Emphasis should be given to the mood disorder alternative, particularly in treatment-naïve patients, since treatment of mood disorders is generally more specific than treatment of schizophrenia. For instance, ECT is much more effective for psychotic depression than for schizophrenia, and the prophylactic value of lithium in mood disorder is clearly established, while there is relatively little support for its use in schizophrenia. In contrast, antipsychotics ameliorate psychotic symptoms regardless of the underlying disorder. Because of the long-term risk of tardive dyskinesia with typical antipsychotic treatment, and of dyslipidemias and weight gain with atypical antipsychotics, other more specific approaches—lithium, antidepressants, and ECT—should be given preference unless indications for chronic antipsychotic treatment are clear.

A recent meta-analysis has shown that a combination of antidepressant and antipsychotic is more effective in the treatment of psychotic depression than is monotherapy with either drug class (93). Numbers needed to treat (NNT) were 7 for the combination treatment compared to antidepressant monotherapy and 5 for a combination therapy compared to antipsychotic monotherapy. The question of how long combination treatment should be maintained is an important but currently open question.

In the absence of clear indications for long-term use of antipsychotics, these drugs should be discontinued gradually when delusions remit. The clinicians should then determine whether a mood stabilizer or an antidepressant is likely to provide adequate protection against relapse. This requires careful surveillance, particularly in the first 6 months, when the risk of relapse is the highest (94). Because relapse is likely to involve a loss of insight, the family's help will be important in this effort. After one or more episodes, they are likely to learn the early warning signs and be able to help the patient to seek early intervention.

More judgments are necessary when relapse does occur. Was the relapse preceded by poor compliance? If so, does the patient find the side effects peculiar to that drug intolerable, or does he or she simply require more time to develop the acceptance and habits necessary for adequate compliance? In the case of bipolar disorders the options for effective prophylaxis are limited and it is important not to abandon a given drug prematurely. Also, it must be remembered that prophylactic efficacy may require time to develop. In fact, maintenance therapy may take several years to show clear protective effects for depression or mania (95).

7.8. Schizophreniform Disorder

Langfeldt coined the word schizophreniform in 1939 (96) to describe schizophrenia-like psychoses with relatively good prognoses. He intended this to be a heterogeneous group that would include "exogenically precipitated psychosis" (97). Indeed, the words schizophreniform and schizoaffective have been used interchangeably through much of the subsequent literature. In DSM-5, however, individuals who meet criteria for schizoaffective disorder are excluded from these diagnoses. Either no major mood episodes have occurred during the period of illness, or if they have, the major mood syndrome has been present for a minority of the total duration of the illness. Criterion A for schizophreniform disorder is identical to Criterion A for schizophrenia but the duration for schizophreniform disorder is less than 6 months. DSM thus sets schizophreniform disorder apart both from mood disorder with mood-incongruent psychotic features and from schizoaffective disorder. This departure from convention must be borne in mind in any review of recent literature on atypical schizophrenia. The preceding section under schizoaffective disorder describes schizophreniform disorder equally well, according to the definitions in use before DSM-III. This section is, therefore, restricted to studies using the DSM definitions.

Table 7.5 summarizes the studies that described at least 10 patients with schizophreniform disorder and that included comparisons with other diagnostic groups. Nine of ten studies suggest that, like schizoaffective disorder, schizophreniform disorder defines an intermediate or heterogeneous group (45, 98–101).

In some cases, though, the comparison measures placed schizophreniform disorder closer to schizophrenia though in others, schizophreniform disorder had a closer resemblance to the mood disorders.

Consensus may not be forthcoming for several reasons. First, the proportion of mood disorder comparison groups with psychotic features probably differs across studies and psychotic features themselves have adverse effects on outcomes (6–8). Second, the distinction between schizophrenia and schizophreniform disorder often hinges on the presence of a prodromal syndrome and many of the components of this syndrome (i.e., social isolation, blunted affect, and digressive speech) shade gradually into the normal spectrum of behavior. Acutely psychotic patients are often unable to give valid accounts of such features in retrospect. Affective syndromes may also be difficult to assess in patients who are delusional or hallucinating. Even when such patients report typical depressive symptoms, these are often attributed to understandable effects of acute psychosis. A careful history taken from knowledgeable informants will remedy these problems to some extent. Unfortunately, few studies describe the availability of such informants or the thoroughness with which they were interviewed. Reasons for discordance across these studies are, therefore, hard to trace.

In light of this, the clinician must maintain doubtfulness about the true nature of schizophreniform disorder in a given case. As with schizoaffective disorder, the clinician should use all the clinical data available to weigh the likelihood of schizophrenia over an affective disorder, giving at least initial weight to the presumption that the overall course and treatment response will ultimately suggest a mood disorder.

TABLE 7.5. DSM-IIIR schizophreniform disorder: studies of validity[a].

Study	No. with SF	Comparison groups	Design	Results
Coryell and Tsuang, 1982 (25)	93 (of 810 admissions studied: 11.5%)	86 bipolar MD 203 unipolar MD 214 S	Chart follow-up averaging 3.1 years; family history study	16% of SF patients recovered vs. 8% of S patients and 58% of MD patients; SF resembled S patients more than MD patients in terms of MR for S and MD
Weinberger et al., 1982 (102)	35 (of 128 with CT scans: 27.3%)	17 S 23 mood disorder 27 other disorders 26 neurologic controls	Computed tomographic study (CTs routinely obtained)	SF group had distribution of ventricular to brain ratio indistinguishable from those for S group, significantly less than controls, less (but not significantly) than other psychiatric illnesses
Targum, 1983 (101)	21 (of 145 admissions: 14.5%)	86 MD 24 other disorders 14 S	Neuroendocrine evaluation (DST and TRH-ST) with 6-month follow-up of only SF patients	% with: +DST, Blunted TRH-ST MD 44 32 SF 24 29 S 7 7 Neuroendocrine test results predicted outcome among SF patients
Coryell and Zimmerman, 1986 (69)	93	298 MD 219 S	Systematic follow-up of 40 years	SF patients were significantly more likely than MD patients, but only slightly less likely than S patients, to be symptomatic at follow-up
Makanjuola and Adedapo, 1987 (103)	34	66 S	25–38 months follow-up	16% of SF and 43 % of S actively psychotic or residual symptoms of schizophrenia on follow-up
Beiser et al., 1988 (98)	29 (of 575 patients with nonorganic psychosis: 4.5%)	60 S 73 MD	Systematic follow-up of 18 months	18 (62.1%) re-diagnosed as schizophrenic on follow-up; 8 others (27.6% of the sample) had recovered
Kendler and Walsh, 1995 (104)	18	126 S	Follow-up and family study	SF had better functioning on follow-up than S, similar to MD; SF had less S in relatives than those of S probands but more than controls
Fennig et al., 1994 (105)	11	57 S	Diagnostic stability over months follow-up	7 (63.6%) retained SF diagnosis; 3 (27.3%) re-diagnosed as S
Schimmelman et al., 2005 (106)	190	113 S 34 schizoaffective 13 MD	Diagnostic stability over 18 month follow-up	Only 76 (40.0%) retained SF diagnosis; 100 (52.6%) re-diagnosed as S
Whitty et al., 2005 (107)	15	31 psychotic MD	4-Year follow-up	67% of SF and 16% of MD groups had final diagnosis of S
Naz et al., 2003 (108)	34	128 S	2-Year follow-up	SF significantly more likely to have remission at 6+24 months than S

[a]*MD* mood disorder, *SF* schizophreniform disorder, *S* schizophrenia, *DST* dexamethasone suppression test, *TRH-ST* thyroid-releasing hormone stimulation test.

Delusional Disorders

Marc-André Roy, M.D., FRCPC*

Abstract Delusional disorders are characterized by delusions in the absence of any other psychiatric illness that could account for the delusional thought processes. DSM-5 lists erotomanic, grandiose, jealous, persecutory, somatic, mixed, and unspecified subtypes. The prevalence of delusional disorders has been estimated to be 0.18 %. The available evidence does not suggest a shared predisposition with either schizophrenia or mood disorders, but very little is known about its neurobiology. The course of the illness is highly variable; some cases recover rapidly and completely but in others it runs a chronic course. Conditions to be excluded before diagnosing a delusional disorder include paranoid schizophrenia, psychotic mood disorder, dementia, drug-induced psychotic disorder, paranoid personality disorder, and hypochondriasis. Pimozide has been the preferred antipsychotic agent for delusional disorders, particularly the somatic subtype, but in recent years there has been a steady trend toward treating delusional disorders with second generation antipsychotic agents. Some therapists are now using cognitive-behavioral therapy in these patients as well.

Keywords Delusion · Persecutory delusional disorder · Jealous delusional disorder · Grandiose delusional disorder · Delusional parasitosis

8.1. Definition

Delusions are among the most common psychotic symptoms. Forty-eight percent of manic patients and 33 percent of bipolar depressives are delusional (1), and practically all patients with schizophrenia experience delusions at some time during the course of their illness. Therefore, if the concept of a delusional disorder is to have any validity as a diagnostically pure group, it must be defined by delusions in the absence of other psychiatric illness that might account for the delusional thought process. Delusions are false beliefs based on an idiosyncratic interpretation of reality; they are rigidly adhered to so that contradictory evidence is reinterpreted in a manner consistent with the belief rather than the belief being modified by the evidence.

The term *paranoia* dates back to Hippocrates, but Kahlbaum in 1863 was the first to use it to designate a diagnostically separate group of disorders that remained so over their course (2, 3). Kraepelin in 1921 further developed the concept of paranoia as a chronic and unremitting system of delusions that was distinguished from schizophrenia by the absence of hallucinations and other psychotic features. These ideas were incorporated into the first diagnostic manual (DSM-I) of the American Psychiatric Association (4). Paranoid reactions were defined as illnesses with persistent persecutory or grandiose delusions, ordinarily without hallucinations, and with emotional responses and behavior consistent with the ideas held. Subtypes included paranoia, a chronic disorder characterized by an intricate and complex delusional system, and paranoid state, usually of shorter duration and lacking the systematization of paranoia. These concepts of paranoid disorders and their subtypes have been preserved in all their essential features by DSM-II (5) and in DSM-III (6) as Paranoia and Acute Paranoid Disorder.

*This is a revised version of a previous chapter co-authored with Dr. R.R. Crowe.

e-mail: marc-andre.roy@crulrg.ulaval.ca

S.H. Fatemi and P.J. Clayton (eds.), *The Medical Basis of Psychiatry*, DOI 10.1007/978-1-4939-2528-5_8

Beginning with DSM-III-R, continuing in DSM-IV and then DSM-5, the paranoid disorders were renamed *delusional disorders*, because of the confusion arising from the use of the term paranoia in its narrow meaning, e.g., persecutory delusion (7–9). The delusional disorders have been expanded to include persecutory, erotomanic, grandiose, jealous, somatic mixed, and unspecified types. As will be explained below, with the advent of DSM-5, the somatic subtype has a more restrictive definition, due to which pre-DSM-5 literature on this entity may not generalize to the now more restricted category.

International Classification of Diseases (ICD)-10 has also adopted the term *delusional disorders* to replace the *paranoid states* used in ICD-9 and classifies it under *Persistent Delusional Disorders* (10). No subtypes of delusional disorder are specified, but *Other Persistent Delusional Disorders* includes delusional dysmorphophobia, involutional paranoid state, and paranoia querulans.

Both DSM-5 and ICD-10 require delusions in the absence of schizophrenia, mood disorder or a toxic, metabolic or neurological disorder. DSM-5 requires a minimum duration of 1 month, and ICD-10 specifies that the delusions be present for a "few months." DSM-5 further specifies that functioning is not markedly impaired and behavior not odd or bizarre, apart from the impact of the delusion. Occasional auditory hallucinations do not exclude the diagnosis by either set of criteria, as long as they are not prominent. Folie á Deux, was no longer classified as a delusional disorder but as a separate psychotic disorder: *shared psychotic disorder* in DSM-IV, and was dropped from DSM-5, while remaining as *induced psychotic disorder* in ICD-10.

8.2. Epidemiology

Delusional disorders are encountered infrequently in general psychiatric practice, but this may be an under-representation of their true prevalence because these individuals tend to avoid psychiatric assessment due to their lack of insight and may escape clinical attention in the context of absence of grossly disturbed behavior. There are clear indications that delusions of parasitosis are not rare in dermatology clinics (11). Moreover, several surveys have shown that delusion-like beliefs may be frequently found in the general population (12). Thus, it is difficult to have a clear picture of the epidemiology of these disorders, and any numbers reported are likely to be underestimated.

Numbers traditionally provided in the literature illustrate this probable underestimation. Indeed, the prevalence has been traditionally estimated to be 24–30 cases per 100,000 population (i.e., 0.024–0.030%) and their annual incidence to be at 0.7–3.0 new cases per 100,000 population (13). These numbers contrast with newer data from Finland (14), using a very comprehensive sampling strategy and ascertaining psychiatric diagnoses from several sources of information, which support that delusional disorders may be considerably more frequent, with lifetime prevalence estimated at 0.18%. Despite the fact that the numbers are 6–7.5 times higher than the traditional estimates reported above, the authors considered that these higher numbers may still underestimate the true prevalence of delusional disorder given the difficulty to identify such cases in a single interview due to the often plausible character of the delusional beliefs encountered in delusional disorders.

Delusional disorders are most likely to appear in mid-life. Age at onset and age at first admission both peak in the fourth to fifth decade and range from adolescence to senescence. The sexes are affected approximately equally, although studies have found a slight excess of females, 55 percent of first admissions being women (13).

8.3. Etiology and Pathophysiology

Delusional disorders have been a relatively neglected area of psychiatric research, and consequently, the literature on etiology is quite limited, typically consisting of case series. Because schizophrenia and depression can both present with delusions, the question arises whether delusional disorders represent a separate group of disorders or simply atypical forms of these more common conditions. This question is important because of the obvious treatment implications.

If delusional disorders were a form of either schizophrenia or mood disorders, the incidence of these latter conditions should be increased in the families of delusional disorder patients, but this has not been found. Indeed, available studies have found, in relatives of delusional disorder probands, rates of schizophrenia and mood disorders that did not differ from those reported in the general population. Kendler and Walsh (15) found that the rates of schizophrenia, schizophrenia spectrum disorders, and affective illness in the relatives of eight patients with delusional disorder did not differ from the rates found among relatives of controls. Since only 59 relatives of delusional disorder probands were assessed by interview or hospital records, the power of the sample to detect differences was limited.

Reanalysis of data from a large adoption study of schizophrenia did not find a higher rate of delusional disorders in the biologic relatives of schizophrenic adoptees than in other groups of relatives (adoptive relatives of the same adoptees and biologic and adoptive relatives of control adoptees) (16). The observations indicate that Kahlbaum's original concept of paranoid disorders as uncommon but distinct entities may be correct since they appear genetically distinct from the other psychoses.

TABLE 8.1. Family history of delusional disorder.

	Simple delusional	Hallucinatory delusional	Paranoid schizophrenia
Number of cases	101	38	118
Number of relatives	643	285	653
Affective disorder (%)	1.6	1.8	2.1
Schizophrenia (%)	0.5	1.8	1.5
Paranoid traits (%)	2.3	1.1	0.6

Crowe, RR: unpublished data.

However, it should be stressed that these genetic epidemiological studies of delusional disorders typically relied on small samples and/or on diagnoses in relatives based on the family history method (i.e., diagnoses based on information from relatives) rather than on direct interviews with the relatives. Such limitations warrant cautiousness before definitely concluding that delusional disorders are genetically unrelated to schizophrenia.

While there is no evidence suggesting that delusional disorders overlap genetically with either mood or schizophrenic disorders, there is some evidence suggesting an excess of paranoid disorders or traits in relatives of delusional disorder patients. These findings suggest that these two conditions may be genetically related. Our own unpublished data (see Table 8.1) confirm these findings. We reviewed the medical records of 257 patients with either simple delusional disorders, hallucinatory delusional disorders, or paranoid schizophrenia. We reviewed all available information on relatives and assigned them blind diagnoses. As can be shown, the relatives of patients with simple delusional disorders were characterized by a higher prevalence of paranoid traits and a lower frequency of schizophrenia compared with the relatives of schizophrenic subjects, while the relatives of hallucinatory patients were between these two groups. However, only the rates of paranoid traits reached statistical significance. It should also be emphasized that such paranoid traits have also been found to co-aggregate with schizophrenia.

Very little information on the neurobiology of delusional disorders is available. A structural magnetic resonance imaging study found larger ventricles in late onset delusional disorders compared to late onset schizophrenia, both groups having larger ventricles than normal controls (17). A study of eye tracking performance reported deficits in delusional disorders similar to those reported from other research on schizophrenia (18). Together, these studies do not suggest qualitative differences concerning the neurobiology of delusional disorders compared to that of schizophrenia, although there are insufficient data to draw any firm conclusions. More recently, studies on the cognitive processes leading to delusions have received some attention, although more so in the context of schizophrenia than in the context of delusional disorders. These studies have proposed that some cognitive biases (e.g., jumping too rapidly to conclusions or a higher sensitivity to threat) may be the mechanism through which delusions occur (19).

8.4. Clinical Picture

The hallmark of the delusional disorders is the delusional system. This consists of a unique set of false ideas that are rigidly adhered to despite all contradictory evidence. The uniqueness of the delusion distinguishes these patients from persons with idiosyncratic ideas shared by a larger social group, such as a religious cult. The fixed quality of the delusion also separates them from nondelusional persons with unusual ideas. A third feature of delusions is that facts are reinterpreted to fit the delusion, rather than the delusion being modified to fit the facts. The delusion is thus characteristically fed by constant misinterpretations of the facts. It is important to emphasize that the chronic delusional patient does not base the delusional beliefs on hallucinations. For example, the paranoid patient on seeing persons laughing will think they are laughing at him or her. The perception of persons laughing is correct; it is the interpretation of the perception that is abnormal.

The delusions of delusional disorders are usually systematized and encapsulated to varying degrees. *Systematization* refers to the ramifications of the delusional system being connected by a common theme. *Encapsulation* refers to thought processes outside the delusional system remaining unaffected. As the French psychiatric tradition has emphasized, delusions can vary quite a lot in their degree of *extension*. This term refers to the extent of ramification. For example, an *unextended* delusion would be limited to a relatively small sphere of the person's life, while an *extended* delusional system might infiltrate most of the person's activities. However, even in these extreme cases, thought processes outside the delusional system remain unaffected.

DSM-IV stipulated that in delusional disorders the quality of the delusions was not bizarre and considered delusions bizarre if they were "clearly implausible, not understandable, and not derived from ordinary life experiences" (8). However, the reliability of the distinction between bizarre and non-bizarre delusions has been shown to be very poor (20) because of which this criterion was dropped in DSM-5, although DSM-5 includes a specifier to be rated when delusions are deemed bizarre (9).

Many delusional disorders are accompanied by hallucinations which, however, should not be sufficiently prominent to justify a diagnosis of schizophrenia; somatic hallucinations are recognized to be important features in several cases of delusional infestation.

When a thought disorder is present, it is not prominent and does not affect communication as does the thought disorder often observed in schizophrenia. Winokur (21) found loquacity and circumstantiality in 30% of his cases. When this occurs, it usually accompanies descriptions of the delusional system.

Another hallmark of the delusional disorders is the relative preservation of personality. Outside the areas of life involved in the delusional system, patients do not show major impairments in areas such as housework, occupational performance, and social relationships. However, the impairments of delusional patients can be severe, particularly if their delusions are extended to involve many areas of their life. Their behavior will seem normal when their delusions are not discussed or acted on, and they will show neither blunted nor discordant affect. When present, these impairments should be easily explained by the delusions. For example, a person could have problems at work because of a conviction of being persecuted; other than that, the individual's performance should remain relatively unimpaired. This impairment is often further aggravated by the characteristic tendency of these patients to act on their delusions. For example, the person who feels persecuted may complain to the police or attempt revenge; the erotomanic, convinced he is loved, may write or otherwise attempt to contact or stalk the object of his delusion. This is an area that the clinician should always inquire about given the potential consequences of these acts.

DSM-5 outlines seven subtypes that closely parallel those originally proposed by Munro (22). These are erotomanic, grandiose, jealous, persecutory, somatic, mixed, and unspecified types. However, other delusional themes are consistent with a diagnosis of delusional disorder as long as they meet the major defining criteria; in such cases, the mixed or the unspecified subtypes could apply.

Persecutory delusions may develop insidiously from a situation in which some degree of suspicion is justified. As the illness develops, the bounds of reason are exceeded, and simple suspiciousness is replaced by a delusional system. In time, the system becomes increasingly elaborate as more details are incorporated into it. The following case illustrates this development, as well as the preservation of affect leading the patient to act on the delusion.

8.5. Some Illustrative Cases

8.5.1. Case History 1: Persecutory Delusional Disorder

A 22-year-old single man, who lived on a farm with his parents, was brought to the hospital because of increasing suspiciousness of a neighbor. There had been long-standing friction between the patient's family and the neighbor, but over the preceding 3 weeks the patient had become convinced that the neighbor was involved in a grain and beef theft ring (which was indeed operating in the area) and informed the Federal Bureau of Investigation of his suspicions. He became convinced that his house was bugged and that some apples his father bought were poisoned because they had been purchased from a friend of the neighbor. He was hospitalized after he began sleeping with a gun for protection. On interview he was cooperative, although suspicious at times. His affect was appropriate to the delusional system. His speech was circumstantial and, at times, tangential when discussing the delusion. Over a 1-month hospitalization, the delusion cleared rapidly with antipsychotic medication, and at discharge he gained complete insight into the irrationality of his former beliefs. However, his suspiciousness toward the neighbor remained.

A. Meyer suggested the following states in the development of paranoid symptomatology (23). Meyer's stages started with 1) "a rigid makeup with a tendency to pride and self-contained haughtiness, mistrust and disdain," 2) "appearance of affectively charged dominant notions, as autochthonous ideas or revelation which illuminates all the brooding questioning in a manner to leave no need for further check," 3) "an irresistible need for working over the material for evidence to support the dominant notion. That it will support it is a foregone conclusion." 4) "Systematization of a sort that is so tightly knit that it remains logically correct if the original dominant notion be admitted." 5) "When the present has been ransacked for proofs and systematized, the attention is turned to the past with a re-examination of the past experiences in the light of newer certainty. There results misinterpretations of past events and retrospective falsification…" No psychiatrist has ever done a better job describing the march of circumstances in delusional disorder.

8.5.2. Case History 2: Jealous Delusional Disorder

A 35-year-old college man was brought to the hospital for threatening his wife with a hammer. She first became aware of his jealousy on their honeymoon, 3 years earlier, when he accused her of infidelity because she was not home on one occasion when he returned. Over the ensuing 3 years he often nagged her for confessions of past affairs. His bullying led to frequent arguments of such intensity that the police were once called. During the year before his admission, his suspicions had intensified to the

point that he accused her of having affairs after work whenever she was not home as promptly as he expected. He called her at work to check on her, set traps around the house, inspected her underwear, and even examined a vaginal smear under a microscope. He often kept her awake all night attempting to extract a confession of infidelity. His deteriorating work performance was blamed on his wife for the anguish she was causing him. He was hospitalized after the incident with the hammer and viewed the admission as an attempt by his wife and the doctors to "railroad" him and threatened to "even the score." On admission he was antagonistic and threatening, with a superior attitude. Although his speech was pressured, it was coherent. His affect was intense but appropriate to his suspicions. After his admission he became calmer, but the delusion remained unchanged during a 1-month hospitalization. He was discharged to another hospital, and his wife separated from him and subsequently obtained a divorce.

Delusional disorder with jealous delusions is referred to as *conjugal paranoia*, or as Othello syndrome, a reference to Shakespeare's famous character. Such patients become convinced that their spouses are unfaithful, and they become preoccupied with proving the infidelity and extracting a confession. Of all the paranoid disorders, these patients spend the greatest amount of time attempting to verify their suspicious thoughts (24).

8.5.3. Case History 3: Erotomania

A 47-year-old woman was convinced that her supervisor was in love with her, as she interpreted insignificant events as signs asking her to meet with him. After 3 years of such behavior, she had to leave her job on a sick leave. She was otherwise functioning well at work, had several friends and was fully functioning with regard to activities of daily living. She was treated with low-dose risperidone and cognitive-behavioral therapy (CBT). After a few sessions, she was offered a diagnosis and a case formulation based on CBT techniques as well as some basic psycho-education. She rapidly stopped seeing messages from her supervisor and developed full insight into her condition. After a year of complete symptomatic and functional recovery she returned to her job, and risperidone was slowly tapered down and discontinued. Psychotic symptoms relapsed a few months later but resolved when medication was reinstated and did not relapse over 6 years with continued medication. This case illustrates that with proper treatment, good outcome can be achieved in some delusional disorder patients.

Erotic delusional patients have delusions of secret suitors, and they interpret ordinary comments and gestures from the delusional suitor as concealed messages proclaiming their love. The "suitor" is often a prominent person with whom the patient has had some dealings. When their overtures are not reciprocated, these patients only become more convinced of the other's love for them, which, for various reasons, cannot be returned openly. Eventually, they may feel jilted and attempt to avenge themselves against their former "lover." This type of paranoid disorder has been referred to as de Clerambault's syndrome, after the French psychiatrist who formulated its original description, and is now called erotomania in DSM-5 (25–27).

8.5.4. Case History 4: Grandiose Delusional Disorder

A 56-year-old businessman developed diabetes 4 years before admission. Shortly thereafter, he developed his own treatment for the disease, which consisted of replacing sugar lost in the urine with a diet rich in sugar. He began publishing materials on his new treatment and advertised courses in it over the radio. Because he charged a nominal fee for these, he was arrested on charges of mail fraud and hospitalized for a court-ordered psychiatric examination. On admission he was cooperative and discussed his ideas with considerable loquacity and circumstantiality. His affect was appropriate to the ideas discussed. The delusional system remained fixed over a 3-week hospitalization, and he was discharged unimproved.

Patients with grandiose delusional disorder believe themselves to be persons of special importance. Common delusions of this genre include those of inventions and discoveries, as well as delusions of being an important part of an organization such as the Central Intelligence Agency. They can describe their delusions with such enthusiasm and loquacity that they may initially appear manic.

Patients with somatic delusional disorders are preoccupied with the appearance, odor, or function of their body (28). Common examples are delusions of body odor or halitosis. These patients are convinced of having a bad smell. Typically, they do not perceive the odor themselves, but they interpret benign remarks or nonverbal reactions as signs of disgust over the imagined odor. If the patient indeed smells an odor, this is a hallucination, and another disorder such as schizophrenia should be suspected. With delusions of infestation or parasitosis, the patient believes that he or she is infested with insects or parasites (Ekbom's syndrome) or other non-living (Morgellon's disease) foreign bodies under the skin (29). Patients with delusional hypochondriasis believe that they are affected by a serious illness and characteristically visit multiple physicians as well as other healers. However, since the inception of DSM-5, patients with fixed beliefs of delusional intensity about real or imagined defects in their appearance are diagnosed as having body dysmorphic disorder with absent insight/delusional beliefs, based on the research that suggested continuity between psychotic and non-psychotic presentations of these syndromes (9, 30).

DSM-IV would have diagnosed such patients with delusional disorder, somatic subtype; hence, a large part of the pre-DSM-5 literature on somatic delusional disorder may no longer apply, following this substantial revision. DSM-5 also includes a mixed subtype, which applies when no one of the above delusional themes predominates, and an unspecified type, which applies when the dominant delusional theme cannot be clearly determined, or is not described among the specific types.

8.6. Course

It is often stated that the typical course of delusional disorders is chronic with a very high degree of persistence of the delusions. It is difficult to provide reliable figures because of the high degree of heterogeneity among outcome studies. This can be explained by several factors related to sample composition, including differences in the proportion of subjects successfully followed-up, variations in case ascertainment methods, and the use of different diagnostic systems (31). Nevertheless, it is safe to say that there is no uniformity of outcome of delusional cases in any of these studies, i.e., there are broad variations regarding outcome, some being severely impaired, some achieving a very high level of recovery. Thus, this suggests that good outcome can be obtained in a significant proportion of delusional disorder patients (see clinical vignette 3 in section 8.5.3). However, the fact that delusional disorders, particularly jealous, persecutory, and erotomanic subtypes are not infrequent in forensic situations warrants careful risk assessment in such cases (32).

There are relatively few studies examining the issue of diagnostic stability over long periods of time. Available information suggests that in the majority of subjects, the diagnosis of delusional disorders is confirmed at follow-up but also that a significant proportion receives another diagnosis, most often schizophrenia (33).

8.7. Differential Diagnosis

Because delusional disorders are uncommon in clinical practice, the possibility that a delusional illness is caused by some other condition must always be kept in mind. A large number of causes are possible; these include mood disorders, schizophrenia and schizoaffective disorder, schizophreniform disorder, dementias, drug-induced psychoses, and neurological conditions that cause diffuse brain dysfunction (34).

Dementia may be accompanied by delusions and should be suspected in an elderly paranoid patient. Moreover, delusions may be a precursor of dementia. Indeed, in a study based on a Danish population registry, it was found that subjects receiving a diagnosis of delusional disorder performed after age 60 years had an eightfold risk of being diagnosed with dementia, compared to controls with osteoarthritis (35). Suspiciousness and delusional thinking can be more prominent than the cognitive impairment of the dementia, but the latter can usually be uncovered by a careful mental status examination. In questionable cases, psychometric testing should lead to the correct diagnosis. Delirium is characterized by a fluctuating state of consciousness, and the delusions are likewise evanescent and rapidly changing, while those of delusional disorders remain relatively fixed for the duration of the illness. In addition, the cognitive symptoms of delirium (e.g., disorientation and memory impairment) are absent in delusional disorders. Delusions due to other neurological conditions can present a greater diagnostic problem because of the absence of the cognitive impairment of delirium and dementia. For this reason, a careful medical history, with particular attention to the drug history, should be obtained, because delusions can be the result of a variety of medical illnesses and drug toxicities. These include pathology of the basal ganglia as in Huntington's disease and Wilson's disease, or of the limbic system involved in complex partial seizures or space occupying lesions. Other medical etiologies include autoimmune disease (e.g., lupus cerebritis), metabolic disease (e.g., porphyria, pernicious anemia), endocrine and infectious etiologies. Toxicity from substances of abuse such as central nervous system stimulants (e.g., amphetamines, cocaine) and prescription drugs (e.g., corticosteroids, L-dopa) can cause delusions as well. A urine drug screen is helpful in detecting surreptitious drug abuse.

Delusions are often the initial psychotic symptoms of schizophrenia. This diagnosis should be suspected whenever hallucinations are a prominent feature, the delusions tend toward bizarre, when the affect is blunted or inappropriate, when behavior is disturbed beyond direct consequences of the delusion, or when a thought disorder is prominent. If the correct diagnosis is schizophrenia, this will usually become apparent with the passage of time.

Mood disorder should be suspected whenever the delusional content is depressive or expansive, when a pre-existing mood illness is present, or when the family history is positive for one. The chronology of the delusions versus that of the depressive symptoms may help distinguish between a delusional depression and a delusional disorder complicated by a depressive syndrome. Since patients with delusional disorder have relatively preserved affect, they are often distressed by their delusions, and their clinical picture not uncommonly includes a depressive disorder. Examination of thought content may be helpful because prominent guilt, such as considering the delusional belief to be just punishment, militates toward a diagnosis of mood disorder. Grandiose and erotomanic delusions may be so expansive as to appear manic. In these subtypes the psychomotor symptoms of

mania are absent. Illness anxiety disorder (formerly hypochondriasis) differs from somatic delusional disorder in that the somatic concern is not centered around having a disease. Such patient suspects an illness and cannot be reassured by negative examinations but typically lacks the certainty of belief that is characteristic of somatic delusional disorders. Illness anxiety disorder patients may be characterized by poor insight to the extent that the patient fails to recognize that the concern is excessive and unreasonable, but these patients are never convinced beyond argument that they have a disease.

Paranoid personality disorder presents a diagnostic problem when the suspiciousness becomes so pronounced that it resembles a delusion. However, these patients are not truly delusional and are distinguished in this way from delusional disorders, although a person with a paranoid personality disorder may eventually become delusional, which would warrant a diagnosis of delusional disorder.

8.8. Laboratory Examinations

Several laboratory examinations are useful in ruling out other diseases that can present as a delusional disorder. Neuropsychological tests demonstrating cognitive dysfunction raise the possibility of a dementia or a psychotic disorder due to some other general neurological condition. A positive drug screen for amphetamines or other substances known to cause delusions raises the possibility of a substance-induced psychotic disorder.

8.9. Treatment

The medical evidence in support of drug treatment is based almost exclusively on case reports and series, with the exception of a few small, controlled trials of pimozide in delusional infestations. Munro and Mok (36) reviewed case reports published until 1994, totaling 208 patients who met DSM-IV criteria (for 75%, somatic subtype) and reported the majority of patients treated with pimozide experienced favorable treatment outcome, contrasting with a lower proportion of favorable outcome in those treated with other first-generation agents. Although pimozide has been, among first-generation antipsychotics, a preferred antipsychotic agent for delusional disorders, particularly the somatic subtype, there has been a steady trend toward treating delusional disorders with second generation antipsychotic agents. Indeed, a review of cases published since Munro's review until 2004 found a comparable proportion of favorable outcomes with second generation antipsychotics (37). However, as these are uncontrolled observations, drawn from unsystematic sampling, and apply mostly to somatic subtype of delusional cases, claims about the superiority of pimozide cannot be scientifically verified.

A few studies have outlined a particular cognitive style in delusional disorders [see above; (19)] which has stimulated interest in using cognitive behavioral therapy to treat delusional disorder patients, and successful applications of such therapy have been reported (38).

Anxiety Disorders

Taylor C. Preston, M.D. and Richard C. Shelton, M.D.*

Abstract Anxiety is a common and normal phenomenon, involving multiple brain regions, including amygdala, locus ceruleus, and frontal cortex. Moreover, multiple brain transmitters regulate the presence and severity of anxiety; these include classical transmitters such as gamma aminobutyric acid, serotonin, and dopamine, as well as neuropeptides that include corticotrophin releasing hormone, substance P, neuropeptide Y, cholecystokinin, and vasopressin. Anxiety is highly adaptive, and involves both acute fear, related to an immediate threat, and anticipatory anxiety that is associated with possible future threat. Certain individuals are predisposed to develop anxiety disorders. Predisposing variables include both genetic factors (that may dispose toward anxious temperament), emotional traumas, and other psychologically mediated factors. Anxiety disorders represent a family of conditions with important distinguishing elements. Panic disorder and phobias involve reactions that are reminiscent of acute fear (albeit often worse). Specific and social phobias involve excessive fearful responses to identifiable things or circumstances in the environment. On the other hand, panic disorder is characterized by acute and intense fear responses that are not associated with a specific environmental cue, although people with this illness may experience aversive conditioning as a result of having spontaneous panic attacks in specific situations. Generalized anxiety disorder is a condition that, essentially, involves anticipatory fear (i.e., worry). Worries of everyday life are enhanced beyond any normal or adaptive functioning. Finally, acute stress disorder (ASD) and post-traumatic stress disorder (PTSD), while not technically classified as anxiety disorders, will be discussed in this chapter. These occur after a catastrophic, often life-threatening event. People with these conditions suffer persistent re-experiencing of the event (including intrusive thoughts or nightmares), avoidance of reminders of the event, and signs of increased arousal, such as difficulty sleeping, hypervigilance, or exaggerated startle response. Although complex, anxiety disorders are treatable conditions that respond to certain medications and specialized forms of psychotherapy.

9.1. Introduction

Anxiety disorders are common and often serious conditions, which are associated with considerable morbidity. For example, rates of disability with certain anxiety disorders such as panic disorder or post-traumatic stress disorder (PTSD) are high. As well, these conditions are commonly comorbid with other mental disorders such as depression and substance abuse disorders. This, in turn, is associated with an even greater risk of morbidity and mortality. For example, panic disorder associated with major depression has a much higher rate of suicide attempts than either disorder individually (1). However, early diagnosis and intervention will often lessen the overall severity and risk of these disorders.

Overall, the 12-month prevalence rate of having any anxiety disorder is about 12% and lifetime prevalence is nearly 20% (2). Specific and social phobias are the most common, with lifetime prevalence rates of 6.7 and 12.1%, respectively. Moreover, anxiety disorders are commonly comorbid with other psychiatric disorders, including major depression, dysthymia, personality disorders, substance abuse, or even other anxiety disorders.

9.1.1. The Neural Substrate of Anxiety

Anxiety, fear, aversion, and obsessive thinking are distinct symptomatic elements of anxiety disorders, but may reflect exaggerations of normal adaptive emotional responses. The most basic distinction in anxiety is between acute fear and anxious anticipation. Acute fear reflects the response to an acute threat, activating the "fight or flight" response, and involves activation of a number of brain regions, including locus ceruleus and amygdala (Fig. 9.1). The latter is involved in the encoding of fearful memory and, hence, aversive conditioning. Therefore, as well as being involved in acute fear, the amygdala is also intimately involved in negative anticipatory expectation; that is, anxiety (3, 4).

Acute fear activates the sympathetic nervous system, producing peripheral manifestations such as tachycardia, tachypnea, tremor, and diaphoresis. However, the perception of fear or anxiety involves the cortex, especially dorsolateral and orbital frontal regions. The cortex not only consciously registers fear, but also responds with survival behaviors. An important part of the connecting system between cortex and paralimbic structures is the cingulate gyrus, especially the anterior cingulate, which mediates the upward projection of fear- or anxiety-related information and downward regulatory signals, including both formal behavioral responses and more direct inhibitory activity. Hence, the frontal cortex and cingulate are significantly involved in the regulation of both emotional and behavioral response to fear-inducing stimuli.

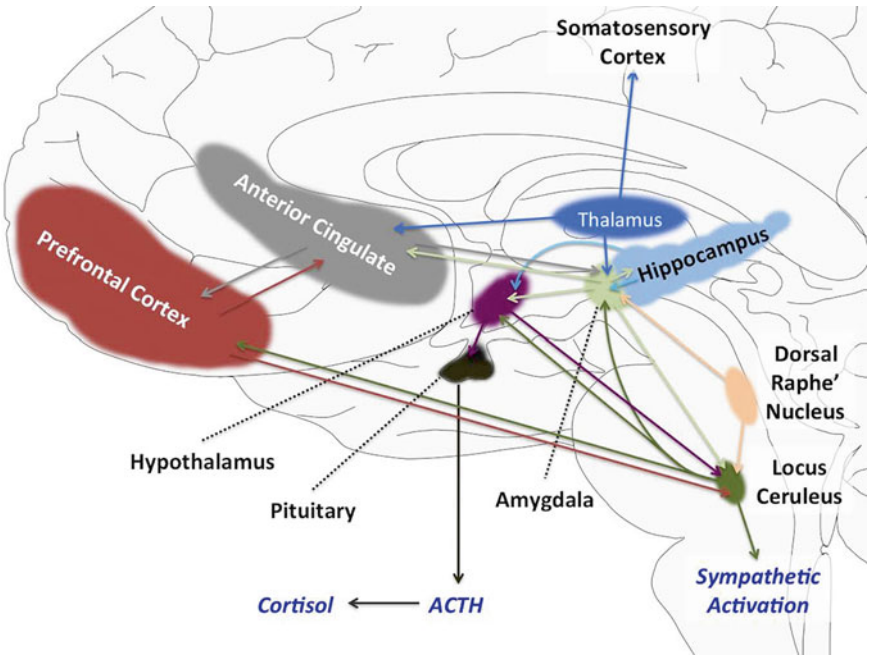

FIGURE 9.1. A simplified diagram of brain structures involved in the regulation of anxiety. Acute fear involves activation of both locus ceruleus and amygdala; the latter also plays a key role in memory encoding related to fearful stimuli. The frontal cortex is involved in both recognition of and complex behavioral responses to threatening cues. The anterior cingulate serves as a conduit of information between cortex and limbic structures, and serves a modulatory role as well. Serotonin, arising from the raphé nuclei, regulates activity in multiple brain areas.

The anxiety-related brain regions normally exist in a relatively quiescent or inhibited state. Redundant inhibitory systems such as those related to gamma aminobutyric acid (GABA) and serotonin modulate the responsiveness of this system. Additionally, neuropeptides such as corticotrophin releasing hormone, substance P, neuropeptide Y, cholecystokinin, and vasopressin, can have either activating or inhibiting effects. Therefore, this is a system that maintains a delicate balance of activation and inhibition. This balance maintains optimal responsiveness (a desirable feature in a stress—threat response apparatus) while also inhibiting anxiety and fear in non-threatening situations. Alternatively, perturbation of one or more of these modulators may induce or maintain anxiety disorders (5).

Pharmacological treatments for anxiety disorders typically activate or augment the natural neuronal inhibitory mechanisms. GABAergic drugs such as the benzodiazepines are a prime example. GABA receptors exist in a complex with chloride channels (6, 7). Chloride channels open in response to depolarization, propagating the action potential. By contrast, GABA receptors open chloride channels in a way that is not related to the propagation of action potentials, increasing the negative charge within neurons, and creating the inhibitory post-synaptic potential state. This inhibits subsequent action potentials until GABA is unbound and the chloride channels close, resulting in hyperpolarization. This decrease in neuronal firing appears to be related to the action of drugs that act on GABA receptors; GABA activation inhibits anxiety and can induce sleep. There are GABA potentiating drugs such as baclofen and gabapentin that exhibit anti-anxiety properties. However, they are not commonly prescribed for anxiety. Receptors for the benzodiazepine drugs such as diazepam and alprazolam exist in the same GABA-chloride channel complex. Benzodiazepines facilitate the action of GABA, which enhances and sustains the channels in the open position, producing a longer lasting effect than with GABA alone and, hence, reducing anxiety.

Serotonin from the raphé nuclei in the brainstem also serves an important regulatory role with regard to the structures that mediate anxiety. Serotonin is a complex transmitter in the CNS, with multiple receptor subtypes that can have opposing functions. However, the inhibition of amygdala activity appears to occur primarily via serotonin 1A receptors (8, 9). Therefore, drugs that enhance activation of this receptor will produce inhibition of amygdala activity. These would include inhibitors of the serotonin transporter (typically referred to as selective serotonin reuptake inhibitors [SSRIs]) such as sertraline and paroxetine, and the serotonin 1A partial agonist buspirone.

As noted earlier, activation of the locus ceruleus, located in the brain stem, is a significant mechanism mediating anxiety, and is thought to be an important brain structure in the generation of acute anxiety. Since anxiety disorders produce symptoms akin to acute anxiety, the locus ceruleus has been hypothesized to be important in the generation of panic attacks. SSRIs have an inhibiting effect on locus ceruleus firing, although only after chronic administration (typically 3 weeks) (10). The effect of serotonin at the locus ceruleus appears to be mediated via a different mechanism than in the amygdala. The serotonin 1A partial agonist buspirone actually enhances locus ceruleus firing activity (11, 12). This may be related to the relative lack of effect of buspirone in panic disorder (13) and reports of the drug actually inducing panic attacks (14, 15). Activation of the serotonin 2A type of receptors, on the other hand, inhibits locus ceruleus firing activity (12, 16). Therefore, the net effect of blocking the reuptake of serotonin is to inhibit both amygdala and locus ceruleus activity. This may explain the broad effects of SSRIs on different anxiety disorders.

9.1.2. Psychological Models

Behavioral models of conditioning and extinction help to explain the generation of fearful responses as well. A fear-inducing stimulus invokes the neural patterns of activation noted above, and also generates memory encoding of the event. With subsequent re-exposure to similar threatening stimuli, behavioral responses are produced more rapidly as a result of learning of the behavioral response repertoire. Repeated aversive stimuli result in a broader modification of behavior, such as inhibition of exploratory behavior in rodents, and sustained emotional activation (anticipatory anxiety). Long periods without exposure to the stimulus would normally result in an extinction of both negative emotions and anxiety-related behaviors. This, then, allows the brain to respond appropriately to an unpredictable environment.

In fact, any novel cue may invoke an initial anxious response. There appears to be a range of responsiveness of these systems between individuals, with some showing heightened reactivity to threat (real or anticipated) and novelty. In fact, behavioral inhibition, a temperamental dimension present in inhibition and characterized by withdrawal from novel environmental cues, appears to predispose to the subsequent development of certain anxiety disorders such as social anxiety disorder (17). Constructed more broadly, the anxious or emotionally reactive temperament seems to predispose to a range of anxiety and depressive disorders (18, 19). The apparent heritability of temperament, then, suggests that certain people are innately more reactive to real or anticipated threats and, therefore, are prone to the development of anxiety disorders.

A so-called tripartite model of mood and anxiety disorders was proposed more than 20 years ago (20–22). This reflects a tendency of symptoms of anxiety and depression, seen as a whole, to associate together in three, supraordinate clusters: negative affect (NA), reflecting a family of symptoms that includes rumination, worry, tension, and worry; positive affect (PA), which reflects the group of symptoms related to energy, interest, and motivation (or the relative lack thereof); and somatic anxi-

ety (SA), representing physical symptoms related to acute fear. As will be shown below, the NA axis tends to be elevated in all anxiety and mood disorders; that is, by definition, all these conditions share certain core distress symptoms. On the other hand, low PA is associated with the energy, interest, and motivation symptoms associated with depression, while most anxiety disorders do not have the same problem (23, 24). One exception is social anxiety disorder, in which PA tends to be low. This may reflect the propensity of people with social anxiety disorder to avoid enjoyable interactions with others. Therefore, the interest and motivation to engage with others may be absent because of the overriding anxiety of doing so. Finally, the SA dimension represents the physical symptoms of anxiety. This tends to be elevated in panic disorder (both during a panic attack and at other times), and in social and specific phobias on exposure to the feared stimulus. Therefore, the pattern of this symptom structure varies depending on the individual disorder.

As a result, there are both unique and shared features of anxiety disorders and mood disorders. Unfortunately, the current diagnostic schemes tend to include many of the symptoms common to the disorders; that is, symptoms associated with the NA dimension. Diagnosis will, then, be aided by focusing first on the unique elements of a specific condition. This would include the obsessions and compulsions of obsessive compulsive disorder (OCD), the low motivation associated with depression, and the somatic anxiety that occurs in a panic attack or, in the case of social and specific phobia, with exposure to a specific environmental cue. This leaves generalized anxiety disorder (GAD), which has substantial symptomatic overlap with other mood and anxiety disorders. GAD is a disorder of almost pure distress (i.e., NA), without strongly distinguishing features. However, as discussed more extensively below, GAD may, in actuality, be related to an anxious temperament and therefore tends to be a stable part of a person's life.

Anxiety disorders in general share certain common antecedents. Genetic factors appear to play a significant, albeit variable role in the genesis of these conditions. Described as so-called internalizing disorders, depressive and anxiety disorders share high rates of comorbidity, which may be accounted for by common genetic and environmental antecedents (25). One common factor appears to be related to temperament, a tendency for heightened negative emotional responses to environmental stressors (termed "neuroticism") (26). Temperament appears to have a significant genetic contribution, and the transmission of this trait is likely to increase the familial liability to this group of conditions.

9.2. Panic Disorder

9.2.1. Overview

The features of panic disorder are the presence of uncontrolled, recurrent, and unexpected attacks of severe anxiety along with the development of worries associated with the attacks, or avoidance of specific situations because of the attacks. Panic attacks are characterized by an abrupt surge of intense fear, together with symptoms of autonomic arousal (e.g., tachycardia and tachypnea), other anxiety symptoms (e.g., depersonalization), and a fear of losing control or dying. At least some of the attacks are unexpected and occur without exposure to phobic objects or situations. They may awaken a person from sleep, or be provoked by strong emotions, excitement or physical exertion. Other manifestations of the illness may include anticipatory anxiety and agoraphobia.

9.2.2. Criteria and Diagnosis

The panic attack can be thought of as an amplified form of what anyone might experience under conditions of acute threat, such as exposure to a deadly animal or a life-threatening accident, although without a clear provocation. As such, normal physiological responses such as rapid breathing or heart rate (with a feeling of chest tightness or discomfort) or tremor can become very severe. The hyperventilation, then, results in a rapid decline in CO_2, which causes vasoconstriction. This, in turn, is related to other symptoms of the attack, including numbness or paresthesias, dizziness or lightheadedness, chills, or the feeling of unreality (derealization) that comes with severe tachypnea. Because the symptoms are physical, unexpected, and not associated with a clear precipitant (at least during early attacks), affected persons can then interpret them as indicating some serious physical problems such as a myocardial infarction. As well, some feelings such as depersonalization or derealization may lead patients to believing that they are "going crazy" or "losing their mind." A full panic attack, then, is a catastrophic and often life-changing experience.

Affected persons will often seek help immediately by going to an emergency room or having an urgent visit with their physician. If the condition is recognized and treated quickly, the subsequent evolution of the condition can be truncated. However, if the panic attacks recur, people will often develop progressive avoidance of situations, culminating in agoraphobia, described below. Panic disorder is diagnosed after typical panic attacks followed by at least 1 month of one or more of the following:

- Persistent concern or worry about additional panic attacks or their consequences. As described below, this is often associated with avoidance behavior.
- A significant maladaptive change in behavior related to the attacks. A significant change in behavior: If panic attacks continue to occur, most people will develop altered behavior patterns, particularly avoidance of certain situations. When this becomes extensive, a diagnosis of agoraphobia is made.

Therefore, stated simply, panic disorder can be thought of as a condition in which recurring panic attacks are accompanied by either serious worry about the attacks or the development of avoidance behavior, or both. The occurrence of panic attacks and the persistent fears that accompany them can have a very adverse effect on daily life. Patients often find themselves unable to effectively engage in social, personal, or work related activities.

People with panic disorder may mistake the symptoms of panic or the more persistent anxiety that can develop along with panic disorder, as symptoms of a serious physical disease. Fears about dying from a myocardial infarction, cerebrovascular accident, or other serious condition, or a fear of becoming psychotic, often occur during attacks. However, worries about other serious conditions such as cancer, a neurological disorder, or other major medical condition, may develop over time. Patients may consult many health professionals and seek multiple medical tests because of the fears.

As with other psychiatric disorders, the diagnosis is excluded if the symptoms can be better accounted for by another psychiatric disorder (such as social anxiety disorder), a discrete medical condition (e.g., pheochromocytoma), or specific substances. This can be associated with the use of certain drugs of abuse such as cocaine. However, severe panic attacks may be precipitated by the use of marijuana or hallucinogens such as LSD or phencyclidine. People may also have severe anxiety symptoms that accompany withdrawal from alcohol or drugs, including sedative-hypnotics, benzodiazepines, or opiates.

9.2.3. Agoraphobia

In DSM-5, agoraphobia is formally defined as significant anxiety or fear about two or more situations such as being in open or enclosed places (27). Examples of commonly avoided situations include shopping malls, grocery stores, theaters, places of worship, or crowds of any kind. Exposure to these kinds of situations can lead to escalating anxiety that culminates in a panic attack. Anticipatory anxiety tends to build as the person approaches the feared situation or, with time, even thinks about it. This, then, functions like a negative reinforcement paradigm in which the avoidance is associated with a reduction in anxiety and is therefore reinforced. The individual fears or avoids these situations because of thoughts that escape might be difficult or help might not be available in the event of developing panic-like symptoms or other incapacitating or embarrassing symptoms. Forced exposure to feared situation almost always results in intense fear.

Unfortunately, the problem often builds over time and can become quite pervasive. Some people may become completely unable to leave their homes. If untreated, panic attacks and agoraphobia may result in progressive disability. As well, suicide can occur, especially when panic is accompanied by depression, which occurs in about 40% of untreated patients.

Agoraphobia may be diagnosed alone or as a comorbid condition with panic disorder or another psychiatric disorder. A diagnosis of agoraphobia alone usually occurs when there are relatively milder attacks or those with fewer than four of the typical panic attack symptoms. These more limited attacks may still lead to progressive agoraphobic avoidance, without a full panic attack meeting the four-symptom criterion in DSM-5. Very rarely, agoraphobic avoidance can develop without evidence of panic attacks at all; however, this is most commonly related to another disorder such as social anxiety disorder and would be diagnosed as such.

The relationship between panic attacks and agoraphobia often evolves in a predictable manner. Mild or limited symptom attacks are not rare in the general population, but often do not progress on to panic disorder or agoraphobia. However, in cases in which panic disorder or agoraphobia does develop, experience with recurrent panic attacks builds and patients will tend to progressively expand the scope of avoidance behavior. Subsequently, this tends to make recovery more difficult.

9.2.4. Epidemiology

As there is not yet new epidemiological data since the new DSM-5 criteria were released in 2013, available data reflect the DSM-IV diagnostic criteria (28). Epidemiological studies from 2006 suggest that the 1-year prevalence rates of panic disorder are 2.8% with the lifetime prevalence of 4.7% (29). Lifetime prevalence of agoraphobia without panic disorder was 0.8% (29). Certain factors tend to increase the risk for panic; these include female gender, being of Native American heritage, and being widowed, separated, or divorced. Panic attacks can occur across the lifespan, although the period of highest frequency tends to occur between about ages 25 and 45.

9.2.5. Etiology

9.2.5.1. Genetic and Biological Factors

Studies suggest that panic disorder is heritable, which contributes about 40% of the variance. Family studies have elucidated a relationship between genetics and the development of this disorder, with multiple studies demonstrating that first-degree relatives of panic disorder patients are more likely to also suffer from panic disorder in particular and anxiety disorders in general than the rest of the population. The genetic diathesis is also supported by twin studies which have shown that monozygotic twins have a higher concordance rate than dizygotic twins (45% vs. 15%) (30).

Multiple neurotransmitters have been implicated in panic disorder, particularly serotonin, norepinephrine, and GABA, all of which are found within the limbic system and cortex. This is based largely on the effectiveness of antidepressants (which act on serotonin and norepinephrine) and benzodiazepines (which interact with GABA receptors). This is further supported by data showing reductions in 5HT1A receptor concentration in panic disorder (31). Additionally, there are data to implicate the gene coding for COMT (catechol-O-methyltransferase), which is responsible for the metabolism of norepinephrine. However, the data are inconclusive (32).

Panic attacks themselves involve activation of cortical and subcortical regions. It should be noted that differences in the neural circuitry of patients with panic disorder have been identified. Decreased volumes of the temporal lobe and amygdala, as well as decreased cerebral glucose metabolism in the amygdala, hippocampus, thalamus, and brain stem have been found (32, 33).

Increased sympathetic activity is characteristic of the activation of panic attacks. At least during early attacks, the occurrence is abrupt, rising to the maxima within minutes, or usually within seconds. The initial upswing of physiological activation appears to occur via activation of the locus ceruleus, the principal source of norepinephrine in the central nervous system. Norepinephrine increases cortical arousal, and stimulates amygdala, hypothalamus, and other brain structures. Panic is associated with acute fear responses. This, in part, may be the result of a misinterpretation of the peripheral manifestations of autonomic arousal. Hence, norepinephrine projections directly activate the amygdala, generating an initial fear response. This, in turn, is reinforced by the interpretation of the signaling by the frontal cortex, which enhances the response. This latter mechanism is especially in force in subsequent panic attacks, which leads to further enhancement of the fearful response.

Therefore, peripheral symptoms of tachycardia, tachypnea, tremor, and diaphoresis are explainable by sympathetic outflow via the vagus nerve. However, a key symptom in a panic attack is hyperventilation. This, in turn, is responsible for some of the secondary features of panic attacks, such as dizziness or numbness and tingling of limbs or lips. This results from depletion of blood CO_2 and elevated O_2. In fact, one theory of the genesis of panic attacks suggests that brainstem sensitivity to CO_2 generates a false suffocation signal (34). This is supported by studies showing that breathing high concentrations of CO_2, or the infusion of sodium lactate (which increases central CO_2 levels), can potentially induce panic attacks. Moreover, panic attacks occur during sleep, typically in the transition from stage II to delta sleep, in which CO_2 concentrations may be high and O_2 relatively low (35).

9.2.5.2. Psychological Factors

Patients with panic disorder showed markedly anxious responses to the bodily cues associated with panic attacks. While anxious temperament or other cognitive predisposition may exist in people who develop panic, the exaggerated reactions to bodily sensations may be generated and are definitely reinforced by the panic attacks themselves. Panic attacks, then, can be seen as an aversive conditioning stimulus, leading to reinforcement of subsequent fearful responses. Patients can, then, become highly sensitized to physical cues such as rapid heart rate or shortness of breath that serve as reminders of panic symptoms, even if they are unrelated to a panic attack per se. In this case, the physical sensations are conditioned stimuli, which produce a conditioned response, generating a panic attack themselves.

Because the attacks generate such a fearful response, people will typically interpret them as indicating that there is a serious physical or mental problem. Both the experience of panic attacks in public places, and the anxious expectation of a panic attack occurring, will result in growing anxiety over time, yielding avoidance behavior. In fact, anxiety often builds as the person approaches the feared place. This, then, results in the physical cues that, as we have seen, can result in a panic attack. Therefore, anticipatory anxiety and avoidance behavior tend to build over time, culminating in agoraphobia.

From a developmental standpoint, panic disorder is more likely to arise with a backdrop of early adversity, particularly sexual abuse (36). This may account, in part, for the higher prevalence rate in women, since they are more likely to experience sexual abuse.

9.2.6. Differential Diagnosis and Comorbidity

Panic disorder is highly comorbid with mood and other anxiety disorders. Rates of major depression vary, but tend to be around 40%. However, these are not necessarily *co-occurring* conditions. That is, both conditions can occur independently over time.

Often, patients will suffer from panic disorder for an extended period before onset of depression, while depression pre-dates panic only occasionally. As well, depression can be a recurring condition in panic patients as it can be in persons without panic. Moreover, it is important to distinguish major depression from simple discouragement, unhappiness, or demoralization that are very common. Regardless, co-occurring depression or other mental disorders such as obsessive-compulsive disorder or personality disorder complicate the illness, making it more difficult to treat.

As with other mood and anxiety disorders, substance abuse rates are relatively high. As noted earlier, certain drugs such as cocaine (or other stimulants) or hallucinogens can precipitate anxiety or panic attacks; therefore, abuse of these drugs is uncommon. However, abuse of alcohol or sedative-hypnotics is relatively frequent, occurring in as many as 30% of patients. The use of benzodiazepines may also become problematic. However, in both instances, this tends to be the result of an attempt to control symptoms of anxiety, rather than a primary pattern of abuse. In many instances, patients will abuse substances such as alcohol for limited time periods, since the anti-anxiety effects of alcohol will wane over time. However, use of these substances is troublesome for a variety of reasons. For example, a pattern of escalating abuse will make withdrawal reactions more likely to occur. Withdrawal itself may be confused with panic, and panic attacks can occur in vulnerable people. In addition, although anxiety may be reduced immediately after the use of alcohol or sedatives, the anxiety may increase above the levels that would naturally occur as the drug clears. This, then, reinforces the behavior, which may result in addiction.

Any medical disorder may be concurrent with panic. Therefore, a good medical evaluation is imperative. Moreover, it is important to be aware that a very anxious patient may indeed be experiencing stroke or myocardial infarction. Note, however, that the features of panic are quite characteristic and, in most circumstances, not difficult to recognize if the clinician is sensitive to the possibility. There are specific distinguishing features with panic that are uncommon in other medical conditions. For example, depersonalization, derealization, or a fear of "going crazy" would not be common with other serious conditions such as MI. On the other side of things, persons who have had a heart attack complain of characteristic MI pain (e.g., radiating to the back, neck, or left arm). Persons with panic often describe a sense of chest "tightness" or "constriction" but seldom of "heaviness" in the chest that is more common with MI. Although stroke may result in numbness or paresthesias, unilateral muscle weakness does not typically occur in panic. A conservative approach to medical evaluation *is* warranted, and an electrocardiogram, exercise stress test, or MRI may be needed. However, be aware that persons with panic may request multiple medical tests as they seek an answer for their condition. An astute clinician should be able to recognize the features of panic disorder and, therefore, "give it a name," so to speak. This can be surprisingly reassuring for patients, and can avoid unnecessary medical expense.

Some medical illnesses can be precipitated by anxiety (e.g., unstable angina or asthma), while the course of others may be aggravated by anxiety (e.g., irritable bowel syndrome [IBS], migraine, or other pain). However, treatment planning will need to take these problems into account. Some can even affect the safety or efficacy of psychopharmacological treatments, such as certain cardiac conduction abnormalities, pulmonary, gastrointestinal or endocrine disorders, and pregnancy or lactation. For example, IBS can complicate treatment with serotonin selective reuptake inhibitors (SSRIs) since patients may be more sensitive than average to the lower gastrointestinal side effects that commonly occur with these drugs.

There are a few medical conditions that can mimic symptoms of panic. For example, pheochromocytoma, insulin- or serotonin-secreting tumors (e.g., carcinoid), or hormone-secreting small cell carcinoma of the lung may cause panic-like reactions to occur. There typically are concomitant features that distinguish these conditions. For example, pheochromocytoma results in a precipitous increase in blood pressure; this is uncommon in panic, and even when the blood pressure goes up, it is not as high. Insulinoma causes a marked drop in blood glucose, which does not occur in panic (although hypoglycemia may precipitate a panic attack). However, in the case of an insulin-secreting tumor, the blood glucose is very low. Although abdominal distress or diarrhea is common in panic, the propulsive diarrhea associated with carcinoid is not. Therefore, the differential diagnosis should not focus on signs and symptoms that are shared between conditions, but those that are unique to each.

Hyperthyroidism can tend to cause anxiety, including the physical symptoms associated with panic. However, these symptoms tend not to be acute and episodic as with panic. Other medical conditions that may cause anxiety or panic-like reactions include supraventricular tachycardia (or other arrhythmias), vestibular dysfunction (e.g., vertigo), or seizure disorders. The latter may be particularly hard to distinguish in the absence of generalized (i.e., tonic–clonic) seizures or loss of consciousness. In fact, certain seizures may cause episodes of anxiety with physical symptoms, and should be considered in the case of panic disorder that is difficult to treat, or when patients faint during a panic attack. Although the latter can occur, it is actually quite rare.

Acute hypoxia, such as that seen with pulmonary failure or an asthma attack, can mimic a panic attack. However, auscultation of the chest should yield an accurate assessment. As well, hypoglycemia, particularly if severe, can produce a panic-like reaction. However, blood testing for glucose can confirm that diagnosis.

Some of the most complicated management situations occur when serious medical problems happen in the context of panic disorder. For example, severe obstructive pulmonary disease is quite difficult; when the patient becomes short of breath, determining whether the problem is related to a panic attack, anticipatory anxiety, or the pulmonary illness itself (although this has been made less complex by the ready availability of pulse oximeters). Moreover, the low pO_2 and high pCO_2 may precipitate panic attacks.

As discussed below, people with panic tend to be quite sensitive to side effects of drugs. This occurs because of the fear of bodily sensations that plagues people with panic. Therefore, the natural physical side effects of drugs will precipitate anxiety and often result in the patient discontinuing or refusing the treatment.

Certain ongoing medical conditions may make the management of panic difficult. Obstructive pulmonary disease has already been mentioned. Unstable medical conditions like hyper- or hypothyroidism, angina, arrhythmias, or vestibular disease significantly interferes with the management of panic, and often those conditions must be treated before panic disorder can be dealt with successfully.

The extent of a medical work-up with a panic patient should be driven in large part by the differential diagnosis. That is, when panic occurs in the absence of evidence of other medical illnesses, then the medical evaluation should be truncated. It is good for the panic patient to receive a physical exam and standard annual laboratory tests with ECG, but this is simply consistent with good medical practice and can be done by the primary care physician (although a thyroid stimulating hormone evaluation is warranted if it is not routine with the PCP). Other laboratory tests should be kept to a minimum, unless there are other physical indicators. This will help to reduce the cost of care, but it also has another important effect. Although panic patients often want medical tests, a negative result is *not* reassuring, and may lead to more requests for testing. Actually, negative testing may actually *escalate* the anxiety, not reduce it. Although the psychological causes are complex, the patient may worry that they have an even more obscure and dangerous condition. The fear of an unknown but presumably serious medical condition can be quite severe.

9.2.7. Treatment

9.2.7.1. Pharmacological

Pharmacological treatment should be considered for most patients with panic disorder. The control of acute panic attacks and reduction of more general or anticipatory anxiety may speed recovery. Table 9.1 outlines common drugs with their daily dose ranges. While many medications are used to treat anxiety, they tend to fall into two basic categories: "antidepressants" with anti-panic properties and benzodiazepines.

9.2.7.1.1. Antidepressants

Of the medications that carry indications for the treatment of panic disorder, the selective serotonin reuptake inhibitors (SSRIs) are the most commonly used. Additionally, the serotonin norepinephrine reuptake inhibitor (SNRI) venlafaxine has been shown to be effective in panic disorder (37). Although certain drugs such as fluoxetine, paroxetine, and sertraline have been granted an indication for panic disorder by the US FDA, the therapeutic benefit seems to be a class effect for drugs that block the uptake of serotonin. SSRIs are first-line therapy because of their relative efficacy, tolerability, and lack of serious adverse effects. Occasionally, especially early in treatment, these drugs may acutely increase anxiety, and may also cause increased suicidal potential as a result. Therefore, patients should be closely monitored, especially at the start of treatment.

Other antidepressants, such as the tricyclics and monoamine oxidase inhibitors, are also quite effective in reducing panic. However, their side effect and safety profile make them quite difficult to use. Panic patients are very sensitive to side effects, and may not tolerate them. Moreover, the normal precautions associated with these drugs (discussed elsewhere in this volume) apply. In particular, the dietary restrictions of MAOIs must be strictly followed.

TABLE 9.1. Medications with FDA indications for panic disorder.

Medication	Starting dosage	Recommended daily dosage
SSRI		
• Paroxetine	10 mg daily	40–60 mg
• Fluoxetine	10 mg daily	20–60 mg
• Sertraline	25 mg daily	50–200 mg
SNRI/SSRI		
• Venlafaxine XR	37.5 mg daily	75–225 mg
• Duloxetine	20 mg daily	30–60 mg
Benzodiazepines		
• Alprazolam	0.5 mg tid[a]	0.5–2 mg tid[a]
• Alprazolam CR	0.5–1 mg daily	3–6 mg daily
• Clonazepam	0.25 mg bid[b]	0.5–2 mg bid[b]

Note that table applies to regular dosing in healthy adults. Pediatric and elderly dosing will be different, and may not be indicated.
[a]Three times per day.
[b]Twice per day.

Certain drugs may be less effective than would otherwise be expected. For example, although drugs that are potent norepinephrine reuptake inhibitors can eventually suppress panic, they tend to induce tremor, "jitteriness," and elevated heart rate. This, then, is anxiety provoking for patients and reduces tolerability. Such drugs would include certain tricyclics like desipramine. Furthermore, bupropion, which acts on pre-synaptic norepinephrine and dopamine, appears to be devoid of anti-panic properties. In addition, buspirone, which has anxiolytic properties for generalized anxiety (i.e., the "worry" type of anxiety), does not improve panic, and may actually worsen it. This probably has to do with the complex relationship between serotonin and anxiety regulation in the brain. Buspirone is a serotonin 1A partial agonist. Stimulation of these receptors actually increases the firing of the locus ceruleus, which is thought to underlie panic attacks.

Regardless of the antidepressant chosen, there are certain common principles to follow. Because of the sensitivity of panic patients to side effects, the adage to follow is "start low and go slow." That is, instead of beginning at a standard, antidepressant dose of a drug, start lower, and titrate the dose of the drug based on tolerability and efficacy. For example, sertraline is available in a 25 mg tablet. It is possible even to break that in half and start at only 12.5 mg. The dose, then, can be advanced in 12.5–25 mg increments every 1 or 2 weeks until panic suppression is achieved. This may ultimately require standard antidepressant doses (e.g., 50–150 mg/day). However, it takes time to achieve the maximum effect dose. Similarly, starting at 10–25 mg of a tricyclic like nortriptyline is appropriate, followed by increases in the same increments (i.e., 10–25 mg every 1–2 weeks) (38, 39).

The target for antidepressant treatment is complete suppression of panic attacks. This speeds recovery, allowing patients to resume a normal life. Although they may experience occasional, mild symptoms, major panic attacks should not occur. If they do, then the treatment is insufficient and should be adjusted accordingly.

The duration of treatment is indefinite, although many patients prefer to stay on the drug permanently for fear of a return of panic. Obviously, the drug is only effective while it is still taken, and panic may return on tapering or discontinuation, confirming the patient's fear. Therefore, antidepressant treatment is often a long-term proposition, which should be taken into consideration at initiation. For example, in a woman of reproductive potential, the prescribing clinician should discuss the pros and cons of treatment during pregnancy and lactation. Concerns have been raised regarding SSRIs and pregnancy because of the potential for birth defects including primary pulmonary hypertension (although a causal link has not been established) (40). As well, these drugs may result in discontinuation reactions in infants after delivery, which include respiratory distress, agitation, excessive crying, sleeping or feeding problems, or other difficulties (41). This may occur more often with short half-life drugs such as venlafaxine and paroxetine, although reactions with other drugs may occur. It should be noted, however, that findings have been inconsistent regarding effects of SSRIs on the children of mothers who took SSRIs during pregnancy. While Casper et al (42) found that children exposed to SSRIs in utero had no difference in IQ, language skills or temperament compared to controls, the same researchers found in a different cohort trial that children born to mothers on SSRIs during pregnancy had lower Apgar scores and scored lower on a psychomotor development index. Also, the clinician and patient must consider that uncontrolled panic attacks during pregnancy can be problematic, and may result in disability or even suicide. Moreover, the risk for cleft lip and palate and perinatal complications may be increased by panic disorder in the mother (43, 44). Therefore, the decision may not be a simple one.

9.2.7.1.2. Benzodiazepines

There are several possible uses for benzodiazepines in panic disorder. For example, relatively lower potency drugs such as oxazepam may be used on an as-needed basis early in treatment to both reduce initial anxiety and the anxious symptoms that can be induced by antidepressants. In this mode of treatment, the medications are used on an intermittent, as-needed basis, until the other treatments (e.g., antidepressant or cognitive behavioral therapy) take effect.

Higher potency benzodiazepines such as alprazolam and clonazepam are very effective to suppress panic attacks, and both have carried a US FDA indication for panic. The dosing range in clinical trials for alprazolam was 1–10 mg/day; however, typical amounts used in practice would range from 1 to 5 mg/day, in two or three divided doses. The dose of clonazepam for seizure disorders ranges as high as 20 mg per day. However, a more typical range for panic is 1–4 mg per day, divided. In both cases, the dose should be started low and titrated upward as needed. Beginning with 0.25–0.5 mg bid, the dose should be advanced within the dosing range in steps of 0.5–1.0 mg per week until either panic attacks are completely suppressed, or there are dose limiting side effects.

Common side effects with these benzodiazepines include excessive sedation and ataxia (clumsiness), which may be associated with an increased likelihood of motor vehicle or other accidents, or falls. Patients, then, must be warned about driving, operating machinery, or other activities requiring fine motor skills. Moreover, this class of drugs should not be combined with alcohol. Benzodiazepines interact with alcohol and increase the intoxicating effects. In severe cases, respiratory suppression can occur, although this is much more common with over dosage.

Uncommonly, unexpected emotional reactions to benzodiazepines can occur. For example, a small percentage of patients will experience a paradoxical increase in anxiety, which may be associated with irritability, agitation, and even combativeness. As well, a small number of patients may actually feel more depressed, and suicidal ideation may occur. In 2008, the FDA formally added a warning (short of a "black box" warning) regarding the increased risk of suicide for patients on clonazepam (and

other seizure medications) (45). Therefore, both the patient and, if possible, a significant other (e.g., a spouse or parent) should be warned of these effects.

However, the most serious concern about the use of benzodiazepines is dependency. Although the rate of true abuse of this class of drugs is relatively low, consistent use will produce physical dependency and a propensity to experience withdrawal reactions on abrupt discontinuation or reduction in dose. Withdrawal symptoms can include nausea, ataxia, dizziness, diaphoresis, anxiety, and elevated blood pressure. Abrupt discontinuation from higher doses may precipitate a seizure. As well, panic patients often experience marked worsening of anxiety with panic attacks on attempts to taper or discontinue the medications. This, in turn, can make these drugs very difficult to stop. For this reason, the potential for dependency and difficulty discontinuing should be explained to the patient before starting. For most patients with panic, the prescription of a high potency benzodiazepine to be used on a regular basis for panic suppression will lead to long-term use. Therefore, these drugs generally should be used as a last resort after other classes have been used.

9.2.7.2. Psychotherapy

A variety of therapies have been tested for panic, with varying success. Classical behavioral therapy, which includes graded exposure (discussed in detail below), can be helpful. The broadest evidence base supports the use of cognitive behavioral therapy (CBT) (46) and now there is also evidence to support the use of internet-based CBT (47). Additionally, there has been one randomized controlled trial supporting the use of panic-focused psychodynamic psychotherapy (48). It should be noted, however, that the comparison condition in that trial was applied relaxation training (another treatment without strong empirical evidence) and there was not a placebo (or equivalent) condition in the study. Other kinds of therapy have limited evidence supporting their usefulness in this condition.

CBT combines several components to manage the breadth of symptoms in panic disorder. For example, CBT incorporates classical behavioral therapy to deal with avoidance behavior. This involves graded re-exposure to the feared place or thing. This may begin with relaxation and guided visualization, leading ultimately to exposure to the situation in gradual steps. However, to get to this point, patients generally must deal with their exaggerated reactions to physical cues. These so-called catastrophic misinterpretations must be identified and confronted. This may require a process referred to as interoceptive exposure, in which physical sensations are generated by a variety of means (including caffeine or vigorous exercise). The therapist, then, will lead the patient through stages of correctly interpreting the physical sensations. This, over time, leads to extinction of the fears of inner stimuli. In turn, with gradual exposure to feared environments, the phobic anxiety can be extinguished (49, 50).

9.2.7.3. Course and Prognosis

The natural course of untreated disease is often chronic, and outcomes can be poor. Often, patients will see many professionals before arriving at an accurate diagnosis leading to effective treatment. This may be due, in part, to the difficulty in differentiating between panic attacks and other medical conditions. The delay in correct diagnosis can be catastrophic, with the development of progressive phobic avoidance. However, with early diagnosis and vigorous pharmacological and psychological treatment, most people have an excellent prognosis. Note that panic may be a recurring problem, although this may be reduced by the use of CBT.

9.3. Generalized Anxiety Disorder

9.3.1. Overview

An essential feature of generalized anxiety disorder (GAD) is unrealistic or excessive worry and apprehension about life circumstances. Sources of such worry can be varied but are often commonplace issues including health, finances, social acceptance, employment and job performance, family and marriage. This disorder may seem like a simple exaggeration of everyday concerns, but it is overshadowed by more severe tension, intrusive worries, anxious mood, and other symptoms. Comorbidity is common, and patients may suffer as "chronic worriers" without treatment. To meet DSM-5 criteria, the anxiety and worry should be present more days than not for at least 6 months, and the person should have difficulty controlling the worry.

The symptoms involved with GAD are both psychological and physical. Psychologically, the person with GAD can experience apprehension, anxiety, and hypervigilance. The latter reflects a propensity to mentally scan the environment to anticipate future stressors. In other words, the negative anticipation of the "next bad thing" is continually present. As well, people with GAD may startle easily and find themselves irritable and impatient. They often ruminate about potential unfortunate events, such as the death of a family member, financial disaster, social rejection, serious illness, or job termination. Even though the person may understand that the fears are unrealistic, the anxious preoccupation persists. Their concentration is often poor, and

some experience difficulty with memory. At night, their minds remain active so that they have difficulty in falling asleep, and when they fall asleep, they may do so in a fitful and interrupted manner.

There are multiple somatic symptoms that a patient may also experience, including muscular tension, aches, fatigue, increased agitation, irritability, restlessness, trembling, and difficulty relaxing. Signs of autonomic hyperactivity may also be present, including palpitations, sweating, hyperventilation with accompanying chest tightness, lightheadedness, and paresthesias. Gastrointestinal symptoms may also be present including abdominal distress, nausea, or diarrhea. Some patients may have increased urinary frequency. It may also affect their diet, with some people overeating and others restricting.

9.3.2. Diagnostic Criteria

Excessive worry is the hallmark of this GAD (27). In order to diagnose GAD, the symptoms must have persisted for at least 6 months. A person must experience multiple psychological and somatic symptoms during this time. These include muscle tension, restlessness, easy fatigue, difficulty concentrating, irritability, and sleep disturbances. While these symptoms can coexist with other disorders, the anxiety experienced must be distinguished from other DSM-5 disorders. For instance, the patient's anxiety and ruminations cannot be about having a panic attack as in panic disorder, social situations as in social anxiety disorder or obsessions as in OCD. Rather, the worries are about real life circumstances, albeit exaggerated. Another important feature of the diagnostic criteria is that the symptoms should cause significant distress and may impair everyday functioning. The symptoms should not merely be the result of effects of drugs or alcohol or general medical conditions that can present in the same way.

9.3.3. Epidemiology

Epidemiological data suggest that the 1-year prevalence rate of GAD is around 2.6%, with a lifetime prevalence rate of 6.2% (51). Since this condition may seem like normal worry, it is underdiagnosed. As with many other mood and anxiety disorders, women are more commonly affected than men. There is also a high comorbidity rate (50% or more) with depression and other anxiety disorders. Patients often present to primary care providers with either somatic complaints that are related to the underlying anxiety (e.g., insomnia or fatigue), or exaggerated concerns about their own health or that of significant others. Together, this leads to overuse of the medical system and frustration on the part of both patient and provider. Unfortunately, only about one quarter of patients are diagnosed.

9.3.4. Etiology

9.3.4.1. Genetics and Biological Factors

The propensity for GAD is at least partially heritable, with strong influence of environmental factors (52). The influence of environment may be either early adversity or recent stressors. However, GAD shows significant concordance with the features of the emotionally reactive temperament (also referred to as neuroticism) (53). Temperament is partially heritable and may serve as the foundation of risk for GAD (54). Moreover, the propensity for exaggerated emotional reactivity to exogenous stressors increases the propensity for major depression; this may explain the high concordance between GAD and depression (52, 55). In many, the GAD is the stable characteristic of personality, with intermittent episodes of depression related to recent stress. Therefore, the evidence of genetic risk, anxiety, and depression may reflect the interaction of genetically derived temperament and life adversity.

In fact, the distress-related symptoms of GAD are commonly found in other conditions (23, 24). Therefore, GAD has almost complete overlap with the symptoms of other mood and anxiety disorder. It is the specific symptoms of those disorders that distinguish them from GAD.

GAD shares symptoms with other anxiety disorders and involves similar neural substrates discussed earlier. For example, exposure to pictures of anxious faces heightens activity of the amygdala (56). Additionally, functional imaging studies have linked increased insular cortex activation to the brain's processing of affect, such as fear and sadness; it also affects how cognitive processing and behavioral responses are linked (57). Because GAD shares similar symptomology with other anxiety disorders, it should not be too surprising that similar neurochemical pathways and anatomical structures are involved as well.

Serotonin and GABA systems have been implicated in GAD; this may reflect more on the effects of psychotropic drugs than the actual causal dysregulation of brain function. As noted in the general discussion of the neural substrate, anxiety is a normal response to certain situations. It is regulated by many distributed and interacting brain systems, as well as the neurotransmitters serotonin, GABA, and others. Therefore, dysregulation in any of several different modulators of the anxiety apparatus may result in persistent anxiety symptoms.

9.3.4.2. Psychological Factors

The prominent psychological feature of GAD is the propensity toward anticipation of future negative events. This is coupled with playing out plans to respond to the potential events. Because the fears are exaggerated, the person spends a great deal of psychological energy in the constant "contingency planning." The question, then, is why does that occur in the first place?

As noted earlier, GAD appears to derive, in part, from temperamental features of high emotional reactivity to stress—either real or anticipated. This pattern of reactivity can be seen as an aversive conditioning paradigm. That is, in past adversity, the person experienced high anxiety that was difficult to control. This, then, represents a negative conditioning paradigm in which the person develops fears of possible future stressors. This becomes further reinforced in at least two ways. First, the worry itself causes distress, which heightens subsequent fear. However, occasionally the fear is realized, in which case future negative expectation is reinforced. Curiously, even though most fears do not come to pass, the occasional accurate prediction overrides extinction, and the worry persists.

This is matched with the anticipation that a future stress will be so bad that the person will not be able to handle it effectively. So, for example, a common fear is about the loss of a loved one—particularly a child being harmed or dying. The expectation is that the experience will be too great to bear.

There also is a kind of self-fulfilling nature to the problem as well. That is, that the fears lead to a modification of future behavior which may increase the likelihood of the event actually occurring. An example would be a person who fears abandonment by a girlfriend or boyfriend. The person may become obsessed with the person's fidelity, repeatedly challenging their faithfulness. Simultaneously, the person may engage in "clinging" behavior, such as insisting on constantly knowing the whereabouts of the other. This leads to frustration in the other person, and an eventual demise of the relationship. The fear, then, fulfills itself.

9.3.5. Treatment

9.3.5.1. Pharmacological

SSRIs or serotonin-norepinephrine reuptake inhibitors (SNRIs), are the most commonly prescribed psychotropics for the treatment of generalized anxiety disorder. People with GAD as a rule are not as sensitive to side effects as those with panic disorder. However, many of the same principles apply: first, start the dose relatively low, and, then, advance as required and tolerated. The notion is to reduce the anxiety to normal levels, allowing the person to live a normal life. The drugs approved for the treatment of GAD are listed in Table 9.2. While it should be noted that paroxetine and escitalopram are the only SSRIs with FDA indications for GAD, head-to-head randomized controlled trials (RCT) showed comparable efficacy between escitalopram, sertraline, and the SNRI venlafaxine XR (58).

Buspirone is a serotonin 1A receptor partial agonist, and has a moderate anti-anxiety effect (59). It is generally well tolerated and it has a low potential for sexual side effects. Furthermore, it does not have the potential for dependency or withdrawal reactions that plague benzodiazepines. Therefore, it is a good initial choice for patients with GAD.

A number of benzodiazepines have indications for GAD and, in fact, have quite potent anti-anxiety effects. However, as discussed with panic disorder, the effectiveness of benzodiazepines makes them highly reinforcing. Therefore, benzodiazepines have a high potential for dependency in this population. Low potency benzodiazepines may be used on an as-needed basis early in the course of treatment with SSRIs or SNRIs. However, generally, other treatments, including antidepressants, buspirone, or cognitive behavioral psychotherapy should be used prior to the regular use of benzodiazepines.

TABLE 9.2. Medications with FDA indications for generalized anxiety disorder.

Medication	Starting dosage	Recommended daily dosage
SSRIs		
• Paroxetine	10 mg daily	20–50 mg
• Citalopram	10 mg daily	10–40 mg
• Escitalopram	10 mg daily	10–20 mg
Buspirone	7.5 mg bid[a]	30–60 mg daily[b]
SSRI/SNRI		
• Venlafaxine XR	37.5 mg daily	75–225 mg
• Duloxetine	20 mg daily	30–60 mg

Note that table applies to regular adult dosing. Pediatric and geriatric dosing will be different, and may not be indicated.

[a]Twice per day.

[b]Usually given in a divided dose 15–30 mg twice per day.

β-Adrenergic agents such as propranolol have been used in the past to treat anxiety disorders. However, the effect is temporary and may facilitate the emergence of depression (60). Therefore, they should be avoided. Tricyclic antidepressants also are effective (61), but due to adverse side effects have given way to better tolerated agents such as the SSRIs.

Other antidepressants often tried in GAD include mirtazapine and bupropion. These are frequently used for patients who cannot tolerate the gastrointestinal or sexual side effects of SSRIs. There are currently no RCTs to support the treatment of GAD with mirtazapine (58), but there is one RCT supporting the efficacy of bupropion in GAD. Additionally, there is evidence to support the use of the anticonvulsant pregabalin, which has had 6 positive double blind RCTs supporting its use (58).

9.3.5.2. Psychological Treatment

Due to the complex environmental contribution in the development of GAD, psychoeducation and psychotherapy can prove helpful. Psychoeducation can identify lifestyle choices and life circumstances that can aggravate symptoms. For instance, many substances, such as caffeine, can lead to increased anxiety if consumed in large quantities. Various self-regulatory treatments such as biofeedback, relaxation, and meditation have been used with mixed results. However, cognitive behavioral therapy has the most evidence demonstrating its efficacy in treating generalized anxiety, and may be coupled with medication therapy (62). Techniques of cognitive therapy include cognitive restructuring; that is, improved reality testing in appraisal of risk. This can be coupled with improving problem-solving skills and relaxation techniques. There is preliminary evidence supporting mindfulness-based cognitive therapy for the treatment of GAD, but there has been no RCT yet to study this modality. This group therapy employs mindfulness meditation in a group setting and was shown to decrease both anxiety and depressive symptoms (63). While there is only one study regarding its use specifically in GAD, one meta-analysis of 39 different studies showed an effect size of 0.97 for the treatment of anxiety symptoms across an array of medical and psychiatric diagnoses (64). Other therapies have limited empirical support.

9.3.6. Differential Diagnosis and Comorbidity

The differential diagnosis of GAD includes an array of physical and psychiatric illnesses. In addition, there is a high degree of comorbidity with GAD and other disorders. Because of a high degree of concordance in symptoms between GAD and both mood and other anxiety disorders, care must be given to differentiate GAD from other disorders. This point is highlighted in the diagnostic criteria for generalized anxiety disorder.

GAD may accompany most any other psychiatric disorder, although it is most commonly associated with mood and other anxiety disorders. Anxiety symptoms are often prominent in patients with depression (e.g., anxious or agitated depression), making the differential diagnosis difficult. In fact, none of the symptoms of GAD are completely unique to the disorder. For example, patients with depression and other anxiety disorders can have negative rumination as a significant associated symptom. Therefore, making the distinction based on shared features is not an effective strategy. Knowing the distinguishing features of other disorders is a much better strategy. For example, patients with both GAD and major depression can have rumination, sleep disturbance, fatigue, poor concentration, and irritability. However, patients with GAD do not have prominent sadness, low motivation, guilt, or suicidal ideation in the absence of comorbid depression. These are features that help distinguish the diagnosis of major depression. Similarly, elements that distinguish anxiety disorders include "true" obsessions and compulsions (obsessive-compulsive disorder [OCD]), panic attacks (panic disorder), circumscribed fears (specific phobia and social anxiety disorder), and re-experiencing traumatic events (post-traumatic stress disorder [PTSD]).

Certain physical illnesses share features with GAD, which can prove problematic if they are not accurately ruled out or diagnosed. This would encompass hyperthyroidism (including Graves' Disease); associated symptoms include palpitations, insomnia, sweating, heat intolerance, increased appetite, diarrhea, tachycardia, tremor, weight loss, and warm, moist skin. Enlarged thyroid or exophthalmos may be present on physical exam. If a diagnosis of thyroid disease is suspected, thyroid function tests should be completed. Other medical illnesses can include angina or myocardial infarction, arrhythmias, Cushing's disease, obstructive sleep apnea, porphyria, and premenstrual dysphoric disorder. Many neurological diseases can have anxiety symptoms associated; this would include stroke, Parkinsonism, Alzheimer's Dementia, Lewy Body Disease, CNS infections (e.g., HIV), or other encephalopathies.

Substance use and withdrawal must also be considered with GAD. Substance-induced anxiety symptoms may appear with intoxication from many substances, such as caffeine, cocaine, amphetamine or other stimulants, hallucinogens, or marijuana. If the anxiety symptoms are substance-induced, they typically resolve after discontinuation of the offending substance. Withdrawal from alcohol, nicotine, benzodiazepines, or other sedatives may be anxiogenic. Many other medications also contribute to the development of anxiety, including sympathomimetics, aminophylline, prescribed stimulants (amphetamines or methylphenidate), levodopa, antihistamines, albuterol (and related drugs), steroids, metaclopramide, interferon, dopamine agonists (bromocriptine, pergolide, amantadine, levodopa), selegiline, and thyroid hormone preparations.

It is worth noting that withdrawal after discontinuation of alcohol, benzodiazepines, or other sedatives can be mistaken for generalized anxiety symptoms, and care should be made in differentiating substance related diagnoses due to potential significant adverse events—delirium tremens, seizure or death. Signs and symptoms of withdrawal can be very easy to misattribute, especially in patients in whom substance abuse is not suspected. This may be a particular issue with short acting drugs—including benzodiazepines such as alprazolam—that are taken on a regular basis. Moreover, inter-dose anxiety may be a particular problem with short half-life agents.

9.3.7. Course and Prognosis

Generalized anxiety disorder is a long-term condition. Prognosis, then, depends heavily on identification and therapeutic intervention. However, it is a treatable disorder with appropriate interventions, both pharmacological and psychotherapeutic.

9.4. Phobic Disorders: Specific Phobia and Social Anxiety Disorder

9.4.1. Overview and Presentation

Phobic disorders are characterized by intense fears of a circumscribed stimulus. In the case of specific phobia, the fear, aversion, and avoidance tend to be of things in the environment; for example, storms, animals or insects, heights, and the like. By contrast, social anxiety disorder is a type of fear that is confined to settings of social interactions. These would include speaking in public, eating in restaurants, and social interactions such as parties.

9.4.2. Specific Phobia

With specific phobia, the stimulus that causes anxiety may be an object or situation. Exposure to these things produces intense fear, anxiety, or feelings of aversion, leading a person to escape the situation or endure it with intense discomfort. The response is tantamount to a panic attack; however, with a phobia, the attack is in response to a specific stimulus, and is not spontaneous (although panic disorder may be superimposed on a long-term course of phobia). However, like panic, anticipatory anxiety and avoidance of feared situations may lead the person to modify his or her lifestyle.

Specific phobias are common and often do not affect a person's life in a major way. For example, a person with a spider phobia may avoid his attic or basement, but may not otherwise be seriously affected, unless exposed to an actual spider. In fact, a majority of affected persons never seek treatment. However, the person may have a substantial impairment. An example would be a person who fears enclosed spaces (claustrophobia) and completely avoids elevators. This may have an impact on their vocational choice or attainment.

9.4.2.1. Diagnostic Criteria

Diagnostically, this disorder differentiates from other anxiety disorders primarily because of a unique fear arising in very specific circumstances. In children, the fear or anxiety may be expressed by crying, tantrums, freezing, or clinging behavior. Confronting the phobic stimulus results in a strong sense of dread and often a desire to flee, and the person may experience physiological and somatic symptoms that are found in other anxiety disorders. Autonomic arousal may result in panic-like symptoms, such as trembling, shortness of breath, sweating, or tachycardia. Certain phobias (e.g., blood phobia) have been noted to have a sharp fall in blood pressure leading to dizziness and possible syncope (a "vasovagal" response). The fear or anxiety is clearly out of proportion to the actual danger posed by the object or situation. The diagnosis should be sensitive to the sociocultural context; the anxiety or fear should be excessive as compared to other members of the sociocultural group.

9.4.2.2. Epidemiology

Specific phobia is one of the most common disorders and may afflict up to 25% of the population with mild symptoms, although specific phobias meeting full diagnostic criteria have a 12- month prevalence of 7.1% and lifetime prevalence of 9.4%. There is increased risk of having this diagnosis in females and persons with low income (65). Onset of symptoms may occur in childhood, and commonly before adult life. Little is still known about the course of untreated specific phobias because phobias may resolve spontaneously or people learn to cope with these stressors, and may never come to attention.

9.4.2.3. Etiology

Little is known about the development of specific phobia from a biological or genetic standpoint. Little research has been done to isolate specific factors in the development of this disorder, both biological and otherwise. Observers have noted that specific phobia runs in families, and there may be a predisposition for family members of an afflicted patient to develop a phobia of the same type. As well, people with other anxiety disorders such as panic or social anxiety disorder may be at increased risk. There is research to suggest that evolutionarily relevant fears can occur without being learned by specific experiences (66, 67). Phobias generally do not occur as a result of a traumatic event. Although traumas may lead to phobic avoidance, this usually occurs in the context of traumatic stress disorders (see below). However, prior abuse or similar early traumas do not appear to predispose to phobias.

Specific phobia involves panic-like responses, and is thought to involve the same pathways as panic disorder (see above). Moreover, unlike spontaneously occurring panic, the phobic stimulus has to be first recognized, which then activates the neural response. Therefore, cortical activity is involved, as well as the amygdala and hippocampus. However, ultimately, midbrain structures, particularly the locus ceruleus, are likely to be involved.

9.4.2.4. Differential Diagnosis and Comorbidity

Comorbidity of other anxiety and depressive disorders is common in specific phobia, which may require treatment. However, care should be taken with regard to certain disorders. For example, people with psychotic disorders such as schizophrenia may have fears of circumscribed objects or situations. However, this kind of fear involves delusional thinking. As well, social anxiety disorder may result in fear and avoidance of certain circumstances that involve exposure to scrutiny by others, as described in greater detail below. With obsessive-compulsive disorder (OCD), the obsessional thinking or compulsive behavior may be stimulated by specific places or things, which then are avoided. As an example, people with OCD often avoid public restrooms because of a fear of contamination. Finally, simple phobias can cause extreme autonomic arousal similar to panic disorder, and may be mistaken for panic attacks. However, the recurring presence of specific stimuli will help differentiate between these two disorders. In fact, specific phobia is quite unlike panic in certain ways. People with phobias usually know precisely what they fear. Further, they seldom, if ever, fear becoming psychotic or having some serious medical illness such as a myocardial infarction. Specific phobias are typically easily recognized.

9.4.2.5. Treatment

No medications are indicated for the treatment of specific phobia. Drugs such as benzodiazepines may ameliorate symptoms, when the exposure can be anticipated. For example, people with a phobic reaction to blood may have high anxiety when blood is drawn. Likewise, people with claustrophobia may not be able to endure an MRI scan, because of being in an enclosed space. In these kinds of situations, a benzodiazepine can be used on an as-needed basis.

However, the treatment of choice for specific phobia is behavioral therapy, particularly exposure and desensitization. This kind of treatment often involves initial relaxation training, which then is followed by progressive exposure to the phobic stimulus. As an example, people with insect phobias might begin their treatment with looking at pictures of feared insects. They can progress to a plastic insect, and then, with time, to the actual insect. When done repeatedly, the fear is usually extinguished, and the phobia is no longer a problem.

9.4.2.6. Course and Prognosis

Phobias can develop throughout the life span. Phobias that develop in childhood may spontaneously remit later in life, although persistence is most common. As data suggests, many persons suffering from phobias will not present for treatment specifically for their phobia. Poorer outcomes have been associated with persons suffering from multiple phobias and lack of motivation or participation in therapy.

9.4.3. Social Anxiety Disorder

9.4.3.1. Overview and Presentation

Social anxiety disorder (previously referred to as social phobia) is defined as excessive fear of situations in which they may act in an anxious manner (e.g., have trembling hands) or otherwise show the anxiety and in which others might negatively evaluate them. They typically fear that they will or do something humiliating or embarrassing, which may lead to rejection or offense to others. This anxiety may be coupled together with a fear of being unable to avoid or escape certain situations. Many people experience fear or anxiety in almost all social situations. In children, the fear or anxiety may be expressed by crying, tantrums,

freezing, clinging, shrinking, or failing to speak in social situations. In social situations, people may experience anxiety that approaches the severity experienced in a panic attack. Consequently, the situations are either avoided or endured with intense discomfort. The presence of fear or anxiety is often not circumscribed to a single type of situation, and may extend to multiple social situations, even generalizing to all social interactions. This latter state is referred to as generalized social anxiety disorder, which may produce significant impairment.

A patient may experience fear when required to perform socially, such as speaking or performing publicly, participating in groups, or engaging in conversation. These kinds of fear are common, and may not meet full diagnostic criteria for social anxiety disorder. Other fears may involve more unusual situations. These can involve fears of eating in public, using public restrooms, or even writing while others are watching (for example, signing a check). Social anxiety disorder usually has a circumscribed fear of embarrassment. For example, although fear of writing may seem strange, the anxiety derives from a fear of appearing anxious, such as having shaking of the hands. Similarly, people often fear speaking in public because of a worry that they may exhibit the fear itself. People fear others' seeing their hands shake while speaking. Therefore, social anxiety disorder has a self-perpetuating characteristic. The symptoms associated with fear, such as shortness of breath, tachycardia, and tremor, actually aggravate the anxiety. This, subsequently, augments the anticipatory anxiety of other similar circumstances. The person often has had growing anxiety over time, which culminates in the actual experience. Showing anxiety, then, is inevitable.

9.4.3.2. Diagnostic Criteria

In social anxiety disorder, a person must show significant fear related to being exposed to scrutiny by others. People with this condition fear showing their anxiety and experiencing embarrassment. In other situations, people may fear saying something foolish, unintelligent, or embarrassing, and, therefore, avoid social interactions. There often is a history of avoiding social or performance situations, or enduring such situations with great distress. The fear often involves multiple areas of social interactions, and may result in significant impairment.

The fear is distressing and often causes significant problems in the person's life, interfering with multiple areas requiring social interactions. Although people may learn to "live around" the phobia, it often is at the price of educational or occupational attainment, or relationships. The symptoms are persistent, usually lasting at least 6 months (27). As in all disorders, social anxiety disorder must be distinguished from general medical conditions, the effects of substances, or other mental disorders.

9.4.3.3. Epidemiology

The 12-month prevalence of social anxiety disorder is 7.1%, while the lifetime prevalence rate is 12.1% (68). However, this may represent an underestimate, since mild symptoms are common. In the same epidemiological survey cited above, 24.1% of respondents reported at least one social fear during their lifetimes. Many people have significant fears of public speaking or being in public while engaging in various activities such as eating or writing, but only a small percentage of them meet full criteria for social anxiety disorder. This may be the result of having engaged in effective avoidance of the kinds of interaction that stimulate the fears. Females have a greater prevalence rate than males in the population, but an equal portion appear to present for treatment. The age of onset is usually during adolescence.

9.4.3.4. Etiology

Genetics and biology may play a significant role in the development of this disorder. One study, using neuroimaging, demonstrated increased reactivity in the amygdala in response to social cues (69). Abnormalities in the serotonergic and dopaminergic systems, as well as hyperreactivity of the autonomic nervous system in afflicted individuals have been noted (70, 71). Family and twin studies suggest that genetics contributes a moderate level of risk, and that the remainder of the risk is largely due to environmentally specific factors. As noted for other anxiety disorders, the emotionally reactive temperament appears to contribute significantly to the predisposition to phobias in general (26). Best-fit models support the notion that genetics, familial (i.e., "shared") environment, and individual-specific environmental factors contribute independent, but interacting, risk (72, 73).

There is also evidence to support that temperament and other factors such as cognitive distortions play a role in the development of social anxiety disorder, along with interaction with the environment. Children who have a first-degree relative with social anxiety disorder appear to be at a two- to threefold greater risk for developing social anxiety disorder than children who do not have a first-degree relative with this disorder. In addition, a mounting body of evidence implicates various neurobiological pathways in the development of this disorder, similar to those found in other anxiety disorders.

Social learning theorists have asserted that social anxiety can be "learned" through vicarious observation of others being humiliated in a social situation . Additionally, it has been found that patients diagnosed with social anxiety disorder are more likely to report that *their* parents avoided social interactions, suggesting that the modeling of social anxiety plays a role.

However, these theorists are quick to note that a temperament known as behavioral inhibition is thought to be the diathesis that separates persons who develop social anxiety disorder from those who do not, as certainly every person who has observed social adversity does not develop social anxiety disorder (74).

Classic behavioral theory posits that persisting fears may be associated with certain environmental stimuli (for example, a threatening animal), or that fears may develop in the context of pairing of a benign cue and another feared stimulus. The latter is a traditional view of "irrational phobias," that is, phobias of relatively neutral, non-threatening objects or situations. Although phobias may occur in the context of an adverse situation, traditional behavioral views have certain significant limitations. The fear of either an unconditioned (i.e., threatening) or conditioned stimulus (one that generates fear as a result of being paired with a conditioned cue) may certainly occur; however, the repeated presentation of the situation without threat typically results in extinction of the fear. This phenomenon, almost by definition, does not occur with phobic disorders. Therefore, although phobias may, on the surface, appear to correspond to a classical conditioning model, certain features are not consistent with this view. Therefore, sustained phobias are likely to arise from a mixed model, which may or may not depend on the presentation of an environmental threat.

9.4.3.5. Differential Diagnosis and Comorbidity

The diagnosis of social anxiety disorder requires differentiation from other similar appearing clinical pictures. The most significant differential is with other anxiety disorders. As already noted, interviewing to elicit specific features is most helpful. Although people with obsessive-compulsive disorder may avoid social situations, the reasons typically are clear. For example, they may have social avoidance because of a fear of contamination by exposure to others. Similarly, panic disorder often results in social avoidance, but in the context of a history of spontaneous panic attacks. Moreover, whereas both social anxiety disorder and panic disorder may share a fear of public embarrassment, the episodes of panic disorder are not context-specific—that is, they do not always occur on social exposure. People with post-traumatic stress disorder may have social anxiety and aversion, but this is specific to earlier trauma. For example, a woman who has been raped may carefully avoid situations in which she is exposed to men. However, the causal thread to the earlier trauma is usually clear.

Various personality disorders also may have a significant component of social avoidance. Patients with schizoid or schizotypal personality disorders may have little social interaction. However, their minimal social interaction is not the result of social anxiety per se, but rather is preferred by the individual. People with avoidant personality disorder also have social fears, including fears of embarrassment; however, this is a life-long and pervasive pattern. Of note, however, generalized social anxiety disorder is difficult to distinguish from avoidant personality and, in fact, may be the same condition, as both tend to be chronic and pervasive.

Psychotic disorders such as schizophrenia must also be considered. For example, psychotic patients may avoid social interaction, but because of specific, paranoid fears. They may, for example, fear that people are plotting harm against them, not simply that they might do something embarrassing. Moreover, the so-called negative symptoms of schizophrenia, which include apathy and social withdrawal, can result in similar avoidance. However, this occurs in the broader context of schizophrenia.

Social avoidance is seldom the result of the direct effects of substances (or withdrawal) or other general medical conditions. People with serious substance abuse may have relatively little social interaction. However, this is usually not the result of fear of embarrassment (although the physical consequences of substance abuse may make people want to avoid others).

9.4.3.6. Treatment

Both pharmacological and psychotherapeutic methods are useful in the treatment of social anxiety disorder. A number of drugs carry specific indications for its treatment. In particular, these include the SSRIs paroxetine and sertraline, as well as the SNRIs duloxetine and venlafaxine extended release. A summary of these medications along with their common dosages are found in Table 9.3. The doses used are similar to those used for major depression. The problem of increased anxiety early in treatment

TABLE 9.3. Medications with indications for social anxiety disorder.

Medication	Starting dosage	Recommended dosage
SSRIs		
• Paroxetine	10 mg daily	20–50 mg daily
• Paroxetine CR	12.5 mg	12.5–37.5 mg daily
• Sertraline	25 mg daily	50–200 mg daily
SSRI/SNRI		
• Venlafaxine XR	37.5–75 mg daily	75–225 mg daily

Note that table applies to regular adult dosing. Pediatric and elderly dosing will be different, and may not be indicated.

with SSRIs and SNRIs seen in panic disorder is not as prominent with social anxiety disorder. However, the principle is the same: start at a low dose and titrate upward until the desired result is achieved—that is, suppression of the social anxiety.

Other medications are also sometimes used in the treatment of the disorder. Benzodiazepines may be helpful when used on an as-needed basis; for example, people may take a relatively low dose of benzodiazepines such as lorazepam, clonazepam, or alprazolam in situations in which the feared social interactions cannot be avoided. This is often done prior to public speaking, for example. However, adverse reactions such as drowsiness or interference with recall may pose a problem. Therefore, the drug should be tested in a "non-demand" situation prior to being implemented. Note that many people have anxiety in multiple social situations, or may have unpredictable social interactions, making the use of benzodiazepines problematic. Due to the issue of dependence, benzodiazepines should generally be avoided for continuous use, particularly given the evidence of the effectiveness of SSRIs and SNRIs. Buspirone may also be effective in social anxiety disorder but the data are conflicting (58). Older drugs such as the monoamine oxidase inhibitors may also be effective, but are seldom used because of the risk of adverse events. Finally, drugs that block the autonomic arousal associated with social situations can also be used. Most particularly, this includes beta-blockers such as propranolol or atenolol, which can be used in anticipation of social exposure such as public speaking. As with benzodiazepines, beta-blockers should be tried prior to the social interaction because of the potential for side effects.

Traditional behavioral and cognitive behavioral therapy are effective. Both involve common elements, most particularly graded exposure to the feared stimulus. For example, a person with a severe fear of public speaking may begin by giving a speech alone to a mirror, followed by giving the speech to the therapist, then a small number of family and friends, a larger number of familiar people, and, eventually, working up to large groups of unfamiliar people.

Cognitive methods include elements such as reappraisal and hypothesis testing. Reappraisal involves actually addressing the negative thoughts associated with the fear, for example, that the person is likely to say something foolish or otherwise be noticed by others. Hypothesis testing may involve having the patient ask other people whether they noticed the symptoms of fear (such as shaking hands), or if the patient had said something foolish. These treatments are often quite effective in producing long-term improvement. In addition, the use of medications in the absence of behavioral methods is often only partially effective.

9.4.3.7. Course and Prognosis

The course of social anxiety disorder is typically chronic in the absence of specific treatment. Moreover, the chronicity may contribute significantly to social and occupational impairment. In addition, other comorbid mental disorders such as depression may contribute independent risk, worsening the overall course. It should be noted, however, that many people have mild symptoms without significant impairment.

9.5. Trauma-Related Disorders: Post-Traumatic Stress Disorder and Acute Stress Disorder

9.5.1. Overview and Presentation

Acute stress disorder (ASD) and post-traumatic stress disorder (PTSD) are conditions that are the result of exposure to extreme and emotionally traumatic events, typically involving a threat to life. Events such as war, torture, violent or sexual assaults, and natural disasters may predispose a person to developing these disorders. Of note, DSM-5 has added that the patient does not need to have been directly exposed to the trauma, but that they may have been traumatized by learning of something traumatic happening to a family member or friend (27). Also included are patients, such as emergency first responders, who have been repeatedly exposed to the horrific details of traumatic events, although this does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related. The majority of people do not experience lasting effects of exposure to severe threats; many develop acute stress disorder, only to recover completely. In the case of post-traumatic stress disorder, symptoms may manifest immediately or after months or even years after an event happens.

Acute stress disorder is very much like PTSD, and may be considered its precursor. However, most people who suffer from ASD will not necessarily develop PTSD, and not all people who develop PTSD initially had symptoms of acute stress disorder. However, ASD and PTSD have many common elements. ASD is diagnosed when symptoms are present for at least 3 days but not more than 1 month; beyond the month timeframe PTSD should be diagnosed.

9.5.2. Diagnosis

ASD and PTSD share many common characteristics, but have some key distinguishing features. Both of them require exposure to a traumatic event, most often one that involves a threat to their life or the lives of others. They have similar symptomology,

but the temporal onset and duration of symptoms distinguish them. ASD requires a minimum of 3 days from time of the trauma before the diagnosis can be considered. The reason for this is that the majority of people will have acute symptoms that resolve rapidly after exposure to such an event. By definition, ASD should abate within 1 month. Therefore, ASD serves as an intermediate disorder on a continuum between immediate stress reactions and PTSD, in which symptoms must be present for at least 1 month. If symptoms last longer than 6 months, then PTSD is considered chronic.

A formal diagnosis of ASD or PTSD requires that a person experience at least one extremely traumatic event, such as a life-threatening situation, serious injury, or a significant threat to well-being of the identified patient or other people. This involves the perception of an extreme threat, particularly of physical integrity. The person will have an extreme fear response to such an experience. Events commonly associated with development of these disorders include direct exposure to war or combat, torture, violent crime, sexual assault, and natural disasters. People who suffer from ASD or PTSD will continue to manifest significant emotional responses, which may be severe, after the event.

Diagnosing these disorders requires symptoms out of five concurrent ongoing sets of symptoms. First, the person must exhibit intrusion symptoms; that is, the person will relive events and feel as though they are actually happening again. This can include disturbing, intrusive recollections, dissociative events which are usually in the context of a reminder of the trauma, vivid dreams of the event, and visual, auditory, or other illusions that may elicit fear. Second, they may have a persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings). Third, patients may have dissociative symptoms, including derealization and an inability to remember aspects of the traumatic event (dissociative amnesia). Fourth, these experiences will result in avoidance of triggers for the anxiety—that is, reminders of the event. For example, combat survivors often avoid war movies. Fifth are arousal symptoms, the flood of intense feelings and experiences can be overwhelming for a person, and drive physiological arousal and activation. This can be exhibited as hypervigilance, exaggerated startle response, irritability, or difficulty sleeping. ASD can be diagnosed with the presence of any nine of the symptoms listed in DSM-5. For the diagnosis of PTSD, patients must have at least one symptom from all categories, intrusion symptoms, avoidance of stimuli, negative alterations in cognition and mood associated with the event(s), and alterations in arousal and reactivity. The requirement of experiencing negative alterations in cognition or mood is a category of symptoms that was newly added to the diagnostic criteria in DSM-5. This may include feelings of detachment or loss of interest in activities. The diagnosis of PTSD may also be accompanied with a specifier indicating the presence (or absence) of dissociative symptoms. The onset of symptoms may be significantly delayed in some patients; if the onset is delayed by at least 6 months, then the delayed expression specifier should be used. For a full list of symptoms, refer to the full diagnostic criteria in DSM-5, which also includes diagnostic criteria for children 6 years and younger. Note that the memories may manifest primarily in art or play in young children.

9.5.3. Epidemiology

The epidemiology of PTSD/ASD is directly associated with exposure to trauma. However, less than 10% of people exposed to trauma go on to meet full criteria for PTSD. The lifetime prevalence of PTSD in the US general population is around 6.8%, though rates are higher among women, children, and the elderly (75, 76). Many people who have been exposed to traumatic events may not meet full criteria for ASD or PTSD, but may have significant symptoms causing impairment or distress. In DSM-5, these can be classified as other or unspecified trauma-related disorders (27). Specific demographic groups are at a higher risk for ASD and PTSD. For instance, rates in war veterans are substantially higher than the general population. Similarly, refugees, survivors of concentrations camps, people who have been tortured, people with a history of early abuse, and those exposed to serious natural disasters are at high risk.

9.5.4. Etiology

The proximate cause of ASD and PTSD, the trauma itself, is clear. Unlike other anxiety disorders, these require an exposure to a specific environmental contributor (i.e., a significant traumatic event outside the range of normal experience). However, the stressor is, by itself, insufficient to cause traumatic stress disorders, as only a small proportion of people exposed to such stressors develop a full symptom picture. In addition, stressors that do not involve a direct threat to the person, such as divorce or the death of a loved one (with the exception of a traumatic death), do not typically cause ASD or PTSD.

Increased vulnerability to PTSD appears to be familial, and not due entirely to shared environmental factors such as abuse (77). Clearly, even with a genetic predisposition, the occurrence of ASD or PTSD requires traumas that are specific to an individual (77). Shared and non-shared environmental factors may be difficult to tease apart; for example, siblings may all experience abuse, while only one may have a subsequent life-threatening experience. Moreover, shared childhood environment should not be assumed in siblings raised in the same environment. Abuse or neglect may occur more with one child than another, depending on specific circumstances. One child may even be singled out for abuse, relatively sparing siblings. Of note, twin studies comparing PTSD in monozygotic and dizygotic twins demonstrated that PTSD is approximately 30% heritable (78).

Thus far, the candidate genes that have been postulated to have a role in PTSD have all been in the HPA axis, the locus ceruleus/noradrenergic system or the frontal/limbic system (78). Altered regulation of the hypothalamic–pituitary–adrenal (HPA) axis has been well studied in PTSD. Unlike what is seen in some patients with depression, this includes a relatively lower cortisol level and an enhanced feedback inhibition by cortisol (or analogs such as dexamethasone) (79). This, in turn, is consistent with the general inhibition or arousal associated with the condition. This pattern occurs in the case of PTSD related to recent traumas, but not in the context of prior traumas (such as remote abuse) (79). The opposite appears to emerge in the case of early trauma. In such cases, persistently elevated cortisol and blunted feedback suppression of the HPA axis is found, which is more like HPA axis abnormalities associated with depression. In either case, persistent dysregulation of the HPA axis appears to be significantly associated with PTSD.

Dysregulation of other neural systems has been postulated. For example, serotonin has a significant role in dampening stress responses, such as activation of the amygdala. Moreover, norepinephrine has a key role in mediating the enhanced central and peripheral arousal seen in these conditions. Further, neuropeptides that regulate these systems, such as corticotrophin releasing hormone, neuropeptide Y, and substance P (neurokinin) may be involved (80–82). However, the causal relationship is not clear.

Imaging studies suggest the involvement of specific brain regions in PTSD, particularly the hippocampus, amygdala, and frontal cortex (83). fMRI studies of exposure to reminders of the trauma suggest that the amygdala is hyperreactive. Further, the hippocampus often is reduced in volume (83), a phenomenon that may be associated with altered regulation of cortisol (84). Altered higher brain regulation of stress reactivity may be a consequence of trauma (83).

9.5.5. Differential Diagnosis and Comorbidity

The criteria for the diagnosis of ASD and PTSD are reasonably clear. However, care must be taken in making the diagnosis. PTSD-like symptoms may occur following a less severe trauma and, although this may be clinically meaningful, it does not meet criteria for diagnosis. In a related way, people with other anxiety or depressive disorders may have histories of serious trauma, including life-threatening events. Other conditions may share certain features with ASD and PTSD. For example, the insomnia associated with PTSD is found in many other conditions, such as major depression. Recurrent hyperarousal is present in other conditions such as panic or phobic disorders, and may even be present in OCD when the person is exposed to a stimulus that elicits obsessions (e.g., contamination). Moreover, PTSD is commonly associated with other DSM-5 disorders, such as major depression. However, since the treatment is quite different depending on the specific diagnosis or comorbid condition, accurate diagnosis, including recognition of comorbid conditions, is critical.

Psychotic disorders such as schizophrenia or delusional disorder may present after a significant trauma, since stressful events may precipitate acute psychosis. In fact, brief psychotic disorder may occur specifically after a serious trauma. In any psychotic condition, the content of the trauma may be incorporated into a delusional system, complicating diagnosis. Moreover, people with psychosis may have delusions about past traumas that did not occur and yet are firmly believed. Several factors, then, should be taken into consideration in the differential. It should be stressed that a psychotic diagnosis does not preclude the diagnosis of ASD or PTSD. However, in the presence of psychosis, consider several factors: 1) The plausibility of the story. 2) Proximity to the stressor—was the person actually present in the specified location at the time of traumatic event? 3) Corroboration by significant others, particularly family members. It is important to remember that corroboration may not be accurate either. The family member may believe the incorrect history, or they may deny an event that actually exists. Therefore, the whole picture has to be taken into context.

Another aspect to keep in mind is the possibility of factitious disorder or malingering. In factitious disorder, the symptoms are consciously fabricated in order to gain the sick role. As well, they may achieve attention, nurturance, and other desirable outcomes. However, in malingering, the exaggerated claims of injury (in this case PTSD) are still consciously fabricated, but occur as a result of a desire for compensation, to avoid prosecution for a crime, or to avoid work or other responsibilities. In other words, the patient is motivated by secondary gain. This may be difficult to distinguish from actual PTSD, since it may occur after a major trauma, and can co-occur with other symptoms or syndromes, such as depression or personality disorders.

Dissociative disorders can also be confused with PTSD. Dissociative conditions often occur after major traumas, especially childhood abuse. Although a dissociative event may occur on exposure to a reminder of a trauma, the person is often unaware of the event having occurred. Further, they may not exhibit other symptoms of PTSD, such as persistent hyperarousal, insomnia, or reliving the trauma.

Neither drugs nor medical conditions imitate the full syndrome of ASD or PTSD. However, medical illnesses or reactions to drugs (either acute effects or withdrawal) may occur in people who have had life-threatening traumas. These would be similar to those conditions that can cause panic type responses: pheochromocytoma or other hormone-secreting tumor, as well as alcohol or drug withdrawal.

9.5.6. Treatment

Treatment of ASD and PTSD depends on the severity and scope of symptoms, and usually requires a multifaceted approach including pharmacological, psychotherapeutic, and psychoeducational intervention, crisis management, and involvement of extended social support network such as family members, where possible.

At this time, two SSRIs—sertraline and paroxetine—carry an indication for treatment of PTSD and are considered first-line treatments for the disorder, although there is no reason to believe that the effect is limited to these two drugs. Recommended dosages are found in Table 9.4, though higher doses of these medications are often used. Medication management of ASD may simply be symptom focused, such as the temporary use of sedatives (e.g., zolpidem) or anti-anxiety drugs such as benzodiazepines. However, if the acute response is severe, or if more serious depression is comorbid, then an antidepressant is indicated.

Other medications have been studied, including the tricyclic antidepressants and MAO inhibitors, and have been found to be at least somewhat effective for PTSD. Atypical antipsychotics have shown promise for the treatment of moderate to severe PTSD, especially with concurrent psychosis; however, the evidence base is limited. Other medications are typically used to ameliorate specific symptoms of PTSD such as anxiety or insomnia. However, care must be exercised, especially with benzodiazepines, since co-occurring substance use disorders are common.

Many psychotherapeutic interventions have been tried, and a few seem to be effective. Probably the most effective approaches are trauma-focused CBT interventions, which typically involve exposure to the trauma using mental imagery, either in group or individual therapies. For example, uniform group therapies that bring together people with shared traumatic experiences appear quite effective. Effective therapies typically use exposure techniques such as exposing combat-related PTSD patients to sounds of gunfire in order to extinguish the associated fears. There is significant empirical support from controlled trials suggesting that these specialized forms of cognitive behavioral therapy are effective (85, 86). In addition, early aggressive treatment, particularly after the emergence of ASD, seems to help avert PTSD (87). For example, rapid interventions have been developed by the US military and others to avert combat-related PTSD. Particular techniques, such as exposure therapy, allow the patient to learn to confront and develop fear management strategies. However, patients may not tolerate re-experiencing, and high rates of dropout can be common. Therefore, management of factors, such as excessive anxiety, which may influence dropout, should be used.

One treatment method for trauma-related mental disorders is Eye Movement Desensitization and Reprocessing (EMDR). This method couples specific eye movement exercises with trauma-focused psychotherapy. Although there is some evidence indicating benefit, most studies of this method have had small sample sizes, often without adequate blinding, and without a placebo-equivalent condition. They also have not controlled for "allegiance effects"—that is, the comparison treatments have been delivered by EMDR adherents. Moreover, the specific eye movements that are thought to be an essential part of the treatment may not be necessary to achieve positive results (88), although this remains controversial (89). Therefore, the existing data should be interpreted with caution (90).

9.5.7. Clinical Course and Prognosis

The onset of acute stress disorder will be associated with recent trauma events. The course of acute stress disorder is self-limited, with symptoms lasting no longer than 4 weeks, though it may evolve into a more chronic pattern of symptomology. The onset of PTSD symptoms may occur at any time during the life of an individual. Delayed onset of symptoms after trauma can make predicting who will experience symptomology difficult, and many persons may have a subclinical presentation.

TABLE 9.4. Medications with indications for post-traumatic stress disorder.

Medication	Starting dosage	Recommended daily dosage
SSRIs/SNRI		
• Escitalopram	10 mg daily	20 mg
• Fluvoxamine	50 mg daily	50–300 mg
• Fluoxetine	20 mg daily	20–80 mg
• Paroxetine	10 mg daily	20–50 mg
• Sertraline	25 mg daily	50–200 mg
• Venlafaxine XR	75 mg	75–225 mg
Benzodiazepines		
• Alprazolam	0.5 mg tid	0.5–2 mg tid
• Clonazepam	0.25 mg bid	0.5–2 mg bid

Note that table applies to regular adult dosing. Pediatric and elderly dosing will be different, and may not be indicated.

Full recovery is variable, and may or may not be dependent on treatment. There are instances of spontaneous remission without treatment, with estimates at about 30%. Approximately one third never fully recover despite interventions. Many people suffering from PTSD will continue having mild to moderate symptoms despite treatment. The average time until significant recovery is 24–36 months with treatment and 64 months without. A more favorable prognosis is associated with rapid onset and short duration of symptoms, good premorbid functioning, and strong social support systems.

Obsessive Compulsive Disorder

Tanya K. Murphy, M.D., S. Evelyn Stewart, M.D., and Demian Obregon, M.D.

Abstract OCD is the fourth most common neuropsychiatric disorder with lifetime prevalence estimates of 0.4–3.5%. Family and twin studies suggest a strong genetic component, and molecular genetic studies are being carried out to identify genes contributing risk to OCD. It is postulated as a frontal-striatal disorder and functional neuroimaging studies provide a strong support for the dysfunction of cortico-striatal-thalamic-cortical neurocircuit. OCD can be secondary to a variety of medical conditions that range from deteriorative neurological illness, to head injury, and to autoimmune disorders. Few reports and no controlled studies exist in the treatment of acquired/secondary OCD. Both CBT and pharmacotherapy are effective first-line treatment modalities for OCD. Brain stimulation and/or psychosurgery have been tried with varying success in treatment of refractory OCD. Environmental, genetic, and clinical factors interact in a complex fashion in the individual patient. This chapter will examine OCD from the medical perspective.

Keywords Obsessive compulsive disorder · Cortical-striatal-thalamo-cortical circuit · Genetics · Neuroimaging · Autoimmune · Treatment

10.1. Introduction

As defined in DSM-5, obsessive compulsive disorder (OCD) is characterized by obsessions (recurrent, unwanted, and distressing thoughts, images, or impulses) and/or compulsions (complex, repetitive, rule-governed behaviors that the patient feels driven to perform). Patients usually try to actively dismiss obsessions or neutralize them by seeking reassurance, avoiding situational triggers, or engaging in compulsions. Obsessions and compulsions are maladaptive, and lead to impaired functioning. They typically center on four themes: contamination, sexual/aggressive/checking, and ordering and symmetry. Common compulsions include excessive cleaning, checking behaviors, ordering and arranging rituals, counting, and repeating routine activities. Compulsions usually involve observable behaviors (e.g., hand-washing) but may also consist of covert mental rituals (e.g., counting, or ritualized performance of mental math). Symptom themes can vary over the course of the illness but those without a personal or family history of tics are more likely to have more frequent contamination themes. In

the DSM-5, hoarding has been categorized as a distinct disorder, and is no longer considered a specific form of OCD. The addition of a separate diagnosis is supported by extensive research suggesting that, although the two disorders can co-occur, patients with symptoms of hoarding have a number of significant phenomenological differences than those with OCD, including distinct cognitive processes, reinforcement patterns, and response to treatments commonly used to address symptoms of OCD (1).

The proposed lifetime prevalence of OCD in the pediatric and adult population ranges from 0.4 to 3.5% in national and international epidemiological samples (2–7). Approximately half of all OCD patients first present in childhood, before age 15 (8) with biphasic symptom presentation (9) of around age 10 and then again in early adulthood with males presenting with an earlier onset. In adulthood, the proportion of affected males and females is about equal. In clinical samples, OCD appears more common in Caucasians than African-Americans. However, epidemiological data are conflicting with one study suggesting no differences in prevalence as a function of ethnicity or geographic region (10) and another suggesting that the prevalence of OCD is significantly lower in African-Americans and Hispanic-Americans compared to Caucasians (11). Minorities, particularly African-Americans, are often under-represented in research studies on OCD (12). It is unclear whether recruitment efforts geared to African-Americans have been inadequate (e.g., not culturally sensitive) or that the prevalence of OCD is actually lower in this population. One study suggests a later age of OCD onset in African and Caribbean Americans (13).

The clinical course of OCD is often described as chronic and unremitting. The proportion of patients having chronic course has been reported in a range of 44–84% (14, 15), while the proportion of patients having an episodic OCD was observed only in 5–10% (15, 16). That some cases of OCD can show an episodic course is less well recognized (17). In studies on the course of OCD in children and adolescents, the rate of symptom remission is not uncommon but still represents a minority of cases. In a 2-year follow-up study of a community-based adolescent cohort, the remission rate was 69% (18); however, in studies of clinical adolescents, the majority had some symptoms and remained on medication 2–7 years later (19–21). Factors that contribute to a more benign course include the presence of precipitating event, episodic nature of the symptoms, and good social/occupational adjustment (22, 23). Factors that contribute to a more disabling, chronic course include early age of onset, presence of tics, comorbid major depressive disorder, parental psychopathology, poor response to medication, severe OCD symptoms at onset, and poor insight (15, 20, 23, 24). Once OCD becomes entrenched in the daily lives of those affected (due to the patient's social adaptation to time-consuming rituals and intrusive thoughts), the illness often becomes chronic and disabling.

Evolution acts to conserve normal behaviors in both animals and humans. One way is by "hard wiring" fixed, repetitive behaviors such as grooming, nesting, harm avoidance, reproduction, maternal bonding, and all the behaviors essential to the propagation of the species. A number of mechanisms and contributions (i.e., stress, illness, and genetic predisposition) can disinhibit or overactivate these fixed, repetitive behaviors leading to OCD (19), to the degree that functionality is impaired. Obsessional thoughts centered on the loved one are proposed to contribute to the social networks needed for the maintenance of the human race (25). Preservation of neurohormonally induced behaviors is postulated as the common pathway between humans and animals. Specific neuropeptides are essential to memory acquisition and maintenance or retrieval of behavior sequences in the grooming, maternal, sexual, and aggression categories (26, 27).

10.2. Neuroanatomical Features of OCD: The Basal Ganglia

OCD is postulated as one of the frontal-striatal disorders, which include a variety of neuropsychiatric disorders, such as tic disorder, Tourette's syndrome (TS), body dysmorphic disorder (BDD), and trichotillomania (28). A characteristic of this group of disorders is a complex interaction between the exogenous and endogenous stimuli and the neural systems that link stimuli to cognitive and behavioral responses. The basal ganglia serves as an important node in a complex system of parallel, segregated and somatotopically organized cortical-striatal-thalamo-cortical (CSTC) loops that integrate motor and cognitive functions. Inputs flow from the cortex to the basal ganglia through the globus pallidus internus (GP_i) and substantia nigra pars reticulata (SN_r) to thalamus and, in turn, back to cortex. Projections from a specific region of motor cortex synapse with neurons in the caudate and putamen, which in turn project to the internal segment of the globus pallidus and substantia nigra, pars reticulata, whence axons arise and project to the thalamus, and from thalamus back to the same cortical region. Cognitive and emotional processes are handled by CSTC loops which project from associational and limbic areas to the striatum, particularly the ventral striatum or nucleus accumbens (NAc). The ventral striatum serves a critical role in the integration of emotional and cognitive behaviors and is thus highly relevant to OCD. Other models of OCD incorporate other frontal circuits including the dorsolateral prefrontal cortical-parietal network involved in executive planning, orbitofrontal as well as anterior cingulate cortices (29). Neuroimaging studies support the dysfunction of CSTC neurocircuit in OCD (30) and further implicate deficits in feedback inhibition circuits from dorsolateral prefrontal cortical-parietal network coupled with possible hyperactivation of orbital frontal and anterior cingulate cortices (31).

10.3. Neuropsychiatric Disorders Frequently Comorbid with OCD

In early onset OCD, comorbid psychiatric disorders are present in about 80% of the cases. Major depression is seen in approximately 66%, attention deficit hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), or multiple anxiety disorders in 50% and enuresis or speech and language disorders in 33% (32). Tics often develop during the course of OCD in childhood, if they are not present at the time of symptom onset. In the presence of tics, obsessions often involve violent or sexual themes, or focus on symmetry and compulsions involve checking, counting, repeating, touching, or "evening up" (i.e., to make items or actions symmetrical or even on each side) (33). In adults, lifetime comorbidity of major depression is reported in a range of 32–78% and the comorbidity of other anxiety disorders, such as specific phobia, panic disorder, generalized anxiety disorder, and social phobia ranges in 14–54% (34). Interestingly, OCD is frequently comorbid with schizophrenia. The OCD comorbidity rate was 14% in a study of patients with first episode of schizophrenia, which had less potential of confounding effects, such as medication-induced OCD (35). This high level of comorbidity (that is more evident in early onset OCD) suggests that the underlying relationship between OCD and other disorders is nonspecific or is due to overlapping neurophysiology of central nervous system (CNS) dysfunction.

10.4. Genetics of OCD

Although exact pathophysiologic mechanisms remain elusive, the importance of genetic contributions to OCD etiology has been supported by numerous lines of research. Using family and twin study methodology, the long-standing observation that OCD "runs in families" has been empirically confirmed. Moreover, given remarkable advances in technology over the past few decades, the search for OCD genes and mechanisms of inheritance has involved thousands of OCD subjects and utilized segregation analyses, linkage, candidate gene studies, and genome-wide association study methodologies.

Family and twin studies provided substantial evidence for genetic factors in predisposing individuals to OCD. Several family studies reported a higher rate of OCD and subthreshold obsessive compulsive symptoms (OCS) among the first-degree relatives of persons with OCD (36). First-degree relatives of OCD probands were approximately six times more likely to have OCD, compared to control relatives, and OCD was more common in relatives of probands with early age of onset, compared with adult onset probands (37–40). A meta-analysis of data from five family studies with OCD probands revealed a summary odds ratio (OR) of 4.0 (95% CI: 2.2–7.1) for OCD in the first-degree relatives (41). The unadjusted aggregate risk based on 1,209 total first-degree relatives of OCD probands equals 8.2% versus 2.0% in 746 control relatives (42). Increased rates of tics among first-degree relatives of OCD probands (43) as well as increased rates of OCD among first-degree relatives of TS probands (44) suggest some cases of OCD may share components of the same genetic origin as tic disorders (43, 44). Interestingly, the younger age-at-onset of OCD symptoms and possibly male gender were associated with increased tic disorders in relatives.

Since Lange published the first cases of twins with OCD in 1929 (45, 46), numerous twin studies have shown elevated concordance (80–87%) among monozygotic (MZ) twin pairs compared with dizygotic (DZ) twin pairs (47–50%) (47, 48). The heritability estimates were 44% for obsessive–compulsive traits and 47% for obsessive–compulsive symptoms in a study with 419 twin pairs (49). Moreover in children, estimated heritability rates for obsessive–compulsive symptoms from other studies were even higher, ranging between 45 and 65% (45).

Several complex segregation analyses were performed to investigate the mode of inheritance for OCD. The results supported the existence of genes that have major effects on the transmission of OCD (50–52). A complex segregation analysis of OCD in 153 families (80 case and 73 control families) found evidence consistent with involvement of a dominant or co-dominant gene or genes of major effect, especially in families ascertained through a female proband (39). A recent study of 52 families (35 cases and 17 controls) ascertained through pediatric probands also revealed a major susceptibility locus when age-at-onset was incorporated into the model (40). However, Mendelian factors only partially explained the familial aggregation of the phenotype and residual familial effects were necessary to adequately fit the data, which implied that polygenic factors may also contribute to the etiology of OCD (39, 40).

Because of the strong genetic component involved in OCD, there have been efforts to identify the susceptibility genes by means of whole genome linkage analyses, candidate gene studies, and a genome-wide association study. Several genome-wide linkage scans of OCD have been published, which aimed to narrow down regions of the genome that may be responsible for genetic vulnerability in OCD-affected families (53, 54). In the first genome-wide linkage scan (53), seven pedigrees (56 subjects) containing pediatric probands with OCD and at least two affected relatives were genotyped, the initial findings on 2q, 9p, and 16q were followed up by genotyping additional markers in the original subjects plus ten additional family members. The strongest finding was on 9p24, which originally had a dominant parametric LOD score of 2.25 at D9S288. This finding on 9p was supported by the Johns Hopkins group in a follow-up linkage study targeting this region (55). Interestingly, a glutamate transporter gene (*SLC1A1*) that encodes excitatory amino acid transporter 3 (EAAT3) resides in this 9p24 chromosomal region,

and several groups reported an association between this gene and OCD (56–59). Most recently, a meta-analysis of SLC1A1 found only weak associations between OCD and a single nucleotide polymorphism (SNP) rs301443 in the overall sample and between OCD and SNP rs12682807 in males-only, neither of which maintained significance following correction for multiple testing (59). The second genome-wide scan was performed in 219 families at an approximate density of 9 cM, and found suggestive signals from chromosomes 3q27–28, 7p, 1q, 15q, and 6q (54). In a similar study of Costa Rican families, chromosome 15q14 (LOD 3.13) was identified (60, 61).

Over 80 candidate gene studies of OCD have been published (36). These have focused primarily on the serotonergic and dopaminergic system-related genes, such as serotonin receptor/transporter, dopamine receptor/transporter, Catechol-O-Methyltransferase (COMT), and Monoamine Oxidase A (MAO-A) genes. For the serotonin system, serotonin 1B receptor (*5HT1B*), serotonin 2A receptor (*5HT2A*), serotonin transporter (*SLC6A4*), and Tryptophan hydroxylase 1 (*TPH1*) were studied for association; and except for *5HT2A*, negative results outweighed positive findings (62–70). The dopamine receptor types 2, 3, and 4 (*DRD2*, *DRD3* and *DRD4*) and dopamine transporter (*DAT1*) genes were investigated (71–73), and the positive association was only replicated for a 48-bp repeat in exon 3 of DRD4 (71–74). For COMT, Val158Met polymorphism has been studied by several groups using both case-control and family-based association methods, with mixed results (42). Finally, two groups have reported an association between MAO-A gene (65, 75) and OCD. Interestingly, they also found sexually dimorphic effect of MAO-A on genetic susceptibility to OCD. As mentioned above, an association between a glutamate transporter gene that encodes EAAT3 (*SLC1A1*) and OCD was reported by several independent groups (56–59), although a meta-analysis of these data did not identify significant association (59). Glutamate system genes warrant further investigation as functional candidates for OCD, based on multiple lines of evidence, including: 1) elevated glutamate levels in brain regions within OCD patients in magnetic resonance spectroscopy studies (76–78); 2) corticostriatal glutamatergic mediation of stereotypic behavior in mice (79) and results of glutamate modulating agent augmentation studies in OCD (80, 81). However, sample sizes in OCD candidate gene studies to date have resulted in low power to reliably detect significant association.

The existing animal models of OCD, such as the Sapap3 mutant mouse (82), Hoxb8^{lox} mutant mouse (83), DAT1 knock-out mouse (70), and 5-HT$_{2C}$ receptor knock-out mouse (84), may be very useful in identifying specific genes and neurobiologic pathways involved in the pathogenesis of OCD. However, the question whether the behavior is a direct result of the specific gene or caused by the other downstream events may still remain (85). Moreover, significant limitations exist with respect to identifying an animal phenotype for obsessions, which comprise a major component of this disorder's symptomatology.

Finally, the first genome-wide association study of common SNPs in OCD examined data from 400 OCD-affected probands and their parents, 1,465 OCD-affected cases and 5,557 ancestrally matched controls. The strongest p-value (3.84×10^{-8}) was found for SNP rs6131295 near BTBD3 (broad complex tramtrack bric a brac domain containing 3), a common structural domain within proteins, although this did not meet the threshold for genome-wide significance ($p < 5 \times 10^{-8}$). Of interest, significant enrichment of frontal lobe expression quantitative trait loci (eQTLs) was observed among the most strongly associated SNPs (86).

In summary, family and twin study data support the familial aggregation of OCD, particularly in early-onset cases. Segregation analyses implied a major gene effect. However, genome-wide linkage and association studies have not confirmed any susceptibility locus, probably due to phenotypic and genetic heterogeneity. A number of candidate gene studies were conducted for association, with mixed results. Several lines of evidence support further investigation of glutamate system-related genes as candidates for OCD. A better understanding of environmental triggers, OCD subtypes, comorbid tic disorders, OCD pathophysiology, and further development of animal models may ultimately lead to locating genes that confer risk to OCD (87). Lastly, much larger sample sizes and collaboration across international OCD research centers will be required to achieve this goal.

10.5. Neuroimaging Studies

Although not always consistent, structural MRI brain imaging studies have suggested basal ganglia and frontal pathology, such as reduced volume of bilateral orbitofrontal cortices and amygdala, absence of the normal hemispheric asymmetry of the hippocampus–amygdala complex, and decreased caudate volume in patients with OCD (88–91). In studies investigating brain structures in medication-naïve children with OCD, significantly smaller striatal volume, larger ventricle, and larger corpus callosum were observed (92, 93). In addition, the size of corpus callosum was correlated significantly with OCD symptom severity, and age-related increase in callosal size seen in normal subjects was absent in OCD patients (93). The significance of corpus callosum differences in OCD was further supported by case reports of OCD patients with hypoplasia of the corpus callosum (94) and small anterior and posterior callosal regions compared to healthy control subjects (95). Further evidence of connectivity abnormalities in OCD is suggested by conflicting findings of reduced fractional anisotropy in cingulate, parietal, and right occipital areas versus increased fractional anisotropy observed in right medial frontal, left cingulate bundle, and internal capsule regions by diffusion tensor imaging (96–98). Moreover, greater number of subcortical hyperintensities are seen by T_2-weighted MRIs suggestive of microvascular pathology (99); whereas smaller pituitary volumes implicate hypothalamic-pituitary-adrenal (HPA) axis dysregulation (100, 101).

Functional neuroimaging studies also revealed dysfunction or increased activity in the corticostriatal pathways in individuals with OCD (102). In addition, OCD patients appear to preferentially activate bilateral medial temporal structures (typically used for conscious, explicit information processing) instead of the striatum during implicit sequence learning tasks in a PET study, which also support the corticostriatal dysfunction in OCD (77).

Several functional neuroimaging experiments using a symptom provocation paradigm or the use of cognitive-behavioral probes of corticostriatal circuitry and limbic (amygdala) circuitry to study changes of brain activities in individuals with OCD found activation of isocortical, paralimbic (medial orbital gyrus, anterior cingulate, temporal cortex, and insular cortex), limbic (amygdala), and striatal (caudate and lenticulate) areas in association with OCD symptoms (29, 103). Similarly, adults and children with OCD displayed deficits in cognitive flexibility and decreased fronto-striatal activation by fMRI (104, 105). Connectivity studies using resting-state fMRI suggest poor connectivity in frontal-striatal-thalamic circuits in youth with OCD in contrast to excessive connectivity in areas implicated in emotional processing (dorsal striatum/medial prefrontal cortex connections) in youth and adults with OCD (106).

The neural correlates of OCD symptom dimensions have been examined using functional neuroimaging techniques (28, 107). For example, cerebral blood flow in the striatum was increased with checking symptoms and decreased with symmetry/ordering symptoms, while washing symptoms correlated with increased cerebral blood flow in bilateral anterior cingulate and left orbitofrontal cortex in a study using fMRI (108). In another study using fMRI with symptom provocation paradigm, bilateral ventromedial prefrontal regions and right caudate nucleus correlated with washing; putamen/globus pallidus, thalamus, and dorsal cortical areas with checking; left precentral gyrus and right orbitofrontal cortex with hoarding; and left occipitotemporal regions with aversive, symptom-unrelated provocation (109). A small study of pediatric OCD found reduced activity in the right insula, putamen, thalamus, dorsolateral prefrontal cortex, and left orbitofrontal cortex during contamination symptoms provocation whereas lower activity was observed in right insula and thalamus in symmetry provocation experiments using fMRI (28, 110).

Also neuroimaging studies suggest that right hemisphere structures are more frequently or more dramatically involved than the left hemisphere (111–113). In several studies reporting neurological examination findings, subtle left hemibody signs and dyskinesias (fragmented movements) in both children and adults were detected, suggesting more prominent right than left hemisphere involvement (114–116).

In summary, structural neuroimaging studies have been inconsistent; however, functional neuroimaging studies have provided a strong support for a subtle developmental brain anomaly and altered function in the CSTC circuitry. The preliminary data from functional neuroimaging studies with or without a symptom provocation paradigm suggested different OCD symptom dimensions may be mediated by distinct, albeit partially overlapping, neural systems (28, 117).

10.6. Neuropsychologic Studies

Characteristics of OCD such as doubting, overvalued ideas, and perfectionism may have a neuropsychological basis. Studies of neuropsychological function in OCD have suggested deficits in executive function, attention, set-shifting and manipulating spatial information in adult patients. Adult research also suggests that OCD symptoms influence problem-solving efficiency (related to speed) rather than accuracy. For example, when performing on the Wisconsin Card Sorting Test (a set-shifting task), one study found that patients with OCD required significantly more trials, besides making more perseverative and other errors than controls (118) whereas another study showed no differences (119) suggesting these findings may relate more to the symptoms rather than vice versa. However, another study found first-degree relatives of those with OCD shared similar impairments in neurocognitive domains of delayed verbal recall, set-shifting, response inhibition, and visuoconstructive abilities compared to controls implicating these specific domains of executive functioning as endophenotypes for OCD (120). Another study also showed impairment in set-shifting, response inhibition but intact short-term memory (digit span, etc.) (121).

Reduced verbal and design fluency in patients with OCD was found when compared to controls, with evidence of a correlation between severity of OCD symptoms and design fluency (122). Additionally, patients with OCD may have non-verbal and praxic memory deficits, which may represent the cognitive substrate of doubt-related phenomena such as checking (123). In a review by Olley, Malhi, and Sachdev (124), it was proposed that OCD patients have a selective deficit in learning new task rules on the basis of external feedback. Other research shows a selective deficit of OCD patients in associative learning tasks (125). Reward processing is largely dependent on ventral striatal-orbitofrontal circuitry and brain imaging studies in OCD have consistently shown abnormal activation within this circuitry. Figee et al. (126) compared brain activity during anticipation and receipt of a reward between patients with OCD and healthy controls, using a monetary incentive delay task and fMRI. Patients with OCD showed attenuated reward anticipation activity in the nucleus accumbens compared to healthy control subjects.

Neuropsychological studies have revealed impaired visuospatial processing, deficits that are consistent with right frontal-subcortical dysfunction. Studies have shown poor performance on the Rey-Osterreith Complex Figure Test (ROCFT) suggesting deficits in non-verbal memory (127, 128) perhaps based on poor strategy selection in reproducing the figure (127). This

interaction between deficits in organizational strategies and memory problems when tasks require implicit organizational strategy (i.e., effort to recall unstructured information) may have contributions to doubting. Children with OCD have shown similar neurocognitive profiles albeit much fewer studies exist. Marked impairment in visuospatial recall memory (as assessed using the ROCFT) was observed in spite of average to above-average performance on academic and other neurocognitive measures. Those with elevated streptococcal antibodies fared worse on executive function measures (129). However, discrepant findings have been reported both in the pediatric and the adult literature suggesting that few differences exist between patients with OCD and carefully matched controls on an array of neuropsychological tests (130–132). Heterogeneity in presentation may be explained by environmental and genetic variations. For example, BDNF Val66Met polymorphism which attenuates BDNF activity does not appear to be a risk factor for OCD but the presence of a BDNF Met allele may be associated with a poorer executive functioning in OCD (133).

10.7. OCD Induced by Psychological Trauma

Early stressful events (trauma, disruption of social environment secondary to moves, illnesses, etc.) have been associated with the onset of OCD in some cases (134). Over 50% of children and adolescents cite a precipitating event (135). Prolonged exposure to stress and trauma are theorized to increase the hypersensitivity to perceived threats leading to OCD symptoms (136, 137). The relationship between OCD and post-traumatic stress disorder (PTSD) found in clinical samples is likely due to symptom overlap between the disorders (137) as well as comorbid depression (138) but post-traumatic OCD may differ in specific clinical features (139–141) and cognitive domains (142). Individuals with hoarding were more likely than those with OCD but without hoarding to have a history of a traumatic experience (143).

10.8. Structural Brain Etiologies of Obsessive Compulsive Disorder

Clear and mounting evidence suggests that abnormalities in the orbitofrontal cortex, basal ganglia, thalamus, and the interconnecting pathways are responsible for the symptom presentation of OCD. Given these anatomical associations, it would logically follow that structural insults to these areas could precipitate OCD symptoms. Although there have been few studies to systematically study these relationships, there are a growing number of case reports and case series showing that there are, indeed, sporadic acquired cases of OCD that result from insults to these brain areas. Cases of damage to frontal-subcortical structures have been shown to be the result of epilepsy, traumatic brain injury (TBI), strokes, tumors, carbon monoxide poisoning, wasp sting necrosis, and manganese intoxication (144–148). Other progressive neurological disorders that affect components of frontal-subcortical circuits (e.g., postencephalitic Parkinson's disease, neuroacanthocytosis, progressive supranuclear palsy, and Huntington's disease) also can present with OCD symptoms (146). While the symptom presentation in these cases is similar to idiopathic OCD, because they are caused by a secondary condition, they are classified in the DSM-5 as "Obsessive-compulsive and related disorder due to another medical condition (state medical condition) with specifier OCD-like symptoms due to another medical condition."

The rate of onset of OCD following traumatic brain injury is unknown, although previous reports have placed the incidence at between 0.5 and 7.8% of brain injuries (149). Although symptoms that would meet full diagnostic criteria of OCD are relatively uncommon following TBI, it has been well documented that up to 30% of all brain-injured patients will develop anxiety-spectrum disorders including generalized anxiety disorder, specific phobias, panic disorder, and stress disorders (149). The emergence of other psychiatric disorders is common as well. In one study examining the new onset of psychiatric disorders in children following TBI, it was revealed that 76% of the subjects developed a new psychiatric disorder within 2 years of a head injury (150). In this particular study, one of the 50 patients with TBI went on to develop OCD (a rate of 2%) (150). Although it was once thought that long-term psychiatric and neurocognitive sequelae occur only with moderate or severe brain injuries, more recent evidence indicates that significant psychiatric sequelae including OCD can occur even in mild TBI (150, 151) and without any evidence of abnormalities on MRI or CT scans (152–154).

The incidence of new-onset OCD symptoms following other brain insults including tumors and strokes is unknown. Given the relatively few numbers of cases reported in the literature, it is likely that the rates are very low. The scant literature describing OCD symptoms following carbon monoxide poisoning, Huntington's disease, Parkinson's disease, and other causes of acquired OCD, also points to the likelihood that the overall incidence of secondary OCD due to neurological disease is very low. In all cases of acquired OCD, it is implied that the immediate cause of the OCD symptoms is the insult itself. In cases where acquired OCD presents in the elderly population, it becomes more likely that there is an underlying medical cause for the OCD symptoms, as the rates of idiopathic OCD decline with advancing age (155) and rates of strokes and tumors increase. Given this shift in risk, some have argued that it is prudent to pursue a medical workup including brain imaging when new-onset OCD symptoms occur after age 60 (156).

Brain damage from TBI is often diffuse or involves multiple areas of the brain. The most common areas of brain involvement in secondary OCD involve the frontal, temporal and cingulate cortices, the basal ganglia, or the interconnecting areas (145, 157–161). Corresponding SPECT data reveals areas of hyper-or hypoperfusion reflecting changes in function in these brain areas (145). Similarly, in studies that show clear structural damage to single or multiple areas, corresponding SPECT studies show more extensive areas with abnormal perfusion than would be explained by only the structural damage (145). It has been postulated that focal damage may cause a disruption in the circuitry which then results in area of underuse or compensatory overuse in other parts of the circuit (154).

Brain insults that result from strokes or tumors are more likely than traumatic insults to involve a single area which makes localization somewhat less complex. Brain tumors located in the basal ganglia (162–164) and frontal lobes (165) have been reported to cause secondary OCD. Ischemic or hemorrhagic lesions to either the right or the left basal ganglia have been shown to cause OCD (147, 157, 166–168), although others have reported that bilateral damage is needed to cause these symptoms. In one case, a patient developed transient apathy after suffering an ischemic stroke to one side of the caudate. Two months later he suffered a second ischemic stroke to the contralateral caudate which then resulted in OCD symptoms (169). Strokes affecting the parietal lobe (170) and the frontal lobe (145, 156, 171) have also been reported to precipitate OCD. Following brain injury, the onset of OCD generally occurs shortly after the insult, although there are reported cases of a delayed onset of up to 7 months. In one report, new-onset OCD symptoms developed in four adults within 24 hours of a brain injury (152). The onset of the OCD may or may not be related to psychological reaction related to the trauma (149, 172). In these cases of delayed onset of OC symptoms, it is put forward that underlying structural damage done to the septohippocampal area from the brain injury then leaves the patient more susceptible to OCD in the face of ongoing psychological stressors (172). The nature of symptoms may change over time as well (159).

Similar to the case of TBI, the onset of OCD may begin abruptly after a stroke occurs. Depending on the location of the injury, there may or may not be associated neurological or cognitive sequelae that accompany the OCD. In the case of tumors, the onset would likely be more insidious. In one case, a 16-year-old male with a brain dysgerminoma affecting the left lenticular region and right internal capsule developed OCD symptoms, which then improved as the tumor was treated with chemotherapy. Changes in personality and the reappearance of OCD were one of the early signs indicating the relapse of the tumor on several separate occasions. With each episode, the symptoms improved as the tumor was treated (162). Similarly, acute hemiplegia and OCD developed in a boy secondary to a lesion in lentiform nuclei associated with a history of recent varicella infection. He was treated with sertraline and made a full recovery (173).

A wide variety of presentations have been reported in cases of secondary OCD many of which have the same constellation of symptoms as is seen in primary OCD (149, 157). One study comparing idiopathic OCD, acquired OCD and normal controls across a variety of neuropsychological indices, reported that similar deficits in attention, memory, language and executive functioning were seen in both OCD groups but not in the normal controls (157).

However, some cases differ in presentation. Although also seen in 20% of primary OCD, secondary OCD may be more likely to present with only obsessions or compulsions, rather than a combination of both (159, 174). Patients who showed significant apathy, lack of flexibility and treatment resistance in acquired cases of OCD were accompanied by a general lack of feelings of anxiety and depression (175). This lack of anxiety has been reported in those patients with damage primarily to the basal ganglia (147).

Few reports and no controlled studies exist in the treatment of acquired/secondary OCD. In some cases, treating the underlying disorder will successfully improve the OCD symptoms. For example, in one case a cranioplasty was instrumental in the resolution of symptoms in a patient following TBI, and in another case, chemotherapy successfully treated OCD caused by a dysgerminoma (176). Several cases report on the benefits that specific patients have derived from SSRIs including fluoxetine (145, 177). In one case, a patient with acquired OCD was successfully treated with fluoxetine 60 mg daily with a decrease in his Yale-Brown Obsessive Compulsive Scale (YBOCS) score from 30 to 10 over a 90-day period. In this case, there were multiple brain lesions shown on MRI including injuries to the orbitofrontal cortex bilaterally as well as low serotonin transporter density in the midbrain and hypothalamus shown on SPECT (178). Several authors have reported on the effectiveness of cognitive-behavioral therapy in addition to treatment with medications (161, 167). In one case, a 78-year-old male who developed OCD after an infarct to the left basal ganglia had minimal response to SSRIs but achieved significant improvement after undergoing cognitive behavioral therapy (CBT) in an intensive inpatient program. In this case, the patient's YBOCS went from 24 to 2 with good maintenance up to a year after treatment (167). Another group reported on the combination of cognitive rehabilitation and cognitive behavior therapy for a patient with a brain injury. In this case, memory problems after the injury lead to obsessional checking, and it was important to work on implementing an external memory system as well as engaging in exposure/response prevention in order to treat the OCD symptoms (179). In some cases, improvements using standard treatments for OCD are ineffective. In one case, a patient who developed OCD after a frontal lobe infarct failed to respond to more than 35 different medications (156). Despite the reports of treatment resistance, those patients with secondary OCD often will respond to traditional therapies.

Many challenges remain in systematically studying the onset of OCD after TBI and other brain injuries. Cases of acquired OCD are relatively rare, and often, rigorous evaluation is needed to tease out these symptoms. Eliciting symptoms of OCD may be difficult for inexperienced examiners, and symptoms of OCD that are elicited may be misattributed to other causes such as

decreased processing speed due to a neurological deficit versus obsessional slowness, or perseveration that is often seen in brain injuries vs. OCD. In addition, patients may be reticent to report OCD symptoms because of stigma or embarrassment. Further, symptoms often change significantly during the initial stages after an acute brain injury, which makes tracking psychiatric symptoms more challenging. Albeit uncommon, acquired OCD can provide insights into circuitry that has gone awry to produce OCD symptomatology (180). Please see Table 10.1.

10.9. Autoimmune Etiologies of OCD

Several autoimmune diseases have been shown to confer a greater risk of the co-development of OCD. Some cases of OCD may be related to various autoimmune diseases including systemic lupus erythematosis (SLE) (181, 182), multiple sclerosis (MS) (183–185) and acute disseminated encephalopathy (186). Another group reported a 10- to 15-fold increase in OCD in patients with SLE when compared to rates in community-based samples of OCD (181). Similarly, others have shown a higher than expected rate of OCD in patients with MS (185) and thyroid dysfunction (187, 188). On the other hand, evidence from a chart review (136) showed higher than expected rates of immune related disease in psychiatric patients with OCD when compared to patients with other psychiatric illnesses. The immune association that has been the most clearly shown is the association between some cases of childhood-onset OCD and group A streptococcal (GAS) infections (189, 190). Some symptoms in Sydenham's chorea (SC) overlap with those of primary OCD, including aggressive thoughts and contamination fears, and a higher than expected incidence of OCD is seen among patients with SC (191–194). Although it is not as striking, an increased incidence of OCD in rheumatic fever (RF) without chorea exists (195), occurring only during acute episodes of RF.

Over the past several years, significant strides have been made to characterize the association of OCD and tics with infectious triggers such as viruses (196), mycoplasma (197), Lyme disease (198), and GAS (199, 200). While tics and OCD that have a dramatic temporal association associated with GAS are termed PANDAS (201), a newer classification of acute and severe onset OCD does not require a specific infectious trigger, and is termed Pediatric Acute-onset Neuropsychiatric Syndrome (PANS) (202). In addition to OCD, these children often have dramatic changes in behavior and personality, mood disturbance, food refusal, frequent urination (pollakiuria), handwriting deterioration, sensory defensiveness, tics, hyperactivity, sleep disturbances, and separation anxiety (202). While the notion of an infectious trigger for OCD and tics has remained controversial, the concept

is not new. The first report of a potential association between infectious disease and tics occurred in 1929, when Selling reported on three cases of tics that were associated with sinusitis (203). Following that initial report, there have been many case reports, and more recently, case series further elucidating this phenomenon (199, 204–211). Some complications exist in attempting to investigate these cases. In many cases of infections, symptoms are subclinical and will therefore miss detection (212). In rheumatic fever, an illness which is clearly associated with GAS infections, one study reported that in upwards of 75% of cases, the onset of symptoms occurred with minimal or no evidence of a preceding case of pharyngitis (213). Further complicating the ability to establish a definitive GAS link to OCD symptoms is the observation that elevated GAS titers are common in the prepubertal age group (214), so a single elevated titer in a child with new-onset OCD would not imply a causal relationship with an infection nor does a specific titer value. Ideally, serial titers would be needed before, during, and after the onset of OCD symptoms to more convincingly correlate the infection with the onset of OCD/tic symptoms. Some children with tics and OCD, similar to reports in RF (215), may have persistent or an overactive immune response to GAS (216). This possible unique immune response may be a consequence of multiple factors including developmental and/or environmental influences. Titers may remain elevated for 6 months to a year without clear evidence of preceding streptococcal infection. For example, Murphy et al. found that those with a dramatically fluctuating neuropsychiatric symptom course had more evidence of persistent elevations in one or more strep titers compared to those that had a course inconsistent with PANDAS (217). This finding may be due to the relative proximity of the streptococcal infection at the time of study enrollment and then repeated streptococcal exposures without clinical pharyngitis leading to more severe and turbulent symptoms. Alternatively, a chronically activated immune system may be predisposed to other neuroimmunologic triggers such as stress and nonspecific infections (218, 219).

Frequent GAS infections may also predispose children to neuropsychiatric sequelae (220). Reasons for GAS recurrence are likely complex and numerous. Most of the recurrences are relapses, in other words, infection by the same streptococcal strain as opposed to new infections of a different strain (212). Reasons for relapse could include poor compliance or inadequate duration of antibiotic therapy, poor antibiotic penetration into lymphoid tissue, beta-lactamase producing bacteria inactivating the antibiotic's efficacy, alterations in protective microflora, re-exposure, or immunological defects (221). The consequences of recurrent tonsillopharyngitis are largely unknown. Many OCD/tic patients report onset of their neuropsychiatric symptoms after repeated streptococcal infections over the course of a few months (222). Published support for the risk associated with repeat GAS infections was a recent epidemiologic study that used population-based data from a large health maintenance organization (220) and found that patients with OCD or TS were more likely than controls to have had prior streptococcal infection in the 3 months before onset date. Having multiple GAS infections within a 12-month period was associated with a markedly increased risk for TS (OR = 13.6) (220). The number of prior GAS infections has been shown to correlate with a more severe course and a greater incidence of relapse (208). A school study examining motoric signs and behavior while obtaining monthly GAS cultures on 693 school children, found that those with repeated GAS infections during the 8-month study had more frequent neuropsychiatric findings (223). Further complications occur as some non-GAS strains may have a role in OCD symptoms. It has been shown that some virulent factors have transferred from GAS to group C and group G streptococcus (224), allowing these strains to activate the immune system without being detected by standard culturing techniques. Conversely, group C and G strep may cause false positive results, as these strains may lead to elevation in strep titers without causing a corresponding increase in OCD symptoms (217).

Seasonal variations are often seen in autoimmune illnesses (225). For example, the peak incidence of rheumatic fever is from January to March, which lags the peak incidence of GAS by a short period (226). In addition, rheumatic fever has lower rates in the summer months when GAS infections are also lower. Similarly, tic symptoms and acute exacerbations are seen at increasing rates in the fall and winter months which mirrors the increased rates of streptococcal pharyngitis during this time (217, 227). Other factors may be involved in this increased incidence, including increased upper respiratory tract infections caused by other viruses and bacteria during the fall and winter months and a general increase in stress levels because of school (196, 198). It is possible that some individuals have a heightened susceptibility to OCD/tics which are triggered by these other factors rather than GAS.

There are various theories as to how strep infections may cause OCD/tics. One of the best supported is the concept that antibodies produced against GAS proteins cross-react with host proteins that are similar in structure, a phenomenon known as molecular mimicry. Damage to the blood–brain barrier may allow these antibodies to pass into the central nervous system where they may act as agonists or antagonists to receptors in the basal ganglia or may cause an inflammatory response in these brain areas. In attempting to further characterize this process, drawing parallels with Sydenham's chorea is potentially helpful. In SC, there is a well-characterized rise in anti-basal ganglia antibodies to the caudate (228). Similarly, an increase in antibodies has been found to the caudate in patients with Tourette's syndrome (206, 229). Despite the presence of some positive studies, there are also several studies using different techniques and epitopes, which show minimal differences in antibody binding when comparing patients with OCD/tics to controls (230–233). It has been postulated that these negative results may be the consequence of benign autoimmunity (false positives) among the control group or tests that lack the level of sensitivity needed to detect these changes (230–233). The symptoms of PANDAS and SC may be mediated by direct effects of cross-reactive antibodies on receptors in the basal ganglia affecting signal transduction and subsequent release of excitatory neurotransmitters (229, 234, 235).

While PANDAS is, by definition, seen only in the pediatric population, immunological abnormalities that are present in adult cases of OCD have been evaluated by peripheral cytokine profiles, lymphocyte subsets, viral antibodies, and autoantibodies (236–239). Some have shown abnormalities in immune function in adults with OCD (237, 240), although other studies do not (236, 241, 242). The need for further investigation is emphasized by the mixed results of adult OCD immune function studies, small sample size and lack of evidence to determine the relative contribution of alterations in the HPA axis due to stress versus autoimmunity. Other evidence of immune alterations seen in OCD and/or tic disorders reflects changes in indices for cellular, cytokine, or markers of inflammation (200, 219, 243–249).

10.10. Medication-Induced Obsessive Compulsive Symptoms

Certain pharmacologic agents, such as methylphenidate/dextroamphetamine (250), zonisamide (251), and m-chlorophenylpiperazine (m-CPP) (252) have been reported to trigger obsessive compulsive symptoms (OCS). In addition, worsening or production *de novo* of OCS related to the use of atypical antipsychotics has been documented in numerous case reports, despite their anti-obsessional effects in OCD (253). In terms of frequency, most cases involved the use of clozapine, followed by risperidone, olanzapine, and quetiapine. Clothiapine, an antipsychotic related to clozapine, has also been reported to cause OCS (254). There has been no case report of OCS related to the use of aripiprazole or ziprasidone yet. Interestingly, all antipsychotic-induced OCS have involved patients with primary psychotic disorders, mostly chronic schizophrenia, rather than pure OCD (253). In most cases, OCS emerged 3–15 months after the medication was started and was of transient nature (253). Co-administration of a selective serotonin reuptake inhibitor (SSRI) diminished OCS in some patients receiving clozapine (255). Given the higher affinity for serotonin 5-HT_2 receptors than dopamine D_2 receptors at low dose, 5-HT_2-receptor antagonism has been postulated to play a role in atypical antipsychotic-related OCS, whereas anti-obsessional effects may occur through D_2 receptor antagonism at higher dose (253, 256). In concordance with this hypothesis, Ramasubbu et al. reported reversal of risperidone-induced OCS by increasing the doses of risperidone in a patient with bipolar disorder and comorbid OCD (256).

In summary, all cases of atypical antipsychotic-induced OCS involved patients with primary psychotic disorders, rather than pure OCD. This phenomenon further suggests that the interplay of serotonin and dopamine may be substantially different in pure OCD versus primary psychotic disorder with comorbid OCD (257). In addition, the anti-obsessional effect of atypical antipsychotics may be more pronounced at higher does (256, 257).

10.11. Medical Consequences of OCD

It is well known that OCD can be very debilitating, limiting patient's ability to work, maintain meaningful relationships and affect multiple areas of quality of life. What has been less well documented are some of the potential medical consequences of OCD (258–260). The most clearly documented medical consequences of OCD involve dermatological problems. Several studies have been done examining the rates of patients with OCD who present in outpatient dermatology clinics. One study looked at 92 consecutive new evaluations to a dermatology clinic and found that 18 patients (20%) met criteria for OCD, only one of whom had a prior diagnosis of OCD. In this study they showed that the dermatologic diagnoses varied widely and were not necessarily directly related to OCD (261). Another study, focusing on pruritic dermatological conditions found 14% of a randomly selected group of patients had OCD, which had not been previously diagnosed (262). Further supporting the high rates of OCD among dermatologic patients, another study looked at 166 patients for OCD and found that 41 patients (24.7%) met criteria for OCD; only six had been previously diagnosed. In this study, the most frequently seen obsessions were contamination fears (61%), pathological doubting (53.7%) and need for symmetry (51.2%), and the most common compulsions were excessive washing (61%), checking (51.2%) and orderliness (41.5%). Of the various dermatological diagnoses such as sebaceous gland diseases (eg., rosacea, acne) eczema, pruritis, urticaria, and psoriasis, there were no statistical differences between the OCD and non-OCD groups in the frequency of dermatological illnesses except sebaceous gland diseases which appears unrelated to most OCD symptoms except the potential of being exacerbated by stress (263). Perhaps this finding has more to do with proposed immune dysfunction in patients with OCD. Although in psychiatry clinics, patients with OCD often have dermatitis from excessive hand-washing or the use of chemical cleansers, in a dermatology clinic, the increased incidence of OCD appears to be unrelated to specific OCD symptoms or anxiety. Perhaps patients with dermatological sequelae from OCD related disorders such as excessive skin picking, lip licking, trichotillomania, and nail biting, do not frequently seek dermatological consultation.

Other potential medical consequences that may be due to OCD include those related to food refusal and decreased motor movements. There have been cases where patients have refused to eat and lost enough weight that placement of a gastric feeding tube has been necessary. Some obsessions that may lead to this type of food refusal include fear of eating poisoned or contaminated food. In one case, a patient refused to eat after developing an obsessive fear that he had swallowed a utensil (264).

In addition to the obvious complications of weight loss, the need for placement of a gastric tube confers the added risk of bleeding or infections and clearly places patients at significant medical risk. Decreased motor movements, and catatonia, are also potentially severe results of OCD with diminished use of muscles, with subsequent potential for muscle atrophy over time. Although very rare, cases with prolonged catatonic states that were part of severe OCD and responded to conventional OCD treatments have been described (265, 266). Patients who refuse to get out of bed may develop bedsores and orthostasis and general weakness over time. While these are clearly rare and exceptional risks of OCD, they have been noted and are worthy of consideration. In addition, cases of pica have been reported to be secondary to OCD (267).

10.12. Treatment

10.12.1. Behavioral

Exposure-based CBT for OCD is a skill-based treatment approach which has been found to be efficacious in clinical trials and has shown excellent maintenance of symptom reduction at follow-up (268–272). The premise that compulsions are performed to reduce or avoid anxiety that is associated with obsessions underlies CBT for OCD. CBT is composed of three core components: exposure, response prevention, and cognitive restructuring. *Exposure* relies on the gradual decrease in anxiety after being exposed to a feared or ritual-provoking stimulus. This leads to decreased elevations in anxiety and more rapid attenuation of distress in future exposures. *Response prevention* is based on the assumption that rituals and compulsions serve to reduce anxiety in the short-term through negative reinforcement, escaping and/or avoiding distress. Individuals with OCD perform rituals to relieve anxiety, and never have the experience of natural anxiety reduction. Response prevention exercises allow for the anxiety to naturally subside by requiring the patient to avoid performing their compulsion so the anxiety can be reduced through habituation. Variations of CBT with response prevention include weekly CBT, intensive CBT, family-based CBT, group CBT, individual CBT, and web-based CBT (268, 271–273).

10.12.2. Pharmacological Treatment

While CBT is clearly an effective treatment for OCD, there is evidence that the combination of psychotherapy and pharmacotherapy achieves greater response rates in some patients than either modality alone (269, 273, 274). Pharmacological treatment should be considered to be more of a first-line option if there is significant impairment in functioning, past therapy has shown little improvement, comorbid conditions will interfere with therapy or if the patient is psychotic.

Serotonin (5-hydroxytryptamine, 5-HT) has remained the leading target for investigations of the neurochemical underpinnings of OCD, largely because of the remarkable efficacy of SSRIs in the treatment of OCD. While the role of the 5-HT system appears to be more important in the treatment than in the etiopathology of OCD, more direct measures of neurochemical dysfunction, including paradigms that employ biological markers, pharmacologic challenges, or functional neuroimaging are needed to corroborate the pathophysiologic role for 5-HT.

Acute blockade of 5-HT reuptake appears to be the critical first step in a chain of neural events leading to efficacy in the treatment of OCD. It is believed that long-term SSRI treatment likely produces its effects by enhancing 5-HT concentrations in the synaptic cleft which, after prolonged exposure, ultimately leads to desensitization of presynaptic 5-HT1B autoreceptors in various brain regions (275). This desensitization occurs with varying time courses in different regions of the brain. Structures that are involved in depression, including the hippocampus and hypothalamus have been shown in animal models to achieve desensitization within 2 weeks (276). In contrast, the prefrontal cortex (PFC), thought to be the main target in the treatment of OCD, does not undergo desensitization for up to 8 weeks (276). In addition, animal studies have indicated that higher concentrations of SSRIs are needed to achieve desensitization in the PFC than in the hypothalamus and hippocampus (277). These observations are congruent with clinical experience that longer medication trials and higher doses of medications are needed to achieve therapeutic benefit in the treatment of OCD than those needed in the treatment of depression.

Many studies have demonstrated the efficacy of SSRIs in the treatment of OCD in both adults and children (278). The clear superiority of this class of medications makes them the first-line treatment for OCD. Clomipramine (CMI), a tricyclic antidepressant with fair specificity for serotonin reuptake, was the first medication to show clear efficacy for the treatment of OCD (279). In adults, response rates for SSRIs and clomipramine have been reported to be between 40 and 60% of participants, compared to less than 20% for placebo (280). CMI and SSRIs consistently show superiority over placebo in the treatment of OCD symptoms (281–289). In meta-analyses of CMI compared to other SSRIs, CMI continues to show better efficacy than any single SSRI or SSRIs as a pooled group in both children and adults (280, 290, 291), although this superiority has not been shown in individual trials comparing CMI directly to fluvoxamine, paroxetine or fluoxetine (280). No clear differences in efficacy have been shown when comparing any single SSRI to another, and it is generally accepted that except for possibly CMI; all SSRIs are essentially equally effective.

Despite CMI's superiority in these studies, it has significant liabilities including a more significant side effect profile, the need for cardiac and plasma monitoring, and the increased risk of serious adverse events including cardiac arrest and death. For these reasons, although CMI may be considered the *"Gold Standard"* treatment of OCD, it is not generally felt to be a first-line agent. Instead, SSRIs are considered to be first-line medications in this disorder (292). Given the relative similarity among the SSRIs, the choice should be based on medical history, concomitant medications, and the adverse effect profile. Factors to consider include half-life, active metabolites, linear vs. nonlinear metabolism, CYP-450 inhibition, and side effects. Some side effects of the SSRIs include nervousness, insomnia, restlessness, nausea, and diarrhea. Concerns regarding increased suicidality in patients taking SSRIs prompted the FDA to require "black box" warnings on all SSRIs to increase physician awareness and knowledge of this issue, although there is a great deal of controversy regarding both the new requirements and the findings (293).

Once a medication choice has been made, it is important to address several important issues in the treatment of OCD. First, 10–12 weeks at adequate dosage is necessary to evaluate the efficacy of the medication (287). It is generally accepted that if one SSRI fails, a second SSRI should be tried, as failure of one does not mean that all SSRIs will be ineffective. If, however, symptoms remain unresponsive to trials of multiple SSRIs, augmentation may be necessary (287, 294). Although there are few studies looking at continuation of medication following improvement of symptoms, it is thought that ongoing administration of the medication at the treatment dose will be necessary for at least 1–2 years following the improvement in symptoms prior to tapering and discontinuing the medication to minimize risk of relapse. However, some patients need to be maintained on their medication for several years (287).

Many augmentation strategies have been attempted in the treatment of OCD (295). Given the benefits of enhancing the serotonin system in the treatment of OCD, one such strategy was aimed at increasing serotonin via other mechanisms. However, studies examining SSRI administration with the addition of lithium (296–298), buspirone (299–301), and clonazepam (302) have shown little effect. A second strategy is based on the observation that repetitive stereotypies and OCD-like behaviors can be produced in humans by the administration of exogenous D2 agonists or stimulants. This observation, along with the well-known comorbidity of tic disorders and OCD have led to the theory that excess dopamine may be involved in the pathophysiology of OCD. Subsequently, the most promising augmentation strategy to date has been the addition of antipsychotic medications to SSRIs. Several studies examining SSRI augmentation with the low dose dopamine antagonists pimozide (303) and haloperidol (304, 305) showed clear benefits in the treatment of OCD symptoms, particularly in patients who had comorbid tics or schizotypal personality disorder. Further studies looking at augmentation with low dose risperidone have shown similar improvements in treatment refractory OCD (305–309), although differences were not seen in the benefits for patients with comorbid tics or schizotypal personality disorder when compared to patients without these comorbidities. Studies have shown mixed results with augmentation of quetiapine, with some studies showing benefit (310, 311), while others showed no statistically significant improvements over placebo (312, 313). Augmentation with olanzapine has also shown mixed results. One study, which added olanzapine after an 8-week trial of fluoxetine showed no increased benefit over extension of the SSRI-only treatment group (314), while a second study, showed significant improvement in OCD symptoms after the addition of olanzapine (315). Given the number of reports of OCD improvement with aripiprazole, a partial dopaminergic agonist and partial 5-HT1A agonist, it is perhaps one of the more promising augmentation strategies (316–320). It has a milder side effect profile than most typical or atypical antipsychotics, particularly regarding sedation, extrapyramidal symptoms, cardiovascular effects, or elevations in serum prolactin.

Dysfunction of glutamatergic neurotransmission has been implicated in the pathophysiology of OCD (321) and recent clinical reports suggest that some glutamate modulating agents are efficacious in the treatment of this disorder (322, 323). Rosenberg and colleagues (2000) have shown an elevation of a glutamate signal in the caudate of children with OCD using ^{1}H nuclear magnetic spectroscopy (77). Furthermore, this elevated signal normalized following effective SSRI treatment. The precise mechanism of SSRI modulation on the glutamate signal is not known. Other agents may exert such a dampening effect on glutamate release such as riluzole (324) and *N*-acetylcysteine (325). Memantine, a non-competitive NMDA receptor antagonist has shown promise as an augmentation strategy in OCD (80, 326). In addition, direct antagonists of the postsynaptic AMPA-type glutamate receptors such as topiramate that moderate the excitatory action of this neurotransmitter in the head of the caudate nucleus could have anti-OCD activity (327, 328). NMDA partial agonist D-cycloserine (DCS) has been proposed to facilitate cognitive behavioral therapy of anxiety disorders; small studies thus far have had positive outcomes (329) and negative outcomes (330). The use of DCS with CBT in the treatment of OCD has recently been studied (331, 332). It is proposed that DCS decreases the time needed to reach therapeutic targets (333, 334). Other agents with the potential to affect the glutamatergic system include beta lactam antibiotics (335), which may add an interesting dual action in children with PANDAS/PANS (336). Any agents affecting this system would have to be fairly selective for such neurons to avoid generalized adverse events due to generalized attenuation of glutamate transmission.

In many patients when OCD is comorbid with tics, bipolar disorder, or schizophrenia, combination of medications is frequently required. Comorbidity often clearly effects a negative treatment response (337) as demonstrated in one pediatric trial (338). Those with "pure" OCD had a much higher response rate than those with comorbid disruptive behavior disorder. The impact of comorbidity on treatment response needs further research and exploration.

10.12.3. Neurosurgical and Brain Stimulation Approaches to Treatment

The ability to perform minimally invasive psychosurgery for very severe and chronic neuropsychiatric disorders has made tremendous gains in the last few years. Ablative techniques such as cingulotomy, anterior capsulotomy, limbic leucotomy, and gamma knife capsulotomy have been used for very refractory cases of OCD with some success but at the risk of irreversible effects such as personality changes and residual neuropsychological deficits (339). Brain stimulation techniques such as deep brain stimulation (DBS), electroconvulsive therapy (ECT), vagus nerve stimulation (VNS), and repetitive transcranial magnetic stimulation (rTMS) have all been tried with varying success in treatment refractory OCD (340). DBS is currently being performed in refractory OCD cases (341, 342). DBS has the added benefit of very specific targeting of the regions likely involved in the neurocircuitry mediating OCD symptoms (such as anterior limb of the internal capsule) and the reversibility of the procedure (removal of stimulator, clipping leads) (343).

10.12.4. Treatment Relevant to PANDAS

The current standard of care for PANDAS/PANS is the same as that for OCD and tic disorders; namely, treat with SSRI and/or CBT and follow the course of illness. While immune-based treatments are being researched (i.e., antibiotics, intravenous immunoglobulin, plasma exchange), it is reasonable to check for an active infection (GAS rapid test or culture, influenza rapid test, etc.) for a child presenting with an acute and severe onset presentation of OCD. In order to mitigate high risk therapies in patients that are not clearly PANDAS/PANS and to assist clinicians with a suspected case of PANS/PANDAS, clinical guidelines for assessment and treatment are under development.

10.13. Conclusions

OCD is a fascinating disorder from a neurobiological point of view because the repetitive behaviors and thoughts associated with OCD have an array of rather unique characteristics: 1) they echo phylogenetically old behaviors (e.g., nest building, grooming) that are programmed into vertebrate brains, 2) they can result from genetic predisposition as well as acquired brain lesions that affect frontal-subcortical circuits, 3) they are triggered and exacerbated by anxiety and stress, 4) they can result from dysregulation of multiple neurotransmitters (dopaminergic, glutamatergic, and serotonergic systems), 5) they may be triggered as an inflammatory or immune mediated response to infections, 6) they increase with repetition (e.g., reward or practice, a characteristic "striatal" pattern) and are decreased by exposure and response prevention in controlled therapeutic settings. Given what we know about frontal-striatal circuitry, it would appear that OCD is not the result of a single specific factor, such as too little serotonin, too much dopamine, too much anxiety, but rather reflects dysregulation or imbalance of the striatal system. This system serves to integrate "hard-wired" motor and cognitive programs with newly learned programs. Thus, if the system becomes dysfunctional, one would expect to see impaired selection and "sticky" shifting of motor and cognitive behaviors.

Somatizing and Dissociative Disorders

C. Robert Cloninger, M.D., Ph.D. and Mehmet Dokucu, M.D., Ph.D.

Abstract Most patients consulting physicians have a mixture of physical and mental complaints that require careful differential diagnosis. Somatization is the production of recurrent and multiple physical symptoms in excess of any underlying medical disorder. Patients may have well-documented medical diagnoses, but their complaints are excessive or disproportionate in the judgment of the clinician. In DSM-5 the diagnosis of somatization emphasizes the presence of characteristic positive symptoms and signs for the diagnosis, whereas in DSM-IV the emphasis was on the absence of a medical explanation. DSM-5 makes it clear that the clinician is making a judgment about the complaints being excessive rather than on the absence of any medical diagnosis, but with either criterion, the clinician must make a judgment about the underlying medical basis for the complaints. The assessment and treatment of somatizing disorders requires patience and compassion to maintain a therapeutic alliance, and randomized controlled trials show that treatment with antidepressants, cognitive-behavioral therapy, or mindfulness-based therapies reduce health care utilization and subjective distress.

Somatization Disorder is the best-validated prototype of somatizing disorders, so we will use the adjective "somatizing" to specify the group of disorders referred to as "somatoform disorders" in DSM-IV and as "somatic symptom disorders" in DSM-5. Somatization Disorder has been shown to be a chronic and heritable disorder that is clinically manifest with complaints of multiple bodily pains, gastrointestinal, psueudoneurologic symptoms, sexual, and reproductive symptoms. Unfortunately, general medical practitioners found the criteria for Somatization Disorder in DSM-IV to be time-consuming to apply, so for their convenience DSM-5 has introduced an easy-to-use category of Somatic Symptom Disorder that may be diagnosed on the basis of a single somatic complaint that the clinician judges to be excessive, even though much research shows that such subjective judgments are unreliable. Conversion disorders involve acute or chronic loss of voluntary sensorimotor functions, such as psychogenic blindness, paralysis, or tremors, that can be shown to be inconsistent with neuroanatomy and neurophysiology. In DSM-5, conversion disorders may be diagnosed in the absence of a known psychosocial stressor because recent research has shown that the inconsistent neurological signs are a more reliable basis for the diagnosis. In contrast, some somatizing disorders more closely resemble physical phobias (e.g. hypochondriasis) or social phobias (e.g., body dysmorphic disorder).

Dissociative disorders involve the disruption or loss of the integrative mechanisms of consciousness, memory, identity, or perception. Dissociative disorders include amnesia (a disruption of memory), fugue (a disruption of identity), depersonalization (a disruption of perception), and Dissociative Identity Disorder (a disruption of consciousness and identity formerly called Multiple Personality Disorder). In dissociative disorders, transitions between personalities or the onset of amnesic or fugue states are usually precipitated by psychosocial stress like those observed in conversion disorders. Thus both conversion and dissociative disorders are typically precipitated by severe psychosocial stress, but it is often difficult to elicit the relevant history before treatment until the clinician can contact collateral informants. Recent brain imaging results suggest that hyperactivity of the anterior cingulate cortex can actively inhibit motor activity (e.g. psychogenic paralysis), sensory perception (e.g., psychogenic anesthesia), memory (e.g., amnesia), or identity (e.g. fugue) as a defensive response to stressors.

11.1. Introduction: The Dualism of Psychogenic Versus Physiological Is False

Most physicians are tempted to try to separate patients who have a mixture of physical and psychological complaints into those who have psychogenic versus physiological complaints. The temptation has always been strong because of the common belief in mind–body dualism. Unfortunately, such dualistic thinking cannot capture the complex interactions among the components of a human being, so physicians have long been frustrated in their efforts to understand psychosomatic disease processes. For example, patients with well-documented epilepsy often have some conversion reactions ("pseudoseizures") (1, 2). Patients with non-physiological findings that change with sedation or suggestion are often later documented to have medical disorders with well-defined organic causes.

Yet psychiatrists and other physicians persist in subscribing to the dualistic idea that signs and symptoms of illness are either psychologically initiated under voluntary control or they are the result of involuntary pathophysiological mechanisms. Such simplistic thinking is elaborated and enshrined in the Diagnostic and Statistical Manual (DSM) for mental disorders, as shown in Table 11.1. Somatoform and dissociative disorders are presumed to be associated with psychological factors and not fully explained by any physical mechanism, such as a medical condition associated with many somatic complaints like hyperparathyroidism (3). In addition, they are not intentionally produced (as in "factitious disorders") or feigned (as in "malingering"). These distinctions are conceptually clear in the abstract, but lead to many problems in practice because they are based on a false dualistic concept of human nature.

First of all, the distinction between psychological and physical disorders is not reliable in the vast majority of cases of somatizing disorders. The most common somatizing disorder in primary care was called "undifferentiated somatoform disorder" in DSM-IV and required only one symptom that is not fully explained by a known general medical condition to the satisfaction of the examining physician. Unfortunately, many physicians assume that a symptom is psychogenic in origin if the patient appears too anxious, too dramatic, too indifferent, or responds to suggestion, sedation, or obtains secondary gain from their complaints (1). However, many people with well-documented physical disorders have many of these features, as summarized in Table 11.2. Many people get anxious or take advantage of their symptoms when they get sick, and may show non-specific and transient improvement when they are relaxed (4). Past history of somatizing disorders predict more of the same, but what are often assumed to be current features of psychogenicity are an unreliable basis for understanding the etiology and prognosis of the complaints (5–7). Personality disorders also vary widely in their association with somatizing disorders as seen in Table 11.2. Some character disorders are associated with a high risk of somatizing disorders (e.g., borderline and antisocial personality disorders), but others are associated with a low risk. This suggests that there may be different routes to disorders of character that depend on individual differences in the intelligence of different aspects of our being (i.e., the body, the thoughts, and the soul).

Second, the classification encourages psychiatrists to think in terms of whether someone has a mental or a physical disorder, when these are often comorbid. Chronic lifestyle choices and patterns of stress reactivity lead to many chronic medical conditions. Most complaints to primary care physicians are associated with psychosocial stress. Primary care physicians prescribe more psychotropic drugs than do psychiatrists. Effective care of general medical conditions requires good mental health care, and vice versa. The realms of physical disease and mental disease are not really separable.

Third, the classification encourages psychiatrists to think like a detective, judge, or adversary, rather than a hopeful, compassionate, encouraging, and truth-seeking caregiver, about whether someone is faking or not. In fact, people with factitious disorders or malingering often have severe mental disorders that require treatment, though not treatment for the complaint that they are making. Even if a patient is judged to have a somatizing disorder, they are often left to feel that the doctor thinks the problem is not real because the doctor implicitly communicates that what is real is in the body (8). Exclusion of general medical conditions seems to imply to many that the problem is imagined, dramatized, or exaggerated "in excess of what is expected" in

TABLE 11.1. DSM-5 criteria used in the differential diagnosis of symptom(s) suggesting physical illness.

Classification	Physical mechanism explains the symptoms	Symptoms are linked to psychological factors	Symptom initiation is under voluntary control	Obvious recognizable environmental goal
Somatic symptom and dissociative disorders	No	Yes	No	Variable
Factitious disorders	Variable	Yes	Yes	No
Malingering	Variable	Variable	Yes	Yes
Psychological factors affecting medical condition	Yes	Yes	No	Variable
Undiagnosed general medical condition	Variable	Variable	No	No

TABLE 11.2. Utility of psychiatric criteria for distinguishing conversion and dissociative reactions from physical disorders.

Putative diagnostic criteria	Predicts no physical disorder
Past history	
Somatization Disorder	Yes
Prior history of conversions	Yes
Prior history of somatic complaints	Yes
Personality disorder	
With prior history of somatic complaints	Yes
No prior history of somatic complaints	No
Current presentation	
Excessive worry or La belle indifference	No
Current anxiety or dysphoria	No
Excessive time and energy devoted to health concerns	No
Emotional stress before onset	No
Secondary gain	No
Partial improvement with suggestion or sedation	No

their medical condition (to quote DSM-IV). DSM-5 continues this emphasis on "excessive thoughts, feelings, or behaviors related to somatic symptoms or associated health concerns,"—even though the body makes contributions to thought and vice versa. For example, people who are high in Harm Avoidance are prone to anxiety and have more intense pain responses given the same objective stimulus than do people who are lower in Harm Avoidance. Their increased pain sensitivity is real, although it may *appear* exaggerated to someone who does not appreciate their unique pattern of reactivity, because the release of endogenous opioids is objectively reduced in anxiety-prone individuals (9, 10). Personality traits like Harm Avoidance predispose to anxiety, which in turn amplifies somatosensory perception and intensifies the experience of pain (11). The dualistic concept underlying the DSM classification of somatizing disorders may put the physician in a judgmental position that makes it difficult to establish a cooperative and respectful therapeutic alliance. The contributions of the soma (i.e., the body), the psyche (i.e., the soul), and the thoughts and memories with which they communicate, all make real contributions to current symptoms.

Fourth, the classification fails to recognize the inseparability of the body, the thoughts, and the spirit of every person as an integrated whole. Each aspect of our being has its own form of intelligence, and our healthy functioning requires that our multiple forms of intelligence be integrated. The intelligence of the body is displayed by a ballet dancer or an acrobat; the intelligence of analytical thought is displayed by an intellectual or logician; the intelligence of the soul is displayed by a wise contemplative mystic. The emotional intelligence of a person is a characteristic of the limbic system of his/her brain, which influences nearly every system of the body through the hypothalamic-pituitary-adrenal axis. The limbic system interacts constantly with higher cortical systems that underlie rational thought. The cognitive and emotional life of a human being is a complex and dynamic process that depends on the inseparable interplay of the body, the thoughts, and the soul of the person as a whole (12).

Despite all these problems with DSM, the syndromes described within it can be used effectively in patient assessment and treatment if a coherent concept of human nature is recognized and the classification is not reified into a description of discrete disease entities. In particular, in order to understand somatizing and dissociative disorders, it is crucial to have a broad understanding of both the cognitive components of the human body and the somatic components of human thought. In other words, it is important for a psychiatrist to understand that there are marked differences between people in the degree to which they are self-aware of the functions of their body and its sensations, drives, emotions, intelligence, and sentiments. An understanding of the degree of self-awareness of the body is particularly useful for the treatment of chronic somatizing and dissociative disorders like Somatization Disorder or Multiple Personality Disorder. It is also important for a psychiatrist to know how to appease and calm the emotional brain of an individual so that the short-circuiting of the rational parts of the brain can be stopped in order to treat acute somatizing and dissociative disorders like conversion reactions or fugue states. Psychiatrists often become accustomed to treating patients with medications or with talk therapy, but these methods are simply inadequate with patients with somatizing or dissociative patients. Somatizing and dissociative patients are people whose chief problems are difficulties in understanding and coping with the signs and symptoms of their own body. Accordingly, they need therapies that address the needs of their body in the language of the body, which requires experiential methods that are concrete and tangible.

11.2. Emotional Drives and Emotional Intelligence

People differ markedly from one another in their emotional style. Nearly 2000 years ago, Galen recognized four temperaments that he attributed to the effects of different body humors: the melancholic (due to melancholy or black bile), the choleric (due to choler or yellow bile), the sanguine (due to blood), and the phlegmatic (due to phlegm). The four humors were body fluids con-

TABLE 11.3. Descriptors of individuals who score high and low on the four temperament dimensions as measured by the Temperament and Character Inventory (reproduced with permission of the author; for more detailed descriptions, see http://psychobiology.wustl.edu).

	Descriptors of extreme variants	
Temperament dimension	High	Low
Harm Avoidance	Shy	Outgoing
	Pessimistic	Optimistic
	Fearful	Daring
	Fatigable	Vigorous
Novelty Seeking	Exploratory	Reserved
	Impulsive	Rigid
	Extravagant	Frugal
	Irritable	Stoical
Reward Dependence	Sentimental	Critical
	Sociable	Aloof
	Warm	Detached
	Sympathetic	Independent
Persistence	Perfectionist	Pragmatist
	Industrious	Apathetic
	Determined	Spoiled
	Ambitious	Underachiever

sidered responsible for a person's health and emotional disposition. People were thought to have a predominance of one of these, which determined their emotional body type. Modern personality research confirms the presence of four temperaments but has shown that these vary quantitatively. Descriptions of people who score high or low on each of these four personality traits are given in Table 11.3. These personality traits are approximately normally distributed with about one-third of people being near average and the two extremes being designated as high or low scorers (13). These traits are all about equally influenced by individual differences in genetic factors and in variables unique to each individual (such as spiritual or environmental influences that are not familial). These traits are called temperaments because they involve differences in the regulation of basic body emotions and aspects of social relationships that are regulated by the oldest part of the human brain, the limbic system: fear (driven by Harm Avoidance), anger (driven by Novelty Seeking), disgust (driven by Reward Dependence), and ambition (driven by Persistence).

Rather than there being only four types of emotional predisposition, everyone has some score on all four dimensions. All possible combinations of profiles on these four temperaments are observed in the general population, thereby maintaining extensive variability in the population. The variation is maintained because there are both advantages and disadvantages to the extremes of each temperament. For example, consider the extremes of Harm Avoidance. If a person is too shy and pessimistic, she/he will miss many opportunities that could have benefits but at the same time she/he is less likely to be exploited or to be killed in dangerous circumstances. On the other hand, a person who is too optimistic, will not experience much anxiety, but may get killed from his or her risk-taking. For the extremes of Novelty Seeking, a person who is highly impulsive will explore opportunities quickly but also may get into frequent fights because of his or her quick temper; a person who is highly rigid will be orderly and conserve resources well, but has difficulty making inquiries and asserting him- or herself. For the extremes of Reward Dependence, a person who depends on external approval may make many friends but she/he is also vulnerable to peer pressure and exploitation, whereas a person who is cold and aloof will be independent-minded but isolated without much social support or help in times of need.

Temperament is the emotional core of human personality and it has substantial influences on our pattern of human relationships. Our relationships with people are often formed quickly and outside of our consciousness because emotional reactions among people have evolved to be quick and partly unconscious in the ancient limbic system of the human brain that is shared with reptiles and mammals that evolved millions of years ago (14). People have the capacity to become self-aware of their emotional reactions and feelings of relationship to one another by means of limbic cortical communication via the Papez circuit that connects the anterior cingulate cortex with the hypothalamus, thalamus, and hippocampus (15). The anterior cingulate cortex provides a key interface for the regulation of emotional drives, cognition, and motor behavior (16). As a result, it plays a key role in contemporary neural models for the heterogeneous category of major depressive disorder (17). The size of the anterior cingulate cortex and its functional connectivity with cortical and limbic structures is strongly moderated by temperament traits, particularly Harm Avoidance (18–20). Accordingly, emotional stress from sexual, physical, and mental trauma can precipitate overactive emotional responses at the expense of higher cortical processes, thereby short-circuiting or hijacking the function of the rational and self-aware parts of the brain. In particular, somatizing and dissociative disorders are associated with overactivity of the anterior cingulate cortex and highly variable over- or underactivity of various parts of prefrontal cortex (1, 21).

The degree to which a person has self-awareness of their body and the responses regulated by its temperaments may be defined as his or her "emotional intelligence" quotient (EQ). This definition is more specific than definitions that equate emotional intelligence to character in general (22, 23). Emotional intelligence can be dissociated from the speed and accuracy of information processing in rational thought, which depends largely on working memory capacity and is measured by capacity for intellectual analysis or IQ. Both EQ and IQ can also be dissociated from wisdom or spiritual intelligence quotient (SQ) (24–26). People can be high in EQ and/or IQ, but not wise in a spiritual sense. Wisdom leads to a combination of foresight, creativity, well-being, and virtuous living, so wisdom supercedes EQ and IQ in scope. Wisdom provides a holistic intuitive awareness of the whole being that allows it to integrate reason and love in action.

When a person is wise, emotional and intellectual intelligence are integrated in action and augmented by well-being and virtues. There is also the emergence of self-transcendent character traits associated with self-awareness of certain subtle sentiments like awe, humility, self-abnegation, reverence, and compassion, described in more detail later. These self-transcendent sentiments and the self-transcendent values that arise from the experience of these sentiments provide a phenomenological basis for describing the spirit of a person.

In summary, there are three dissociable forms of intelligence that a clinician can recognize in every human being: emotional intelligence of the body, analytical intelligence of rational thought, and spiritual intelligence from listening to the soul. Emotional intelligence and spiritual intelligence are both important for character development, and deficits in either or both can lead to personality disorders. On the other hand, IQ has little impact on the risk of personality disorder, but it can contribute to personal and social complications from personality disorders. When emotional intelligence is deficient, then the risk of somatizing and dissociative disorders is increased. Therefore, to understand the etiology and treatment of somatizing and dissociative disorders, we need a fuller description of deficits in emotional intelligence.

11.3. Alexithymia: Deficits in Emotional Intelligence

Alexithymia is a deficit in the self-awareness of emotions that results in difficulties in the regulation of emotions and particularly a reduced emotional and fantasy life and difficulty in identifying, understanding, and describing the emotion of one's self and other people (27, 28). The term was coined from the Greek for "lack of" (*a-*), "words" (*lexis*), and "emotions" (*thymos*), so it literally means "lack of words for emotions". However, the literal meaning is misleading because the designated patients can describe their emotions with words, although not with much depth of understanding. In other words, they lack insight into the causes, significance, and regulation of emotions. Essentially alexithymia refers to a deficit in intelligence about the understanding and regulation of emotions.

The syndrome was first described when Peter Sifneos and John Nemiah observed that many of their patients with somatizing disorders had so much difficulty talking about their emotions that they did not respond well to insight-oriented psychotherapy. These patients also usually had other common features, including a stiff posture, an externally oriented focus on concrete functional details, and a barren fantasy and dream life with little emotional content (29). Subsequently extensive research has shown that alexithymia can be reliably measured, is distinct from other measures of personality, and is associated with increased risk of somatizing and dissociative disorders more than other mental or physical disorders (28, 30–34).

A fuller description of the deficits in emotional intelligence in people with alexithymia is presented in Table 11.4. It is useful for purposes of assessment and treatment planning to organize these diverse features according to the five planes of self-aware consciousness that have evolved in a stepwise manner in human beings (12). The five planes of self-aware functioning of the body can be distinguished by distinct roles in processing physical sensations (in the sexual plane), motivational drives (in the material plane), affective attachments (in the emotional plane), emotional communication and symbolization (in the intellectual plane), and subtle sentiments like awe and compassion (in the spiritual plane). The corresponding content of these planes for thought and for the psyche is described elsewhere (12), but in discussing somatizing and dissociative disorders we must focus primarily on the awareness of the body.

People with alexithymia often have personality disorders, but not all patients with personality disorders are alexithymic. In particular, patients with antisocial and borderline personality disorders are often highly alexithymic (35). More generally, scores on the Toronto Alexithymia Scale (TAS) are moderately correlated with all three dimensions of character of the Temperament and Character Inventory (TCI) (12). The strongest relations are between the TAS subscale for externally oriented thinking and the TCI scale for material aspects of self-transcendence (self-forgetfulness). Such individuals are slow to become self-aware of physical sensations (36).

People with alexithymia are also at higher risk for somatizing disorders, substance dependence, depression, and particular psychosomatic disorders, such as hypertension, irritable bowel syndrome, and fibromyalgia (28, 37, 38). For example, patients with fibromyalgia are higher in alexithymia and have greater anxiety and inwardly directed anger than healthy controls (37). Such findings suggest that alexithymics experience emotional stimuli in the normal physiological ways (e.g., tense muscles, peristaltic contractions) but are unable to identify and interpret them insightfully in self-awareness (39). Not knowing the

TABLE 11.4. Features of alexithymia grouped according to planes of self-awareness (12, 29).

Plane of awareness	Abnormalities observed in alexithymics
Sexual plane (physical sensations and fantasy)	Stiff, wooden posture
	Difficulty distinguishing between bodily and emotional feeling
	Dreams and fantasies are few, mundane, and unimaginative
	Difficulty identifying different types of feelings
	Anxiety about the significance of feelings
Material plane (motivational drives)	Lack of pleasure seeking
	Narrow, repetitive focus of interests
	Low frustration tolerance, overwhelmed by practical tasks
	Limited understanding of causes of emotions
	Difficulty describing own emotions
Emotional plane (affective attachments)	Lack of capacity for enjoyment
	Unable to appreciate beauty in art or nature
	Lack of empathy and understanding of feelings of others
	Awkward and/or detached in social relationships
Intellectual plane (emotional communication and symbolization)	Concrete, chronological thinking without emotional contextual analysis
	Lack of mindfulness about emotions of self and others
	Lack of symbolization
	Lack of achievement and creativity
Spiritual plane (sentiments)	No sentiment of awe about natural wonders and mysteries
	No sentiment of connectedness with nature or other people
	No sentiment of reverence for anything sacred
	No sentiment of unity and integration in thinking

TABLE 11.5. Experiential methods for elevating emotional intelligence in chronic somatoform and dissociative disorders, that is, of reducing alexithymia by elevating self-awareness of the body and its sensations, drives, emotions, and sentiments (Cloninger and Cloninger, 2011 (81) and the Know Yourself © well-being coaching program of the Anthropedia Foundation).

Indicators of elevated body self-awareness	Methods for elevating body self-awareness
Sexual plane	
Fluid and expressive body movement	Gymnastics and yoga
Facility identifying emotions	Expressive dance
Imaginative fantasy and dreams	Body remodeling and acupuncture
Material plane	
Broadening of interests and sources of satisfaction	Individualized healthy diet for body type and balancing cravings
Non-violent assertive communication	Compassionate communication training
Emotional plane	
Appreciation of beauty in art and nature	Experiencing beautiful artistic creations
Empathy and understanding others feelings	Active listening and empathy training
Intellectual plane	
Awareness of emotional drives and conflicts of one's self and others	Psychoeducation about temperament and conflict resolution with self and others
Intelligence in emotional problem-solving	Psychodrama and group therapy
Artistic and other creative communication	Personal engagement in communication
Spiritual plane	
Awareness of subtle sentiments and self-transcendent values:	
Awe about mysteries and wonders	
Connectedness with nature	Union with nature meditation
Abnegation of self-respect and compassion for others	Personal engagement in self-transcendent activities
Reverence for sacred things	

emotional significance or cause of the sensations, somatizing patients interpret them incorrectly as symptoms of physical illness and feel sickly. The associated distress may set up a vicious cycle or downward spiral of somatic anxiety.

Alexithymia interferes with talk therapies that require facility with uncovering and describing emotions and that are anxiety-provoking. Therefore, appropriate therapies require promotion of calmness and communication in the language of the body. Treatments of choice based on our clinical experience and available research are presented in Table 11.5 along with the corresponding target problem in chronic somatizing and dissociative disorders. Treatment recommendations are sometimes made for complex protocols in which it is unclear what is being done and for whom. Some forms of mindfulness therapy, cognitive-behavioral therapy (CBT), or eye movement desensitization and reprocessing (EMDR) are useful for some symptoms of some

somatoform patients (40–42), but it is unclear what therapeutic elements are useful for particular symptoms of particular patients. In the past treatment of somatizing patients, results have often been incomplete with much refusal of psychiatric treatment, frequent drop-out, and weak to moderate results of those retained (1, 43, 44). We have found it important, therefore, in developing and optimizing treatment methods for individual patients to relate what is done to specific target signs and symptoms, as in Table 11.5.

For example, improved fluidity and expressivity of body movements can be facilitated by gymnastics and expressive dance. Physical therapies and exercises are beneficial in randomized controlled trials of a variety of chronic somatizing disorders (43). Greater awareness of one's body and enjoyment of a healthier diet can be facilitated by individualized diets that require awareness of body type and food cravings like what has long been done in Ayurvedic medicine (45). Training in non-violent assertive communication can be explained in a concrete way to facilitate more effective self-expression (46). Methods for identifying emotion can be taught, beginning with listening to verbal and physical cues, and then learning to resolve conflicts without personal criticism or sarcasm (47). A training program has also been developed to assist well-being coaches and therapists to teach an understanding of emotional processes and specific meditations that enhance sensory awareness, appreciation of beauty, empathy, and the principles of well-being (48). The promotion of health through increased self-awareness is applicable to a wide range of people, including individuals with deficits in any form of self-awareness, including alexithymics and chronic somatizing patients.

The methods described in Table 11.5 are designed for long-term treatment of chronic patients and additional methods are needed for intervention with acute patients, such as acute conversions or fugues. The methods of Table 11.5 are focused on elevating self-awareness of the body's sensations, motivational drives, emotional attachments, emotional symbols, and sentiments. These are what we label as the components of the body that can be elevated in self-aware consciousness, bringing what has been lost down in the unconscious up into conscious self-awareness.

In contrast, the procedures recommended for acute patients are directed at what we label as the "body component of thought": namely, feelings of self-respect, self-mastery, intimacy, capacity to work through mental trauma, and the spirit of self-sacrifice. These cognitive phenomena require different treatment methods. In particular, the therapy is directed at somatic aspects of thought so the quality of therapist's relationship to the patient is crucial. Without words, the therapist must relate directly to the patient with hope, compassion, and faith while helping the patient find ways they can learn the art of living well. This quality of compassion provides appeasement, rather than provoking anxiety, frustration, or other forms of negative emotion, in both the patient and the therapist. In the context of this kind of therapeutic relationship, the patient can be helped to reconcile emotional conflicts in each realm of their life, as described in Table 11.6. When possible, graded physical exercise can be both relaxing and helpful in building self-respect and fitness, as has been shown in randomized controlled trials of patients with complaints of fibromyalgia and chronic fatigue (49). Particular somatic methods are helpful in dealing with the effects of mental trauma and stress according to randomized controlled trials; these include eye movement desensitization, cardiac coherence, supplementing diets with omega-3 fatty acids for brain fluidity, and others (50). Group therapy has been shown in a randomized controlled trial to improve physical and mental health in Somatization Disorder for at least a year after treatment (51). In addition, a meditation on Union with Nature in which a person increases their awareness of sensations from all five of their special senses is particularly useful but needs to be practiced for 30 minutes at least three times daily following mental trauma like

TABLE 11.6. Experiential methods for elevating the body component of thought in acute somatizing and dissociative disorders (e.g., conversion or fugue).

Indicators of elevated body component of thought	Treatments of choice
Feelings of self-respect	Therapist's hopeful validation
	Reconciliation of conflicts between extremes of Harm Avoidance (anxiety versus risk-taking)
	Cardiac coherence
	Physical exercise for fitness
Feelings of impulse control and self-mastery (ability to delay gratification, responsibility, purposefulness)	Therapist's forgiveness and kindness
	Reconciliation of conflicts between extremes of Novelty Seeking (impulsive versus rigid)
	Goal-setting and accomplishment
Feelings of intimacy and security in social attachments	Therapist's spiritual appeasement
	Reconciliation of conflicts between extremes of Reward Dependence (approval versus privacy seeking)
	Engagement in social activities
Retentive and flexible working memory	Therapist's non-judging patience
Capacity to work through mental trauma calmly	Reconciliation of conflicts between extremes of Persistence (perseverative versus impersistent)
	Eye movement desensitization and integration for trauma
Spirit of self-sacrifice	Therapist's integrated intelligence
	Union in nature meditation 3×/day
	Engagement in self-transcendent activities

those typically associated with acute conversions or fugues in order to allow de-stressing of the limbic system (12, 48). This meditation is a means of enhancing sensory awareness to bring satisfaction and joy from everyday natural experiences of everyday life like walking, eating, smelling, hearing, and seeing. Detailed recommendations about choice of medications that are useful for target symptoms in somatizing and dissociative disorders, such as somatic anxiety, are described in the chapter on personality disorders.

Up to now we have presented a flexible target-symptom approach to somatizing and dissociative disorders that addresses the underlying deficits in emotional intelligence because most patients will not fit neatly into specific categories as described in DSM-5. However, different clinical syndromes do have some particular features that are helpful in clarifying how to apply the general principles in a flexible manner tailored to the individual patient. Therefore, we will now consider several specific syndromes in terms of assessment, etiology, and treatment.

11.4. Somatization Disorder (Briquet's Syndrome)

Somatization Disorder is the prototype of all somatizing disorders. Its features can be predicted from the complaints expected to arise from deficits in emotional intelligence in all five of the realms of body awareness described in Table 11.4. The deficits in the sexual plane are frequently associated with distress, multiple bodily pains from a low pain threshold, and sexual or reproductive complaints. The deficits in the material plane are frequently associated with low frustration tolerance, poor impulse control leading to substance dependence and violence, and gastrointestinal complaints like irritable bowel syndrome. The deficits in the emotional plane are frequently associated with insecure social attachments, little appreciation of beauty, and emotional lability. The deficits in the intellectual plane are associated with poor emotional communication, such as being a poor historian with little understanding of emotions of one's self or others. The deficits in the spiritual plane are associated with low quality of life due to a lack of positive sentiments, which leads to a low level of integration of one's desires, goals, and values. Nevertheless, it is instructive to know how the syndrome came to be recognized and how the current understanding of Somatization Disorder developed historically.

Originally Somatization Disorder was called chronic hysteria or hysterical neurosis. Patients with hysteria are women in 95% of cases since antiquity so the name was based on the concept from ancient Greece that a wandering uterus caused pains in different parts of the body, which is now largely disproven except in cases of endometriosis. Eli Robins and Sam Guze developed the modern description of the syndrome and validated it rigorously by follow-up and family studies (52). According to their descriptions, hysteria was a chronic disorder in which patients had medically unexplained somatic complaints in nearly all organ systems, including multiple bodily pains, gastrointestinal problems, sexual or reproductive symptoms, and pseudoneurological problems (conversion reactions). The type, number, and distribution of complaints allowed reliable discrimination of patients with a predictable course of illness and characteristic family history, whereas diagnosis and prognosis were unreliable when based on isolated complaints or severity of subjective distress. Young adult women usually presented with the disorder and their course was chronic, although the specific symptoms varied in location and intensity in response to the vicissitudes of their chaotic lives. The patients had poor affective regulation, were notoriously poor and inconsistent historians, and had little awareness of the relations between the personal and social stresses in their life and their physical complaints. As a result of the patient's prominent deficits in emotional intelligence, some people suggested the patients were throw-backs to an earlier point in the evolution of human consciousness. Their way of thinking appears more typical of people who lived about 3000 years ago than it is of the consciousness of contemporary human beings.

Guze carried out blinded follow-up and family studies that showed that patients with this syndrome had a chronic course but were not at increased risk for medical disorders. Studies showed that antisocial personality disorder and hysteria often occurred together in the same individuals as well as in the same families (53).

Most patients and some psychiatrists disliked the use of the term hysteria because it was rather pejorative and also ambiguous. A French psychiatrist named Briquet had described a similar group of patients with multiple somatic complaints (54), so Guze suggested the label of Briquet's syndrome in order to distinguish the syndrome from histrionic personality disorders and acute conversion reactions. Guze's criteria were well validated but were cumbersome, requiring endorsement of over 20 out of 59 possible symptoms of Briquet's syndrome, distributed in at least nine of ten empirically derived groups. As a result, few people used the research criteria in clinical practice.

The widespread nature of the syndrome and its heritability were confirmed in adoption studies conducted in Sweden (55). Somatizing disorders were also shown to be the major cause of all absenteeism from work, thereby causing great economic loss to society as well as individual suffering. The adoption studies also confirmed the genetic overlap in the causes of somatizing disorders and personality traits associated with criminality, such as antisocial and borderline personality disorder.

In 1980 the term Somatization Disorder was adopted in DSM-III, which tried to be strictly descriptive, not to make etiological assumptions, and to avoid all eponyms. The criteria for diagnosis were simplified but remained lengthy and little used. For DSM-IV, Cloninger developed the DSM-IV criteria using the same methods he had developed in the Swedish adoption studies (4).

The criteria were designed to be easy to remember and use: at least four bodily pains, two gastrointestinal complaints, one pseudoneurological symptom, and one sexual or reproductive symptom. If any one of these requirements were not met, the diagnosis cannot be made so inquiry can stop at that point. The criteria for Somatization Disorder identified essentially the same patients as the original criteria of Guze. The high sensitivity and specificity of the criteria were confirmed in DSM-IV field trials at multiple independent sites, including psychiatric and primary care populations (4). As a result, practical criteria are now available for the diagnosis of Somatization Disorder.

Medical specialists with little knowledge of psychiatry often conclude that patients with Somatization Disorder have fibromyalgia and irritable bowel syndromes. Such diagnoses by medical subspecialists reflect their special interests and do not explain the full somatization syndrome, the prominent and widespread deficits in emotional intelligence and character development, or genetic association with impulsive personality disorders. Furthermore, treatment of the complaints of fibromyalgia and irritable bowel syndrome often involves the use of psychotropic medications and cognitive-behavioral treatments. Primary care physicians and medical specialists often play prominent roles in managing the lives of patients with Somatization Disorder, and there should always be collegial communication among their various physicians. Even when the goal is merely management of a chronic condition, it is useful for all of a somatizing patient's physicians to be educated about the nature and scope of the underlying disorder. However, if a patient is really interested in getting well, then they require treatments addressing the underlying causes of their complaints. Accordingly, comprehensive treatment of patients with Somatization Disorder requires a specialist in psychiatry to deliver the psychiatric care and coordinate the various facets of treatment in consultation with other specialists. Which physician is the overall supervisor will depend on the patient's therapeutic relationships and most prominent problems. Such coordinated care can work very well even with the most difficult of patients (1).

Unfortunately, general medical practitioners in busy practices who spend only a few minutes with each patient have found it challenging to apply the full diagnostic criteria for Somatization Disorder, even though the criteria can be efficiently screened in a stepwise manner. Many somatizing patients present in primary care settings so to accommodate the needs of primary care physicians, DSM-5 has introduced a new category called Somatic Symptom Disorder, even though this diagnosis has doubtful validity, as we will discuss later. The diagnosis of Somatization Disorder was dropped from DSM-5 despite strong evidence of validity and a rich history. Accordingly we recommend that clinicians who wish to practice on the basis of scientific evidence should continue to use the well-validated DSM-IV criteria for Somatization Disorder and not use the unvalidated DSM-5 criteria for Somatic Symptom Disorder.

Traditional ways of treating Somatization Disorder begin with particular attention to the way the diagnosis and a therapeutic alliance are established. Patients with SD are reassured when their physician takes the time to collect a thorough history, obtains past medical records, and obtains collateral information from family members with informed consent. Such careful documentation often corrects inconsistencies and omissions, avoids the need to repeat medical tests, and communicates the respect of the therapist for the dignity and past suffering of the patient. Comorbid conditions, such as disorders of personality, mood, and substance abuse, are common and may require treatment also. It is useful to assess personality with a questionnaire with internal validity controls, such as the Temperament and Character Inventory, particularly since this is prescriptive of treatment targets, as described in the chapter on personality disorders. This helps to focus patients on their active role in developing a healthy life by developing greater self-awareness and beginning on the path to their well-being. No one can be forced to become more self-aware, so there is a wide range of possible goals. The possible goals include at least education to help reduce excessive health care utilization and exposure to unnecessary tests and procedures, as is often done by providing consultation to their primary care physician (56). It can also include pharmacotherapy for target symptoms of somatic anxiety, depression, impulsivity, emotional detachment, and cognitive distortion, as described in the chapter on personality disorders. For example, as adjuncts to psychotherapy, antidepressants may be useful for anxiety and mood symptoms, mood stabilizers for impulsivity, and atypical antipsychotics for emotional detachment and/or cognitive distortion (43). Cognitive-behavioral therapy has been recommended as a treatment of choice based on a meta-analysis of 29 randomized trials, but the effects were only moderate: symptom severity was reduced in 71% of cases but functional status was only improved in 26% (57). A later randomized trial of CBT showed that it can produce moderate but clinically meaningful reductions in health care utilization and subjective complaints for about a year after treatment, even though it does not correct underlying deficits in emotional intelligence (58). However, relapse and recurrence are major problems for treatments like CBT that do not correct the underlying deficits in emotional intelligence of patients with somatizing disorders (59). More ambitious work, still unproven by randomized controlled trials, includes efforts focused on the habilitation of emotional intelligence as described earlier.

11.5. Somatic Symptom Disorder in DSM-5

The contributors to DSM-5 recognized that it requires time and skill for a physician to determine whether a patient's complaints are medically explained or not, as was required for the diagnosis of somatoform disorders in DSM-III and -IV. However, the contributors to DSM-5 failed to appreciate that it is even more difficult for physicians to judge whether a person's subjective

distress is excessive. The proposed criteria for Somatic Symptom Disorder in DSM-5 require only that a clinician judges a person's distress about one or more physical complaints to be excessive or disproportionate in order to label them with the diagnosis of a mental disorder. Unfortunately this criterion still requires a clinician to judge whether the patient's complaints can be medically explained or not. It is even more problematic that in DSM-5 there are no restrictive criteria about the underlying pathophysiology or about the number, type, or duration of the complaint. Duration is noted to typically be 6 months or more, but this is not required. Likewise, there is no exclusion based on presence of other disorders, except that it is noted in the text that the diagnosis should not be made when the somatic complaints only occur during episodes of depression. Overall, these broad criteria are dangerously over-inclusive; this diagnosis alone would result in 8% of people in the general population being labeled as mentally ill on the basis of a clinician's subjective judgment that their complaints are excessive (60). These criteria are clinically simplistic, superficial, and are not justified by scientific evidence as needed for a valid diagnosis. They do not avoid any of the problems of mind–body dualism that its well-intentioned but ill-informed proponents suggest.

The emphasis in DSM-5 is on the diagnostician's subjective judgment that a person's thoughts, feelings, and behaviors are excessive or disproportionate to the seriousness of their somatic symptoms. Such subjective judgments can be made with strong reliability (60, 61) and still be invalid because they depend on many untested or untestable assumptions about the etiology and motivation (62, 63) and occur in large numbers of people with little or no psychopathology or persistent disability (64, 65). For example, more than one in three patients with no mental disorder in primary health care complain of excessive fatigue or pain (65). The choice of the APA to broaden these criteria is a regression to diagnostic approaches that were discredited in the mid-20th century in Europe and the United States, as illustrated by the previously mentioned research of Robins and Guze. The APA criteria for Somatic Symptom Disorder have no demonstrated utility for informing etiology, prognosis, or treatment. The course of a patient's subjective distress depends on the underlying psychiatric syndrome, personality profile, and complex interactions between a person's psychobiological strengths and situational stressors that are not measured by the suggested APA criteria. Hopefully, responsible physicians will ignore the ill-advised criteria proposed by the APA, which actually do not have any compelling scientific or legal force.

Even when there are multiple unexplained somatic complaints, there is little information about prognosis and treatment because of the heterogeneity of the patients. A meta-analysis of 34 trials of patients with multiple somatic complaints reviewed the relations of outcome to diagnosis (chronic fatigue versus irritable bowel versus fibromyalgia versus somatization), treatment (CBT versus relaxation versus exercise), and format of treatment (individual versus group) (66). Treatments did provide modest benefits compared to controls, but there was no differential effect of diagnosis or type of treatment.

In DSM-5, pain disorders are grouped together with Somatic Symptom Disorder, but are distinguished by a specifier "with predominant pain." Because DSM-5 criteria for Somatic Symptom Disorder lack validity, we will henceforth ignore it. Pain disorders will be considered separately because of their distinctive clinical features.

11.6. Conversion Disorders

A conversion disorder is a medically unexplained loss or alteration in voluntary sensori-motor functions. The term "conversion" implies that a psychological stressor is being expressed involuntarily as in the language of the body as a functional neurological symptom. Accordingly, in DSM-IV there was a requirement for documenting a psychological stressor that triggered the symptoms. However, sometimes information about the stressor is not declared or known consciously, so in DSM-5 there is no requirement to document a psychological stressor, which would require getting to understand the patient thoroughly. Instead in DSM-5, the diagnosis of Conversion Disorder is based on demonstrating that the complaint is not compatible with recognized neurological or medical conditions on the basis of rigorous neuropsychiatric examination. Therefore, in DSM-5, conversion disorders may also be called "functional neurological symptom disorders." However, it is a fundamental logical error to assume that the absence of a neurological explanation implies the presence of a psychiatric disorder. Proper diagnosis of a conversion disorder requires an understanding of the whole person, including the functioning of their neurological system in its biopsychosocial context.

The classic examples of conversion disorders are sensorimotor abnormalities that mimic neurological disorders, so they often require coordinated evaluation and treatment with neurologists and other medical specialists (1). These deficits include loss of the special senses of sight, hearing, smell, taste, and touch. Alterations of these sensory functions, such as double vision, can also be conversion disorders. Any of these deficits or disturbances of the special senses are specified in DSM-5 as a conversion disorder "with special sensory symptom."

Other common examples of conversion disorders are specified as "with weakness or paralysis", "with abnormal movement" (e.g., tremor, dystonic movement, myoclonus, gait disorder), with swallowing symptoms, with speech symptom (e.g., dysphonia, slurred speech), with attacks or seizures. Such conversions are usually called "psychogenic movement disorders" in neurology (1). These motor deficits include psychogenic tremor or shaking, psychogenic dystonia, impaired coordination or balance, ataxia or gait disturbance (e.g., astasia–abasia), functional paralysis or localized weakness, psychogenic Parkinsonism, difficulty

swallowing, aphonia, or urinary retention. In movement disorder centers, tremors are the most common psychogenic movement disorders (40%) followed by dystonias (31%) (67). The classic conversion symptom of globus hystericus is usually described as a "lump in the throat" that makes swallowing uncomfortable or difficult. The classic conversion symptom of astasia–abasia is the inability to stand or walk in a normal manner. The gait is bizarre and not consistent with a specific neurological lesion; for example, often the patient sways wildly and nearly falls, but recovers at the last moment.

Patients also frequently present with Conversion Disorder with seizures or seizure-like attacks. Such conversions are usually called "pseudoseizures" or "psychogenic non-epileptic seizures" (PNES) by neurologists (1). Many patients with recurrent seizures confirmed by electroencephalograms also have some pseudoseizures, so the diagnosis of such patients can be challenging. The key distinction is that conversion disorders involve some voluntary sensori-motor signs and symptoms mimicking a seizure (67).

Still other people present symptoms of more than one category of conversion and are designated as "Conversion Disorder with mixed symptoms" in DSM-5. Some patients have exaggerated behaviors during the later phases of a startle response, as in Latah, but these syndromes are usually classified among the culture-bound disorders.

There are no specific laboratory tests or signs on physical examination that are diagnostic of conversion disorder. As a result, the differential diagnosis of conversion disorder or a general medical condition requires knowledge of both psychopathology and general medicine. Efforts are made to detect psychopathology or associated psychological factors, as well as alternative medical explanations. Psychopathology can coexist with other medical disorders, as when individuals with epilepsy also present pseudoseizures on occasion. Also chronic conversion disorders can lead to atrophy or contractures or other physical lesions from long-term disuse. Conversion disorders should *never* be based only on exclusion of known medical disorders. What physicians know is finite and it is an error of logic to assume that the absence of proof is the proof of absence of a physical cause. Therefore, in DSM-IV the diagnosis of Conversion Disorder required positive evidence of psychological factors that are judged to be associated with the medically unexplained symptom or deficit. The reliance on only inconsistent neurological signs without any requirement of psychological disturbance is expedient but questionable; best practice would be to require both evidence of a close relationship between psychological stress and functional neurological disturbance, which is what is actually observed clinically in valid cases (1).

The etiology of conversion disorders and dissociative disorders is an area of rapidly growing knowledge from recent work in functional brain imaging. Hyperactivity of the anterior cingulate cortex (ACC) is found in most, but not all, studies of conversion and dissociative disorders, usually along with either increased or decreased activity of the dorsolateral prefrontal cortex. The ACC is an interface for emotional regulation, motivation, and motor processing to determine an appropriate motor response, as discussed earlier. For example, hyperactivity of the ACC has been suggested to actively inhibit motor activity in psychogenic paralysis (68). Hence treatments are directed acutely at emotional appeasement of the emotional brain, as described earlier. The methods that have been used effectively for acute interventions include hypnosis, interviews concomitant with sedative injections (usually amytal or lorazepam), or other forms of reassurance and relaxation. Such interventions can lead to a dramatic catharsis with rapid relief of the symptoms. Then further treatment can be carried out as suggested earlier in this chapter to reduce stressors and to understand and mitigate the underlying vulnerability to the symptoms. Practical advice on implementation of such methods has been presented in detail (1, 44).

11.7. Other Somatic Symptom Disorders

The somatoform cluster in DSM-IV included a heterogeneous collection of disorders, including pain disorders, hypochondriasis, body dysmorphic disorder, and others like pseudocyesis that are not otherwise specified. The somatizing conditions recognized in DSM-IV involve diverse mechanisms and principles and some are unrelated to Somatization Disorder. As a result, we will focus mainly on differential diagnosis with brief comments about etiology and treatment.

According to DSM-IV, if the chief complaint or predominant focus of the patient is pain, the diagnosis of Pain Disorder should be considered. In DSM-5 Pain Disorders are grouped under Somatic Symptom Disorder and specified as "with predominant pain". In view of the inadequacy of DSM-5 criteria, the diagnosis of pain disorder can be based on DSM-IV criteria for pain disorder when there is need for reliability and validity, as in disability evaluations. Specifically, pain is the predominant focus of the presentation, causes clinically significant distress or impairment, and psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain. A mental disorder is diagnosed only if the pain disorder is associated with significant distress or impairment from psychological factors, or if it is associated with both psychological factors and a general medical condition.

Pain disorders are heterogeneous, and are often comorbid with other physical and mental disorders. As a result it is important to identify the underlying psychopathology and any associated stressors. Once this is done, there are many patients with pain disorder who are alexithymic, which predisposes to complaints about pain (31, 69). In these pain patients, the same treatment approach is indicated as described earlier for improving emotional regulation in alexithymics.

Body Dysmorphic Disorder (BDD) involves the preoccupation with an imagined or slight defect in appearance. Preoccupation with the skin, hair, and nose are the most common, but any body area can be the focus of concern. Patients with BDD often can be observed to pick their skin, check their appearance in the mirror frequently, or to try to camouflage their appearance with a hat or make-up (70). These patients often seek cosmetic surgery repeatedly, only to remain dissatisfied with their appearance. Nearly half of the patients are delusional, particularly having delusions of reference (71). BDD is associated with severe anxiety and frequent suicide attempts. Clinically it appears to be more closely related to social phobia and obsessive-compulsive disorder than to Somatization Disorder. Patients are usually able to describe their emotions well, even though they are socially phobic, obsessive, and rejection-sensitive. Serotonergic antidepressants and cognitive-behavioral therapy like that used for social phobias and OCD is frequently effective in the treatment of BDD.

Hypochondriasis is the preoccupation with unrealistic fears of having a disease, or the belief that one has a disease. This fear or idea persists despite medical reassurance and lasts more than 6 months. Patients with hypochondriasis are typically fearful and anxiety-prone, reacting quickly and strongly to sensory stimuli. Until the late 19th century, hypochondriasis was associated specifically with complaints involving the "hypochondriac" region of the abdomen – that is, below the costal cartilages—rather than with regionally non-specific morbid disease preoccupation (55). Hypochondriasis is called Illness Anxiety Disorder in DSM-5. The DSM-IV and DSM-5 criteria are essentially the same as proposed by Gillespie in 1928,who believed that hypochondriasis was an independent, discrete disease entity (72). Others concluded that hypochondriasis was always a secondary part of another syndrome, usually a depressive disorder (73). More recent studies confirm that patients with hypochondriasis frequently have other co-occurring mental disorders, particularly anxiety and depressive disorders.

Hypochondriacs have an increased past history of serious childhood illnesses and experience with disease in family members. These patients are often highly verbal and aware of their emotional processes, but are easily triggered to anticipate the worst. Adoption studies have identified hypochondriacal patients who are harm avoidant and have fewer biological relatives with criminality; this is in direct contrast to somatizing patients who have an increased risk of biological relatives with criminality (74). Essentially hypochondriasis is a disorder of phobic anxiety, rather than a deficit in emotional awareness. Accordingly, the recommended treatments of choice are similar to those for anxiety and mood disorders, such as serotonergic antidepressants, cognitive-behavioral therapy, or psychodynamic therapy. In DSM-5, hypochondriasis is classified with both anxiety disorders and somatic symptom disorders.

11.8. Dissociative Disorders

Dissociative disorders involve the disruption or loss of the integrative mechanisms of consciousness, memory, identity, or perception. These disruptions may be sudden or gradual, and transient or chronic. Dissociative disorders include amnesia, fugue, depersonalization, and dissociative identity disorder (formerly called Multiple Personality Disorder). There are no major diagnostic changes for dissociative disorders between DSM-IV and -5, except that DSM-5 excludes states of possession that are recognized as a normal part of cultural or religious practice. Dissociative amnesia is a disruption of memory: specifically, it is the inability to recall important personal information in excess of what can explained by ordinary forgetfulness. Dissociative fugue is a disruption of identity: it involves the sudden travel away from home and work, accompanied by inability to recall personal identity or at least the assumption of a new identity. Depersonalization Disorder is a disruption of perception: it involves the feeling of being detached from one's mind or body, as if they can be observed from a distance. Dissociative identity disorder (DID) is a disruption of consciousness and identity. Two or more distinct identities or personality states recurrently take control of the individual's behavior in DID, and the person is unable to recall important personal information about their other states. It involves the fragmentation of identity, rather than the possession of multiple personalities that are each complete but separate, so the name has been changed to DID, rather than multiple personality disorder, to correct this popular misconception. Transitions between personalities or the onset of amnesic or fugue states is usually precipitated by psychosocial stress, such as marital quarrels, personal rejection, or events associated with a high risk of injury or death. Early childhood abuse is often a predisposing factor (75). Thus both conversion and dissociative disorders are typically precipitated by severe psychosocial stress, but it is often difficult to elicit the relevant history before treatment until the clinician can contact collateral informants. Caution and restraint is required for the clinician to avoid iatrogenic suggestion of false memories and identity disturbances in patients, as illustrated in the infamous example of Sybil (76–78).

DSM-5 is careful to distinguish DID from states that are considered normal expressions of particular religious or cultural practices in which a benign spirit is believed to have taken temporary possession of a person. The approach taken in DSM-5 (i.e., to distinguish DID from states accepted as culturally normal) leaves the decision about what is normal to a person's subculture or religion of choice. This exclusion still allows inclusion of possession states as cases of DID when possession states impair a person's functioning or cause distress, as in cases where a person seeks exorcism.

DID and Somatization Disorder are both chronic conditions, so they are sometimes grouped together as chronic hysteria. Likewise, conversion disorders and dissociative amnesia, fugue, and depersonalization are often acute in onset and brief in duration, so they are sometimes grouped together as acute hysteria (68). The separation of somatoform and dissociative disorders is artificial because many patients present with combinations of somatization, conversion, and dissociation, as is typical of patients with Somatization Disorder. Furthermore, functional neuroimaging results confirm the utility of groupings based on course; acute hysteria, whether a conversion or dissociative disorder, is most consistently associated with hyperactivation of the anterior cingulate cortex (68). Essentially, stress activates the limbic system and the anterior cingulate cortex serves as an interface to regulate a wide variety of aspects of motor activity (e.g., seizure or paralysis in conversion disorders or runaway in dissociative fugue), perception (e.g., detachment in depersonalization or blindness, deafness, or anesthesia in conversion), or consciousness and identity (seizure-like trance states in conversion disorders or new identities in dissociative disorders).

Before functional imaging was possible, detailed clinical studies of patients with conversion and dissociative disorders were a major impetus to the development of psychodynamic concepts by Janet and Freud. Both men thought that the development of hysterical symptoms was the result of disturbing mental associations becoming unavailable to consciousness by voluntary recall. Janet proposed that hysterical symptoms could arise when forces that normally serve to integrate mental function fail and some functions escape from active central control. This theoretical process was referred to by Janet as dissociation (79). In contrast, Freud suggested that there was an active process by which disturbing mental associations were removed from conscious awareness (80). This active process of inhibition or removal from availability to voluntary recall was called repression. Repression was conceived as a mechanism to protect the patient from emotional pain arising from either disturbing external circumstances or anxiety-provoking internal urges and feelings. The theoretical formulation of Freud is remarkably well supported by contemporary findings from functional brain imaging; in fact, hyperactivity of the anterior cingulate cortex in response to stress can actively inhibit motor activity, sensory perception, and conscious recall of unpleasant events or even one's identity (1).

The recent progress in the assessment, etiology, and treatment of patients with somatoform and dissociative disorders offers encouragement to clinicians and neuroscientists alike that modern psychiatry is a clinical field that integrates the neurobiological and psychosocial sciences with compassion and respect for human dignity. The complexities of somatizing and dissociative disorders are mysteries that continue to stimulate an ever-deeper appreciation of the wonders of human nature.

Anorexia Nervosa and Bulimia Nervosa

Scott J. Crow, M.D. and Elke D. Eckert, M.D.

Abstract The most widespread eating disorders, AN and BN, are potentially serious disorders with high morbidity and mortality primarily affecting young females. The disorders are related; often there are no clear boundaries between the two disorders. Recent advances have been made in defining the interplay of risk factors leading to the disorders. These include various biologic and genetic factors, such as personality and comorbid psychiatric symptoms. Although there have also been advances in the treatment of the disorders, much more research is needed, particularly in AN, to define effective treatments.

Keywords Anorexia · Bulimia · Eating disorders · Binge-purge · Binge eating

12.1. Etiology and Pathogenesis

An eating disorder can be defined as a persistent disturbance of eating behavior and/or a behavior intended to control weight which impairs social function or physical health significantly but is not due to a medical or other psychiatric disorder. The most widely recognized eating disorders, AN and BN are common, potentially serious disorders that primarily affect young females. Both disorders are characterized by peculiar attitudes and behaviors directed toward eating and weight accompanied by intense weight gain. AN is further characterized by obsessive pursuit of extreme thinness leading to emaciation and disturbance of body image. One important change to the AN criteria in DSM-5 is that the amenorrhea criterion from DSM-IV has been eliminated.

The cardinal feature of BN is eating binges which are powerful and intractable urges to consume large amounts of food over a short time. Usually, this is followed by either self-induced vomiting or ingestion of laxatives in an attempt to prevent weigh gain. However, BN does not produce the emaciation which accompanies AN. The only change to the BN criteria for DSM-5 is that the required frequency for binge-eating and purging is reduced from twice to once per week.

Although AN and BN are separate diagnostic disorders, there are no clear boundaries between the two conditions. Not only can the one develop from the other, but characteristics of both disorders are frequently present together in the same individual. Also, there are similarities in many of the important characteristics of the disorders (see Table 12.1).

The specific etiology of AN and BN is elusive and still unknown, although the genesis appears to be multifactorial, with the vulnerability to AN and BN arising from interplay of genetic, biologic, psychological, and environmental risk factors. Earlier psychological theories centered mostly on phobias and psychodynamic interpretations. One view was that AN can be seen as an eating or weight phobia; regardless of the initial stimulus for dieting, eating or weight gain begins to generate severe anxiety, while failure to eat or weight loss serves to avoid anxiety (1). Crisp (2) has postulated that a weight phobia springs from an

TABLE 12.1. Comparison of important clinical features of AN and BN.

Important features for AN	Important features for BN
Significantly low body weight[a]	Weight maintenance in normal range[b]
Intense fear of weight gain[a]	Intense fear of weight gain[a]
Peculiar food handling (*may* include recurrent binge–eating)[c]	Peculiar food handling (*must* include recurrent binge-eating)
Severe self-inflicted behaviors directed toward weight loss (*may* include vomiting, laxative or diuretic abuse)	Severe self-inflicted behavior directed toward weight loss (e.g., laxative or diuretic abuse, or excessive exercise or fasting)[a]
Disturbance of body image or overconcern with body shape and weight[a, d]	Overconcern with body shape and weight[a]
	Menstrual irregularities

Adapted from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Washington. APA.
[a]Required for the diagnosis according to DSM-5.
[b]A minority of BN are above normal and some are below normal weight range.
[c]In DSM-5, AN is subtyped into binge-eating/purging and restricting subtypes.
[d]In DSM-5, denial of the seriousness of the low weight may substitute for this criterion.

avoidance response to the sexual and social demands of puberty. Bruch (3) described early false learning experiences as causing disturbance in body image, disturbance in perception, and, in turn, lack of recognition of hunger, fatigue, and weakness.

12.1.1. Environmental Factors

Many of the same environmental factors that predispose to the development of AN are risk factors for BN. Socio-cultural theories have pointed to a shift in cultural standards for feminine beauty toward thinness (4). This cultural ideal may indirectly contribute to the development of AN and BN, particularly among vulnerable adolescents, who equate weight control and thinness with beauty and success. A recent study examined influences of socio-cultural effects by studying the incidence of AN in Curacao, a society undergoing a socioeconomic transition (5). The overall incidence of AN was much lower than in the United States or in the Netherlands, and the authors found that socio-cultural differences within the island were related to AN. The majority population on this island is black, and no cases of AN were found in this segment of the population, in which, interestingly, being overweight is socially more accepted than in the white and mixed population segment on this island. Many of the white or mixed cases who had AN had been more exposed to high income western cultures. The incidence of AN among the white and mixed-race Curacao population (9.1 per 100,000 person-years) was similar to the incidence in the United States and the Netherlands.

Other environmental factors have been identified as contributing to eating disorders, particularly BN. Although early reports suggested a specific association between bulimia and a history of sexual abuse, since it does occur with some frequency in BN patients, this apparent association is not specific to BN, but rather a nonspecific risk factor for psychiatric illness in later life (6). Some data does suggest that early sexual trauma may contribute to a worsened course and greater comorbidity in BN (7). Other data suggests some differences in early experiences occurring in AN and BN. For example, critical comments by family about eating, weight and shape have been found as more prevalent in BN compared to anorectics (8).

12.1.2. Biologic factors

Although psychosocial factors may be significant risk factors, arguments for a biological vulnerability include the fact that despite the emphasis on thinness in industrialized countries the world over, only a small percent of females develop eating disorders. Also, descriptions of AN go back to the 19th century, long before there was an emphasis on thinness.

12.1.2.1. Neuroendocrine Factors

Early neuroendocrine theories for AN were based on the observation that amenorrhea and disturbed hypothalamic thermoregulation are independent of emaciation in AN, and thus Russell (9) proposed that hypothalamic dysfunction contributes to the disorder. Neuroendocrine alterations in AN are common, and controversy on the pathogenesis of these changes continues (10–12). Many of these changes relate directly to weight loss. These include alterations in TSH response to TRH, in resting gonadotropin levels and luteinizing hormone (LH) responses to provocative stimuli. Other hypothalamic disturbances, such as plasma growth hormone, T_3 and reverse T_3 directly relate to caloric restriction, since they respond rapidly to food (carbohydrate) intake before significant weight changes can occur. Some changes, including increased cortisol production and an immature pattern of LH, are probably mostly related to weight loss. Thus, although the possibility of an underlying hypothalamic abnormality remains, it appears likely that activation of the hypothalamic-pituitary-thyroid axis is precipitated by weight loss. Factors such as amount of exercise, relating to a high incidence of amenorrhea in runners and ballet dancers (13, 14), and emotional distress, perhaps relating to the elevated cortisol production rate, probably play a role.

Recent work has examined the impact of neuroendocrine factors on the expression of heritable risk for disordered eating. This line of work has shown that pubertal stress (likely reflecting ovarian hormone state) critically impacts monozygotic twin concordance for disordered eating (15). In other twin analyses the degree of disordered eating among dizygotic twins is related to both the subject's and co-twin's gender. These findings are hypothesized to relate to intrauterine testosterone exposure, with higher degrees of exposure thought to provide a protective effect (16).

12.1.2.2. Neuropeptide Factors

More recently, research has focused on the possible role of neuropeptide abnormalities resulting in disruption of normal feeding and altered appetitive drive as contributing to the etiology of eating disorders. Patients with AN and with BN do behave as if their satiety and control of eating mechanisms are deranged. Anorectic patients, compared with normal controls and those with BN endorse lower hunger ratings and higher fullness ratings in response to test meals (17). In contrast, BN patients eat significantly more food and rate their hunger afterwards as higher and their fullness as less than non-eating disordered controls when provided meals in laboratory settings (18). An extensive body of animal research has shown that satiety is determined by post-ingestive events in the upper gastrointestinal tract, and a number of abnormalities relative to satiety and post-ingestive events have been found in BN patients. Cholecystokinin, a peptide secreted by the gastrointestinal system in response to food intake, transmits satiety signals to the brain by way of vagal afferents. Post-prandial release of cholecytokinin was found to be abnormally low in BN patients (19), while in anorectics, some studies found elevations of basal levels of cholecytokinin (20). Other abnormalities relative to satiety in BN include enlarged gastric capacity (21), delayed gastric emptying (22), impaired gastric relaxation (23), and even abnormalities in functioning of the vagus nerve (24). Other neuropeptides, including beta-endorphin, neuropeptide Y, peptide YY, vasopressin, ghrelin, insulin, pancreatic polypeptide, gastric inhibitory peptide, glucagon-like peptide 1, glucagon, gastrin, orexin, and leptin have been investigated in AN and bulimia with variable results (11, 25, 26). Although these abnormalities in anorectics usually tend toward normality with weight recovery, there is evidence that leptin levels (which are normally positively correlated with body fat mass in individuals across a broad range of weight), may be higher than expected in anorectics based on the extent of weight loss, and that with weight recovery, leptin levels may prematurely normalize, leading to difficulties in achieving and sustaining a normal weight (27, 28).

12.1.2.3. Neurotransmitter Changes

Extensive work has examined the possible role of neurotransmitters in eating disorders (29, 30). A central challenge in such work is disentangling the effects of starvation from primary illness mechanisms. Barry and Klawans (31) proposed that increased dopaminergic activity may account for major signs and symptoms of AN, specifically, anorexia, hyperactivity, decreased libido, and a morbid fear of becoming fat. Altered dopamine activity has been found in both low weight and weight recovered anorectics (32, 33). Using Positron Emission Tomography (PET) to assess dopamine D2/D3 receptor binding, a recent small controlled study of weight-recovered anorectics found increased receptor binding in the antero-ventral striatum in the anorectics, and receptor binding in the dorsal caudate and dorsal putamen was positively correlated with harm avoidance (32). Although the data lends support to the possibility that dopamine changes could contribute to the characteristic harm avoidance or increased physical activity found in anorectics, much work still needs to be done to assess the role of dopamine in eating disorders. One potential approach is the use of animal models of disordered eating (34–36). For example, a model for AN has been employed that involves obsessive wheel-running in calorie-restricted mice (the activity-based anorexia model). This model is now being used to study potential medication interventions (37).

Much attention has recently been given to the role of serotonin in the eating disorders, both in human and animal studies (34). Those with AN and BN have been found to have alterations in 5-HT metabolism. Reduced basal levels of CSF 5-HIAA have been found during the acute low weight phase of the illness in anorectics compared to controls, and since the levels have been found to normalize with weight gain, it is thought that the low levels during the acute illness is a consequence of starvation (32, 38). However, levels of CSF 5-HIAA have been found to be elevated in long-term recovered anorectics (38), leading to the possibility that there may be a trait serotonin abnormality which predisposes one to the possibility of AN. Since increased serotonin activity has been implicated in obsessive and anxious individuals, it is also possible that this altered serotonin activity in weight recovered anorectics may contribute to their persistent symptoms of perfectionism, obsessiveness, and anxiety. It could be that in anorectics, dieting reduces the serotonin levels and hence protects them from the anxiety they experience with weight gain. Evidence of serotonin dysfunction (CSF 5-HIAA and indirect probes for serotonin) also occurs in BN, both during the acute symptomatic phase (39) and after symptom recovery (40), but since dieting itself can affect serotonin (41), we cannot conclude that serotonin abnormalities predate the illness. It could be that dieting provides a potential mechanism by which women, who are vulnerable for other reasons, develop eating disorders. Further evidence of a serotonergic component to BN comes from the fact that in multiple placebo-controlled double-blind studies using serotonergic antidepressants to treat those with BN, there is a significant reduction in binge-eating and purging behavior, even in BN subjects who are not depressed (42).

Using selective neurotransmitter radioligands with PET, studies confirm altered 5-HT neuronal pathway activity in AN subjects. Compared to controls, recovered restricting AN subjects have been found to have reduced 5HT2A activity in the amygdala and hippocampus, as well as in cingulate, sensorimotor, and occipital/parietal cortical regions (43). Additionally, recovered AN subjects have increased 5HT1A receptor activity in the pre-synaptic raphe nucleus and cortical-limbic-striatal post-synaptic receptors (43). Since 5HT1A post-receptor binding in many cortical areas was positively correlated with trait anxiety and harm avoidance in AN, these findings support the possibility that these alterations might contribute to increased anxiety, a common premorbid trait in AN, and hence also to vulnerability for the development of eating disorders.

12.1.2.4. Structural/Functional Brain Changes/Imaging Studies

Neuroimaging work in the field of eating disorders focused first on looking for gross structural/alterations in brain morphology, especially in the setting of starvation. Over time, this work has evolved toward functional imaging studies, initially examining activation in select regions, but increasingly now examining neural circuit function. Structural brain imaging studies have confirmed that low-weight AN is associated with enlarged ventricles and widened sulci (44) (see Fig. 12.1). Although these alterations appear to be at least partly reversible with weight restoration, some data suggests that changes may persist after recovery (45). MRI technology has used methods to determine volumetric gray and white matter alterations in AN and BN. A recent meta-analysis of such studies found that individuals with AN may have decreased gray matter volume, while those with BN may have increased gray matter (46). Such differences may normalize with clinical recovery.

Initial work examined perfusion in individuals with low-weight AN and found hypoperfusion, which appeared not always to normalize with recovery (47–50).

Stimulus processing in AN has recently been studied using fMRI. For example, people with AN, compared with healthy controls, showed a significantly greater signal response in the emotion-processing regions after viewing images of food (51). Extensive

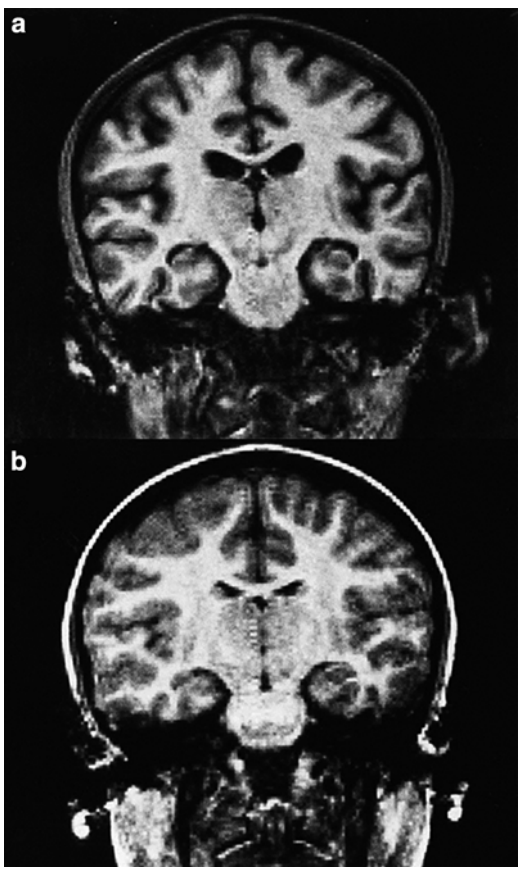

FIGURE 12.1. Coronal MRI image of an 11-year-old patient with anorexia nervosa (**a**) compared with that of an 11-year-old healthy control subject (**b**). (**a**) Sulcal enlargement and marked dilation of the third and lateral ventricles. (**b**) Normal anatomy at the same level. Reprinted from Golden NH, Ashtari M, Kohn MR, Patel M, Jacobson MS, Fletcher A, Shenker IR. Reversibility of cerebral ventricular enlargement in anorexia nervosa, demonstrated by quantitative magnetic resonance imaging. J Pediatrics 128(2), 296–301, Copyright (1996), with permission from Elsevier.

work has now examined the neural correlates of distorted body image (52). This work has generally used visual images of own or others' body images: in some studies, the images are presented unaltered, while in others they are altered to appear longer or smaller. Altered activation of numerous brain structures has been reported, again focusing on emotion-processing regions. As research in this area progresses, this work has been transitioning from examining a single region of interest toward an approach that conceives of functioning neurocircuitries in the brain as the appropriate level of analysis (53).

12.1.2.5. Genetics

Family, twin, and molecular genetic studies are demonstrating a substantial role for genetic factors in the development of the eating disorders. There is uncertainty about the size of the genetic versus environmental contributions, both for AN and BN, although such studies commonly find genetic factors account for 40–60% of susceptibility to the illness (54). Increasingly, risk for ED is conceived of as reflecting a gene–environment interaction (55).

Increased rates of eating disorders among female family members of anorectic patients have been reported in several large series (56–58). For example, Theander (58) found a morbidity risk of AN among sisters of AN probands to be 6.6%. There is evidence of cross-transmission between the eating disorders, suggesting a shared familial liability (59). Klump et al. (60) found the lifetime risk of AN or BN among female relatives of an individual with an eating disorder to be 7–20 times that of the general population. Families with eating disorders also have increased rates of other psychiatric disorders including depression, anxiety, and obsessive-compulsive disorder. However, the vulnerabilities for depression and anxiety appear to be transmitted independently of the vulnerability for eating disorders, while obsessive-compulsive personality traits, like the vulnerability for eating disorders, appear to be a shared familial vulnerability (57).

Twin studies help to clarify the contribution of genetics to the familiality of eating disorder. Clinic-based samples indicate the concordance rate for AN is about 55% in MZ twins and 5% in DZ twins, whereas for BN it is 35% in MZ twins and 30% in DZ twins (59). While this suggests a significant heritability for AN but not for BN, population-based studies have also shown a significant heritability for BN as well (61, 62). Although it is estimated that greater than 50% of the variance in the occurrence of AN can be accounted for by genetic factors, twin studies suggest that 17–46% of the variance in both AN and BN is accounted for by non-shared environmental factors (63). Initial data indicate that differential paternal relationships, body weight teasing, peer group experiences, and life events may account for the development of eating pathology in one sibling versus another (63). More data are available for bulimia than for AN.

A wide variety of molecular genetic studies have been completed or are underway to identify underlying genes and loci. This work has focused in part on genes in neurotransmitter systems implicated in eating disorders (for example, serotonin or dopamine systems) (64). Symptoms thought to influence food intake have also been examined. This work has now migrated in the direction of genome-wide association studies, which may lead to the identification of a wider variety of genes (65). Such studies are challenging to conduct due to large sample size requirements but may be quite useful for identifying targets for future research.

12.2. Comorbidity

It has been hypothesized that eating disorders represent atypical affective disorders occurring in adolescent females at a time in their lives when body image issues are important. There are some findings supporting this view. Major depression, with about 45–68% meeting diagnostic criteria, is the most common comorbid disorder in both AN and BN (66–69). There is some evidence that women with the BN subtype of AN have more affective disorders than those with the restrictor subtype of anorexia (70). Symptoms of depression often predate the onset of the eating disorder, and follow-up of anorectics suggests an increased risk for affective disorder (69, 71). Controlled family studies have shown an increased incidence of primary affective disorder in the families of anorectics compared with families of controls (56, 69, 72). Biologic markers associated with primary affective disorders, such as elevated plasma cortisol levels, dexamethasone nonsuppression, low urine 3-methoxy-4-hydroxyphenylglycol levels, impaired growth hormone response to provocative stimuli, and an abnormal thyroid-stimulating hormone (TSH) response to thyrotropin-releasing hormone (TRH), also are found in anorectics, although the abnormalities appear reversible with weight gain. Semi-starvation can certainly contribute to depression (73), and there is evidence that starvation can lead to elevations in corticotropin-releasing hormone (CHF), which can contribute to depression (74).

A relationship between bipolar disorder and eating disorders has been suggested. Studies evaluated bipolar disorder in the relatives of eating disorder probands. Two studies found significantly higher rates of bipolar disorder in the relatives of anorectics than controls, and one study found higher rates of bipolar in relatives of BN than controls. Three controlled family interview studies have found depressive disorders, but not bipolar disorders, in the relatives of eating disorder probands. Numerous studies have now examined eating disorders among individuals with bipolar disorder and these studies have found elevated rates of ED, with binge eating disorders (BED) being most prominent in a number of these samples. This issue deserves further

attention, since phenomenologically, eating dysregulation, mood dysregulation, impulsivity and compulsivity, and exercise and activity, show some commonality between bipolar and eating disorders (75).

Newer evidence suggests that both AN and BN are related to anxiety disorders, including obsessive-compulsive disorders, and that anxiety is central in both the etiology and maintenance of eating disorders. During the acute illness, anorectics suffer from obsessions about food, weight, and body image, and they often have compulsions concerning dieting, exercising, food preparation, and weighing. There is evidence that caloric deprivation has a role in causing obsessional symptoms (73), and caloric deprivation may create an environment which allows the exacerbation of obsessional tendencies. A 10-year follow-up study indicated that 65% of anorectics had lifetime diagnosis of an anxiety disorder, with 34% having social phobia, 15% with agoraphobia, and 26% with obsessive-compulsive disorder (OCD) even excluding obsessions and compulsions concerning the eating disorder symptoms (69). In BN patients, although one study resulted in a lifetime diagnosis of OCD in 32% (76), other studies find a lower rate of OCD in BN patients compared to anorectics (77). In one recent study, 2/3 of both types of eating disorders had one or more lifetime anxiety disorder diagnosis, with OCD occurring in 41% and social phobia in 20%. The majority reported the onset of the anxiety disorders in childhood, before the onset of the eating disorder, thus pointing to a vulnerability factor for the development of the eating disorder. Also, subjects who had a history of eating disorder but were not currently ill with it still showed evidence for high anxiety (78). Recent imaging studies indicate that in anorectics compared to controls, there is evidence of greater activation of the limbic and paralimbic fear network when confronted with food and body image stimuli (79, 80).

The relationship between eating disorders and substance abuse has received considerable attention. The available data supports a relationship between the BN behaviors of binge-eating and purging and substance abuse, whether this is in an individual with BN or in the binge/purge subtype of AN (81). Substance abuse is not common in the restricter subtype of AN. Roughly 22% of BN patients report high alcohol intake, and 28% report a history of other drug abuse (82). There is also a high frequency of eating disorders in women who present for treatment of substance abuse. In a study of 61 adolescent females with a substance abuse problem, 28% had a diagnosable eating disorder (83). One possible reason for the association of eating disorders and substance abuse is that food deprivation increases the likelihood of substance abuse (84). However, this does not explain why there is so little substance abuse in restricter AN, who show even more food deprivation than the BN patients, and why there is more substance abuse in the binge/purge anorectic subtype than the restricter AN subtype. Another possible explanation for the relationship between eating disorders and substance abuse is through mediating factors, including personality factors, in eating disorders. There is evidence that women who have eating disorders but no substance abuse have fewer Cluster B personality disorders than women with substance abuse (85).

A "multi-impulsive" syndrome has been described in some patients with BN (82), which is characterized by heavy drinking and other drug abuse, stealing, suicide attempts, and self-injurious behavior (cutting). It may be that this form is a variant of borderline personality disorders (BPD). Several studies have found a strong relationship between BN and axis II disorders, particularly Cluster B or BPD (86, 87). In the study by Herzog et al., 27% of an outpatient sample of 210 females with eating disorders were diagnosed with personality disorders and the most common personality disorder was BPD (9%); none of the restricting AN patients had this diagnosis, but 8% of the BN patients and 12% of the binge/purge subtype of AN had this diagnosis.

In contrast to the high prevalence of Cluster B personality disorders in those eating disorders with binge/purge behavior, Cluster C personality disorders are most frequently observed in those with restricting AN. In one study of eating disorder patients, 35% of those with restricting AN met criteria for obsessive-compulsive personality disorder (OCPD), compared to 5% of those with BN (77), and in another study of adolescent females, those with AN had higher rates of OCPD compared to the normal controls (88). Cluster C changes may in part be related to starvation. Changes consistent with OCPD have been described in men undergoing semi-starvation, without these characteristics being present before the semi-starvation period (73). However, in a 6-year follow-up study of patients with a history of AN who no longer met diagnostic criteria for AN and who no longer were malnourished, Cluster C personality traits were still present, compared to a control group (88).

12.3. Epidemiology

AN historically has seemed an uncommon illness. In 1973, three separate psychiatric case registers in Scotland, England, and northeastern United States supported a low annual incidence of about 1 case per 100,000 population (89). Evidence suggests that the incidence of AN has increased. One study indicates that the incidence nearly doubled from 1960 to 1976 (90). Another study, which identified all anorectics in one Midwestern community between 1935 and 1984, indicated that the incidence has increased among females 15–24 years of age but not among older women or among males. The overall age-adjusted incidence rate per 100,000 person-years was 14.6 for females (91).

Prevalence studies indicate AN to be a common disorder in the age group at risk: 12–30 years of age. In 1976, Crisp et al. surveyed nine populations of high school girls in England. The prevalence was one severe case in 200 girls, and in those age 16 or older, the prevalence was even higher—one severe case in every 100 girls. In the Midwestern community study described above, the prevalence also was 1 case per 200 girls 15–19 years of age. Crisp et al. (92) and other authors have reported AN to be more prevalent in the higher socioeconomic classes, but no controlled studies support this hypothesis.

AN occurs predominantly in females, though the gender imbalance in AN may be less prominent than once thought. Historically, it was thought that only 4–10% of cases are males (91, 93), but recent evidence from the National Comorbidity Survey (94) finds a female to male ratio of 3:1, not 10:1. Clinically, except for amenorrhea, male anorectics are remarkably similar to the females. AN appears to be uncommon in poorly developed countries, and it is infrequent among blacks in the United States. It is overrepresented in females in certain occupations, such as models and ballerinas, who must rigorously control their body shape (4, 13).

BN is more common than AN with the lifetime prevalence estimated to be 1–3% of females in the United States. Most research studies of prevalence have been done in college and high school females, but it is unclear what the prevalence rate is in the general population. As with AN, BN has been thought to occur predominantly in females, with only about 10% of cases being males, but NCS-R data suggest that, in community samples, about 25% of those with BN are male. BN typically develops a bit later than AN, in later adolescence or early adulthood. Like AN, BN is more common in western cultures where food is abundant and slimness is highly valued. There is evidence that BN increased and is more prevalent in those who were born after 1960 (95). Dieting typically precedes the onset of BN symptoms, although there are cases where binge-eating precedes dieting (96).

12.4. Clinical Picture

12.4.1. AN

The essential clinical features of AN and a comparison with the features of BN are listed in Table 12.1. AN typically begins with a simple diet adopted in response to concern about real or imagined overweight. At first, high-calorie foods are eliminated. Then other foods are systematically curtailed as negative attitude toward food develops. As weight loss progresses, disgust about eating and intense fear about being obese begin to outweigh hunger. The term “anorexia” is a misnomer because true loss of appetite is uncommon until late in the illness. Weight loss progresses until the patient becomes emaciated. The anorectic is typically unaware of her extreme thinness; instead, she continues to feel fat and loses more weight.

Attempts to assess body image disturbance, or the anorectic’s failure to recognize her starved body as being too thin or to regard herself as normal, or even overweight, in the face of increasing cachexia, have relied on visual size estimation devices. Using these devices, various investigators have confirmed that anorectics overestimate the width of body parts, but there are wide individual variations among anorectics in their body size estimates (97, 98). Compared with anorectics who more accurately estimate the size of body parts, those who are relatively inaccurate have been found to be more likely to fail to acknowledge their illness, to vomit, to be more severely malnourished, to gain less weight during treatment, and to have failed to gain weight during previous hospitalizations (97, 99). Although body size overestimation is significant in a subgroup of AN, it cannot be considered unique to this population, since some studies have found no significant mean differences between anorectics and control groups (97, 99).

Anorectics exhibit odd behavior around food. They hide food all over the house. During mealtimes they deviously dispose of food. They cut food into tiny pieces or spend much time arranging food on their plates. Confrontation about these behaviors is often met with denial. Yet anorectics think constantly about food, often collect recipes, and engage in elaborate food preparation for others. Approximately 50% begin to gorge themselves with food (binge eat), up to 40% induce vomiting, and may begin using laxatives and diuretics in an attempt to reduce weight (100, 101). They also may become hyperactive and engage in strenuous ritualistic exercises to control weight.

Attempts to delineate subgroups have focused on clinical differences between anorectics who binge eat and those who do not. In two large surveys, BN anorectic patients were characterized by self-induced vomiting and by abuse of laxatives and diuretics (100, 101). They displayed impulsive behaviors, e.g., alcohol abuse, stealing, and suicide attempts. They were more extroverted but manifested greater anxiety, guilt, depression, and interpersonal sensitivity and had more somatic complaints than did anorectics who exclusively dieted to lose weight. In one study, a high frequency of obesity was found in mothers of the BN anorectics (101). The delineation of these subgroups extends to the families. The incidence of alcoholism and drug abuse disorders is higher in families of BN anorectics than in families of non-BN anorectics (102, 103). The BN subgroup of AN remarkably shares characteristics with BN. Possibly these two populations form a single group within the eating disorders. Anorexia Nervosa patients who purge but who do not objectively binge-eat also are encountered.

12.4.2. BN

The main feature that distinguishes BN from AN is that early attempts to restrict food intake leads to episodes of binge-eating, defined as rapid consumption of large amounts of food, usually while alone, with a sense of loss of control. Typically individuals with BN restrict their food early in the day. Binges are typically in the afternoon or evening, and although the amount eaten

in a binge varies, patients may eat 5,000 or more calories in a few hours (104). Subjects with BN can usually identify safe foods which do not result in a binge, and unsafe or "forbidden" foods which result in a binge (usually high-calorie carbohydrate or fat foods). This was demonstrated in a study which found that subjects with BN reported a greater urge to binge and higher levels of stress and physiological arousal when confronted with favorite binge foods compared with a control group (105). Binge-eating is usually followed by self-induced vomiting, although other purging compensatory mechanisms, including misuse of large amounts of laxatives or diuretics, follows. Although people with BN at first feel they can control their eating binges, over time there is an increase in binge frequency and duration. There is a small subgroup who do not purge. Body weight in BN is typically in the normal weight range.

As in AN, a subgroup of bulimia has been identified with diffuse difficulties in controlling impulses; this "multi-impulsive" group may abuse alcohol or drugs, may steal compulsively, and may engage in frequent self-injurious behavior such as cutting (82).

12.5. Clinical Course

12.5.1. AN

Onset of AN occurs from prepuberty to young adulthood, generally between the ages 10 and 30. Most commonly, the disorder begins between the ages of 13 and 20, and the mean age of onset is 16 (58, 106). Although rare cases outside this range are described, they must be scrutinized to rule out other psychiatric or organic disorders simulating AN. Some investigators find no distinct premorbid personality, whereas others describe a typical case as well behaved, perfectionistic, obsessional, introverted, and shy. Onset of dieting has been associated with precipitating events, such as moving to a new school, or a traumatic event involving dating or peer relations, but often, no specific reason is apparent.

AN has a variable course and outcome. The course varies from spontaneous recovery without treatment to gradual or rapid deterioration, resulting in death. There may be lasting recovery after an episode of weight loss or a fluctuating pattern of illness marked by remission and exacerbations over many years. Although the short-term response of anorectics to well-organized hospital treatment programs is good, there are no consistent data concerning the effect of treatment on long-term outcome.

No follow-up study done has been free of methodological problems involving, primarily, sampling biases, inconsistent follow-up intervals, and different outcome measurement (58, 71, 107–110). Reviews of studies with similar longer term follow-up periods indicate the following (111, 112). Overall, about 50% fully recover over time, about 30% do fairly well but continue to have significant eating disorder symptoms as well as problems with social, sexual, and psychological adjustment, and about 20% do poorly. A significant number remain amenorrheic despite a return to normal weight. Body weight remains persistently below 75% of normal in up to 25%. Obesity develops in less than 8%. Although weight may be normal at follow-up, abnormal eating behavior may persist; one-half still practice dietary restriction and avoid high-calorie foods, and binge-eating or compulsive overeating, vomiting, and laxative abuse are common, and many meet the criteria for BN at follow-up. Thus, there is a fair amount of crossover from AN to BN. Up to half the anorectics have unipolar affective disorder at follow-up (69, 71). Other common psychiatric problems at follow-up are obsessive-compulsive symptoms, social phobias, drug dependency, and stealing. Several studies indicate that psychiatric symptoms are more common and severe in anorectics who at follow-up have low weight and abnormal eating behavior or are preoccupied with food and weight (69).

The most consistent favorable prognostic feature is early age of onset, and the most consistent unfavorable ones are late age of onset and more previous hospitalizations (58, 113). Poorer outcome also has been associated with greater length of illness, the presence of bulimia, vomiting and laxative abuse, overestimation of body size, disturbed family relationships, more physical complaints, and symptoms of neuroticism, depression and obsessionality. Recently, lower weight at hospital discharge has been found to be a predicter of relapse (114).

Anorexia Nervosa carries a considerable mortality, with a standardized mortality ratio up to 12.82 (108). The usual causes of death are starvation and electrolyte disturbance, but suicide is also a significant contributor. Although most studies report a death rate of less than 8%, several report a rate greater than 15%. Longer term studies tend to show higher mortality rates (113, 115–117). The most notable of these, a Scandinavian study conducted over 22 years, found an 18% mortality (116). The suicide rate was 5%. Most studies report suicide rates of around 1%. A recent meta-analysis of 36 mortality studies finds a standardized mortality rate in AN of 5.86 (118) likely due to the establishment of specialized care units (119).

12.5.2. BN

The mean age of onset of BN is a bit later than AN, with mean age of onset of binge-eating of 18 years (120). The onset of vomiting is on average 1 year later. Premorbid characteristics are similar as for AN, except, unlike the restricter anorectics, in many there are generalized impulse-control problems. The typical individual with BN is symptomatic for 3–6 years before seeking treatment, and the frequency of the BN behaviors generally increases over time (120).

Less is known about the course of BN than about AN, but it is clear that BN has a relapsing course. Multiple treatment studies indicate significant improvement over the short term, but in the longer term relapses are frequent, both with treatment and in naturalistic studies (121). There is very little crossover to AN. A recent meta-analysis of mortality rates in BN found them to be modestly elevated [SMR = 1.93; (120)]. Most of the follow-up reports of treatment studies indicate that about 50% had recovered at a follow-up interval of 5 years or more, while 20% continue to meet full criteria for BN, and 30% had experienced relapse into BN symptoms. One recent review of the follow-up studies for bulimia (122) indicates that there is no stable recovery for the first 5–6 years after intake into a BN study, but there is a general tendency for increase of recovery with increasing length of follow-up, so that after about 10 years about 70% show at least partial recovery. However, as many as 25% may still have BN symptoms, indicating a high rate of chronicity.

Several prognostic indicators for BN have been identified (122). There is general agreement that a high degree of severity of BN symptoms, particularly vomiting, predicts a worse outcome, while a short duration of illness predicts a better outcome. Substance abuse seems to predict a worse outcome. Borderline personality disorder and Cluster B personality disorders predict a worse outcome, perhaps related to the issue of multi-impulsivity, which is present in many people with BN and which also predicts a worse outcome.

12.6. Medical Findings

Medical abnormalities and complications noted in AN and a comparison with those noted in BN are given in Table 12.2. Physical and medical abnormalities in AN are largely secondary to the compromised nutritional state and disturbed eating habits, and most of these resolve with restoration of sound eating behaviors, sound nutrition and return to normal weight, with the possible exception of reduced bone density, which does not recover (123). Prolonged amenorrhea with low weight is associated with potentially irreversible osteopenia and an increased rate of pathologic fractures (124). Prepubertal patients may experience growth arrest and may not grow to anticipated heights. Amenorrhea is invariably present and may begin before, concurrently with, or after the onset of dieting (125). Some patients do not regain their menses with weight gain, suggesting that other factors than body weight influence this process. One of these factors may be a finding in anorectics at low weight of an "immaturity" in the pattern of 1uteinizing hormone (LH) functioning, resembling that of prepubertal girls. After weight gain, the LH pattern usually returns to normal, but some anorectics continue to have an immature pattern. In one study those patients who continued to have abnormal eating patterns also continued to have an immature LH secretory pattern (126). There are some other abnormalities which are not clearly resolved with weight gain. For example, abnormal CT scans of the brain may be found in more than half of anorectic patients (127) and there is evidence lacking that this always resolves with weight gain. Common physical findings in AN are hypotension, hypothermia, bradycardia, dry skin, and lanugo. Less common features include hair loss, petechiae, peripheral edema, and carotenemic skin.

BN patients are less medically compromised (128, 129). Their most common problem is fluid and electrolyte abnormalities, which are found in about 50%, secondary to variable combinations of vomiting, laxative, and diuretic abuse. The most common picture is one of alkalosis manifested by elevated serum bicarbonate, sometimes accompanied by hypokalemia and hypochloremia. These fluid and electrolyte abnormalities are found in a more severe form in the BN subtype of AN. People with BN may be intermittently amenorrheic. Salivary gland swelling, typically of the parotid glands is common. The etiology of this is somewhat unclear, but likely related to vomiting, and mildly elevated salivary amylase changes are likely associated. BN patients often also have dentition problems, particularly erosion of the surface dental enamel on the back of the teeth where the highly acid contents project due to vomiting (130). Rare but dangerous complications include gastric rupture or esophageal tear.

12.7. Differential Diagnosis

The major confounding diagnosis is BN. The unclear boundaries between AN and BN are indicated by the fact that one frequently develops from the other and by the overlap in their essential features (see Table 12.1). Although binge-eating occurs in both BN and AN, BN patients generally maintain weight within a normal range and do not show extreme pursuit of thinness. Body image disturbance has not yet been systematically assessed in BN.

AN must be differentiated from peculiar eating behaviors and weight loss which can occur in several other disorders. In general, the differentiation can readily be made on the basis of positive criteria of AN, such as fear of becoming obese and pursuit of thinness, which are absent in the other disorders. For example, weight loss is common in depressive disorders but is generally more severe in AN. Whereas depressed patients are aware of a loss of appetite, anorectics generally have a normal appetite, which they may deny. Anorectics, in contrast to depressives, are preoccupied with food. Agitation can be seen in depressive disorders, but it differs from the ritualistic activity of an anorectic. Weight loss and peculiar eating behavior are also

TABLE 12.2. Major medical abnormalities of AN and BN.

	AN	BN
Hematologic	Leukopenia	
	Thrombocytopenia	
	Bone marrow hypocellularity	
	Low ESR	
Renal	Elevated BUN (dehydration)	Elevated BUN (dehydration)
	Decreased GFR	
	Partial diabetes insipidus	
Metabolism	Hypercholesterolemia	
	High carotene	
	Low plasma zinc	
Gastrointestinal	Delayed gastric emptying	Altered gastric emptying
	Low gastric secretion	Salivary gland swelling
	Abnormal liver function results	Elevated amylase
	Superior mesenteric artery syndrome	Pancreatitis
	Pancreatitis	
Cardiovascular	EKG abnormalities:	Cardiomyopathy in ipecac abusers
	Arrythmias, QT prolongation, bradycardia	Hypokalemic-related ST changes,
	Altered circulatory dynamics	QT prolongation in EKG
	Hypotension	
	Edema	
	Congestive heart failure with refeeding	
Dental	Dental caries	Dental caries
	Enamel erosion	Enamel erosion
Skeletal	Demineralization,	
	Stress fractures	
	Delayed bone age	
Fluid and Electrolyte	Dehydration	Dehydration
	Alkalosis	Alkalosis
	Hypochloremia	Hypochloremia
	Hypokalemia	Hypokalemia
C.N.S.	Nonspecific E.E.G. abnormalities	Nonspecific E.E.G abnormalities
	CT/MRI: enlarged ventricles,	CT/fMRI: decreased cerebral blood flow changes
	Decreased gray and white matter	
	Changes in blood flow	
Gonadal Steroids	Low LH, FSH	May be hypoestrogenemic
	Impaired response to LHRH	
	Immature LH pattern	
	Low urinary gonadotropins	
	Low urinary estrogens	
	Abnormal estrogen metabolism	
Thyroid	Low T3, high rT3	Impaired TRH responsiveness
	Impaired TRH responsiveness	
Growth Hormone	Elevated basal GH	Pathological responsiveness to provocative stimuli
	Pathological responsiveness to provocative stimuli	
Prolactin	Pathological responsiveness to provocative stimuli	Elevated basal prolactin
Glucose	Abnormal glucose tolerance test	
	Fasting hypoglycemia	
Adrenal	Elevated cortisol	Dexamethasone test positive
	Change in cortisol metabolism and secretion	
	Dexamethasone test positive	

sometimes seen in schizophrenics, usually on the basis of delusions. However, the delusions of schizophrenics differ in content and are not concerned with caloric content or fear of weight gain.

It is important to ascertain medical conditions that accompany or simulate AN. Lesions of the pituitary or the hypothalamus may be accompanied by appetite disturbance and weight loss. Starvation results in some of the symptoms found in AN and BN. One important study, the Minnesota Semi-starvation Experiment (73), demonstrated that like eating disorder patients, the healthy male conscientious objectors who were subjected to semi-starvation quickly developed an intense preoccupation with food and eating, mood changes, diminished social interest, and after several weeks even a tendency to binge-eating, However, in general, starvation, resulting from causes other than AN, is associated with inactivity and apathy and not with the intense fear

of weight gain, body image distortion, alertness, and hyperactivity seen in anorectics (131). In a recent follow-up study of 19 of the original 36 conscientious objectors who participated in the Minnesota Semi-starvation Experiment, subjects described tiredness and apathy, and none recalled feelings of alertness or hyperactivity during the semi-starvation (132).

The differential diagnosis of BN includes a variety of organic syndromes which result in hyperphagia (Prader–Willi, Klüver–Bucy, Kleine–Levine). However, these patients do not show the typical episodes of binge-eating. Rather, they display a near constant hyperphagia.

BN must be differentiated from binge-eating disorder. These patients have the episodic pattern of binge-eating like the BN, but they do not show the inappropriate compensatory behavior characteristic of BN (e.g., purging, fasting, excess exercise). Also, individuals with binge-eating disorder are almost all overweight, in contrast to BN, who are generally in the normal weight range.

12.8. Treatment

12.8.1. AN

AN remains a serious disorder remarkably resistant to a wide range of interventions. To date, no psychological or pharmacological intervention has been identified which dramatically and reliably alters the dysfunctional thinking and associated behaviors which accompany it in adults, although family-based therapy shows considerable promise in adolescents. Overall, few controlled treatment trials have examined the treatments for AN. Since there are multiple causative factors and multiple deficiencies in psychological, social, behavioral, and physical functioning, the treatment program must be multidimensional and flexible. There is no agreement about the best treatment for adults. Treatment currently involves a combination of medical management, nutritional education and rehabilitation often using behavioral techniques, re-educative personal therapy to change core dysfunctional cognitions and attitudes, family therapy, and, sometimes, pharmacotherapy.

The immediate aim of treatment during the acute anorectic phase is to correct dehydration and electrolyte imbalance and restore the nutritional state to normal. Starvation itself can lead to many problems, including depression, sleep disturbance, preoccupation with food, and irritability, and improvement in the patient's psychological state will occur with nutritional rehabilitation (133, 134). Treatment during the acute state is done most efficiently in a structured hospital treatment program, and also in specialized partial hospital programs. It is advisable to prescribe a structured diet gradually increasing calories to avoid stomach dilatation and circulation overload. Close observation during and after meals will minimize surreptitious mealtime behavior, such as hiding food and vomiting. Behavioral contingencies after an operant conditioning paradigm probably increase the rate of weight gain (135). However, a randomized controlled treatment study did not demonstrate a clear advantage, expressed as weight gain, for behavior therapy (136). Because many anorectic patients do not acknowledge that a problem exists, it is essential to obtain the family's support so that firm treatments can be effected.

Those patients who are less severely ill, are not vomiting or using laxatives, are motivated to adhere to treatment, and have family that will cooperate with prescribed treatment may respond to outpatient treatment, but they should be carefully monitored and referred to more intensive settings such as inpatient or partial hospital care if no progress or deterioration occurs over several weeks.

Counseling of family members is a necessary component of an effective treatment program. This involves educating the family about the disorder, assessing the family's impact on maintaining the order, and assisting in methods to promote normal functioning of the patient.

Evidence suggests that a specific type of structured family therapy, typically referred to as family-based therapy (FBT), which first addresses the specific eating issues followed by psychological issues is helpful for adolescents with AN who still reside at home (137–140).

Psychotherapy is typically a regular part of treatment. Individual psychotherapy should aim at correcting cognitive errors of thinking, promoting independence, accepting responsibilities, improving psychosocial skill deficits, and promoting a positive self-concept.

However, the few studies that have been done do not clearly demonstrate superiority of any specific therapy. The specific therapies that have been studied include cognitive behavior therapy, cognitive psychoanalytic and educational behavioral therapy, dietary counseling, individual supportive therapy and family therapy (141–146). Although cognitive behavior therapy has shown to have some effectiveness (144), interpersonal psychotherapy has also received attention (147). A recent controlled outpatient study comparing cognitive behavioral, interpersonal and a control treatment of nonspecific supportive clinical management (involving education, nutritional advice and supportive therapy), found the nonspecific supportive clinical management to be superior to the two specialized therapies, while the cognitive behavioral and interpersonal therapies did not differ significantly from each other (148).

Recent reports have described a revised form of Cognitive Behavior Therapy (CBT-E) for adults and adolescents with AN (149, 150). There is as yet no proven pharmacological treatment for AN. A major problem may be due to the neurochemical effect of starvation. Although a variety of medications including antidepressants, classical antipsychotics, atypical antipsychotics, lithium, and antihistamines have been studied in the treatment of low weight anorectics, primarily focusing on their ability to promote weight gain and improve symptoms, no drug has proven to be of clinical value (151–158). Another approach is to utilize medications after weight recovery and evaluate their effectiveness on weight maintenance and improvements in comorbid psychopathology. One placebo-controlled study indicated that fluoxetine benefited non-BN weight recovered anorectics in prevention of relapse after 1 year (159). However, a recent well designed, randomized, double-blind placebo-controlled study of fluoxetine in weight recovered anorectics treated for 1 year failed to demonstrate a benefit from fluoxetine in the prevention of relapse (160). All patients in this study received cognitive behavior therapy. There was no difference in results in the restricter versus BN subgroups.

Recent work has examined atypical antipsychotics for AN. Results have been mixed, with some studies suggesting benefits (155, 156) as it appears that patient concern about weight gain with these agents is prominent (161). Despite the generally negative results in controlled studies, many clinicians utilize a variety of medications in an attempt to treat the associated comorbidities of depression, anxiety, and obsessive-compulsive problems, more often during the weight recovered phase than the acute low weight phase. The most frequently used medications are the SSRIs to treat depression and obsessive-compulsive symptoms, but low dose atypical antipsychotics are also utilized, as well as antianxiety agents. More studies of the antipsychotics, antidepressants, and newly developing agents are sorely needed. Such pilot studies should probably target potential symptom maintenance mechanisms, rather than global AN outcome (162).

12.8.2. BN

In contrast to anorectics, most patients with BN can be successfully treated with outpatient care and inpatient care is rarely indicated. More than 40 randomized controlled trials have been done to assess treatment efficacy of medications (primarily antidepressants), medication plus therapy, and therapies alone (163, 164). Many antidepressants have been demonstrated to be effective in significantly reducing the BN symptoms in the short term, and there is a definite anti-binge effect separate from the effect on mood (42, 158). Fluoxetine is the only medication that has been approved by the US Food and Drug Administration in the treatment of BN, and in the supporting controlled study, a higher dose of 60 mg was found to be the most effective, which is higher than the typical dose to treat depression (165). The difficulty is that the positive effect of the antidepressants is not sustained, and that relapses occur despite continued treatment with medications (158).

A novel pharmacological approach to the treatment of bulimia, targeting the peripheral nervous system, was reported by Faris et al (24). The group hypothesized that increase in vagal nerve activity resulted from repeated cycles of binge-purge episodes, which led to increased urges to maintain the binge-purge behavior. They chose ondansetron, an inhibitor of the $5HT_3$ receptors primarily in the vagal afferents, in an attempt to correct the vagal hyperactivity. In a randomized double-blind placebo-controlled 4-week treatment study of severe BN, there was a 50% decrease in binge-purge episodes, a 50% decrease in time spent in binge-purge activity and a 33% increase in the number of meals not followed by purging. This interesting hypothesis requires further study.

Cognitive behavior therapy (CBT), either in a group setting or individual format, which focuses on restructuring the maladaptive behaviors plus the associated thinking which supports and maintains the disorder, has been repeatedly shown to be the most effective treatment for bulimia, even when compared to antidepressants (166–168). Results indicate about one-half of patients recover during the usual 4–6 months of treatment. An enhanced version of CBT (CBT-E) has been developed and appears to be effective for bulimic symptoms (169). Of note, a recent trial compared CBT-E given for 20 sessions to 2 years of weekly psychoanalytic psychotherapy (170). Despite the large difference in trearment dose, CBT-E was more effective than psychoanalytic psychotherapy. Another short-term therapy, interpersonal psychotherapy, has been studied and found to be comparable in efficacy to CBT for bulimia, except that it appears to take longer to get similar results (171). For adolescents, there is evidence that Family-Based Therapy may be effective (172).

Studies have also been done investigating the combination of psychotherapy, usually CBT, and antidepressants (166–168, 173). In general, CBT is more effective than antidepressants, and the combination of antidepressants and CBT is more effective than antidepressants alone. Although BN symptoms do not appear to be improved with the combination of antidepressants and CBT over CBT alone, there is evidence that depression, anxiety, and possibly dietary restriction improve with the combination (168).

Although the treatment of choice for BN is psychotherapy, many clinicians begin with an SSRI like fluoxetine or sertraline because specialized therapies may not be available. This is initially helpful to many, particularly if there are substantial concurrent symptoms of depression, anxiety, or obsessions. Further, these medications are often helpful to those who have had a suboptimal response to psychotherapy. Some clinicians favor starting antidepressants along with CBT. It is important to remember that despite initial success with treatment, relapses later on are common.

Antisocial Personality Disorder

Karen J. Derefinko, Ph.D. and Thomas A. Widiger, Ph.D.

Abstract The present chapter discusses the medical understanding of antisocial personality disorder (APSD), including research concerning its etiology, prevalence, pathology, differential diagnosis, and treatment. ASPD, and the closely related diagnosis of psychopathy, appear to be products of a strong genetic disposition interacting with a variety of environmental contributions. Epidemiological studies indicate that ASPD and psychopathy are much more prevalent in men than in women, a finding that is supported by general personality research. Theories of pathology are numerous, but generally point to several distinct deficits; psychopathy has been associated empirically with abnormal affective processing, neuroanatomical abnormalities, psychophysiological arousal system impairments, deficits in cognitive functioning, and maladaptive personality constellations. While considered diagnostically reliable, ASPD and psychopathy are highly comorbid with substance dependence and narcissistic personality disorder due to similar criteria, making differential diagnosis difficult. Finally, treatment for psychopathy and ASPD remains a very controversial subject; while meta-analytic findings demonstrate positive results, considerable evidence also indicates that these disorders are resistant to typical interventions.

Keywords Antisocial • Psychopathy • Personality disorders • Pathology • Dimensional models

13.1. Definition

The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) (1) defined antisocial personality disorder (ASPD) as a pervasive pattern of disregard for and violation of the rights of others. DSM-IV has been supplanted by the fifth edition of this diagnostic manual [DSM-5; (2)]. However, no changes were made to the personality disorders section. Therefore, all references to DSM-IV apply as well to DSM-5. DSM-5 does include within Section 3, for emerging models and measures, a reference to a dimensional trait model conceptualization of the personality disorders. This conceptualization is also included herein.

The primary diagnostic criteria for ASPD include criminal activity, deceitfulness, impulsivity, aggression, recklessness, irresponsibility, and indifference to the mistreatment of others. The DSM-IV conceptualization of ASPD was based substantially on the features of psychopathy originally outlined by Cleckley (3, 4). In fact, the text of the DSM-IV indicated that psychopathy is another term for the disorder (1). However, some have argued that the constructs of ASPD and psychopathy are not interchangeable due to the failure of DSM ASPD to include the breadth of Cleckley's psychopathy traits (5, 6). In support, the most widely recognized psychopathy measure, the Psychopathy Checklist-Revised (PCL-R) (7, 8), includes a few traits not found in the DSM-IV definition of ASPD: Glib charm, lack of empathy, shallow affect, and arrogance. Additionally, Cleckley identified other psychopathy traits not present in either the DSM-IV or the PCL-R criterion sets, notably the "absence of 'nervousness'" (3) (p. 206), which some suggest is a fundamental trait of psychopathy (9).

TABLE 13.1 Domains and facets of the Five Factor Model (FFM).

Domains	Facets
Neuroticism (N)	N1: Anxiety
	N2: Angry hostility
	N3: Depression
	N4:Self-consciousness
	N5: Impulsiveness
	N6: Vulnerability
Extroversion (E)	E1: Warmth
	E2: Gregariousness
	E3: Assertiveness
	E4: Activity
	E5: Excitement seeking
	E6: Positive emotions
Openness to Experience (O)	O1: Fantasy
	O2: Aesthetics
	O3: Feelings
	O4: Actions
	O5: Ideas
	O6: Values
Agreeableness (A)	A1: Trust
	A2: Straightforwardness
	A3: Altruism
	A4: Compliance
	A5: Modesty
	A6: Tender-mindedness
Conscientiousness (C)	C1: Competence
	C2: Order
	C3: Dutifulness
	C4: Achievement striving
	C5: Self-discipline
	C6: Deliberation

It is also helpful to understand ASPD from the perspective of general personality structure; more specifically, as a maladaptive variant of personality traits evident within the general population. Our preference is to use the five factor model of personality (FFM), the predominant dimensional model of general personality (10–12). The FFM includes five broad domains, each with six specific facets. The domains include neuroticism (N: anxiousness, angry hostility, trait depression, self-consciousness, impulsiveness, vulnerability), extroversion (E; warmth, gregariousness, assertiveness, activity, excitement seeking, positive emotions), openness to experience (O; fantasy, aesthetics, feelings, actions, ideas, values), agreeableness (A; trust, straightforwardness, altruism, compliance, modesty, tender mindedness), and conscientiousness (C; competence, order, dutifulness, achievement striving, self-discipline, deliberation). A complete list of the domains and facets of the FFM can be found in Table 13.1. The five domains of the FFM align with the five domains of the DSM-5 dimensional trait model (DSM-5 negative affectivity aligns with FFM neuroticism, DSM-5 detachment with introversion, DSM-5 antagonism with low agreeableness, DSM-5 disinhibition with low conscientiousness, and DSM-5 psychoticism with openness) (13).

Considerable research has been conducted using the five-factor model to understand psychopathy (14–17) and ASPD (17–20). Importantly, the five-factor model conceptualization articulates the similarities and differences between the psychopathy and ASPD constructs within a common framework. For instance, while both ASPD and psychopathy are represented by the A facets of low straightforwardness (deception), low altruism (exploitation), and low compliance (antagonistic aggression), psychopathy also includes the other A facets of low modesty (arrogance), low tender-mindedness (callousness), and low trust (suspiciousness). ASPD and psychopathy share several facets of C, including low dutifulness (irresponsible), low self-discipline (negligent), and low deliberation (rash). With regard to N, both ASPD and psychopathy are represented by high angry hostility and high impulsiveness. However, psychopathy is also characterized by the N facets of low self-

consciousness (glib), low anxiety (absence of nervousness), low depressiveness (self-contentment) and low vulnerability (fearless). In terms of E, both psychopathy and ASPD are represented by high excitement seeking (foolhardy), and high assertiveness (dominant), but the psychopath is also low in warmth (cold and distant). An advantage of conceptualizing psychopathy from the perspective of the FFM is that it allows for a clear distinction between the successful psychopath (who manages to avoid exposure or arrest) and the unsuccessful psychopath (21). The successful psychopath is characterized by the traits of high conscientiousness (self-discipline, achievement-striving, and competence), whereas, conversely, the unsuccessful psychopath by low traits of conscientiousness [rash, irresponsible, and negligent; (22)]. There is also now a published measure to assess psychopathy from the perspective of the FFM (23), which aligns well with the DSM-5 traits for ASPD (24), albeit the latter does not include traits involving low neuroticism (i.e., glib charm and fearlessness) or extroversion (e.g., dominance).

Thus, while ASPD and psychopathy appear to have substantial overlap, the pronounced differences with regard to aspects of personality indicate potentially meaningful divergence. This divergence is reflected in epidemiological and pathological differences across the two alternative conceptualizations. For this reason, these diagnoses will be discussed separately in the relevant sections. In addition, among the two conceptualizations, considerably more research has been conducted for psychopathy, particularly within the pathology domain. Again, while we do not want to use the disorders interchangeably, the weight of the psychopathy literature deserves consideration.

13.2. Etiology

There is considerable evidence of the heritability of antisocial behavior. In animal studies of temperament, selection studies (where brother-sister matings are carried out over many generations) have been successful in breeding rats for specific traits, including aggression, indicating that part of what is genetically transmitted is temperament (25, 26). In research with humans, the results of twin and adoption studies indicate a strong genetic component for antisocial behavior. Generally speaking, genetic factors are believed to account for approximately 50% of variation in antisocial behavior, although this estimate may be influenced by the interaction among genes, or between genes and environment (27, 28). However, when additive (interactive) and nonadditive (singular) genetic contributions are assessed, the genetic contribution remains resilient. Waldman and Rhee (29) provided results of a meta-analysis of 51 twin and adoption studies of antisocial behavior that indicated a substantial contribution of both additive genetic factors (*effect size* = .32) and nonadditive genetic factors (*effect size* = .09). These results indicate that specific, heritable genes may be important contributors to generalized antisocial behavior. Of interest, twin studies that have explored the development of antisocial behavior in children suggest that there may be differences in heritability of antisocial behavior dependent on the presence of psychopathic features. Viding and colleagues (30) found that the additive genetic heritability of antisocial behavior without traits of psychopathy is similar to prior estimates (30%) and the expression more heavily influenced by shared environmental factors, whereas antisocial behavior with traits of psychopathy is considerably more genetically-based (81%), with little or no influence of shared environment [see (31) for a review]. Other research has indicated that the stability of psychopathic traits is also primarily genetically-based (32), suggesting a chronic and refractory course. This may suggest that assessing for psychopathic traits may be of value when exploring the development of antisocial behavior, and this resilience to environment may be a factor in treatment development efforts for psychopathy.

Although no genes have been clearly identified as etiological precursors to ASPD or psychopathy, several candidates remain a focus of this research, including those that are thought to underlie the related predisposing disorder of attention-deficit/hyperactivity (ADHD), and those that are related to neurotransmitter systems relevant to aggressive and criminal behavior, such as the dopaminergic and serotonergic systems (29, 33, 34). In a 2006 review of this area, Minzenberg and Siever provided several genetic polymorphisms that are the focus of recent research in antisocial and aggressive behavior (33). Within the serotonergic system, alleles that are involved in the synthesis (*U* and *LL*), transportation (*s*), reception (*5HTR1B, 5HTR1A*), and metabolism (*MAO-A*) of neuronal serotonin have all been associated with anger, aggressive behavior, impulsivity, and antisociality, as have several receptor polymorphisms (*DRD2, DRD3, DRD4*) and genes related to metabolism (DBH) of the dopaminergic system, and catechol-O-methyltransferase (*COMT*), a polymorphism associated with the breakdown of dopamine and norepinephrine [see (33, 35) for a review]. A 2012 review of genetic contributions specific to psychopathy has implicated the valine allele of the COMT gene, the low activity allele of the MAOA gene (MAOA-L), and the short allele of the serotonin transporter linked polymorphic region gene (5-HTTLPRs) (36). However, as others have noted, this area of research is still very new and almost no replication of these findings has been achieved, suggesting that these preliminary findings are not yet considered conclusive evidence of any specific genetic contribution (31).

Numerous environmental factors have also been implicated in the etiology of antisocial behavior. Shared, or common, environmental influences account for 15% to 20% of variation in criminality or delinquency (28, 37). This finding is remarkably robust even when compared to other psychiatric disorders with known environmental components such as affective and substance use disorders (38), and indicates something distinct about the shared environmental influence on antisocial behavior.

The modeling or learning of aggressive behaviors is more likely to occur in environments that have higher incidents of this type of behavior, or that condone antisociality and violence (39). Not surprisingly, shared environmental factors such as low family income, inner city residence, poor parental supervision, single-parent households, rearing by antisocial parents, delinquent siblings, parental conflict, harsh discipline, neglect, large family size, young mother, and depressed mother have all been implicated as risk factors for antisocial behavior (40). The effects of these factors are not limited to learning, however. For instance, neglect and physical abuse can generate several possible courses to antisocial and aggressive behavior, such as desensitization to pain, impulsive coping styles, changes in self-esteem, and early contact with the justice system (41). Nonshared environmental influences are also substantial contributors. Factors specific to the individual appear to account for fully 30% of antisocial behavior variance (27). In short, this is the remaining variance not accounted for by genetic (50%) or shared environmental (20%) influences. Nonshared environmental factors may include delinquent peers, individual social and academic experiences, sexual abuse, or sustaining an injury not shared by siblings, such as a head injury.

Unfortunately, the interactive effects of genetic and environmental influences are difficult to tease apart, and likely create confusion about what these estimates mean in terms of causation. For example, the individual who is genetically predisposed to antisocial behavior will subsequently elicit environmental factors associated with criminal outcomes, such as peer problems, academic difficulty, and harsh discipline from parents. In addition, antisocial individuals receive their genes from antisocial parents who also exhibit delinquent and irresponsible behavior, thus creating an immediate home environment that is likely to model instability and criminality. Concerns surrounding the interaction of environmental and genetic factors have led to research designs that have focused more directly at making these distinctions. Studies that explicitly address this issue have found that environmental factors continue to play a large part in etiology of antisocial behavior beyond genetic factors alone. For instance, after controlling for the genetic component of physical maltreatment, Jaffee, Caspi, Moffitt, and Taylor (42) found that the environmental etiological effect of physical maltreatment remained.

In addition to genetic and environmental influences, other work has focused on the relative contribution of the interaction of genes and environment to the development of antisocial behavior. For example, Caspi and colleagues (34) found that MAOA interacted with adverse environment to form a vulnerability to antisocial spectrum behaviors in children, suggesting that the phenotype of antisocial behavior is much more than a sum of the genetic and environmental parts. However, these findings are difficult to replicate (43, 44), indicating that considerably more work is needed in this area to understand the relative contributions of genes, environmental influences, and their interactions.

13.3. Epidemiology

The prevalence of ASPD in the general population indicates strong gender differences, with higher incidence in men than in women. Using the Diagnostic Interview Schedule (2), the Epidemiologic Catchment Area study estimated ASPD prevalence to be 4.5% in men and 0.8% in women (45). Similarly, the National Comorbidity Survey (NCS) indicated substantial gender differences, with 5.8% of men and only 1.2% of women meeting ASPD criteria (46). In addition, ASPD prevalence rates tend to be similar across all races. For example, ECA estimates demonstrated little difference between African American and Caucasian races (2.3% vs. 2.6%, respectively), suggesting that ASPD tends to present with equal incidence across race and ethnicity (45).

In contrast to the substantial epidemiological research conducted for ASPD, studies of the prevalence of psychopathy are lacking in number and scope. Importantly, psychopathy prevalence estimates have previously been based primarily on incarcerated samples, thereby making comparison with general population ASPD epidemiology difficult. Many individuals in corrections settings meet the criteria for ASPD, thus raising the prevalence rates to 50% to 60% for incarcerated offenders (5). Psychopathy prevalence rates in prisons tend to be significantly lower than those for ASPD [estimated from 15.0% to 7.7% for men and 7.0% to 1.9% in women in corrections settings (7, 47)], leading researchers to believe that psychopathy must be quite rare in the broader general population. Low prevalence rates appear to be supported in empirical findings; the few epidemiological studies using psychopathy-specific criteria have estimated prevalence rates between 0.6% (48) and 3.6% (49), although these two studies were based upon the same small sample using different cutoff criteria.

It should be noted that these prevalence differences between ASPD and psychopathy, and the relative "rarity" of psychopathy, may be indicative of a confound between the criteria and the correctional setting. It has been suggested that the heavy weighting of the DSM-IV (and DSM-5) ASPD criteria toward criminal and delinquent behavior inflates ASPD prevalence in prison settings due to the nature of a correctional population (50). In addition to the behavioral elements of ASPD, the diagnosis of psychopathy is contingent on the presence of several personality traits (e.g., glib charm, arrogance) that would not necessarily be intrinsic to correctional populations. Because of this asymmetric criterion overlap, it is little wonder that 90% of incarcerated offenders who meet the PCL-R criteria for psychopathy also meet the behavioral criteria for ASPD, but as few as 30% of those with ASPD also meet the trait criteria for psychopathy (51). It may be that the widely accepted incidence differences between ASPD and psychopathy would cease to exist (or even be reversed) in other populations where the psychopathy traits of manipulation and glib charm are emphasized, such as the professions of law or politics (50).

Very few studies have exclusively focused on racial or gender differences in psychopathy prevalence. At this point, there is little evidence that psychopathy exists differentially across race in terms of how the construct validity is preserved (52–54) although a handful of studies have reported a higher incidence in African Americans than Caucasians or European Americans (55, 56). Gender differences in psychopathy prevalence are generally consistent with the ASPD findings (57), indicating that women are less psychopathic than men overall (58). Known gender differences in the facets of the FFM (59) may explain why. For example, Costa et al. (59) report that women score much higher on all facets of agreeableness and neuroticism than men, as well as on the warmth and positive emotions facets of the extroversion domain, and the dutifulness facet of the conscientiousness domain. Additionally, women score lower than men on the excitement seeking and assertiveness facets of extroversion. In sum, the facets in which the psychopath is low (see Definition section) are precisely those facets in which men tend to score lower than women (e.g., all facets of agreeableness, the anxiety, depression, self-consciousness and vulnerability facets of neuroticism, the warmth facet of the extroversion domain, and the dutifulness facet of the conscientiousness domain). Likewise, the facets in which the psychopath is high are facets in which men score higher than women (e.g., the excitement seeking and assertiveness facets of extroversion). That is, the facets of general personality structures involved in psychopathy are ones that are more characteristic of men than women. Thus, from a personality standpoint large gender differences in psychopathy are to be expected. Despite gender differences, evidence to date suggests that when clinical levels of disorder are present, psychopathy and antisocial traits look remarkably similar in presentation, and lead to similar outcomes (60, 61).

13.4. Clinical Picture

According to the DSM-IV (and DSM-5), a diagnosis of ASPD is contingent upon the early manifestation of conduct problems with onset before age 15 years, thereby documenting a stable and pervasive pathology. In adulthood, the antisocial individual has little regard for societal norms, and is often engaged in unlawful behaviors such as gambling, stealing, drug use, and destruction of property. Irresponsibility, recklessness, and impulsivity are hallmark features of ASPD. The antisocial individual is often unable to plan ahead, and generally fails to consider the consequences of his hedonistic actions to himself or others. This failure to construct organized plans and deliberate about the consequences of behavior creates pervasive instability in many areas of the antisocial individual's life, both in personal and professional domains. The employment histories of those with ASPD are often marred by unexplained absences and early terminations from jobs, and personal relations tend to be short-lived, and filled with strife and conflict. Further, antisocial individuals are often irritable and aggressive, leading to numerous physical and verbal altercations with others. Contact with the legal system is not uncommon for those with ASPD. Interpersonally, ASPD individuals are known to be remorseless, exhibiting little or no consideration for those whom they harm with their delinquent acts. In addition, those with ASPD are notoriously deceitful and manipulative, and are known for their ability to lie, con, and cheat others without detection.

As stated previously, the psychopathy criteria of the PCL-R have considerable overlap with the DSM-IV (and DSM-5) ASPD criteria. Both conceptualizations call for early diagnosis of conduct problems (although childhood conduct disorder is not in fact required for the PCL-R), and indicate several similar traits and behaviors, such as failure to plan ahead, impulsivity, delinquent and criminal behaviors, irresponsibility, remorselessness, and deceitfulness. However, the psychopathy criteria of the PCL-R also include a few personality characteristics absent from the DSM-IV (and DSM-5) ASPD criterion set, specifically glibness, arrogant self-appraisal, lack of empathy, and shallow affect (62). These indicators might suggest that the psychopath is more charming, self-assured, and cold-hearted than his ASPD counterpart, thereby making the psychopath seem both capable of, and successful at completing the most heinous of crimes.

An additional psychopathy criterion that has remained absent from both the ASPD and PCL-R conceptualizations is the absence of anxiety. According to Cleckley, the psychopath "appears almost as incapable of anxiety as of profound remorse," (3) (p. 340) and demonstrates "a relative immunity from such anxiety or worry as might be judged normal or appropriate" (p. 206). Many experts in the psychopathy field continue to support Cleckley's assertion that the psychopath is low in anxiousness (14) although this criterion ultimately failed to appear in the PCL-R due to poor item-total correlations (63). In sharp contrast to psychopathy, ASPD is said to be associated with high levels of anxiety and other affective disorders (1). The DSM-IV stated that individuals with ASPD "may also experience dysphoria, including complaints of tension, inability to tolerate boredom, and depressed mood" (p. 702) and may be prone to both anxiety and depressive disorders (1). While the presence of anxiety disorders may be an artifact of the psychiatric samples traditionally used to study ASPD, epidemiological studies also support the diagnostic comorbidity of ASPD and anxiety in community samples, suggesting that the relation is resilient beyond the clinical domain (64, 65). Thus, in the anxiety domain, the clinical pictures of psychopathy and ASPD are strikingly different in how they present. Further research is needed to better understand why these conceptualizations diverge in their respective relations to anxiety and to provide insight into whether this divergence is clinically meaningful to outcomes.

The inclusion of additional personality criteria in the psychopathy conceptualization also indicates that psychopathy has a heavier weighting toward the interpersonal and affective traits associated with crime than ASPD. The strong behavioral

focus of the ASPD criteria has received extensive criticism, as it makes the assumption that criminal behavior, rather than personality features, is a primary symptom of the disorder (5, 52). Hare makes explicit use of both behavioral and personality characteristics in the PCL-R, and has designated these domains as separate but equal through a two-factor structure. Hare's original PCL-R two factor solution characterized Factor 1 as consisting of the affective and interpersonal set of items termed the "selfish, callous, remorseless use of others", and Factor 2 as the behavioral criteria which he termed the "chronically unstable, antisocial, and socially deviant lifestyle" (52) (p. 79). Many studies have indicated that the ASPD criterion set correlates more highly with Factor 2 than with Factor 1 [e.g., (8, 62, 66, 67)], thereby supporting the heavy concentration of behaviors and the relative lack of personality characteristics in ASPD. However, while smaller than the relations with Factor 2, correlations between PCL-R Factor 1 and ASPD are significant, and indicate that at least some personality features are represented in both conceptualizations. In addition, studies of the ASPD criterion set have also indicated a two-factor structure, with facets that distinguish between the callous exploitation of others and impulsive disinhibition (68, 69), indicating that interpersonal characteristics play at least some part in the diagnosis of ASPD, albeit a more minor role. It should also be acknowledged that despite a concerted effort by the authors of the PCL-R to include distinct interpersonal and affective characteristics, much of the assessment of the PCL-R personality traits relies heavily on the existence and consideration of criminal behaviors. Due to this saturation of antisocial behavior, the PCL-R has received criticism comparable to the ASPD criterion set (12). To date, it remains unclear whether the PCL-R can be effectively applied within non-criminal settings, as the reliable assessment of antisocial activity becomes much more difficult in such populations.

While criminal and irresponsible behaviors appear to be important to the construct of psychopathy, some maintain that antisocial behavior deserves no role in the diagnosis of psychopathy whatsoever due to its role as a consequence, rather than a symptom, of the disorder (70). These authors argue that while trait descriptions of psychopathy characterize an individual who is prone to delinquency and antisociality, criminal behavior itself may arise from many alternative sources, with psychopathic personality being only one potential cause (71). By designating behavioral criteria as primary, rather than secondary symptoms, a diagnosis of ASPD may be given regardless of the actual genesis of the antisocial acts. Research using Structural Equation Modeling (SEM) supports a secondary hierarchical position for behavioral symptoms in psychopathy (72). Model fit estimates indicated that the simultaneous inclusion of behavioral items from the PCL-R (e.g., criminal behavior, criminal versatility, promiscuous sexual behavior) with impulsive, interpersonal and affective PCL-R items resulted in worse fit estimates than using impulsive, interpersonal and affective PCL-R items alone (72), and "actually degraded the measurement of psychopathy" with their inclusion (70) (p. 98). SEM fit estimates improved dramatically when behavioral items were placed as products (consequences) of the impulsive, affective, and interpersonal factors, leading Cooke and colleagues to argue that "it may be time to 'reconstruct' psychopathy by reducing or eliminating reliance on criteria that are overly saturated with antisocial and deviant behavior, thus putting personality back at the heart of this personality disorder" (70) (p. 99).

Work has begun in placing psychopathy back into the realm of personality. Trait-based alternatives to PCL-R assessment are beginning to gain credence, and demonstrate adequate reliability and validity as indicators of psychopathy (73). Among these are the Psychopathic Personality Inventory (9) and the FFM conceptualization of psychopathy (14), both of which have demonstrated positive associations with criminal and delinquent behaviors (9, 14, 74), convergence with other psychopathy measures (75, 76), and predicted relations to other known correlates of psychopathy including performance on laboratory tasks of aggression and deliberation (15). Thus, the assessment of psychopathy does not appear to be reliant on antisocial behavior, and can be achieved through a personality-based measure.

13.5. Pathology

Considerable research effort has been focused on the pathology of antisocial behavior. Within this domain, various proximal pathways to ASPD have been advanced, including psychoanalytic defenses, neuroanatomical abnormalities, psychophysiological arousal system impairments, deficits in cognitive functioning, and personality factors. Interestingly, rather than supporting one causal factor, this extensive research base indicates that many deficits are involved in antisocial behavior, leading to a very complex picture of pathology.

13.5.1. Psychoanalytic Defenses

The historical conceptualization of antisocial pathology comes from psychoanalytic thought. The antisocial individual was believed to suffer from "superego lacunae" or holes in the conscience (77). This superego pathology is associated with an "incapacity to experience self-reflective sadness" that ultimately results in callous, tough-minded behavior (78). This classical picture of the psychopath was modified in later conceptualizations, and is reflected in Cleckley's and Hare's descriptions of "semantic

dementia," where abnormal affective processing is the prime feature of the psychopath's pathology (3–5). Hare has described the psychopath as being "without conscience," a deficit that ultimately results in ruthless, manipulative, cold-hearted, and violent behavior (79). This prevailing and longstanding conceptualization of psychopathic pathology has pervaded the research, and has recently been extended into laboratory task designs (80). Studies assessing the psychopath's autonomic reaction to emotional words and fearful images appear to be supportive of abnormally deficient affective processing, although the psychopath's cognitive reports of emotional responses have been found to be similar to those of nonpsychopaths (5, 80).

13.5.2. Neuroanatomical Abnormalities

Structural and functional brain impairments have also been advanced as possible underlying pathologies of antisocial behavior (81, 82). Reviews of brain imaging studies of antisocial populations implicate abnormal functioning in the temporal cortex (83, 84), amygdala and hippocampus (85, 86), angular gyrus (87), and prefrontal cortex (87–89). Research in the psychopathy domain suggests much more widespread structural and functional issues, ranging from reduced volumes of the amygdala to abnormal shape of the hippocampus, and aberrant activity in all four lobes of the cortex (frontal, temporal, parietal and occipital), as well as several subcortical structures [see (90) for a review].

The neural dysfunctions implicated appear to be generally consistent with the existing research on both antisocial behavior and psychopathy. However, emerging research in this area suggests that there may also be subtle functional differences between psychopathy and antisocial behavior; work with children suggests that conduct disorder is associated with *increased* amygdalar activity in affective scenarios, but psychopathy is associated with *decreased* amygdalar activity in these same scenarios (91). Further, it has been demonstrated that for typical children and children with ADHD, unexpected punishment results in a reduction in ventromedial prefrontal cortex activity, whereas there is no such reduction for children with psychopathic traits (92). It may be the case that broad abnormalities are similar across disorders, but distinct areas of dysfunction exist, particularly for brain activity surrounding emotion and reward pathways.

While functional and anatomical deficits appear to be fairly replicable, causal conclusions have yet to be determined. Environmental factors may also play a part in creating neural abnormalities in antisocial individuals. For example, closed head injuries, drug and alcohol abuse, and early health factors may serve to exacerbate a genetic propensity, rather than act independently.

13.5.3. Psychophysiological Arousal System Impairments

Another influential theory of ASPD pathology comes from Gray's three arousal model of the nervous system (93). Briefly, this model entails the interaction of three neurophysiological arousal systems that are hypothesized to control behavior. The behavioral inhibition system (BIS) is said to inhibit behavior in response to punishment, in opposition to a behavioral activation system (BAS) that activates behavior in response to reward. The overarching nonspecific arousal system (NAS) can be activated by either the BIS or BAS system. Activation of the NAS generally results in an increase in arousal, with the valence of this arousal (inhibit or interrupt vs. approach) directed by the BIS or BAS. Within this context, normal, adaptive functioning is reliant on the balance of activation between the arousal systems. The observed symptoms of ASPD could be evidence of a malfunctioning BIS acting in concert with a normal or strong BAS (94, 95). In this manner, normal sensitivity and anxiety in response to threatening and stressful situations may be reduced or altogether absent in the antisocial individual. Low arousal may also be a factor in the observed deficits in feelings of guilt or remorse and may serve to increase resistance to aversive conditioning.

In support of Gray's model as applied to ASPD, many psychophysiological deficits have been associated with psychopathy. Lykken's (96) classical conditioning paradigm demonstrated that psychopathic inmates had abnormally low physiological responses (reduced skin conductance) to a conditioned stimulus paired with electric shock, indicating that the psychopath does not develop the expected anticipatory arousal from threat of physical punishment. Additionally, this conditioning showed a more rapid extinction in the primary psychopathic group when compared to secondary or "neurotic" psychopaths. Although low skin conductance is widely discussed in the literature, Raine's (97) review of this research indicates that this finding has not been altogether consistent. In contrast to Lykken's findings, contemporary research does not support group differences in skin conductance levels for psychopathic versus nonpsychopathic offenders (97). Interestingly, while low skin conductance has been associated with crimes of evasion [e.g., white collar crimes and customs offenses; (98)], it has not been found to be associated with other criminal activity, such as violent offenses (98). Additionally, although low skin conductance is associated with later institutionalization in behaviorally disordered children, it does not appear to be predictive of arrest (99).

Other autonomic arousal assessments have also been used to investigate psychophysiological functioning in the psychopath, including heart rate and startle response (100, 101). Low resting heart rate levels have been associated consistently with antisocial behavior in noninstitutionalized individuals, providing support for Gray's theory (97). However, studies of incar-

cerated populations generally fail to find group differences between psychopaths and nonpsychopaths, indicating that this finding may be a predisposing factor to antisocial behavior in general rather than psychopathy (97).

Some have argued that it is not generalized arousal deficits, but arousal deficits associated with the experience of emotion that best characterizes the psychopathic dysfunction (102). Interestingly, Casey, Rogers, Burns, and Yiend (2013) found that individuals with higher psychopathy scores were more autonomically responsive (as assessed by cardiovascular activity) when processing negative information, possibly indicating that psychopaths find unpleasant material somewhat rewarding (103). Emotionally valenced startle response tasks have also demonstrated reliable psychopathic psychophysiological deficits. Patrick, Bradley, and Lang (101) found that psychopaths do not show normal startle potentiation when viewing negatively valenced photos, although normal attenuation of startle was documented with positively valenced photos. Startle response deficits have been replicated numerous times, and may be considered supportive of a generalized deficit in behavioral inhibition dysregulation (104–107).

13.5.4. Deficits in Cognitive Functioning

Cognitive functioning deficits have also been implicated in the pathology of antisocial behavior. Historically, psychopathy has not been associated with "classic" cognitive dysfunction (e.g., intelligence, memory, executive ability), as the psychopath typically appears to be intact in most of these areas (3, 108). In fact, recent evidence indicates that violence is positively correlated with intelligence scores in psychopathic adults (109), and psychopathy scores are positively related to verbal, analytic, creative, and practical abilities in children (110, 111). However, the psychopath's notorious disconnect between successful planning and understanding of contingencies and subsequent violent, impulsive behavior indicates that a psychopathic cognitive deficit may exist, albeit in a more subtle form (112, 113).

Existing literature on the cognitive attributes associated with psychopathy indicates that the psychopath experiences stable deficits in the cognitive domains of attention (113, 114) and response modulation (115, 116). Laboratory task paradigms designed to assess the allocation of attention indicate that despite intact perceptual and autonomic processes, the psychopath is unable to switch attention from an ongoing task to secondary (or peripheral) information when appropriate (114, 117–119). The deficits in attention associated with psychopathy have been incorporated into the limbic dysfunction literature, and contribute to what Newman has coined the "response modulation hypothesis" (116). Many researchers believe that this may underlie the behavior control problems that characterize psychopathy (116). According to Newman, psychopaths continue approach behaviors even while maladaptive, and are unlikely to consider contextual information that may be helpful in choosing alternate responses (115). Newman, Patterson and Kosson (116) explored the inability of the psychopath to inhibit a dominant response to a card playing task of worsening odds and found that psychopaths continued for more trials of unlikely success with a dominant response set in comparison to nonpsychopaths. This effect has been replicated several times over, with different forms of stimuli and in conjunction with event-related brain potentials, and continues to a productive area of research in the pathology of psychopathy (116, 119, 120).

13.5.5. Personality Factors

Finally, personality differences are also considered an important aspect of the pathology of ASPD and psychopathy. Antisocial behavior has been associated with various personality traits and trait-like behaviors which are believed to underlie the construct, such as aggressiveness, impulsivity, sensation-seeking, lack of empathy, and impairments in cognitive functioning (14, 121). Eysenck's theoretical framework placed personality between the physiological processes of arousal and antisocial behavior, implying that personality moderates the relation (122). In other words, physiological functioning deficits may or may not develop into antisocial behavior depending on the personality characteristics present in the individual.

Indeed, Cleckley's description of the psychopathic personality is a testament to the importance of this aspect to the construct of ASPD. Since Cleckley's time, many other researchers have proposed personality-based models to understand psychopathy. Lykken's fearlessness hypothesis (96) proposed that the absence of anxious behaviors typically demonstrated by psychopaths is due to the psychopath's deficient emotional response to punishment or danger. In a description of this deficit, Lykken states that for the psychopath, "the fear of punishment and the coercive voice of conscience both are, for some reason, weak or ineffectual" [(123); p. 134]. According to Lykken, this absence of fear allows the psychopath to remain collected in high-stress situations, and inoculates against anxiety disorders. Rather than considering fearlessness as a correlate of psychopathy, Lykken considered it a precursor to the disorder.

Other models of psychopathic trait pathology abound, and have gravitated toward integrating dimensional models of personality with the psychopathy literature. Rather than focusing on individual characteristics, dimensional models of personality disorders incorporate the broad spectrum of personality to improve predictive capacity (124). By viewing psychopathy as a constellation of personality traits, the model can be used to subsume existent literature on the notable deficits associated

with ASPD and psychopathic pathology (16). The multifaceted nature of psychopathy is reflected in the varied pathology; simply put, different investigators are exploring different aspects of the psychopathy profile. For instance, the disinhibition and poor deliberation associated with response modulation deficits are likely representative of low conscientiousness, whereas the lack of empathy and ruthlessness of semantic dementia appear to represent low agreeableness or antagonism. Likewise, Lykken's fearlessness hypothesis seems to relate to hasty decision-making and recklessness, traits also associated with low conscientiousness. While an elegant conceptualization, the dimensional modeling of psychopathy remains in its early stages, and proposed mappings of traits to deficits have yet to be tested empirically.

13.6. Clinical Course

Although ASPD and psychopathy are considered pervasive disorders, the specific antisocial behaviors associated with these diagnoses tend to remit with age (3, 4, 125). Robins' influential longitudinal study of delinquent children indicated that approximately 40% of antisocial youths show a reduction in antisocial activity in adulthood, and that the median age of clinical improvement was 35 years (4). Similar findings have been reported in the psychopathy research, albeit with slightly higher age estimates for remission of symptoms (125, 126). In addition, cross-sectional prevalence estimates in prisoners reflect this trend with a linear decline in PCL-R and ASPD scores beginning at age 20 (127). Simply put, there appears to be a higher prevalence of ASPD and psychopathy in prisoners between the ages of 20 to 40 than after age 40. However, the clinical improvement documented is relative to the group; before the drop in criminal behaviors, psychopathic individuals participate in more criminal activity, have higher conviction rates, and serve longer sentences than nonpsychopathic offenders, and after age 40, conviction rates drop but remain comparable for psychopathic and nonpsychopathic criminals (125, 127). Thus, while the reduction of criminal behaviors over time is significant for the psychopath, this "improvement" merely renders them comparable in criminality to their nonpsychopathic counterparts.

Interestingly, while the psychopath appears to "age out" of his criminal activity over time, there is evidence that the personality characteristics that accompany psychopathy remain remarkably stable. In their cross-sectional study, Harpur and Hare (127) demonstrated that the psychopathy factors were differentially related to age; while Factor 2, which assesses the "traits and behaviors associated with an unstable and antisocial lifestyle" (p. 605) was found to have the predicted negative relation with age, Factor 1, which describes the "affective and interpersonal traits central to the classical clinical descriptions of the psychopath [including] egocentricity, manipulativeness, callousness, and lack of empathy" (pp. 604–605) was unrelated to age. In fact, Factor 1 scores of the 15–20 year-old age group were strikingly similar to Factor 1 scores of the 46–70 year-old age group, indicating that the personality characteristics present in Factor 1 show no significant age reduction. Thus, although criminal behaviors become less prevalent over the life course, the traits associated with psychopathy appear to continue to cause problems for the psychopath long after his criminal career ends.

The personality literature also supports these findings. Longitudinal studies of the NEO PI-R indicate that the factors of agreeableness and conscientiousness tend to increase across age (128). Importantly, these domains are those believed to be most important to psychopathy, ASPD, and antisocial behavior in general (15, 16, 124). Thus, independently of the psychopathy and ASPD research, predictions about the course of these disorders are supported from the broad personality literature.

13.7. Differential Diagnosis

Differentiation between ASPD and psychopathy and other DSM-5 diagnoses can be problematic as many other disorders may present with overlapping symptoms. For instance, the ASPD criteria of irresponsibility, aggressiveness, and impulsivity may also be associated with DSM-5 diagnoses such as schizophrenia, bipolar disorder, or major depression. In fact, longitudinal studies of delinquent children indicate that early conduct problems can sometimes be predictive of adult manifestations of schizophrenia, rather than ASPD (4). Conversely, the substance abuse and psychiatric malingering associated with ASPD and psychopathy may initially present as schizophrenia, also leading to difficulties in diagnosis. However, the antagonistic personality criteria (e.g., deceitfulness and lack of remorse), lack of psychotic symptoms, and pervasiveness of ASPD and psychopathy typically allow for sufficient differentiation between these disorders and most other DSM-5 diagnoses. Despite this, two disorders continue to cause concerns in categorical diagnosis of ASPD. Substance use disorder and narcissistic personality disorder remain difficult to distinguish from ASPD, and in fact substance use and antisocial behaviors have been shown to form a coherent "externalizing factor" according to epidemiological studies (129), suggesting that some variety of true overlap in pathology exists. For the purposes of this chapter, substance use disorders and narcissistic personality disorder will be discussed to identify potential divergence in diagnostic features and to inform treatment efforts.

Despite the relative reliability of the diagnostic criteria for ASPD, controversy remains about the adequate differentiation between ASPD/psychopathy and substance use disorders. Comorbidity estimates indicate that ASPD is strongly associated

with substance use disorders (1), and in the ECA study, 84% of those diagnosed with ASPD also reported some form of substance use or abuse (64). Additionally, PCL-R scores are strongly associated with substance use, particularly with Factor 2 of the PCL-R (130). However, the comorbidity estimates reported may be indicative of overlapping criterion sets (131); the history of those involved with dyscontrolled drug use generally include some of the same traits and behaviors associated with ASPD and psychopathy, including theft, deception, poor work history, and irresponsibility. Thus, differentiation between the disorders remains difficult. While suggestions have been made to incorporate exclusion criteria for DSM-IV ASPD in lieu of substance use disorder presence (132), the early onset of behavioral problems specific to ASPD (versus the lack of early onset for substance use disorders) has been presumed to be an adequate differentiation criterion, ultimately preventing a substance use exclusion criterion from being included in revisions of the DSM (50). On the other hand, both disorders appear to share a common underlying pathology and course (133, 134), and each may contribute to the development of the other, making the use of the early onset criterion a troublesome differentiation factor.

The other psychiatric diagnosis that is often reported to be comorbid with psychopathy and ASPD is narcissistic personality disorder [NPD; (135, 136)]. In contrast to the criterion overlap with the irresponsibility and antisocial behaviors associated with substance use, NPD appears to share the manipulative, exploitative, and callous traits associated with ASPD and psychopathy. In support, PCL-R total scores and Factor 1 scores correlate significantly with NPD, but Factor 2 scores do not (66), a pattern of correlations that is the mirror image for ASPD. While the clinical and theoretical literatures of NPD and ASPD/psychopathy have grown independently, psychodynamic views generally incorporate narcissism into the psychopathy conceptualization (137, 138). In fact, many have explicitly suggested that NPD is a lower-order facet of the psychopathy construct, and have argued that NPD is a closer conceptualization of psychopathy than ASPD (139). However, due to concerns about diagnostic overlap and differentiation, authors of the DSM-IV ultimately decided to incorporate components of the PCL-R (i.e., lack of remorse) into the ASPD criterion set to increase the validity of the assessment of ASPD within prisons and other forensic settings (140).

From a personality standpoint, the diagnostic comorbidity and poor differentiation between personality disorders is understandable, and even predicted. Dimensional models of ASPD and psychopathy indicate that these disorders obtain diagnostic comorbidity with other DSM-IV (and DSM-5) personality disorders to the degree that they share overlapping constellations of personality traits (141). Lynam and Derefinko (142) conducted a comparison of predicted comorbidity (based on expert-generated personality prototypes) and empirical comorbidity between the psychopathy and the DSM personality disorders. Expert prototype predictions indicated that psychopathy would share the highest comorbidity with ASPD (with shared low agreeableness and low conscientiousness), followed by NPD (with shared low agreeableness). These predictions were supported by meta-analytic results of empirical findings (142).

13.8. Treatment

There is considerable debate surrounding the efficacy of treatment for ASPD and psychopathy (143). Although some treatment-outcome research has indicated positive results for therapeutic interventions (144–147), other empirical evidence appears to suggest that the antisocial behaviors associated with ASPD and psychopathy are resistant to intervention, particularly for the psychopath (148–150). Authors on both sides of the argument cite significant shortcomings in the existing treatment-outcome research, such as the lack of control groups, the use of clinically insignificant outcome measures, the use of inappropriate treatment strategies, high variability in results, and the clinical (vs. statistical) meaningfulness of effect sizes (143, 147, 151, 152). All of these factors contribute to the confusion about whether treatment of those with ASPD and psychopathy is a viable pursuit, or should be abandoned in favor of traditional management through incarceration.

Several studies indicate that psychopaths benefit less from treatment than nonpsychopaths, demonstrating higher attrition rates, lower clinical improvement, higher violent recidivism, and more immediate recidivism upon release than their nonpsychopathic counterparts (153–155). In addition, high PCL-R scores (particularly Factor 1 scores) have been associated with significantly higher recidivism rates in treated psychopaths than untreated psychopaths, suggesting that psychopaths actually get worse with therapy (148, 149, 156). Thus, it is generally accepted that "nothing works" with respect to treating psychopathy (157); the psychopath seems to benefit less from treatment than nonpsychopaths, and in some cases, therapeutic interventions appear to increase future criminal activity in the psychopath, indicating that management, rather than treatment, may be the prescribed course for this type of offender (158).

This pessimism regarding treatment is enhanced by the over-reliance on findings of a handful of landmark studies that report notably disappointing outcomes (159). This is unfortunate, given that some of the studies cited are of questionable scientific value. For instance, in the most famous treatment outcome study of psychopathy, the Penetanguishene study, Harris and colleagues (148) reported that therapeutic community (TC) treatment significantly increased recidivism in psychopaths compared to the untreated psychopathic group (77% vs. 55%, respectively). However, the TC treatment employed in this study was an unlikely candidate for success; the "total encounter capsule" involved nude encounter groups, feeding through tubes in the

walls, and LSD and alcohol administration for many days at a time [(148)pp. 285–288]. Remarkably, the Penetanguishene study continues to be used as evidence that treatment of the psychopath is contra-indicated. Perhaps even more surprisingly, although it seems apparent that therapeutic communities are not effective at reducing future criminal behavior (160, 161), they remain popular in prisons and psychiatric hospitals in Europe (143). But perhaps it is not surprising that unconventional therapies are often used. It is recognized that the characteristics of antisocial individuals create very difficult obstacles for treatment, thereby limiting the number of available options for intervention. While pharmacological research suggests that specific symptoms of ASPD can be effectively reduced through medication (151, 162), concerns about compliance outside of controlled settings and the high potential for abuse associated with some substances inhibits the degree to which this type of treatment can be used. For instance, while dopaminergic stimulants such as methylphenidate have been found to improve symptoms of inattention, irritability, conduct problems, and impulsivity in adults and adolescents with antisocial behaviors (163–165), the comorbidity between ASPD and substance abuse limits the use of this intervention beyond controlled settings due to its high potential for abuse when appropriate use of this medication cannot be monitored (151).

Other pharmacological treatments have also shown promise in the reduction of the aggressive behaviors associated with ASPD and psychopathy, but may also be limited in their use due to concerns about long-term treatment compliance (166, 167). Lithium has received considerable attention for use in those with ASPD due to its efficacy at reducing impulsive violent behaviors in nonbipolar adults and adolescents (168, 169). Additionally, selective serotonin reuptake inhibitors (SSRIs) such as sertraline and fluoxetine have been associated with significant reductions in overt hostility, aggression, and antisocial behavior (170–172), as have anticonvulsants, including valproic acid (173), or its salt form, divalproex sodium (174, 175), and phenytoin (176). Like methylphenidate, the use of lithium and antipsychotics to control aggression is suitable in forensic settings, but the poor treatment compliance demonstrated by those with ASPD may reduce the effectiveness of this treatment in the long-term (166, 167).

In addition, the manipulative and remorseless traits associated with psychopathy do not bolster optimism for therapeutic interventions. Some researchers believe that despite good compliance with therapy and reported therapeutic improvement in correctional settings, the psychopath is simply using what he uses in therapy to enrich his criminal versatility and skill, thus accounting for negative outcomes (143). For instance, structured cognitive-behavioral techniques designed to target the behaviors associated with ASPD and psychopathy have demonstrated insignificant, or even inverse relations with recidivism, despite reported therapeutic gains such as conduct during sessions and therapists' ratings of motivation ((149); see (143) for a review). Radical therapeutic change techniques aimed at modifying the character of the psychopath have been proposed, but to date, have limited empirical support (177). One example of this type of treatment is Cloninger's (151) coherence therapy which is designed to address the unseemly character of those with ASPD in the hopes of increasing "trust, hope, and compassion" in the remorseless individual. Cloninger (151) posits that deficiencies in self-transcendence and emotional awareness underlie antisocial traits, and can be improved through meditative exercises, exposure to classical music, and therapeutic exercises in self-efficacy. While many agree that therapy targeting dysfunctional characteristics may be a very important aspect of the treatment of those with ASPD, it is perhaps unrealistic to expect self-transcendence exercises to be the most effective way of eliciting this type of change (178).

In contrast to those who hold little hope for changing the outcomes of those with ASPD and psychopathy, some authors contend that the treatment of ASPD and psychopathy can be beneficial, and that the reported failures in treatment response are simply not the norm (147, 151, 159). In fact, large meta-analytic studies indicate that many forms of treatment (e.g., electroconvulsive therapy, psychodrama, cognitive-behavioral therapy, psychoanalysis, therapeutic communities, and pharmacotherapy) have a positive overall effect on the reduction of recidivism for adult offenders (147, 179, 180), and juvenile offenders alike (181, 182). In addition to overall effect sizes, Lipsey (181) conducted moderator analyses on over 400 treatment-outcome studies to identify important factors that contribute to therapeutic success; reductions in criminal recidivism are associated with greater therapeutic intensity (longer duration and more frequent contacts), structured treatments (e.g., cognitive-behavioral therapy and skills training), and multimodal treatments (e.g., individual and group therapy coupled with vocational training, pharmacological treatment and work assignments). Thus, the quantitative treatment results appear to indicate something quite different than the dismal conventional standard. When specific guidelines are followed, it appears as though significant gains can be attained (159, 182).

Many of these same techniques have been recommended in a recent review of treatment outcomes for psychopathy (152). Salekin and colleagues suggest several possible "practical problem areas" (p. 256) when conducting therapy with psychopathic individuals, including addressing motivation to change, deceptiveness/manipulativeness, and lack of emotion and empathy leading to poor attachment, as these appear to be areas that prevent optimal outcomes. However, this review also noted that of the recent treatment studies, only 3 of 8 adult studies indicated any success. This same review identified 8 recent studies of treatment in psychopathic youth, and unlike the adult outcomes, youth treatment seemed much more effective; 6 of 8 studies indicated some therapeutic gain in terms of recidivism and latency to recidivism suggesting that early intervention is likely to be the best practice in terms of instituting relevant changes (152).

However, even though individual studies and some meta-analytic work indicates that treatment has a positive influence on recidivism, it is still questionable whether these are truly meaningful gains. Importantly, reported effect sizes in this area tend

to gravitate toward a value of .20, which is comparable to that of a placebo effect (179–183). The clinical meaningfulness of this improvement may simply be insignificant. For instance, the treated offender may have committed rape fewer times in the five years following release than the untreated offender, but the fact that he continues to rape (albeit with less frequency) speaks to the inadequacy of contemporary interventions. Although modest reductions in antisocial behavior are important, these reductions do not indicate that treatment is eliciting substantive change. In addition, many of the studies used in meta-analytic research of the treatment of ASPD and psychopathy rely on one group, pre-post treatment designs (143). This type of study design has been found to overestimate treatment effects, thereby making these positive effect sizes even less convincing (182). Finally, very few treatment studies have examined long-term efficacy of treatments, reporting primarily on short-term outcomes. This can result in the inflation of positive results, as well as mask discouraging survival statistics. As can be seen in a recent study by Olver, Lewis, & Wong (184), even large therapeutic treatment gains in the short-term may not have lasting effects; of 38 incarcerated offenders with high psychopathy scores who responded well to treatment, only 10% had violently recidivated during the first year post-treatment. However, this number increased to over 60% within 10 years (184). Thus, while meta-analytic results provide compelling suggestions that treatment interventions addressing the criminal behaviors of ASPD and psychopathy should continue to be pursued, they do not actually document that contemporary programs are having a substantial, meaningful effect.

In sum, clear conclusions about the efficacy of treatment for ASPD and psychopathy are difficult to draw. While meta-analytic findings appear to support further investigation into treatment interventions, they also fail to fully contradict the argument that these disorders are largely unresponsive to treatment in general. Although even mild to moderate changes in antisocial personality traits can be associated with benefits to the person and to the wider society, the relative modesty of therapeutic gains indicates that treatment needs to improve before we can decisively conclude that ASPD and psychopathy are treatable disorders.

Alcoholism

Afshan Anjum, M.D.*

Abstract The use of alcohol is woven into our culture in a most complex fashion. The majority of adults in the United States consume alcohol, yet alcohol also causes nearly 100,000 deaths per year and cost the society $223.5 billion in 2006 alone. Harm from alcohol can occur in a number of ways. First, if alcohol is consumed above a certain threshold, on the order of one drink/day for a woman or two drinks/day for a man, medical consequences, e.g. hypertension, cirrhosis, or depression, can occur over time. Second, if alcohol is consumed to the point of intoxication and impairment, the risk of domestic violence and child abuse, motor vehicle accidents, criminal behavior, and problems at work or school are greatly increased. Third, in susceptible individuals, alcohol use leads to the development of a true addiction to alcohol—alcoholism. Alcoholism is characterized by loss of control over alcohol use, compulsive use, and the development of physical dependence. The negative consequences of alcoholism are generally severe.

Alcoholism, or alcohol dependence, was first suggested to be a disease in the 1780s but only recognized as such by the American Medical Association in 1958. The diagnostic criteria for alcoholism have shifted somewhat over time but the core elements of loss of control, compulsive use despite adverse consequences, and physical dependence remain. Alcoholism is a common disorder with a lifetime prevalence of 20% in men and 10–15% in women (1). The etiology of alcoholism involves biopsychosocial components with an estimated 50% of risk coming from genetics. Alcoholism and unhealthy alcohol use are under-recognized by clinicians though a variety of medical symptoms and laboratory findings or positive answers to simple questions should alert the clinician to alcohol-related problems. Alcoholism should be viewed as a chronic disease; individuals are not "cured". However, alcoholism is a treatable disorder and many patients achieve long-term sobriety or greatly reduce their use of alcohol. Treatments for alcoholism include a variety of psychosocial techniques such as brief intervention, relapse-prevention therapy, and traditional residential programs. Alcoholics Anonymous is a self-help organization that has helped many alcoholics. Recently, medications that target neurobiological factors involved in relapse have become available—naltrexone and acamprosate. The evolving treatment of alcoholism includes an integration of psychosocial interventions with medication coupled with awareness that treatment requires long-term management.

14.1. Definition

Alcoholism (alcohol dependence, alcohol addiction) was first described as a disease by Benjamin Rush in the United States and Thomas Trotter in England in the late 1700s (2). The concept that a pathological use of alcohol is a disease was quite novel and in opposition to the idea that alcoholism represents a moral problem or a deficiency in will power. However, acceptance of the disease model of alcoholism has not been straightforward and it was not until 1958 that the American Medical Association

S.H. Fatemi and P.J. Clayton (eds.), *The Medical Basis of Psychiatry*, DOI 10.1007/978-1-4939-2528-5_14

recognized it as such. The lay population and the medical community continue to have varied perspectives regarding the disease concept of alcoholism.

The diagnostic criteria for alcoholism continue to evolve. The successive editions of the American Psychiatric Association's Diagnostic and Statistical Manual of Disorders since 1980 reflect changing opinions about what elements in the definition should be emphasized. The 1980 DSM-III emphasized problems from drinking (called substance abuse) and specified that the term alcohol dependence (the officially preferred term for alcoholism) required evidence of physiologic tolerance and/or withdrawal. These criteria for abuse and dependence drew considerable criticism, and in 1987, the criteria were revised in DSMIIIR with greater emphasis on patterns of compulsive use and less emphasis on dependence and withdrawal. DSM-IV (3) criteria resembled those in DSM-IIIR in not making physiologic dependence essential to the definition of the disorder, but the order of the criteria was changed so that items related to dependence were listed at the outset.

The criteria for alcohol dependence presented here are from the DSM-IV criteria for Substance Dependence.

In DSM-IV, published in 1994, substance abuse was categorized under two distinct disorders of abuse and dependence with separate criteria for each disorder (3). Abuse and dependence were seen on a continuum with more severe illness with legal repercussions being labeled dependence which probably was the closest term used to describe alcoholism. The DSM IV-TR was published in 2000 and contained additional information on the diagnosis (4). Under the new DSM-5 criteria released May 2013, alcohol abuse is categorized under the overarching diagnosis of substance abuse disorder which is defined by 11 different criteria and categorical distinction ranging from mild to moderate to severe based on the severity of alcohol use (5). The legal consequence criterion included in DSM-IV has been dropped and a new craving criterion has been added. Thus, based on DSM-5 definition, if a person exhibits any two symptoms from a list of 11 criteria, during the same 12-month period, he/she is diagnosed as having an alcohol use disorder.

It is highly unlikely that alcoholism is a unitary disease. Fifty years ago Jellinek described subtypes of alcoholism that varied based on severity, use patterns and prognosis (6). We continue to revise and refine our definitions of alcoholism with awareness that there are likely several forms of alcoholism. As discussed below, scientific advances should allow us to eventually classify alcoholism more precisely—based on a clearer understanding of the genetic and pathophysiologic disease processes.

14.2. Epidemiology

Epidemiologic studies of alcohol use and abuse are bedeviled by the uncertainties of what to measure and how to measure it. Prevalence rates for a disease are, of course, dependent on the current definition for that disease. For alcoholism, there has been no absolute and unchanging reference point. Therefore, the trends in alcoholism prevalence over time are difficult to accurately assess. Nevertheless, modern epidemiologic tools targeted towards the general population provide us with a broad picture of the landscape of alcohol use, misuse, and alcoholism and give a sense of the extent of the problem. For the purposes of this chapter epidemiologic studies focused on the United States will be reviewed.

14.2.1. Consumption

The United States is a drinking culture. Recent population studies indicate that 60–65% of the adult population report consuming alcohol in the past year (7). Average consumption, based on sales, for adults (ages 14 and older) was 2.23 gal of ethanol in 2004, and 2.31 in 2007. (www.niaaa.nih.gov/Resources/DatabaseResources/QuickFacts/AlcoholSales/consum01.htm). Average consumption had been trending downward since the 1970s but has had a slight increase since 2000.

One of the more concerning issues regarding consumption is the prevalence of binge drinking, particularly among young people. Binge drinking is defined as consumption of five or more standard drinks in a row for men or four or more for women. A standard drink is considered 12 oz of beer, 5 oz of nonfortified wine, or 1.5 oz of liquor and, in the United States, to contain 12–14 g of ethanol. Among US adults surveyed in 2011 using behavior risk factor surveillance system (BRFSS), 18.3% reported binge drinking an average of four times per month and consumed approximately eight drinks per episode (http//www.appsnced.cdc.gov/brfss). Studies in college students reveal an increasing trend in binge drinking. Weschler et al. (8) reported that 44% of college students reported binge drinking in the 2 weeks prior to completing a screening questionnaire ($n = 14{,}138$). Over half of the binge drinkers reported binge drinking three or more times over 2 weeks—identified as frequent binge drinkers. Disconcertingly, frequent binge drinking was significantly higher in the 1999 population compared to samples questioned in 1993 and 1997. In the overall U.S. population, survey studies indicate that about 36% of men and 16% of women ages 18 years or older report at least one binging episode (five or more drinks) in the previous 30 days (9). The average number of binge episodes per year was 20.1 in men and 5.8 in women. Binge drinking is, understandably, more prevalent in heavy drinkers but 72.9% of binge drinkers are moderate drinkers. Binge drinking is of particular concern to society and to clinicians because, regardless of whether a formal alcohol use disorder is present, it is associated with increased morbidity, mortality, and social problems such as accidents, crime, and absenteeism.

14.2.2. Prevalence of Alcohol Abuse and Alcohol Dependence (Alcoholism)

Results from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), a population survey of 43,093 adults in the United States, conducted in 2001–2002 revealed that the 12 month prevalence rate of DSM-IV defined alcohol dependence was 5.42% for men and 2.32% for women (10). Lifetime rates were 17.18% for men and 7.84% for women (11). Twelve-month prevalence rates were highest in the 18–29 year old range and declined with increasing age. 12 months rates for abuse were 6.93% in men and 2.55% in women (10).

A second wave of NESARC survey was conducted from 2004 to 2005. These surveys and data obtained were unique in that there was a 81% response rate, with people from all walks of life being surveyed and minorities were oversampled to examine the impact of race and ethnicity on comorbidity and access to health care (11). Trends for alcohol use were observed overtime and compared between 1991 and 1992 vs. 2001 and 2002. Alcohol abuse was reported to have increased to 4.6% from 3.03% and dependence decreased to 3.81% from 4.38%.

14.2.3. Morbidity and Mortality Attributable to Alcohol

Morbidity and mortality associated with alcohol is considerable. The Center for Disease Control reports that, for the period of 2006–2010, in the United States, excess alcohol consumption contributes to 88,000 deaths/year and that excessive alcohol use is the third leading cause of lifestyle-related death (http://www.cdc.gov/alcohol/quickstats/general_info.htm). Alcohol is a major contributor to domestic violence and other crimes, to child maltreatment, and to traumatic injuries. In 2005, nearly 17,000 individuals died in alcohol-related traffic accidents.

The medical consequences of alcohol are broad. Alcohol affects nearly every organ system in the body including the brain. A patient does not need to meet criteria for alcohol abuse or dependence in order to develop deleterious consequences from alcohol consumption. It is incumbent upon clinicians to consider a role for alcohol in many medical or behavioral problems. One of the challenges to interpreting the health consequences of alcohol for the clinician and lay public alike is the evidence that low levels of alcohol consumption can reduce the risk of coronary artery disease and stroke (12). This evidence has sometimes been referred to as the "red wine" benefit and is frequently noted in the lay media. This effect has often been misinterpreted that since alcohol can be good for you, its risks are not that serious.

14.2.3.1. Medical Illness

There is a vast literature devoted to the medical consequences of alcohol. The interested reader is encouraged to consult traditional medical textbooks or medical journals for more information on this topic. Epidemiological studies have attempted to estimate the relationship between levels of consumption and various illnesses (13, 14). Low-moderate levels of alcohol consumption in the 1–2 drinks/day range are associated with lower risk for coronary heart disease and ischemic stroke, but this is balanced by increased risk for other disorders including liver cirrhosis, essential hypertension, pancreatitis, gastroduodenal ulcer, hemmorhagic stroke, and several types of malignancy including breast cancer. Though some benefit for coronary heart disease remains evident at alcohol consumption levels of 3–4 drinks/day, the risk for other disorders increases significantly as higher levels of alcohol are consumed. For example, the relative risk for cirrhosis goes from 2.9 at 25 g alcohol (~2 drinks)/day to 7.1 at 50 g alcohol (~4 drinks)/day to 26.5 at 100 g of alcohol (7–8 drinks)/day) (14). Women develop medical consequences from alcohol at lower total consumption levels than men and their disease progression is faster than men (15).

Alcohol is involved in approximately 50% of fatal motor vehicle crashes, 17–53% of fatal falls, 37–64% of fatal burns, and 38% of fatal drownings (16–18). It is likely that alcohol's relationship to these traumatic deaths is significantly underreported.

14.2.3.2. Alcohol, Structural Brain Damage, Cognitive Impairment, and Dementia

A relationship between excessive alcohol consumption, cognitive impairment, and frank dementia has been noted for years. Whereas nutritional deficiencies, particularly thiamine, have been shown to be essential for some forms of alcohol-related dementia, e.g., Korsakoff's syndrome, there is increasing evidence that alcohol can induce structural brain changes and cognitive impairment independent of thiamine deficiency. The development of noninvasive brain imaging techniques has led to a wealth of findings regarding brain changes in alcoholism [see (19) for review]. Noteworthy are loss of cerebral cortical mass (particularly prefrontal cortex) and cerebellar atrophy along with subcortical white matter loss and atrophy of other structures including hippocampus, striatum, and thalamus as shown in Fig. 14.1 (19). Paralleling these structural changes are neuropsychological deficits particularly in gait and balance, executive function, and visuospatial abilities. The deficits in executive function may contribute to the disease process by interfering with a patient's ability to change behavior.

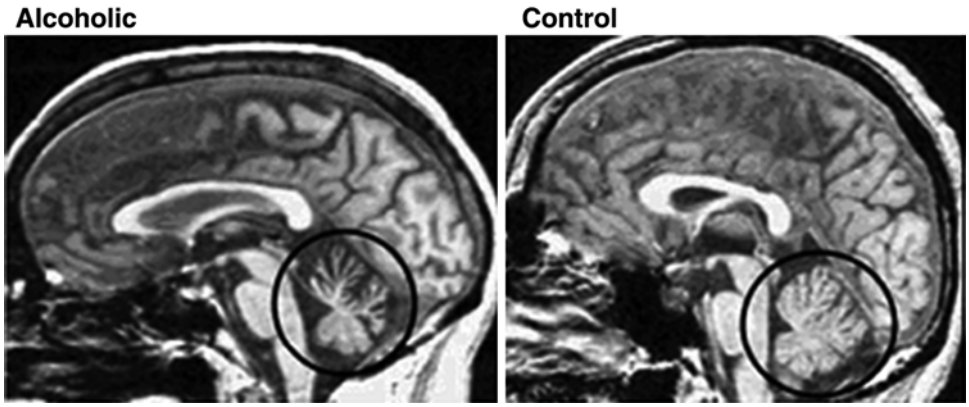

FIGURE 14.1. Midsagittal view of an MRI of the brain of an alcoholic, showing severely shrunken folia of the anterior superior vermis compared with an age-matched control man. With kind permission from Springer Science + Business Media: Psychopharmacology (Berl), Neurocircuitry in alcoholism: a substrate of disruption and repair, volume 180, 2005, pages 583–594, Sullivan EV, Pfefferbaum A, Fig. 2.

14.2.3.3. Alcohol Induced Psychiatric Disorders

There is extensive comorbidity of alcohol dependence with psychiatric disorders. The Epidemiologic Catchment Area study completed in the 1980s indicated that 37% of individuals with an alcohol use disorder had a comorbid mental illness (20). In many cases, the use of alcohol is thought to precede the psychiatric disorder and lead to a secondary psychiatric disorder or substance-induced disorder. However, it is often a challenge to sort out the primacy of alcoholism vs. another psychiatric illness and many times it simply cannot be done.

Depression is one of the most common consequences of heavy alcohol use. In a study of patients admitted for alcoholism treatment, Brown and Schuckit (21) found that 42% had Hamilton Depression Rating scores higher than 20 in the first week of admission—a level compatible with significant depression. Inpatient treatment and supportive care without the use of antidepressants was associated with a marked reduction in depressive symptoms with only 6% of patients having significant symptoms by week 4. Of course, as noted by the authors, rating scales for depression indicate presence of sleep and appetite problems, somatic symptoms, and anxiety symptoms, as indicators of the severity of depression. Withdrawal from chronic alcohol use, especially in hospitalized patients, is associated with disturbances in these same domains leading to false-positive assessments of depression. Nevertheless, depressed mood, guilt and suicidal ideation and attempts—core symptoms of depressive illness—are common in alcoholic patients and it is clear that, in some patients, alcohol induces a true depressive disorder.

Insomnia has been reported to occur in anywhere from 36 to 72% of alcoholic patients (22). Sleep problems vary across the cycles of alcohol use and binging, acute alcohol withdrawal, and protracted alcohol withdrawal. Key sleep findings during abstinence include initial insomnia, reduced total sleep time, reduced slow wave sleep, and disturbances in REM sleep (23). Sleep disturbances can normalize with sobriety though this may take months (24).

Anxiety is a common symptom of alcohol withdrawal and may persist for an extended time. There is basic science evidence that alcohol can induce anxiety-related behavior and that this may relate to relapse (25). Differentiating alcohol-induced anxiety from primary anxiety disorders is challenging and anxiety disorders should be carefully screened for in all alcoholic patients (26).

Suicide is a significant risk factor in alcoholism. One estimate is that up to 40% of alcoholic subjects will attempt suicide and 7% of alcoholics will end their lives by suicide (27). A number of risk factors have been identified in alcoholic patients that increase the chance of a suicide attempt including being male, having a comorbid major depression or significant medical illness and living alone (27).

14.2.3.4. Fetal Alcohol Spectrum Effects

The consequences to the fetus of maternal alcohol consumption include a number of neurobehavioral deficits and physical abnormalities collectively referred to as fetal alcohol spectrum effects (FASEs) (28). The classic fetal alcohol syndrome (FAS) is associated with developmental abnormalities including a triad of dysmorphic facial features, growth retardation and central nervous system abnormalities. The facial dysmorphic features include thin upper lip, nearly absent philtrum, and small palpebral fissures. Cognitive and behavioral impairments include overt mental retardation as well as deficits in more specific domains such as executive function, attention/hyperactivity, and social skills. FAS is a significant cause of mental retardation and one that is completely preventable. Although there have been major public health efforts to educate women about the risks of drinking

during pregnancy, the CDC estimates that 3% of pregnant women drink at levels associated with FASEs (29). Physicians should counsel all women to the potential danger to their fetuses of drinking during their pregnancy. The frequency of binge drinking among young women represents another concern for FASEs because binge drinking in the early phase of fetal development, when some women are unaware that they are pregnant, is associated with FAS.

14.3. Clinical Picture

The clinical presentation of the alcohol-dependent patient is contingent on when in the course of the illness he or she presents. There are no pathognomonic signs or symptoms of alcohol abuse or dependence. Although medical symptoms may bring an alcoholic into his or her first contact with a possibility for therapy, early in the course of the illness there may be no physical or laboratory signs of this condition. Additionally, physician discomfort, judgmental attitudes, or inadequate training and patient denial raise additional barriers to effective diagnosis. Often, indications of an alcohol problem can be gained only through a careful social and medical history. Specific inquiry regarding marital conflict, absenteeism from work or school, job losses, accidents, and legal difficulties should be made; such problems occur more commonly in alcoholics than in nonalcoholics. Patients who indicate that they have such problems should be asked about the relationship of alcohol to the problems and about specific drinking practices. Not infrequently, the alcoholic will deny or rationalize the relationship of alcohol to his or her problems and will underreport the quantity of alcohol consumed. If willing to admit to problem drinking, the early alcoholic may report sneaking drinks, hiding alcohol, feeling comfortable only with other drinkers, experiencing guilt associated with drinking, and attempting to control drinking by using alcohol only at specified times (30).

Medical complaints early in the course of alcoholism include anorexia, morning nausea and vomiting, gastroesophageal reflux, diarrhea, palpitations, insomnia, amenorrhea, impotence, and polyuria. Psychiatric and neurologic complaints may include depressed mood, anhedonia, insomnia, anxiety, irritability, nervousness, blackouts (memory lapses), and subjectively poor memory (31–33).

Early in the course of alcohol use, hypertension can occur with as few as three drinks per day, with higher consumption associated with higher blood pressures (34). An estimated 5–24% of hypertension is associated with alcoholism (34); thus internists should screen all hypertensives for possible alcoholism, and psychiatrists should measure blood pressures regularly and consider an alcoholism diagnosis in hypertensive patients. The physician should be aware that blood pressures can decline and rise in tandem with active drinking.

As alcoholism progresses, physical signs may begin to appear, such as an alcohol odor on the breath, careless grooming and hygiene, signs of intoxication (ataxia, slurred speech), multiple traumas, hepatomegaly (31), and certain facial features, including rhinophyma and persistent erythema, with or without telangiectasias. Later in the course, signs of chronic liver disease may appear, including jaundice, ascites, palmar erythema, spider angiomata, purpura, abdominal varices, testicular atrophy, gynecomastia, and Dupuytren's contractures. Associated symptoms of liver, pancreatic, and other chronic gastrointestinal disturbances may be reported, including abdominal pain, food intolerance, hematemesis, melena, weight loss, weakness, and fatigue.

Neurologic and psychiatric signs and symptoms may occur in later-stage alcoholism and include seizures (unrelated to active drinking or withdrawal), withdrawal syndromes (seizures, hallucinations, delusions, delirium), psychotic syndromes (paranoia, hallucinations, and delusions in a clear sensorium), peripheral neuropathy (usually in the lower extremities, bilateral, symmetrical, and sensorimotor in type), and cognitive deficits (ranging from minor memory problems to dementia and the anmestic syndrome) (35–39).

Uncommonly, myopathy may occur acutely with muscle pain and swelling or chronically with progressive weakness and atrophy. Also, rarely, cardiomyopathy may occur with signs and symptoms of congestive heart failure.

As noted earlier, certain psychiatric diagnoses, including antisocial personality, mania, drug abuse, panic disorder, depressive disorder, and schizophrenia, are found more frequently in conjunction with alcoholism than in patients without these disorders, and hence patients with these diagnoses should raise a psychiatrist's index of suspicion that alcoholism also may be present (40).

It is important to emphasize that early phases of the disease may be marked by subtle or no physical, psychiatric, or laboratory signs and thus require a high index of suspicion by the physician coupled with a sensitive and thorough approach to history taking.

14.4. Case History

J. W., a 35-year-old plant foreman, arrived at his physician's office with chief complaints of 3 weeks of intermittent epigastric pain, anorexia with a 5-pound (2.3-kg) weight loss, and nausea and vomiting. He related that these symptoms were worse in the morning and improved as the day progressed. He indicated that he was not too worried by the symptoms but had come at the urging of his supervisor, who was concerned because of his frequent absences from work.

He denied all other gastrointestinal symptoms, and review of systems was negative except for numerous—colds-in the past year, causing frequent work absence. Physical examination was within normal limits.

When questioned about his drinking practices, he said that he drank—"no more than anyone else." When asked to elaborate, he stated that he went to a local tavern with fellow employees after work for "a few beers" and drank "a six pack or two on the weekends while watching football on TV." When asked about drinking at other times, he replied, "That's all. Why do you keep badgering me about my drinking?" He was then asked if others badgered him; he answered, "Yes, my wife-she thinks everybody drinks too much. Just because I was arrested for driving under the influence last year … but I'm here for my stomach, Doc. Can you help me?" He was scheduled for routine laboratory tests and endoscopy and was asked to return in 1 week.

J. W. may or may not be an alcoholic, but the pattern of his symptoms and his responses to questions about his drinking habits should raise his physician's index of suspicion.

14.5. Laboratory Findings

As is true of signs and symptoms, there are no pathognomonic laboratory measures that can be used to diagnose alcoholism. There are a number of laboratory findings, however, that, when present, should increase the physician's index of suspicion that alcohol may be a problem.

- *Blood alcohol level*. The National Council on Alcoholism includes among its criteria for diagnosing alcoholism a blood alcohol level greater than 300 mg/dl at any time or a level greater than 100 mg/dl recorded during a routine clinical examination (41). It also has been noted that a blood alcohol level of more than 150 mg/dl in a patient not obviously intoxicated is strong evidence of significant tolerance to alcohol, and hence potentially of alcoholism. Blood alcohol levels may be obtained either by direct measurement of blood levels or by estimation from the amount of alcohol in expired air using a breathalyzer.
- *Gamma glutamyl transferase* (*GGT*) is an hepatic enzyme that is induced by moderate to heavy alcohol consumption. GGT has been reported to have a sensitivity for detecting heavy alcohol consumption in the 50–70% range (42, 43). Its specificity is in the 75% range (i.e., in 25% of those with elevated GGT, the cause is not due to alcoholism or heavy alcohol intake). GGT in alcoholics returns to normal after approximately 4–5 weeks of abstinence, and it takes about 2 weeks of heavy drinking to acquire abnormal GGT levels (44). GGT levels may also be elevated in patients with hepatobiliary disorders, obesity, diabetes, hypertension, and hypertriglyceridemia.
- *Aspartate aminotransferase (AST)* and *alanine aminotransferase (ALT)*. AST and ALT are increased in liver damage from a variety of causes. AST and ALT have been reported elevated in 30–75% of inpatient alcoholics (31, 45). A ratio of AST to ALT of greater than 2 with ALT values in the 2–8X upper limit of normal range suggest alcoholic hepatitis (46).
- *Carbohydrate deficient transferrin (CDT)* is a relatively new blood test approved by the FDA to screen for heavy alcohol use. Transferrin is involved in the transportation of iron in the body and contains carbohydrate groups on its primary protein. Heavy alcohol use impairs the process of adding carbohydrate groups to transferrin, thus the name carbohydrate deficient transferrin. Elevations in CDT generally occur after the consumption of 60 g of ethanol per day (4–5 standard drinks) for at least 2–3 weeks and persist for 1–2 weeks after sobriety. The advantage of CDT is its greater specificity compared to most other screening tests, e.g. specifity in the 90% range vs. 75% range for GGT. CDT has also been proposed as a tool to monitor treatment outcome as decreases in CDT support reports of sobriety and increases indicate possible relapse to heavy drinking (47).
- *Mean corpuscular volume (MCV)*. Macrocytosis, as indicated by an elevation of the MCV (commonly reported as part of a complete blood count), has been reported to occur in 35–95% of actively drinking alcoholics, with most studies reporting 35–40%. An elevated MCV can also occur in folate and B12 deficiency, hypothyroidism, malignancies, and nonalcoholic liver disease and these causes need to be ruled out. The cause of the elevated MCV in alcoholics is unknown, and it is more marked in alcoholics who smoke. MCV returns to normal 2–4 months after alcohol ingestion ceases (48). Although low in sensitivity this test has been recognized for its low cost and screening value by several studies.
- *Uric acid*. Uric acid levels have been reported to be elevated in heavy drinkers and to return to normal several days after alcohol ingestion ceases (31).
- *Combined GGT/CDT*: A variable derived from the combination of GGT and CDT, the gamma-CDT = 0.8 ln(GGT) + 1.3 ln(CDT), has been shown to enhance discrimination of heavy alcohol use from social drinkers (49). A multinational WHO study (49) reported that this combination was more effective than GGT or CDT in identifying alcohol problems in men but that GGT alone was more accurate in women.

- *Hexosaminidase* serum and urine levels are increased with heavy alcohol consumption and serum levels return to normal after 7–10 days of abstinence and urine levels return to normal after 4 weeks of abstinence (50). Serum hexosaminidase levels can be also elevated in liver disease, diabetes mellitus, hypertension, myocardial infarction, and thyrotoxicosis. Karkkinen et al. (51) reported sensitivities of 69 and 81% for serum and urine hexosaminidase in detecting heavy drinking. The urinary hexosaminidase demonstrated sensitivity of 72% in detecting heavy drinkers after 7 days of abstinence. This was reported to exceed the sensitivity of GGT, ALT, or AST (52).

In summary, a number of laboratory tests can detect heavy drinking with CDT, GGT, and their combination showing the best overall balance of sensitivity and specificity. Efforts to further improve the use of laboratory tests for the identification of heavy drinking and alcoholism are ongoing (43). Functional biomarkers for the acute effects of alcohol on the central nervous system are another important area that is being investigated currently. Clinicians will still need to be educated to utilize laboratory tests for these benefits to be realized.

14.6. Sensitivity and Specificity of Rating Scales for Detecting Alcohol Dependence and Abuse

Self-administered or rater administered questionnaires represent direct screening methods to identify patients with alcohol problems. These questionnaires have been developed to screen populations that are not already identified as having an alcohol problem such as patients in a general hospital, a primary care practice, or a general psychiatric clinic. For the most part alcohol screening questionnaires are greatly underutilized despite the evidence demonstrating their value.

The two questionnaires that have been evaluated the most are the CAGE (53) and the Alcohol Use Disorders Identification Test (AUDIT, (54)). The CAGE is a four item questionnaire (see Table 14.1) and the AUDIT is a ten item questionnaire (see Table 14.2). To reduce the time needed for screening, selected questions of the AUDIT have been evaluated including using just the first three questions (known as the AUDIT-C) or simply using the third question, "Have you had six or more drinks on one occasion in the past year". Overall, the CAGE and the AUDIT have shown acceptable sensitivity (50–90% range) and specificity (70–90%) to detect heavy drinking or alcohol use disorders (55). The AUDIT is better designed to detect heavy and hazardous drinking while the CAGE is better at identifying alcohol abuse and dependence (55, 56). Interestingly, the AUDIT-C and the third question of the AUDIT have shown results nearly comparable to the full AUDIT (57) leading to the suggestion that busy clinicians may wish to simply ask if a patient has consumed six or more drinks on one occasion in the past year in order to identify patients in whom additional inquiries would be of value.

14.7. Clinical Course

Understanding the clinical course of any disease requires longitudinal investigations of individuals with that illness. The clinical course of alcoholism is obscured by a dearth of such longitudinal studies and a lack of agreement on the definition of the illness. The studies that have been done have investigated a subset of patients with alcohol problems, e.g., felons (58), public hospital inpatients (59), private clinic outpatients (60), patients attending various units of a large university hospital or its affiliates (61), married or cohabiting residential treatment inpatients (62), college students (59) and untreated alcohol abusers (63). Despite the limitations of these studies, there are enough of them to provide a reasonable idea of the various clinical courses alcoholism can take.

Historically, the first modern attempt to delineate the course of alcoholism was undertaken by Jellinek (64). He analyzed questionnaires from 2,000 Alcoholics Anonymous members, and from their responses, he postulated that alcoholism is a progressive disease in which 43 distinct symptoms occur in more or less definite order. He grouped the symptoms into three phases:

TABLE 14.1. CAGE questionnaire.

1. Have you ever felt you should *C*ut down on your drinking?
2. Have people *A*nnoyed you by criticizing your drinking?
3. Have you ever felt bad or *G*uilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (*E*ye opener)?

Scoring: Item responses on the CAGE are scored 0 or 1, with a higher score an indication of alcohol problems. A total score of 2 or greater is considered clinically significant.

TABLE 14.2. AUDIT.

Please circle the answer that is correct for you
1. How often do you have a drink containing alcohol? Never Monthly or less 2–4 times a month 2–3 times a week 4 or more times a week
2. How many standard drinks containing alcohol do you have on a typical day when you are drinking? 1 or 2 3 or 4 5 or 6 7–9 10 or more
3. How often do you have six or more drinks on one occasion? Never Less than monthly Monthly Weekly Daily or almost daily
4. During the past year, how often have you found that you were not able to stop drinking once you had started? Never Less than monthly Monthly Weekly Daily or almost daily
5. During the past year, how often have you failed to do what was normally expected of you because of drinking? Never Less than monthly Monthly Weekly Daily or almost daily
6. During the past year, how often have you needed a drink in the morning to get yourself going after a heavy drinking session? Never Less than monthly Monthly Weekly Daily or almost daily
7. During the past year, how often have you had a feeling of guilt or remorse after drinking? Never Less than monthly Monthly Weekly Daily or almost daily
8. During the past year, have you been unable to remember what happened the night before because you had been drinking? Never Less than monthly Monthly Weekly Daily or almost daily
9. Have you or someone else been injured as a result of your drinking? No Yes, but not in the past year Yes, during the past year
10. Has a relative or friend, doctor, or other health worker been concerned about your drinking or suggested you cut down? No Yes, but not in the past year Yes, during the past year

Scoring the audit. Scores for each question range from 0 to 4, with the first response for each question (e.g., never) scoring 0, the second (e.g., less than monthly) scoring 1, the third (e.g., monthly) scoring 2, the fourth (e.g., weekly) scoring 3, and the last response (e.g., Daily or almost daily) scoring 4. For questions 9 and 10, which only have three responses, the scoring is 0, 2, and 4. Reproduced from Saunders JB, Aasland OG, Babor TF, De La Fuente JA, Grant M, Development of the alcohol use disorders identification test (AUDIT): WHO collaborative project on early detection of persons with harmful alcohol consumption-II, Addition 88:791–804, Copyright (1993) with permission from John Wiley and Sons.

prodromal, the first symptom of which is blackouts; crucial, the first symptom of which is loss of control; and chronic, the first symptom of which is binge drinking. In a later work, Jellinek (6) introduced the concept that there are five types of drinking patterns and complications, which he labeled alpha, beta, gamma, delta, and epsilon. He suggested that gamma (characterized by tolerance, craving, and loss of control) and delta (characterized by tolerance, craving, and inability to abstain) represented true diseases that followed most closely his 43 symptoms' progression. In Jellinek's view, once the disease of alcoholism was established, usually when an individual was in his or her early or middle 20s, its course was inexorable, with progression over 20–30 years, ending at any stage in death or abstinence. Many studies then followed, some supporting in part and some seriously questioning Jellinek's conclusions and methodology (65–70).

One of the first studies to challenge Jellinek's hypothesis of an inexorable progression of alcoholism was Lemere's 1953 study (71), in which he asked his patients about the drinking histories of their deceased relatives who had had alcohol problems. He thus collected information on 500 presumed alcohol abusers and found that 28% increased their alcohol use before death; 10% decreased alcohol use substantially, with 3% of the total sample returning to social drinking; 29% did not change their alcohol consumption; approximately 20% stopped drinking because they were too ill to drink; and approximately 10% achieved abstinence. Because of lack of treatment resources available, Lemere concluded that these results, with approximately 20% of those with alcohol problems becoming abstinent or reducing their drinking, represented the natural history of untreated alcoholism.

Vaillant (59) reviewed ten major follow-up studies of alcohol abusers, each of which followed patients for 7 years or longer. The studies had different methodologies and followed different subgroups of alcoholic patients. These studies and others (61, 62), although methodologically disparate, are remarkably similar in indicating that approximately 2–6% of alcoholics remit (are abstinent or drinking in a controlled fashion) each year. These approximations hold for samples of both treated alcoholics [e.g., (59, 72–74)], "skid row" alcoholics (75), and untreated alcoholics (58, 62). Patients in successful remission are about two to three times more likely to be abstinent than drinking in a controlled fashion (59, 62), although one study, which followed socially stable patients, found the reverse (76). The majority of studies have concluded that remitted patients able to drink in a social manner at follow-up were mild cases to begin with (61, 77), although not all studies concur with this conclusion (76). These studies, therefore, partially support Davis's hypothesis that alcoholism is, for some, a self-limiting disorder. However, as is pointed out in studies by Vaillant (59) and Pokorny et al. (78), the more numerous and more severe the symptoms of alcoholism, the closer the clinical picture is to Jellinek's stages and the more alcoholism appears to be a progressive disease, ending in abstinence, serious morbidity, or death. Such conclusions, however, may be tautological; the more serious and numerous the effects (many of which are also symptoms) the more serious the prognosis unless halted by abstinence.

It should be emphasized that the rate of improvement noted earlier applies to patients who are probably diagnosable as being alcohol-dependent. Many patients with alcohol problems, especially those in their teens and 20s, return to social drinking and abstinence at much higher rates. For example, Fillmore (79), in her 20-year follow-up of college students, found that only 30% of 31 individuals who had been problem drinkers in college were still having problems with alcohol at follow-up.

All alcoholics, including those who become abstinent or return to social drinking, are at risk to experience significant medical and psychiatric morbidity from their illness. In addition to the medical and psychiatric complications alcoholics experience, which were noted earlier in this chapter and which frequently lead patients into outpatient or inpatient medical or psychiatric care, alcoholics also experience a great deal of psychosocial morbidity. Given that alcoholism is diagnosed in part by its psychosocial consequences, it is somewhat difficult and arbitrary to separate psychosocial complications from symptoms of alcoholism. It is worth emphasizing, however, that job difficulties and loss; marital tensions, separations, and divorces; and arrests for traffic offenses, disturbing the peace, and criminal behavior are all strongly associated with alcoholism (77).

The various morbidities and traumatic events associated with alcoholism lead to an average age of death of 55–60 years (37). Also of note is the finding of Vaillant (59) that offering intense, readily available treatment to alcoholics does not lower their mortality rate and the finding of Pell and D'Alonzo (80) that the mortality rate of recovered alcoholics is not significantly different from that of alcoholics who continue to drink. Although this latter finding has been supported (62), there are studies that indicate that survival is greater in those alcoholics who are able to abstain or drink moderately than in those who continue as heavy and/or problem drinkers (81–83).

An overall view of the natural history of alcoholism reveals that an alcoholic's first drink occurs at age 13, problem drinking begins between the ages of 18 and 25, first hospitalization for drinking problems occurs at about age 40, and death occurs between the ages of 55 and 60 (37, 77, 84). This natural history differs somewhat for women, who begin problem drinking later than men and have a more rapid development of symptoms (15). Women also have been found to have the onset of physical complications at an earlier age, have more psychiatric disability, have a greater likelihood of co-occurring psychiatric disorders (especially depressive disorder), have a worse prognosis, (especially in relation to mortality), and have an equal response to treatment (37, 40, 85–91).

There are many exceptions to this natural history for both men and women, as there are to the onset, order, and occurrence of specific signs and symptoms of alcoholism. The most severe alcoholic spends much of his or her time sober (40, 92), with

concomitant decreases at such times in alcohol-related problems. The disease appears to fit the pattern of a chronic relapsing illness, with periods of remission and exacerbation. Some alcoholics appear to have permanent remissions either spontaneously, through internal resolve, or with the help of various factors in their environment (93). Others continue a pattern of intermittent but not worsening problems, and still others inexorably deteriorate with increasingly severe, debilitating, and often fatal alcohol-related problems. A continuing challenge to those working in the field of alcoholism is to identify the patients with the more benign course and determine what factors lead to such a course and to identify those with a more malignant course and determine what interventions and treatments are effective for them.

14.8. Differential Diagnosis

Alcoholism has been referred to as a modern day syphilis in the sense that its clinical presentation can take many forms. The medical presentation of the consequences of alcoholism can present as liver disease, cardiac disease, neuropathy, pancreatitis, gastric ulcer, various cancers, infections, traumatic injuries and burns and many other problems. As noted previously, the clinician must be open-minded and willing to entertain the diagnosis of alcoholism as an underlying cause of many clinical presentations. The psychiatric presentation of alcoholism is also often misleading. Because of extensive comorbidity and the shame, ambivalence, and denial in acknowledging one's alcoholism, patients with alcoholism frequently present with complaints and symptoms of depression, anxiety, insomnia, and somatic symptoms. Furthermore, many psychiatric illnesses increase the risk of developing alcohol use disorders and patients with these disorders should be carefully examined for alcoholism. Bipolar disorder has been shown to increase the risk for substance use disorders more than any other Axis I diagnosis (20). It has been shown that 40–50% of hospitalized bipolar patients meet criteria for a comorbid alcohol use disorder (94). Other disorders with high rates of comorbid alcohol problems include antisocial personality, schizophrenia, generalized anxiety disorder, post-traumatic stress disorder, social phobia, attention deficit disorder, bulimia and, to a lesser extent, unipolar depression (20).

Results from the National Epidemiologic Survey on Alcohol and Related Conditions revealed significant comorbidity between alcohol use disorders and drug use disorders (95). Over a 12 month period 7.35% of subjects met criteria for an alcohol use disorder, 0.90% met criteria for a drug use disorder and 1.10% were comorbid for both. Individuals with an alcohol use disorder were much more likely to have a drug use disorder than those without an alcohol use disorder. Individuals with any drug use disorder were 7.4 times as likely to have an alcohol use disorder compared to individuals without a drug use disorder. The presence of comorbid alcohol and drug use disorders increased the likelihood that an individual had sought treatment in the previous year.

14.9. Etiology

There are likely multiple forms of alcoholism and multiple pathways to develop alcoholism. Jellinek (6) was perhaps the first to set forth ideas about subtypes of alcoholism based on his observations of patients over many years. Additionally, a variety of subtypes have been proposed including Type I vs. Type II as described by Cloninger (96), Type A vs. Type B (97), and Lesch's subtyping concepts (98). Type I/II subtypes were derived from behavioral genetic studies using adoptees and clinical populations (96). Type A/B subtypes were derived from cluster analyses applied to a battery of clinical and historical variables gathered on clinical populations (97). Lesch's typology was proposed based on longitudinal observations of alcoholic patients followed over years (98). Though a detailed review of the validity and evidence supporting alcoholism subtypes is beyond the scope of this Chapter, it is noteworthy that some common themes are evident. Most subtypes differentiate alcoholism based on severity of dependence, a greater density of family history of alcoholism, behavioral characteristics such as sociopathy, and comorbid problems such as anxiety and depression. For example, both Type II and Type B alcoholism are characterized by early age of onset, strong family history of alcoholism, heavy alcohol use, and sociopathic behaviors. However Babor and Caetano (99) have recommended that subtyping of alcoholics not be included in formal psychiatric diagnostic criteria until the subtypes are clearly validated in diverse populations.

Identifying the etiology of the alcoholisms is complicated by the fact that there do appear to be multiple forms of the illness. This heterogeneity affects efforts to identify the critical biopsychosocial processes that lead to alcoholism. Nevertheless, our knowledge of the causes of alcoholism has advanced greatly in the past few decades.

The etiology of alcoholism, and its overt expression, involves biopsychosocial factors. Biological factors include genetic risk, phenotypic characteristics, and the impact of environmental events on underlying biology. Psychological factors include variations in personality and temperament, the psychological consequences of stress and trauma, and the impact of other mental illnesses. Social factors include cultural influences, the current social milieu, and regulatory policies such as current laws, taxation, health warnings, and limits on advertising.

14.9.1. Biological Influences

14.9.1.1. Genetics

Alcoholism runs in families. This observation was noted thousands of years ago by Plutarch "One drunkard begets another" (100). About four times as many children of alcoholics become alcoholic as do children of nonalcoholics. For years, it was unclear whether this increased rate was a familial effect or represented true genetic risk. Over the past 40 years a number of adoption and twin studies have been completed that unequivocally demonstrate a strong genetic component to alcoholism. The first series of studies were adoption studies in Denmark (101), Sweden (102), and the United States (103). Each of these studies found that the adopted away children of alcoholic parents were significantly more likely to develop alcoholism than the adopted away children of nonalcoholic parents. The Swedish study also indicated that subtypes of alcoholics may vary in the extent of genetic risk. Thus, the Type II alcoholic (more severe form of illness) was found to have a robust genetic influence independent of environmental influence whereas the Type I alcoholic showed evidence for a gene–environment interaction (104).

Twin studies complement adoption studies and have provided a powerful tool for the study of genetic factors in psychiatric disorders. Twin studies are based on the fact that monozygotic (MZ) twins share 100% of their DNA whereas dizygotic (DZ) twins, similar to any sibling, share 50% of their DNA. Therefore, disorders in which genes contribute to etiology should exhibit greater concordance in MZ twins than in DZ twins. Studies in MZ vs. DZ twins using various definitions of alcoholism have revealed strong evidence for a genetic component. This has been demonstrated in both male (105) and female (106) twin pairs. Examination of the contribution of environmental and genetic influences on the development of alcoholism in these studies leads to estimates that genes contribute on the order of 50–60% to etiology. One important point from twin studies is that the development of alcoholism is not inevitable, even if one inherits genetic risk—concordance rates are not 100% for MZ twins. Alcoholism is neither a dominant nor recessive Mendelian trait. Therefore, the inheritance of risk for alcoholism appears to involve multiple genes interacting in a probabilistic manner to increase risk—some individuals are at very high risk and others are below average risk.

14.9.1.1.1. Search for the Genes Underlying Alcoholism

Major efforts have been undertaken over the past 20 years to identify genes that increase or decrease risk for alcoholism. These efforts have been greatly advanced by the rapidly expanding knowledge of the human genome and the development of techniques to identify genes for complex diseases.

Probably the first series of genes to attract interest were those that code for the enzymes involved in alcohol metabolism. Alcohol (ethanol) is initially metabolized by alcohol dehydrogenase to acetaldehyde which is then metabolized by aldehyde dehydrogenase to acetic acid. Variants in either of these enzymes have been shown to affect risk for alcoholism and for alcohol-related pathology such as esophageal cancer (107, 108). When ethanol is rapidly converted to acetaldehyde and/or when acetaldehyde breakdown is reduced, the level of acetaldehyde reaches relatively high levels after alcohol consumption. Acetaldehyde is a noxious metabolite and can produce nausea, dizziness, sweating, rapid heartbeat, low blood pressure, headache, and flushing. This is the same reaction as the disulfiram reaction and is a deterrent to consumption. Therefore if one inherits a slow metabolizing form of aldehyde dehydrogenase, consumption of alcohol will lead to aversive effects and a reduced likelihood of drinking. In fact, it has been repeatedly documented that individuals with the slow metabolizing form of acetaldehyde have very low rates of alcohol dependence (109). These variants are most common in some Asian populations and less common in individuals from a Caucasian or African background.

Genes not involved in the metabolism of alcohol must contribute to those biological forces that promote consumption, loss of control, and compulsive use. Many studies have been published reporting one gene or another to be associated with alcoholism but relatively few have been well replicated. Several associations that have been replicated include genes for the alpha2 subunit of the GABA-A receptor and the cholinergic muscurinic 2 receptor (110) and variants of the dopamine 2 receptor (111). Other identified genes include the gamma-3 subunit of the GABA-A receptor, the kappa 1 opioid receptor and its endogenous ligand prodynorphin, and the TAS2R16 bitter taste receptor (110). These discoveries are building the framework from which to begin to understand the genetic-biological basis of the various types of alcoholism. It will be important to link the genetic findings to phenotypic expressions, e.g., anxious vs. nonanxious, disinhibited vs. inhibited, to draw a more complete picture of the alcoholisms with greater relevance to clinicians and implications for treatment.

14.9.1.2. Phenotypic Risk Factors

The phenotypic expression of risk for alcoholism takes many forms. There is no single high-risk phenotype. Two of the best replicated phenotypes that, in multiple studies, predict risk for alcoholism are: (1) low-level of response to alcohol (LR) (112) and (2) neurophysiological disinhibition (113). LR takes the form of reduced motor impairment and less subjective sense of

intoxication following an alcohol challenge and has been observed in young social drinkers with family histories of alcoholism. Prospective study of these individuals has shown that LR in the early years of drinking is significantly associated with overt alcohol abuse and dependence later in life (112). Efforts are now underway to identify the genetic basis of LR and preliminary findings indicate associations to variations in the serotonin transporter promoter and the GABA-A receptor alpha-6 subunit (114).

Neurophysiological disinhibition has been extensively studied as a risk factor for alcoholism. Begleiter and colleagues were the first to identify a reduced P300 potential in response to an odd-ball task as a potential marker of risk for alcoholism (115). Since then a broader theory of cognitive and behavioral disinhibition as a risk phenotype has emerged (113) and genetic associations to this phenotype have been reported as well (116). One intriguing observation is that this phenotype appears to be associated with conduct disorder and sociopathy which, as noted above, are found in Type II/Type B alcoholics (see Sect. 14.9).

Other phenotypes associated with risk for alcoholism have been reported, e.g. trait anxiety, beta-endorphin response to alcohol, and it is possible that tens or even hundreds of phenotypes will eventually be identified. A great deal of work remains to identify those phenotypes that can be easily assessed by a clinician and shown to have practical diagnostic, prognostic, or therapeutic value.

14.9.1.3. Neurobiology, Neuroadaptation, and Disease Progression

One of the underlying tenets of the etiology of substance use disorders is the critical role played by the endogenous reinforcement system (117). Alcohol, similar to other drugs of abuse such as cocaine or opiates, activates mesolimbic and mesocortical dopamine neurons leading to an acute reinforcing effect (positive reinforcement). Whereas this rewarding effect is important, recent research in neurobiology reveals that, over time, neuroadaptational processes emerge that are equally, if not more important, in the maintenance of alcohol intake and the development of compulsive use patterns (117). Furthermore, recent evidence indicates the development of negative behavioral consequences, e.g. heightened stress sensitivity, decreased hedonic responsivity, anxiety, with chronic consumption of alcohol that are likely important for driving relapse (negative reinforcement) (25, 118). In patients, these neuroadaptations may take the form of a protracted withdrawal syndrome with stress intolerance, insomnia, anxiety, and dysphoria, all of which can contribute to relapse.

14.9.2. Psychological Factors

An addictive personality was part of clinical parlance 30–40 years ago. Assessment instruments were developed, e.g. the McAndrew Scale derived from the MMPI, to identify the addictive personality. However, a unitary "addictive personality" has not been confirmed. Rather, many different personality/temperament types, e.g. antisocial personality features, anxiety traits, and a temperament of behavioral undercontrol, are at risk for alcoholism.

Early life physical and sexual abuse have also been identified as important factors in the development of alcohol use and other substance use disorders in women though their effects may be mediated through psychiatric illnesses (119).

14.9.2.1. Role of Primary Psychiatric Illnesses in the Development of Alcohol Use Disorders

Primary psychiatric illness is a significant factor in the development of alcohol problems. As noted above, a variety of psychiatric illnesses increase the relative risk of having an alcohol use disorder. The highest risk occurs with bipolar disorder, schizophrenia, and antisocial personality. Anxiety disorders including generalized anxiety disorder, social phobia, and post-traumatic stress disorder increase risk for alcohol use disorders as does attention deficit disorder and depression. Unipolar depression only slightly increases risk.

14.9.3. Cultural Factors

The expression of alcoholism requires access to alcohol. Therefore, factors that reduce access such as cultural prohibitions, legal restrictions, and cost, including taxation, all can affect the prevalence of use. Furthermore, cultural norms and pressures can affect drinking related behavior. An excellent example of the latter is the dramatic reduction in alcohol-related traffic deaths that have occurred over the past 20 years following a variety of public policy steps including increased public awareness and stricter legal sanctions (120).

14.10. Treatment

14.10.1. Treatment of Alcohol Withdrawal

The treatment of alcoholism and the management of alcohol withdrawal symptoms present separate problems.

In the absence of serious medical complications, the alcohol withdrawal syndrome is usually transient and self-limiting; the patient recovers within several days regardless of treatment (121). Symptoms of alcohol withdrawal usually begin in the first 12–24 hours after consumption has ceased. Symptoms include activation of the sympathetic nervous system with increased blood pressure and heart rate, sweating, and tremor; nausea, vomiting, headache, restlessness, agitation, anxiety, insomnia, and paranoia; disturbances in tactile, auditory or visual perception which may include dramatic hallucinations though rarely of "pink elephants". Grand mal seizures represent one of the serious consequences of alcohol withdrawal. Alcohol withdrawal seizures usually occur within the first 48 hours after drinking has stopped. Delirium tremens (DTs) is a serious consequence of alcohol withdrawal with a mortality rate in the 5–10% range. DTs are characterized by (1) delirium with disorientation and waxing and waning of consciousness and (2) severe autonomic activation including tremor, tachycardia, increased blood pressure, profound diaphoresis and fever. DTs peak 48–96 hours after drinking has stopped. Probably less than 5% of alcoholics experience serious withdrawal upon stopping alcohol. However, as referred to earlier, a protracted withdrawal syndrome may persist for months to a year or longer and likely contributes to risk for relapse.

The ability to predict which patients will have a serious withdrawal syndrome would be of great clinical value. These patients would require inpatient hospitalization and detoxification while low-risk patients could be monitored on an outpatient basis. Not surprisingly, there are no definitive predictors for serious withdrawal. Rather, a number of factors have been identified that increase the relative risk of having serious withdrawal complications including delirium tremens or a seizure. Factors that increase risk include comorbid medical illness such as acute infections, fractures, or burns, prior history of DTs or a seizure, longer time before treatment starts, increased severity of typical alcohol withdrawal symptoms including systolic blood pressure >145 mm Hg or heart rate >120 (122–126). It is recommended that patients having one or more of these risk factors receive medical detoxification. The Clinical Institute Withdrawal Assessment for Alcohol Revised [CIWA-Ar, (127)] has emerged as the most common assessment instrument to monitor the severity of alcohol withdrawal. The most widely used version consists of ten questions assessing nausea, headache, tremor, sweating, anxiety, agitation, auditory disturbances, tactile disturbances, visual disturbances, and orientation. CIWA-Ar scores greater than ten or so in the first 24 hours after cessation of alcohol indicate that medication treatment could be helpful; scores greater than 15 (124) indicate an increased risk for serious withdrawal problems.

Treatment of withdrawal is generally highly effective—the mortality rate from alcohol withdrawal has been greatly reduced over the past 60 years but not to zero. The benzodiazepines are considered the drugs of choice for withdrawal (128, 129) with solid evidence that they reduce the risk of DTs and seizures. The benzodiazepines are a diverse group of medications that vary across a number of parameters including: (1) half-life; (2) hepatic metabolism, (3) rapidity of onset; (4) availability of IV and IM parenteral formulations. Lorazepam is commonly used in acute medical settings because it is not metabolized by the liver, has a short half-life allowing more rapid control, and can be given parenterally. Conversely, long-acting agents such as chlordiazepoxide or clorazepate, are more commonly used in psychiatric settings. Barbiturates are effective treatments for alcohol withdrawal but their use has declined because of their narrow toxic/therapeutic index compared to the benzodiazepines. For agitation, paranoia, hallucinations, and aggression that do not respond to early intervention with benzodiazepines, antipsychotic medication, particularly haloperidol, has been shown to have clinical value though clear risks as well (129).

Administration of thiamin and other B vitamins is obligatory in the treatment of alcohol withdrawal. Thiamin deficiency is known to contribute to Wernicke–Korsakoff syndrome and its administration can prevent the irreversible memory deficits seen in Korsakoff's. Thiamin is poorly absorbed from the gastrointestinal tract in alcoholism therefore IM or IV doses of adequate amount, e.g. 100 mg, for several days is recommended.

Unless the patient is dehydrated because of vomiting or diarrhea, there is no reason to administer fluids parenterally. Contrary to common belief, alcoholics usually are not dehydrated; actually, they may be overhydrated from consumption of large volumes of fluid (130).

If the patient develops delirium, he or she should be considered dangerous to himself or herself and others, and protective measures should be taken. Ordinarily, tranquilizers calm the patient sufficiently to control agitation, and restraints are unnecessary. Most important, if delirium occurs, further exploration should be conducted to rule out serious medical illness missed in the original examination. When a patient is delirious, an attendant should always be present. It is sometimes helpful to have a friend or relative present.

14.10.2. Post-Detoxification Treatment

It has been said that the treatment of alcoholism begins once acute alcohol withdrawal is over. Of course, not all patients will complete a medical withdrawal and treatment can begin before alcohol consumption stops. Treatment has multiple goals though the key goal is to help the alcoholic maintain sobriety and reduce the impact of relapses. O'Brien and McLellan (131) have persuasively argued for viewing alcoholism as a chronic illness similar to hypertension or diabetes mellitus. Thus, alcoholism requires ongoing management and is characterized by variations in course from long-term sobriety to episodic relapses to progressive deterioration despite treatment.

The biopsychosocial nature of alcoholism has led to the development of biopsychosocial interventions. Traditionally, psychosocial interventions have been most prominent but, recently, biological interventions are gaining more interest as efficacy is demonstrated.

The primary treatment goal for the alcoholic patient is long-term sobriety. A reduction in harmful drinking can be an appropriate goal, particularly in order to maintain a therapeutic relationship with a patient who is not motivated for abstinence. A goal of reduced consumption as a *primary* outcome is more controversial though this has been utilized with some success, particularly in patients with less severe dependence (132).

Because alcohol use disorders are heterogeneous and exhibit a wide range of severity, treatment is equally diverse. Thus, the heavy drinking patient without clear alcohol dependence may respond to brief interventions in a primary care setting (133) whereas the seriously dependent individual with multiple alcohol-related consequences will likely need detoxification and residential care in a specialized program.

When broaching the issue of an alcohol problem to a patient it is useful to have some sense of what the patient's reaction will be. Patients present differently in their readiness to accept the diagnosis of alcohol dependence/ abuse and in their readiness to change. Prochaska and DiClemente (134) have developed a theoretical model for understanding how patients change behavior derived from studies of smoking cessation. The model has five stages: (1) precontemplation; (2) contemplation; (3) preparation; (4) action; (5) maintenance. Precontemplation identifies those patients who are not ready to hear that they have an alcohol problem—it simply is not in their awareness. The goal with these patients is to maintain a therapeutic relationship and, over time, to help them accept that alcohol is causing them problems. Confrontation with these patients may simply lead to a rupture of the therapeutic relationship. Fortunately, many patients can move beyond precontemplation and begin to take steps to change their drinking behavior and come to terms with the role alcohol plays in their life. For these patients a variety of treatment approaches are available.

14.10.2.1. Psychosocial Interventions

Many psychosocial treatments have been tried for alcoholism, from psychoanalysis to cognitive-behavioral therapy to aversive therapy. A comprehensive review of psychosocial interventions for alcoholism is beyond the scope of this chapter. An excellent critical and comparative review of psychosocial treatments that have been studied in clinical trials is provided by Miller and Wilbourne (135). Based on evidence of efficacy, they find that brief interventions, social skills training, community reinforcement approaches, behavior contracting, behavioral marital therapy, and case management show the best efficacy. Least supported are methods designed to educate, confront, shock, or foster insight regarding the nature and causes of alcoholism. What is not clear from the existing literature is what kind of treatment should be utilized for a given alcoholic patient. For example, it would be predicted that a severely dependent patient will benefit more from an intense course of treatment than a brief intervention, though this has not been carefully tested in clinical trials.

Brief interventions are of interest to the nonspecialist clinician because they can be implemented in a general medical setting. Fleming et al. (133), in a randomized, controlled study, found that two brief interventions of 10–15 minutes of counseling, feedback, and a personal contract conducted by general physicians to heavy drinkers led to significant reductions in binge drinking and excessive drinking after 12 months. Importantly, four year follow-up revealed that the patients who had received the intervention continued to have reductions in drinking behaviors as well as fewer days of hospitalization, fewer ED visits, and an overall savings of $43,000 in health care costs for every $10,000 invested in the intervention (136). These findings reinforce the importance of identifying problem drinking in the primary care setting and highlight that noncomplex behavioral interventions can produce significant clinical improvements. It should be noted that the patients in this study were not formally diagnosed with alcohol dependence or in need of medical detoxification.

In contrast to the above findings, a recent meta-analysis of studies of SBI (screening and brief intervention) in primary care settings did not show significant reductions in subsequent health care utilization (137). The efficacy of SBI in other settings, such as emergency departments (EDs) or hospitals, has not been established, although several randomized controlled trials have been conducted (138).

Attempts to predict which psychosocial treatments work best with which alcohol dependent patients have generally not found clear superiority for one treatment over another based on patient characteristics. The largest such trial to date was Project MATCH (139). This randomized trial gathered a wide range of assessments, e.g., drinking patterns, psychiatric symptoms, on 1,726 alcoholic subjects who entered the study following residential treatment (aftercare) or as outpatients. Subjects were randomly assigned to one of three treatments provided over 12 weeks: Cognitive Behavioral Coping Skills Therapy (12 sessions); Motivational Enhancement Therapy (4 sessions); or Twelve-Step Facilitation Therapy (12 sessions). Subjects were evaluated at 1 year and then at 3 years. Overall, outcomes were very good with 35% of aftercare subjects and 19% of outpatient subjects continuously abstinent for 12 months. Furthermore, 60% of aftercare subjects and 54% of outpatient subjects did not experience three consecutive days of heavy drinking during this time. Follow-up at 3 years revealed that 30% of patients were abstinent for the final 3 month evaluation and those who did report drinking were still abstinent an average of two-thirds of the time (140). Each of the three interventions was effective but the hypothesis that subgroups of alcoholic patients would respond preferentially to one of the treatments was not demonstrated.

14.10.2.2. Alcoholics Anonymous and Other Self-Help Groups

Alcoholics Anonymous (AA) has been widely viewed as providing more help for alcoholics than any other approach. AA was started in the 1930s by two alcoholics, Bill W. and Dr. Bob, and the interested reader is referred to any number of historical accounts to learn more. Key elements of AA include the acknowledgement that one is powerless over alcohol (Step 1), a fellowship of recovering alcoholics who meet regularly, and the acceptance of a belief in a power higher than oneself. The full 12 steps of AA provide a framework that many individuals report has led to long-term sobriety and a positive transformation in their lives. AA estimates that there are currently about 1.1 million AA members in the United States in about 52,000 groups. Their 2004 membership survey reports 65% of members are men and that 36% report sobriety for more than 10 years and 26% report sobriety for less than 1 year. AA discourages research or formal relationships with medical institutions so a controlled clinical trial of AA has not been completed. Studies have been completed of interventions designed to facilitate AA attendance, including the Twelve Step Facilitation program designed for Project MATCH, and these have shown efficacy (139). However, probably no more than 5% of alcoholic individuals are active in AA.

There is no question that AA provides help for many alcoholics that they cannot obtain elsewhere. No doubt it has saved many lives. Most clinicians who treat alcoholics commonly encourage their patients to attend AA meetings. It is not possible to predict in advance whether one patient will benefit from AA and another will not. AA just about everyone agrees should be given a fair opportunity.

Clinicians should also consider referring family members of the alcoholic to Alanon or Alateen. These self-help groups are designed for the families of an alcoholic individual with awareness that the family needs support regardless of whether the alcoholic is in treatment. As family members become educated about alcoholism they can feel empowered and, sometimes, help the alcoholic to enter treatment.

There are aspects of AA that lead some individuals to avoid it. One key issue is the role of the "higher power" or "God as we understood Him". A significant number of individuals interpret this as an endorsement of a form of religion and find this off-putting. Partly in reaction to this, other self-help groups have emerged including rational recovery and Smart Recovery. These programs utilize techniques similar to cognitive-behavioral therapy and do not call upon a "higher power."

Women for Sobriety is another self-help program that differs from AA and was founded to address the needs of women seeking recovery. Women meet in groups for support and are encouraged to reflect daily on 13 affirmations such as "I have a life-threatening problem that once had me". Many women attend both AA counseling and Women for Sobriety.

Clinicians should be aware of these alternative self-help programs and whether they are available in their area. Several online counseling service, treatment programs, and interactive websites are offered currently for individuals who are unable to access traditional treatment programs or who want to strengthen their recovery after a traditional program. Their impact has yet to be studied. Online apps have also shown some promise as another strategy for self-help but these also need to be systematically studied.

14.10.2.3. Medication Treatment

The use of medications to treat alcoholism entered a new phase in 1995 with the FDA approval of naltrexone. Prior to that the only FDA approved medication for alcoholism was disulfiram (Antabuse®).

14.10.2.3.1. Disulfiram

Disulfiram is an alcohol-sensitizing aversive treatment that was discovered serendipitously in the 1940s. Disulfiram irreversibly inhibits aldehyde dehydrogenase leading to a buildup of acetaldehyde when ethanol is consumed. Acetaldehyde produces a number of aversive symptoms including headache, weakness, dizziness, flushing, rapid heartbeat, low blood pressure, nausea, and sweating. This experience can be severe and, in vulnerable individuals, several fatalities have been reported (141). Deaths from disulfiram have not been reported in recent years probably because of the use of lower doses and the exclusion of patients with cardiovascular disease (142). Disulfiram treatment of alcoholism is therefore based on two principal actions—a psychological deterrent to use because of the threat of a reaction and a physiological deterrent to use because of the overt reaction if alcohol is consumed.

Early reports based on case series were quite positive. Case series can be misleading and with the development of modern clinical trial methodology, randomized, placebo-controlled trials of disulfiram were completed. However, even these trials were complicated by the fact that a significant component of the disulfiram effect is provided by the knowledge that one is taking the drug. Therefore, a placebo disulfiram can accomplish this same action. The largest controlled trial of disulfiram was a VA study of 605 subjects (143). In that study, 250 mg of disulfiram was blindly compared to a 1 mg disulfiram dose and an open vitamin condition was provided to control for counseling. Subjects were followed for 1 year. No differences were detected between medication assignment and rates of complete abstinence. Compliance with treatment was strongly related to abstinence. However, in subjects who relapsed to drinking and in whom assessment was complete, those randomized to disulfiram had significantly fewer drinking days. Additional work has noted the value of supervised administration with disulfiram (144), such as by a spouse or treatment center. Overall, the evidence suggests that disulfiram has value in the treatment of alcoholism (145). Clearly, patients must be motivated to take disulfiram, preferably under some form of supervised use. Patients need to be warned about exposure to other sources of alcohol in mouthwash, cologne, and foods. They also need to be aware that the disulfiram effect can last up to 2 weeks after disulfiram is stopped while aldehyde dehydrogenase is resynthesized.

14.10.2.3.2. Naltrexone

Naltrexone is a nonspecific opioid antagonist that blocks μ, δ, and κ opioid receptors. Based on the knowledge that part of alcohol's reinforcing effects are mediated through brain opioid systems, clinical trials of naltrexone were completed in the early 1990s. These early trials (146, 147) revealed that 50 mg of naltrexone reduced the risk of relapse to heavy drinking compared to placebo by about half. Effects on abstinence were not as robust. Since these initial reports, naltrexone has been studied in about 3,000 subjects in placebo-controlled trials throughout the world. Meta-analyses reveal that the strongest effect of naltrexone is to reduce the risk of relapse to heavy drinking (5 or more drinks on one occasion for a man and 4 or more drinks for a woman) with marginal effects on abstinence (148–150). Reductions in drinking frequency and drinks/drinking days have also been reported. A number of studies have shown that naltrexone reduces the "high" experienced from alcohol if a lapse occurs (151). Other reports have noted a reduction in self-reported craving for alcohol with naltrexone but reductions in craving are not the primary goal with naltrexone,

Naltrexone is usually started after several days of abstinence to reduce side effects and advance the patient's treatment goals. Patients who are abusing opiates or require opiates for pain management should not receive naltrexone. Naltrexone has been reported to cause liver problems when given in higher doses and the physician should probably not use naltrexone in patients with acute alcoholic hepatitis. Patients should probably remain on naltrexone at least 6–12 months and quite possibly longer depending on response and risk for relapse.

14.10.2.3.3. Acamprosate

Acamprosate is structurally related to gamma-amino-butyric acid but its mechanism of action has been proposed to be a reduction in alcohol-induced glutamatergic hyperactivity—a factor possibly contributing to protracted withdrawal (152). Clinical trials with acamprosate in over 4,000 subjects have generally been very consistent and reveal that acamprosate increases the likelihood of complete abstinence about two fold. In patients who do not maintain complete abstinence acamprosate increases the number of abstinent days (148). The majority of acamprosate trials have been completed outside the United States in settings where patients have established abstinence. The two clinical trials completed in the United States recruited many non-treatment-seeking patients who had shorter periods of abstinence and both of these trials were negative (153, 154). Mason et al. (153) did note a positive effect of acamprosate on days abstinent in subjects who had a goal of abstinence.

Acamprosate is well tolerated by most patients with mild diarrhea being the primary side effect. Acamprosate is usually started once a patient has achieved abstinence. The dose is 666 mg orally three times per day. No titration is needed. How long to continue acamprosate is not clearly defined but many clinicians would advocate continuation for 1 year or so to allow the patient to solidify behavioral changes.

14.10.2.3.4. Long-Acting Naltrexone

The development of long-acting formulations of naltrexone was a goal originally envisioned for the treatment of opiate addiction. A long-acting formulation has the advantage of ensuring a steady delivery of medication even in a patient who is ambivalent about taking medication and has compliance problems. The discovery that naltrexone is effective for alcoholism has led to a number of trials with long-acting naltrexone (LA-NTX) in patients with alcohol dependence (155, 156). Both of these studies used formulations that were administered intramuscularly at monthly intervals. The Garbutt et al. (155) study used a dose of 380 mg/month and found a main effect for LA-NTX in reducing heavy drinking by about 50% over a six month trial length. Subjects who were abstinent prior to injection demonstrated the greatest responses and, in these subjects, LA-NTX significantly increased the likelihood of complete abstinence. Kranzler et al. (156), using a different formulation and an initial dose of 300 mg followed by two monthly doses of 150 mg, did not find a significant effect on the primary outcome measure of number of nonheavy drinking days, though a number of secondary outcome measures, including complete abstinence, were significantly improved with LA-NTX. In both of these trials LA-NTX was well tolerated. A concern that long-lasting opiate blockade might present a clinical problem in case opiate medications were needed was not realized. Nevertheless, clinicians need to be aware of this potential issue. Clinical experience with LA-NTX is just beginning and it will be important to gauge its effectiveness in the general clinical setting. The availability of a long-acting medication for alcoholism with demonstrated efficacy is a new and valuable addition to treatment.

14.10.2.3.5. Combinations of Medications

It is clear that for most behavioral disorders combinations of medications sometimes work better than monotherapy. To that end, a variety of medication combinations have been tried in alcoholism. Two trials have examined the efficacy of acamprosate + naltrexone compared to each monotherapy and to placebo. The evidence is mixed. One German study (157) found evidence for superiority of the combination compared to acamprosate or placebo but not to naltrexone. Acamprosate and naltrexone monotherapy were each superior to placebo. A trial in the United States (154) did not find evidence for improved outcomes with the combination but also failed to find a main effect for acamprosate whereas one was found for naltrexone. Naltrexone and acamprosate have also been tried with disulfiram in nonrandomized studies and the combinations appear tolerable though proof of added efficacy remains questionable.

Clinically, based on current evidence, most patients should be offered treatment with either acamprosate, naltrexone, or LA-NTX and then monitored. Some patients may be good candidates for disulfiram. Patients who cannot tolerate one agent should be offered another. In cases where outcomes are less than satisfactory, consideration should be given to combining acamprosate and naltrexone/LA-NTX.

14.10.2.3.6. New Directions

Nalmafene is a newer opioid receptor modulator. It acts as an opioid antagonist at mu and delta receptors and as an agonist at kappa receptors. It has been reported to be safe and effective in a recent 24 week double-blind placebo-controlled trial for treatment of patients with alcohol dependence (158). Six hundred and four alcohol dependent patients were recruited. Half of them were assigned to the active intervention group, the other half received placebo. Patients were instructed to take one tablet on each day they felt they could relapse. Patients who received Nalmafene showed decreased alcohol consumption and their medical status improved with improvement in their hepatic function tests (158). Nalmafene was well tolerated and side effects were mild to moderate and resolved quickly (158). This study shows promise but further research is indicated. Nalmefene is currently approved in Europe.

Although not FDA approved topiramate, which resembles acamprosate in its mechanism of action, was reported to be better than placebo in controlling drinking over a period of 14 weeks (159).

14.10.2.3.7. Pharmacogenetics

An emerging area of science is the identification of genetic polymorphisms that predict treatment response to specific pharmacotherapies. Given the evidence that alcoholism is heterogeneous and that multiple genes are involved in the etiology of alcoholism it would be predicted that genetic variants would preferentially respond to specific pharmacotherapies. However, this area of investigation is very much in its infancy and, so far, no findings have emerged that can be readily translated to the clinic. In a preliminary study, Oslin et al. (160) reported that patients who carried the Asp40 allele for the μ-opioid receptor had better responses to naltrexone than patients who were homozygous for the Asn40 allele. This finding is of interest but needs confirmation. Genetic screening will likely be used by clinicians at some point to help choose a medication for alcoholism.

14.10.3. Overall Effectiveness of Treatment for Alcoholism

O'Brien and McLellan (131) noted that one of the myths about the treatment of addiction is that treatment is not effective. In fact, they presented evidence that the treatment of the addictions, including alcoholism, is probably as effective as the treatment of other chronic medical disorders such as diabetes or hypertension. Furthermore, much depends on the definition of what is successful treatment for the alcoholic. Certainly, long-term abstinence is the primary treatment goal for the alcohol dependent patient but the majority of patients will relapse one or more times after treatment. Should these patients be considered to have failed treatment? O'Brien and McLellan (131) argue no, they should not be considered failures. Other outcomes, including substantial reductions in heavy drinking, should be considered positive in their own right and as way stages on the road to long-term sobriety (161).

The question still arises, how effective is treatment for alcoholism? It is helpful to have a sense of this to be able to inform patients and their families that treatment is effective. To answer this question, Miller et al. (162) examined seven large multisite studies that systematically tracked outcomes. One year after treatment about 25% of patients remained continuously abstinent and another 10% used alcohol moderately and without problems. The remaining 65%, overall, greatly reduced their alcohol use and had significantly fewer alcohol problems. Rates of abstinence and reductions in drinking quantity and frequency will, of course, vary from treatment program to treatment program depending on many factors. Furthermore, some patients will not enter treatment. Nevertheless, the key point noted by Miller et al. (162) and by O'Brien and McLellan (131) is that treatment is effective for many patients and far too many patients never receive treatment.

14.11. Concluding Comment

The understanding of alcoholism as a biopsychosocial disease has changed dramatically since the time of Rush and Trotter in the 1780s and even since the founding of AA in the 1930s. We now know that there is, indeed, a strong genetic factor in alcoholism. We understand at a much finer level of detail the neurobiological and medical consequences that alcohol produces overtime and how these contribute to the progression of the disease. We know that public policy can reduce the deadly consequences of heavy alcohol use given sufficient political will. Yet, our relationship with alcohol remains complex, ambivalent, and conflicted. The majority of adults in the United States consume alcohol. Alcohol is visible at celebrations, in our cities, on our college campuses, and in our media. Physicians all too often avoid discussing the use of alcohol in talking with patients and do not recognize the warning signs of unhealthy alcohol use (163).

Hopefully, one of the next cycles in our relationship with alcohol will be to meld our increasing knowledge of the science of alcohol with a greater awareness and motivation to help the millions of individuals and their families who struggle with the destructive side of alcohol, this "water of life" [(2), pg. 11].

Drug Addiction

Joseph Westermeyer, M.D., M.P.H., Ph.D. and Gihyun Yoon, M.D.

Abstract Drug addiction, a chronic relapsing disorder, causes an enormous burden to patients, families, and societies. This chapter summarizes current concepts of drug addiction, epidemiology, etiology, pathogenesis, pathology, clinical course, laboratory findings, assessment, and treatment on drug addiction. Pathologic consequences from drugs of abuse (e.g., opioids, sedatives, amphetamines, cocaine, cannabis, tobacco, phencyclidine, hallucinogens) are explained as well. The understanding of drug addiction has improved by recent progress in genetics, neuroscience, pharmacology, and psychiatry. It is now possible to treat drug addiction more effectively using advanced psychological and pharmacological interventions.

Keywords Addiction · Drugs of abuse · Behaviors · Course · Treatment

15.1. Definition

Drug addiction is a major health problem that leads to enormous morbidity and mortality. More evidence, especially from animal and neuroimaging studies, has demonstrated that drug addiction is a chronic brain disease, not just a character problem (1, 2), although it can affect personality, moral decisions, and behavior in adverse ways. Repeated drug use causes brain changes in addicted patients, who tend to relapse easily in the context of environmental cues, cravings, or stress. Despite significant negative consequences, drug-dependent patients are often unable to cease their drug use without treatment. Addictive disorders tend to vary widely over time and in various communities, so that environmental factors play a larger role in addictions as compared to many other psychiatric disorders.

Criteria for drug addiction have undergone changes in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) (3). DSM-5 describes drug addiction as a "substance use disorder (SUD)" that combines the former DSM-IV diagnoses of substance abuse and substance dependence. DSM-5 has added drug craving as one of the 11 criteria of SUD, while eliminating legal problems from the criteria (for a detailed list of 11 criteria, please consult DSM-5).

Physiochemical properties of drugs weigh into the diagnosis, but clinical judgment still must be applied regardless of drug dosage. For example, mixed drug abuse, mental retardation, dementia, other psychiatric conditions, comorbid medical conditions, and extreme youth or advanced age may lead to drug-related problems at doses lower than usual. Even relatively mild psychoactive compounds, such as caffeine or tobacco, can lead to disabling symptoms in vulnerable patients or in large doses. Episodes of opioid or cocaine overdose, amphetamine delusional disorder, phencyclidine delirium, or cannabis delusional disorder exemplify other types of pathologic drug use.

Physiological dependence involves the presence of tolerance to the drug or withdrawal upon stopping use. With tolerance, the patient must consume markedly increased amounts of the drug to achieve the desired effect, or there is markedly diminished effect with regular use of the same amount. Sudden drug withdrawal results in abstinence symptoms if tolerance is present. Different drugs produce withdrawal symptoms as follows:

Opioids: Lacrimation, rhinorrhea, mydriasis, piloerection, sweating, abdominal cramps, diarrhea, yawning, anxiety, irritability, mild hypertension, tachycardia, fever, or insomnia.
Sedatives: Nausea, vomiting, malaise, weakness, tachycardia, sweating, hypertension, anxiety, depressed mood or irritability, orthostatic hypotension, coarse tremor, and possible disorientation, hallucinations, or convulsions in severe cases.

Stimulants: Fatigue, disturbed sleep, headache, craving, unpleasant dreaming, or increased appetite.
Tobacco: Craving, irritability, anxiety, depression, or difficulty concentrating.
Cannabis: Anxiety, restlessness, anger, insomnia, decreased appetite, depressed mood, abdominal pain, tremors, headache, sweating, fever, or chills.
Caffeine: Sleepiness, fatigue, difficulty concentrating, depressed mood, or headache.

Onset of abstinence symptoms following the last dose varies with the drug's duration of action, as well as the drug's half-life (the amount of time for half of the drug to be metabolized and inactivated within the body). Withdrawal can begin in 2–6 hours with short-acting drugs (e.g., lorazepam, heroin, morphine, tobacco), in 8–24 hours with intermediate-acting drugs or those with increasing half-lives (e.g., opium, phenobarbital), or in days to weeks with long-acting drugs or those whose half-life has increased with repeated administration of dependence-producing doses (e.g., buprenorphine, ethchlorvynol, diazepam, methadone).

Cannabis withdrawal is included in the DSM-5 (3). Chronic heavy cannabis users experience a need for markedly increased doses to achieve the desired effect and/or markedly diminished effect from regular doses. Lack of clinically significant abstinence symptoms may be due to storage of active cannabis fractions (e.g., tetrahydrocannabinol) in body fat stores, with gradual excretion over days or weeks. In patients with cannabis-related psychosis, symptoms may not abate until these fat stores are depleted of cannabis.

DSM-5 includes tobacco use disorder, which is characterized by tobacco withdrawal syndrome, unsuccessful attempts to stop or reduce its use, or continued use despite a serious tobacco-related physical disorder (e.g., emphysema, coronary artery disease, Berger's arterial disease).

Drugs can induce mental disorders such as delirium, dementia, amnestic disorder, psychosis, mood disorder, anxiety, sexual dysfunction, or sleep disorder. Other drug-related conditions include hallucinogen-induced hallucinosis, hallucinogen or cannabis delusional disorder, and hallucinogen-induced mood disorder. Substance-related amnestic disorder and mood disorder may accompany drug use. Depending on duration and pattern of drug use, these diagnoses may or may not be accompanied by drug addiction.

15.2. Etiology and Pathogenesis

Excessive or problematic drug use and its final common pathways within the brain (i.e., nucleus accumbens, ventral tegmentum, and the frontal lobes) comprise the behavioral and neurophysiological mechanisms for drug addiction. However, numerous risk factors drive these mechanisms so that drug addiction is generally conceived as being multifactorial in its etiology. The public health model of agent (drug), host (drug-using individual), and environment (family, friends, community, society) has proven useful in conceptualizing the complex causes of drug addiction.

15.2.1. Host Factors

15.2.1.1. Genetic Influences

Like many other psychiatric disorders, drug addiction is highly heritable. Genetic components of addiction liability range from 39% for hallucinogens to 72% for cocaine (4). Heritability portions of addiction liability range from 40% to 70% for other drugs, such as stimulants, cannabis, sedatives, tobacco, alcohol, and opioids. One family study reported an eightfold increased risk of substance disorders in relatives of probands with substance use disorders (5). Twin and adoption studies have also demonstrated that substance disorders are correlated with genetic and environmental factors (6, 7). Offspring of heavy tobacco smokers are considerably more apt to become tobacco dependent than the general population (8). Opium-dependent persons show a higher rate of opium dependence among their siblings and relatives than does the general population. Similarly, drug-dependent persons in the United States often have alcoholic relatives, as well as depressed or manic relatives (6).

Several genes contribute to the vulnerability to addictions. The genetic variants of the following genes have been reported to induce addiction vulnerability: the μ-opioid receptor (OPRM-1) gene for alcoholism and heroin addiction (9); catechol-O-methyltransferase (COMT) for heroin, stimulant, tobacco, and alcohol dependence (10); dopamine D4 receptor (DRD4) for

alcohol, heroin, and stimulant addiction (11); serotonin transporter gene (SERT, SLC6A4) for alcohol, tobacco, and heroin addiction (12); and nicotine acetylcholine receptor gene (CHRNB3, CHRNA6) in tobacco addiction (13).

15.2.1.2. Neurobiological Variables

Repeated drug use changes the neurobiological system of the individual addicted to drugs of abuse. In 1954 Olds and Milner reported that rats would stimulate their brain endlessly via implanted electrodes in the pleasure center (14). This center is now known as the reward circuit encompassing the ventral tegmental area (VTA) to the nucleus accumbens. Various drugs of abuse increase dopamine—the "pleasure molecule"—in the reward circuit (15). Dopamine released in this pathway leads to positive reinforcement. Chronic drug use causes neuroadaptations and plasticity (e.g., changes in synapses, gene expression) in the host's brain including the reward circuit. Other areas involved in drug addictions are the prefrontal cortex (e.g., orbitofrontal cortex, anterior cingulate), lateral basal amygdala, and extended amygdala (e.g., nucleus of stria terminalis, central medial amygdala) (16). In the initial stage of addiction, individuals tend to use drugs of abuse to increase positive reinforcement (increasing addictive behaviors to receive pleasure and rewards), but their behaviors become compulsive mainly due to negative reinforcement (increasing addictive behaviors to remove the aversive states) in the later stage of addiction (17).

15.2.1.3. Psychological Variables

Psychological and personality traits usually accompany drug addiction, although it is difficult to ascertain the extent to which these are etiologic or secondary to drug abuse. Factors that initially lead a person to start drug use may change over time so that the original causes may be replaced by different or altered factors that drive continued or increased drug use (18). No one personality type predates drug abuse, although those with chronic pain, anxiety, depression, mania, psychosis, inattention, hyperactivity, impulsiveness, and/or antisocial attitudes appear to be at greater risk. Personality characteristics of drug abusers, perhaps as much acquired as primary, typically include hostile dependence on others, low frustration tolerance, limited flexibility and adaptiveness, low self-esteem, risk taking, and novelty seeking (19).

Several theories regarding host psychology, difficult to test in either laboratory or clinical settings, remain popular but still unproven. The "anxiety reduction theory" states that some people take drugs initially to reduce tension, especially in social settings (20). The "state-dependent theory" holds that drug abusers rely more on internal rather than external cues in making decisions and adjusting to life and thus are vulnerable to exogenous drug administration as a means of modifying internal states (21). The "career-addict hypothesis" suggests that many drug-dependent persons cease their drug-taking career later in life as they "mature out" of drug use (22, 23).

15.2.2. Agent Factors

15.2.2.1. Pharmacology of Drugs of Abuse

Drugs differ in their acute toxicity, chronic toxicity, and relative risk of addiction. For example, addiction liability is highest for cocaine and amphetamine, high for opioids and tobacco, medium for alcohol and benzodiazepines, lower for cannabis, and lowest for hallucinogens (24).

Pharmacologic properties of drugs themselves affect their propensity for abuse. Opioids and sedatives produce rapid, albeit temporary, relief of anxiety, fear, and insomnia. Stimulants relieve boredom, somnolence, low energy, and fatigue. Drugs that alter perceptions or impede memory may aid in blocking out distressing thoughts or feelings. Symptoms relieved by drugs of abuse include pain, hunger, sexual dysfunction, nausea, vomiting, cramps, diarrhea, and cough.

Drugs with more rapid onset of action (e.g., heroin, alprazolam) tend to be preferred for abusive purposes over more delayed-onset drugs (e.g., methadone, clonazepam). Modes of administration with liability for drug abuse include intravenous injecting, smoking, and snuffing, which produce quicker drug effect (several seconds) than subcutaneous injection or ingestion (20 minutes or more).

Tolerance and withdrawal phenomena also contribute to drug abuse syndromes. Tolerance, the need for increasing doses to produce the same effect, is particularly characteristic of opioids and sedatives but also occurs with stimulants, cannabis, and tobacco. As addicted persons consume larger doses to achieve the dwindling target effects due to tolerance, minimal or no tolerance may develop to other unintended effects that become worse with increasing doses (e.g., constipation and sexual dysfunction with opioids, hypertension, and vascular spasm with cocaine). Cessation of drug use in the tolerant individual precipitates withdrawal, a morbid state that persists hours, days, to weeks (depending on the drug) in its acute phase. Subclinical abstinence symptoms can continue for months in the second phase of withdrawal. These subacute abnormalities, best described for opioid

drugs and alcohol, consist of altered sleep patterns, vital signs, and endocrine functions, which may persist for up to a year. Anxiety symptoms, panic attacks, irritability, suspiciousness, low pain tolerance, depressive symptoms, and sometimes manic symptoms may persist for weeks. Sedative or opioid withdrawal produces weakness, anorexia, tachycardia, agitation, insomnia, irritability, social withdrawal, and remorse. Stimulant withdrawal causes fatigue, hyperphagia, bradycardia, and somnolence. In the chronic stages of substance use disorders, drug usage may continue more to avoid withdrawal than to achieve intoxication.

15.2.2.2. Host–Agent and Environment–Agent Considerations

Host factors may interact with drug factors in various ways. Insomniac, anxious, rageful, or chronic pain patients may seek relief of their symptoms in opioids and sedatives. Bored, fatigued, or depressed individuals may pursue liveliness from stimulant drugs. Those seeking a pharmacologic "time out" from their ordinary cognitions may enjoy the effect of hallucinogens.

As availability of a drug increases in the environment, its prevalence increases (22). Distance between sales outlets, hours of sale, and restrictions on sale to minors governs availability of licit substances. Prohibition of a substance usually leads to decreased availability, but this is not inevitably true. Availability of prescribed drugs can be due largely to prescribing habits among physicians. The greatly increased use of benzodiazepines in the late 1960s and 1970s, and their waning use in the 1980s, hinged largely on physician prescribing practices. Amphetamine prescribing, prevalent during the 1950s to 1970s, also declined. The opioid epidemic now raging in the United States and parts of Europe has resulted from overly casual prescribing by licensed prescribers, lax monitoring by clinicians, and the heavy time-and-resource challenge needed for clinicians to address iatrogenic addiction compared with simply filling another opioid prescription (25).

Cost of drugs of abuse influences their use. As price increases, drug use tends to decrease, even if availability is held constant. This is one argument for drug prohibition laws, which often increase the cost of drugs considerably (since they are illicit) but may not greatly reduce availability for those who cannot afford them.

15.2.3. Environmental or Social Factors

15.2.3.1. Social Traditions Regarding Drugs of Abuse

Cultures that effectively prohibit or preferentially ignore certain drugs have little or no problems with them. For example, alcohol abuse is rare in certain Muslim nations that forbid alcoholic beverage for religious reasons. However, sanctions against one substance do not necessarily prohibit use of other drugs. For example, certain Middle Eastern countries have high rates of opioid dependence.

Patterns of use for a particular drug determine the likelihood that the drug will be associated with abuse. Non-ritual use away from family, in a surreptitious fashion, with intoxication as a goal tends to be pathogenic. Safe use occurs primarily when everyone in the society is introduced to the drug experience in a family-sponsored, multigenerational, socially approved, or sacred setting, with ritual feasting and celebration. Peyote use in the Native American Church comprises an example (26).

Only one or a few drugs can be thus woven into the fabric of a society. Families cannot enculturate their offspring into all drugs to which they may be exposed. Cultures generally approve a few mild intoxicants (e.g., tobacco, caffeine, betel–areca) and perhaps a few stronger intoxicants (e.g., alcohol, peyote) but not the more addicting or potentially psychopathologic drugs (e.g., heroin, amphetamine, phencyclidine). Recent state laws permitting cannabis use have shown an increase in use (as one would predict from societal support of use), but problematic use shows early indications of increasing (e.g., more cannabis-related accidents, crime, and health consequences) (27).

15.2.3.2. Drug Laws

Anti-drug laws began to appear several hundred years ago. Prior to 1500 AD, the Aztecs strictly controlled alcohol use by dose, frequency, and social status (28). Asian and European kingdoms enacted laws regarding tobacco and opium in the 1600s AD. Anti-drug legislation accelerated in the eighteenth to twentieth centuries. We are still in the era of worldwide drug diffusion, as modified drugs (e.g., cocaine from coca, heroin from opium), new manufactured drugs (e.g., synthetic opioids, sedatives, stimulants, hallucinogens), and new methods of administration (e.g., skin patches, sublingual preparations) spread from one part of the world to another.

Regulations prohibiting drug use have been most effective in countries with strong centralized power, including both rightist and leftist police states. They have been weakest in democratic and socialist countries that rely heavily on citizen support for compliance. Legislation alone, without other social interventions in education, health, commercial, religious, and ethnic sectors, can exacerbate drug problems by driving drug production, distribution, and use into a criminal subculture (29).

15.3. Epidemiology

15.3.1. Methods of Study

Epidemiologic assessment is key in measuring the extent of drug abuse, in planning interventions, and in observing the results of treatment and prevention efforts over time. Self-report, blood and urine tests, withdrawal signs, and autopsy studies have been used as measures. Sampling methods have ranged from door-to-door surveys to studies of special populations (e.g., students, medical patients, arrested persons in jail).

One special technique used for drug abuse epidemiology is the capture–recapture technique, a method drawn from measuring the number of fish, birds, or other animals in a free-ranging population. In this method, a number of individuals are first "captured," then released, and subsequently "recaptured." For example, the number of diagnosed addicts "captured" in a particular subgroup is measured (e.g., those admitted to a treatment program, say, 100 over a period of time). Then the number of drug abuse cases "recaptured" or surfacing to another group is measured (e.g., deaths in a morgue or arrests by the police, again over a specified period of time). If, say, 1 person out of ten arrested addicts is known to have previously received care at the treatment facility and 100 addicts previously treated at the facility are arrested, then the capture–recapture method would suggest that 1,000 drug abuse persons lived in the community.

Another special method has been the registry, most often used for opioid abusers. One central agency collects data on opioid abusers admitted for treatment or rehabilitation, seeking help at social agencies, arrested, convicted for opioid possession, or dying from an opioid-related cause. Complications used to track drug abuse have included antibodies against serum hepatitis, overdose deaths from opioids and sedatives, and sudden death in association with cocaine use.

The assumptions behind any of these methods may be flawed, leading to estimated rates higher or lower than the true rate. For this reason more than one estimator should be employed. Even if an estimator is flawed, it may be flawed in a consistent way over time, permitting the observation of rate trends over time. For example, mortality from hepatic cirrhosis or drug overdose can reflect age- and gender-related rate changes over time, without necessarily revealing the true prevalence of drug addiction in the population.

15.3.2. Rates of Substance Use Disorder

Prevalence of lifetime and past-year drug use disorder (excluding alcohol or tobacco) is 10.3% and 2.0% in the United States (30). For alcohol use disorder, lifetime and past-year prevalences are 30.3% and 8.5% (31). For tobacco dependence, lifetime and past-year prevalence are 24% (32) and 12.8% (33).

Rates of drug abuse often fluctuate widely over time and from place to place. Several opioid and amphetamine "epidemics" have occurred over the last century. Tobacco dependence increased progressively over the last century among men and more recently among women, although rates among men in the United States have been declining. Cannabis use increased markedly during the late 1960s but has declined somewhat since then while still being widely used. Cocaine use disorder has fluctuated up and down several times from the 1970s until now. Pharmacists annually fill tens of millions of prescriptions for benzodiazepines, with a relatively small but persisting level of abuse. Combined use of opioids with either benzodiazepines or additional secondary opioids has contributed to the greatly increased mortality associated with prescribed opioids (34).

15.3.3. Demographic Characteristics

Men generally engage in drug abuse more frequently than women, although there are exceptions. Betel nut chewing in parts of Asia and prescription sedative abuse in North America and Europe have occurred predominantly among women. In recent years, the rates of tobacco, alcohol, and iatrogenic opioid dependence have been increasing more among American women than men.

Since World War II, drug abuse has begun to affect teenagers to a considerable extent, although it formerly began primarily in adulthood. Elderly people have shown increased rates of alcohol and sedative abuse, often in association with retirement, death of a marital partner, isolation from friends and family in residences for the elderly, major depression, chronic pain, or disabling medical conditions (35).

Socioeconomic variables affect the availability and type of drugs. For example, successful drug smugglers, athletes, and entertainers have had both the money for and access to such drugs as cocaine and heroin. Because of the low rate of drug interdiction by law enforcement officers, students have been able to afford cannabis and other drugs.

Medical workers are especially liable to abuse prescription drugs. Of 10 substance-abusing physicians, 1 is usually abusing drugs only. The remaining 9 are abusing alcohol primarily while often abusing other drugs to offset the effects of alcohol. Drug-dependent physicians have preferred the synthetic opioids in recent years, perhaps because these drugs have been incorrectly touted as less addicting than the opium-based drugs (e.g., morphine). Nurses, pharmacists, and dentists show similar patterns. Some health professionals have abused illicit or "street" drugs, including cannabis and cocaine.

15.4. Pathology

Pathologic consequences from drug abuse vary widely with the drug, dosage, duration of use, and route of administration. In order to provide safe treatment, the clinician must be able to discern intoxication, withdrawal, and overdose for the main drug categories. See Table 15.1 for the symptoms associated with these conditions. Intoxication and overdose tend to exist along a spectrum, with "mild-to-moderate" intoxication being the goal of the typical drug user, but with "severe overdose" posing morbid or even mortal consequences for the patient. For any given drug category, intoxication and withdrawal tend to present as polar opposites of one another due mainly to their neurotransmitter manifestations.

Depending on how much drug the patient has taken, and when, the clinical picture may change dramatically over time. A patient who has not absorbed all of the consumed drug into the blood may progress from intoxication to overdose in the clinical setting. Or a substance-dependent patient may proceed from intoxication into withdrawal.

Depending on the drug, these various clinical stages may be more or less dangerous. With some drugs, some patients, and some clinical conditions, observation over a period of hours or a few days may be the treatment of choice. With other drugs and patients, timely action may be needed to stave off highly morbid or even mortal conditions. If medication is needed, the general rule is an agonist for withdrawal and an antagonist for overdose.

15.4.1. Opioids

Although opioid drugs differ considerably in dosage (see Table 15.2) and duration of action, the maximal potencies of the stronger opioid drugs (e.g., morphine, heroin, fentanyl, methadone) are quite similar. Weaker opioids (e.g., codeine, propoxyphene) cannot equal them, even in large doses. Some opioids, such as pentazocine and buprenorphine, have mixed agonist-antagonist effects, so that increasing the dose or adding it to another opioid drug can precipitate withdrawal symptoms.

Regarding methadone, equivalent doses in Table 15.2 apply only if the patient is not physiologically dependent on the opioid drug. In the presence of tolerance, equivalence between methadone and other opioids cannot be readily determined for two reasons. First, the half-life of methadone lengthens once the dose increases above 20 mg per day, and especially above 40 mg per day. Second, the duration of the increasing half-life and the peak blood level of methadone can differ considerably from one person to the next even after stable doses have been achieved. For both of these reasons, the risk to overdose fatality is great, especially in the hands of clinicians unfamiliar with transitions between other drugs and methadone. A safe transition procedure includes the following steps: administer between 5 and 15 mg doses and then observe the patient for several hours before repeating doses; do not administer more than 30 mg on day one even in a patient with tolerance; and increase by small increments over subsequent days (3–5 mg increments every 3 days).

Buprenorphine is not included in Table 15.2 for three reasons. First, starting buprenorphine in some patients who have another opioid in the nervous system can precipitate withdrawal. Second, like methadone, the half-life of buprenorphine begins to increase beyond 4 mg per day, so that it has no simple equivalence to other opioids above that dose. Third, considerable individual variation in metabolism occurs, so that some individuals may attain atypically low or high blood levels (36).

There are three types of opioid receptors: μ, δ, and κ. Neuroimaging and animal studies have demonstrated that the reinforcing effects and opioid addiction are mediated and modulated mostly by μ-opioid receptor.

Opioids can relieve pain, anxiety, cough, and diarrhea. Especially in the naive user, they produce nausea and vomiting. While early use may relieve social and sexual inhibition, chronic use leads paradoxically to social withdrawal and decreased libido. Tolerance to analgesia begins with the first dose, so opioids are excellent for acute, severe pain but less effective for chronic or recurrent pain.

Acute effects include meiosis or pinpoint pupils (which occur with most but not all opioids), constipation, urinary hesitancy, hypotension, and lethargy. Coma and possibly death by respiratory depression can result from overdose. Arrhythmias, heart block, or death may also result from a prolonged QT duration of the heart rhythm, especially in those with familial prolongation of the QT, older age, and concomitant treatment with other medications prolonging the QT interval. The withdrawal syndrome, beginning 4–36 hours after the last dose (depending on the opioid drug and dose), consists of agitation, piloerection, dilated pupils, muscle aches, and abdominal cramps with elevated pulse, blood pressure, and temperature. A subclinical withdrawal syndrome consisting of sleep disturbance, irritability, vital sign fluctuations, and autonomic nervous system lability may persist for several months in tolerant individuals (37).

TABLE 15.2. Dose equivalents of opioid drugs in patients without opioid dependence.

Drug	Dose equivalent (mg)		Dosing interval (hours)
	Oral	Parenteral	
Morphine	30	10	3–4
Codeine	130	75	3–4
Diamorphine	12.5	5	3–4
Fentanyl	NA[a]	0.1	1–2
Hydromorphone	4–6	1.5	3–4
Hydrocodone	60	NA	3–4
Meperidine	150–250	75	3
Methadone	10	5	3–4
Oxycodone	20	15	3–4

[a]*NA* not available (50 mcg/hour patch).

TABLE 15.3. Dose equivalents of benzodiazepines in patients without sedative dependence.

Drug		Dose equivalent (mg)	Half-life (hours)
Generic	Trade		
Alprazolam	Xanax	0.25	12
Chlordiazepoxide	Librium	10	100
Clonazepam	Klonopin	0.5	34
Diazepam	Valium	5	100
Lorazepam	Ativan	1	16
Midazolam	Versed	1.5	3
Oxazepam	Serax	15	8
Temazepam	Restoril	5	11
Triazolam	Halcion	0.1	2

15.4.2. Sedatives

These drugs include the benzodiazepines, barbiturates, glutethimide, methaqualone, chloral hydrate, paraldehyde, and ethchlorvynol. Although showing cross-tolerance with alcohol, they are synthetic and chemically dissimilar to each other. Sedatives with rapid onset of action tend to be abused more readily. Longer-acting sedatives produce a more stable withdrawal regimen.

See Table 15.3 for equivalent doses of the sedatives. The half-lives depicted are averages; the spectrum ranges considerably lower to higher for these medications. Note the long half-lives of diazepam and chlordiazepoxide—two effective medications for treatment of sedative or alcohol withdrawal. The use of shorter-acting benzodiazepines produces a stormy withdrawal course, with patients alternating between agitation and delirium as blood levels wane, with lethargy to stupor when levels are high.

Benzodiazepines and barbiturates act on the ionotropic γ-aminobutyric acid (GABA) type A receptor. When substances are attached to GABA receptor, GABA opens the chloride channel to render the cell less excitable. Sedative drugs are more apt to be abused by those presenting to physicians with symptoms of insomnia, palpitations, tachycardia, headache, epigastric burning, or similar psychophysiologic symptoms of anxiety. Much sedative abuse in the United States has an iatrogenic component. Careful psychiatric assessment and monitored prescribing reduce sedative abuse.

Duration of action and margin of safety differ widely among the sedatives. Like the opioids and alcohol, they can produce tolerance if taken chronically in increasing doses. Acute effects include incoordination, dysarthria, lethargy, and somnolence; overdose leads to coma and death by respiratory depression. Prolonged QT duration with heart block and sudden death can occur with some sedatives, such as the benzodiazepines, in vulnerable persons. The withdrawal syndrome consists variably of tachycardia, fever, hypertension, headache, agitation, and tremor. Seizures, confusion, delusions, and hallucinations occur in severe cases. Onset of withdrawal can occur within several hours after the last dose of short-acting sedatives or within several days to weeks with the long-acting sedatives (38).

15.4.3. Amphetamines and Similar Drugs

These drugs (including methylphenidate) are often abused by night workers, those doing prolonged repetitive work requiring alertness (e.g., truck driving), or chronically dysthymic individuals. Amphetamines facilitate the release of two neurotransmitters: (1) dopamine from presynaptic vesicles, thereby increasing the robust reinforcement effects, and (2) norepinephrine,

thereby increasing pulse, blood pressure, metabolic rate, and sometimes temperature. Stimulant effects on the central nervous system include mydriasis, tachycardia, elevated mood, heightened self-confidence, alertness, dry red skin, and wakefulness with a decrease in rapid-eye-movement (REM) sleep.

Tolerance and increased daily doses occur in chronic users. Confusion, panic, and paranoia may ensue, and a psychotic state similar to schizophrenia or mania can persist for days, weeks, or months. Hyperthermia, hypertension, arrhythmias, convulsions, and cerebrovascular accidents accompany overdose. Withdrawal consists of lethargy and increased REM sleep. Depression, which often appears following withdrawal, may be a withdrawal effect, a sign of an emerging primary depression, or some combination of both (37).

15.4.4. Cocaine

Like amphetamines, cocaine abuse is apt to ensue in the user who is bored, fatigued, or depressed. Since the intoxicant effect is extremely short compared with other drugs of abuse, the user may snort, smoke, or inject drugs several times an hour to sustain the drug effect. Under such circumstances, the cost of a cocaine habit can mount readily. The heavy user may become financially destitute or enter an illegal occupation (e.g., drug smuggling or selling, burglary, prostitution) to obtain the drug (39). Despite cocaine's brief duration of action, its metabolite benzoylecgonine remains detectible in urine for a few days following use.

One form of cocaine is the hydrochloride form, taken by injection or snorting. The paste form, used for smoking, involves an extraction from coca leaves using a dangerous combination of kerosene and sulfuric acid. Cocaine potentiates catecholamine effect by interfering with reuptake of dopamine, norepinephrine, and serotonin at their transporter sites. Its effects are similar to those of amphetamine but with a half-life persisting over minutes rather than hours. Certain complications resemble those of amphetamine use, such as paranoia, hallucinations, or hypertension.

15.4.5. Cannabis

Although numerous psychoactive compounds exist in cannabis, most of its effect appears to be due to delta-9-tetrahydrocannabinal. Cannabinoids bind to the cannabinoid receptors. Potency of cannabis preparation varies with proximity of the farming site to the equator, climate, plant species, part of the plant consumed, and procedures to increase potency (e.g., hashish). Consumed by eating or smoking, its effect persists for a few to several hours, depending on dose, tolerance, and pattern of use.

Many people seem able to consume small amounts of cannabis at infrequent intervals (i.e., weekly or monthly) without ill effect. Vulnerable individuals may experience hallucinations, delusions, or confusion at low doses. With chronic, heavy use, the percentage of impaired users probably increases.

Intoxication involves aspects of both stimulation and depression, sympathetic and parasympathetic manifestations (40). These include dry mouth, increased appetite, tachycardia, injected conjunctivae, and relaxation. Coordination for simple tasks is not impaired at lower doses, although balance, estimation of time, and complex tasks become increasingly impeded with higher doses. Minutes may be perceived as hours. This may contribute to the enhanced sexual enjoyment reported by some or the impaired speed estimation and distance measurement causing vehicular accidents (41). Short-term memory loss leads to disjointed thinking, with consequent silliness, social withdrawal, or panic.

Some tolerance occurs with chronic use. The cannabis withdrawal syndrome includes anxiety, irritability, chills, sweats, malaise, insomnia, decreased appetite, and craving. Since tetrahydrocannabinol is stored in fat, chronic users may excrete the drug for days or even weeks following the last use.

15.4.6. Tobacco

Whether consumed by smoking, snuffing, or chewing, tobacco's psychoactive effect is largely due to nicotine. Like cocaine, the half-life of nicotine is brief (under an hour). Many carcinogens (e.g., tar) exist in tobacco. Nicotine, which mimics the effects of acetylcholine, acts as a mild stimulant. Nicotine mediates the reward effect and addiction by increasing dopamine in the reward circuit. Although smoking produces almost instantaneous effect, absorption after oral ingestion is slow. Chewing produces an intermediate onset. Effects include increased heart rate, gastric atony, and peripheral vasoconstriction. Large doses may produce nausea, emesis, and convulsions. One cigarette ingested by a small child can be lethal. Withdrawal effects include bradycardia, irritability, and increased appetite.

Heavy smokers maintain plasma nicotine levels by smoking tobacco about every half hour. Tobacco consumption in dependent persons may be linked to such biologic events as waking up, eating, and bowel movements. Smoking also reinforces

activities (e.g., meeting with friends, sexual encounters). If the nicotine content in a cigarette is decreased, dependent smokers adjust by increasing their inhalations.

As a mild intoxicant with few or mild effects on cognition, mood, and coordination, tobacco rarely produces acute problems. However, it can produce numerous, sometimes catastrophic, damage to health, including heart disease, emphysema, Berger's disease, and lung cancer. Health complications increase markedly after 20 pack-years of smoking (i.e., one pack per day, per year, over 20 years). Although tobacco dependence is notoriously difficult to reverse permanently, nicotine withdrawal or replacement pharmacotherapy, bupropion, varenicline, motivational enhancement, cognitive-behavioral approaches, and physician recommendations to cease tobacco use are effective (42). During tobacco cessation, weight gain is a frequent complication.

15.4.7. Caffeine

In lower doses of 50–150 mg, caffeine reduces fatigue and enhances mental activity while causing some tachycardia, vasodilatation, and diuresis. It produces these effects by stimulating catecholamine release. Higher doses (i.e., over 600 mg per day) may produce excitement, agitation, headache, irritability, and insomnia. Withdrawal symptoms in high-dose users (i.e., over 1,000–1,200 mg per day) can include fatigue and somnolence (43).

Caffeine is present in many common beverages, including coffee (120–150 mg per cup), tea (50–80 mg per cup), cocoa, colas (50–70 mg), and other soft drinks. It also occurs in many over-the-counter and prescription drugs taken for pain, appetite suppression, and the common cold. Excessive caffeine use can cause dependence, manifested by withdrawal (i.e., headache, fatigue, craving) and tolerance (44).

15.4.8. Volatile Hydrocarbons

These substances have acute psychotoxic effects similar to alcohol, but with a shorter half-life, often under an hour. Effects include ataxia, dysarthria, elation, and silliness. Special populations such as prisoners, industrial workers, or children sniff them, since they are available, inexpensive, and short acting. Aerosols, glue, cleaning and industrial solvents, and paint thinners can produce hepatic, renal, hematologic, or neurologic damage depending on the chemical, pattern of use, and individual propensity (45). Early symptoms of chronic use, which may come to the attention of a pediatrician or psychiatrist, are irritability, declining academic or occupational performance, memory loss, and personality change. Amyl nitrate use for sexual enhancement has led to chronic abuse (46). Endemic and epidemic use has prevailed among children over the last several decades. Originally reported in American Indian and Hispanic communities, it has spread to other communities.

15.4.9. Phencyclidine (PCP)

PCP functions as an antagonist at the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. This versatile drug may be ingested, snuffed, smoked, or injected. Its effects are variable, so it may produce relaxation or panic, hypotension or hypertension, decreased reflexes, or status epilepticus. In general, however, it potentiates adrenergic effects. Impurities from illicit production may cause anticholinergic effects. Body-image distortions, agitation, and hallucinations are common in PCP users coming to clinical attention. Vertical or horizontal nystagmus, muscular rigidity, and dystonic reactions are clues to the diagnosis. Half-life is relatively short but after-effects can continue over hours or a few days due to enterohepatic recirculation. Acute and chronic users may present to emergency rooms with various psychiatric syndromes from panic attack, to mania, to psychosis, and to delirium (47).

15.4.10. Hallucinogens

These include natural substances (e.g., peyote, morning glory seeds) and synthetic compounds (e.g., n-lysergic acid, or LSD). LSD functions as a partial agonist at the serotonin type 2 (5-HT2) receptor. Altered perceptual states are produced; panic, hallucinations, and delusions may occur. While the half-lives of these drugs are only a few hours, psychic effects may persist for 6–12 hours. Hallucinosis can continue for a few to several days in unusual cases. Vulnerable individuals can experience first episodes or recurrences of mania, psychosis, delusional disorder, or schizophrenia. Physical manifestations are few, except for possible anticholinergic toxicity with dry warm skin, increased pulse, urinary hesitancy, and memory disturbance (47). Accidental poisoning can precipitate a psychiatric emergency, with hallucinations and panic.

15.5. Clinical Picture

15.5.1. The Great Imitator

The clinical picture depends on the drug, duration of abuse, route of administration, the individual's nutritional status, associated medical and psychiatric problems, and socioeconomic impairment. Impairment may be minimal, with early or mild signs or symptoms, or so severe that signs and symptoms irrefutably support the diagnosis. Patients may hide, alter, or accurately describe their drug use and its associated problems, depending on their openness, wish for help, and extent of discomfort. A key factor is the clinician's comfort and skill in aiding patients to relate their history. A nonjudgmental attitude toward patients is critical. Clinical skill as well as judgment in managing drug abuse cases requires supervised clinical training. Without training and experience, the clinician is not likely to perceive the clinical picture accurately nor to manage the case in a supportive and therapeutic fashion.

Substance abuse has been called the "great imitator" of our time for good reason. It may present with medical, psychiatric, or surgical pictures. Drug abusers are found in medical settings more frequently than expected from their number in the population. Drug-related problems are proportionately more common among inpatients than among outpatients. Patients may present quite early in their course or in severely advanced stages. The problem may be acute or chronic, life threatening or minor, readily discerned or vague, and difficult to define. See Table 15.4 for psychological manifestations during early, middle, and late stages of addiction.

15.5.2. Data Collection

Substance use disorders tend to be progressive, beginning with an early phase and advancing into middle and late phases; see Table 15.5. Substance-related behavior comprises a core aspect of these changes over time, but other behaviors also show changes (e.g., grooming, control, reliability, conversation). The rapidity at which these phases progress varies with the type of drug, the individual, and the environment. The entire course may telescope down to a few years or may proceed over several decades.

Drug abuse patients usually seek clinical help in response to some coercive force, either external (e.g., family, work supervisor) or internal (e.g., malaise, depression). An important step in management involves delineating this coercive force. Complicating this process is the patient's frequent lack of awareness regarding the relationship between the current problem and the drug use. Another obstacle may be a tendency to blame others for the current problem rather than to take responsibility for the problem. As with other elements of the addictive course, social consequences and malfunction tend to advance over time; see Table 15.6.

Since drug abuse may present with various surgical, medical, or psychiatric problems, the clinician will want to inquire routinely about each patient's use of drugs. See Table 15.7 for the biomedical harbingers that mark the addicted person's deteriorating health. In order to rule drug abuse in or out, the physician must know each patient's drug use type, dose, duration, pattern of use, and route of administration. Drug abuse patients typically do not volunteer symptoms indicative of depression, anxiety, panic, or psychosis. Specific inquiry is necessary.

TABLE 15.4. Phases of: psychological factors in substance use disorder.

Characteristic	Early phase: problematic usage	Middle phase: chronic dependence, addiction	Late phase: deterioration
Motivation	Uses to enjoy, build up confidence, relieve insomnia and anxiety, etc.; use becomes increasingly important	Uses to feel normal; use is as important as family, friends, work	Enjoys usage less but cannot stop; use becomes the central element of person's life
Emotional concomitants	Mood swings related to usage (anger, remorse, anxiety, shamed or anxious regarding usage); feels weak and remorseful	Personality change and increasing emotional lability; ambivalent about usage; feels guilty, resentful, inadequate, and inferior	Erratic, suspicious, and often apathetic; defensive regarding usage; feels alone, deserted
Cognitive processes	Obsesses regarding next usage; reduced interests and ambition; focuses thoughts and conversation on chemical usage	Increasing self-pity, deteriorating self-image; self-deception regarding usage and effects; loses sense of time	Confused, projects own problems onto others; unable to conceptualize current status objectively
Judgment, insight	Begins to exercise poor judgment; still able to extricate self from most problems; episodic insight and concern with drug or alcohol usage	Large proportion of decisions lead to problems; problem solving increasingly ineffective; avoids being insightful, although capable of insight	Extremely poor judgment in most matters; unable to solve own problems; is not insightful even during abstinent intervals

TABLE 15.5. Phases of behavioral factors in substance use disorder.

Characteristic	Early phase: problematic usage	Middle phase: chronic dependence, addiction	Late phase: deterioration
Drug usage	Increasing amounts and frequency of use	"Titer" or "binge" usage; attempts at abstinence	Continuous usage; uses "substitute" intoxicants
Control over usage	Begins attempts to decrease amounts or frequency of use	Begins to lose control (takes more than intended or for a longer period than intended)	Loses control most of the time
Drug-related behavior	Seeks occasions to use; chooses friends who use heavily; may begin to be secretive about usage	Increased need to use at specific times and places; develops ingenuity at obtaining, paying for, hiding, and using drug	Compulsive usage, despite many problems associated with usage and decreased enjoyment from drug or alcohol; plans daily activities around usage
Drug effects on behavior	Episodic intoxication, dysarthria, and emotional lability; attempts to hide drug or alcohol effects from others	Impairment between intoxication episodes: trite expressions and "non sequiturs" prevail in conversation; fatigue; decreased productivity	Poor grooming and disheveled dress; lack of interest in appearance; unconcern with opinions of others

TABLE 15.6. Phases of social factors in substance use disorder.

Characteristic	Early phase: problematic usage	Middle phase: chronic dependence, addiction	Late phase: deterioration
Interpersonal relationships	Changes associates, from abstainers to moderate users to heavy users	Alienates others by arguing, embarrassing, and taking advantage; breaks promises and lies	Manipulates others to obtain drug or alcohol; compensatory bragging
Family	Argues with family over usage; spends less time at home; neglects family emotionally	Abuses family by lying, stealing, or fighting; spends most of time away from home	Alienated from family; lives away from family
Employment	"Monday morning" absenteeism; conflict with boss	Decreased job efficiency; changes jobs often or is fired; decreasing job prestige; holds jobs for shorter periods	Day labor; unemployed, on relief or social welfare
Residence	Stable residence; lives with others	Begins moving from place to place; loses roommates and family members	Lower socioeconomic neighborhood; lives alone
School[a]	Decreasing grades; complaints from teachers	Suspension from school; school dropout	Requires special educational and rehabilitation facilities
Legal effects	May have legal problems; driving while intoxicated; disorderly; assault	Usually has legal problems and large attorney fees; may be litigious	Defaults on contractual obligations; may be imprisoned for property offenses and manslaughter
Finances	Spends family funds on drug or alcohol; may take extra job to support habit; may become extravagant	Spends ¼ to ½ of annual income on drug or alcohol; heavily in debt and bankruptcy	Spends most of income on drugs or alcohol; destitute
Social Affiliations	Discontinues social activities not involving usage (e.g., church, hobby, theater, sports)	Drops formal group affiliations (e.g., union, guild, club); begins short-lived companionship with chemically dependent persons	Becomes an involuntary client of social institutions

[a]For chemically dependent persons attending school.

TABLE 15.7. Phases of biomedical factors in substance use disorder.

Characteristic	Early phase: problematic usage	Middle phase: chronic dependence, addiction	Late phase: deterioration
Pharmacology	Tolerance increases; larger doses used to relax and relieve insomnia or other symptoms	Withdrawal effects; blackout (for alcohol); morning or daytime usage to alleviate withdrawal	Decreased tolerance (early onset of intoxication or blackout); delirium tremens or withdrawal seizure (with alcohol or sedatives)
Common health problems	Injuries: vehicular or industrial accidents, falls, and burns	Infections: respiratory, urogenital, and skin; injuries; accidental overdosage; suicide attempts	Parenteral users: septicemia, pulmonary edema, endocarditis; alcohols: cirrhosis, pancreatitis, myocarditis; violence: injuries, homicide, suicide; nutritional problems: vitamin, protein, mineral deficiency
Sexual effects	May initially enhance sexual function	Sexual problems: impotence, frigidity, promiscuity or extramarital liaisons, and venereal disease	Difficulty obtaining sexual partner; purchase of sexual services; loss of interest in sex; prostitution to obtain funds for drug
Common symptoms	Insomnia, boredom, chronic anxiety, headache, palpitation, tachycardia, flatulence, belching, cramps, epigastric distress, irritability, puffy face or extremities	Sweating, apprehension, decreased libido, visual disturbances, myalgia, malaise, obesity, diarrhea, weight change (loss or gain), memory lapses, weak, fatigues easily, "dry heaves," depression, panic, fears	Bad taste, impotence, halitosis, cachexia, persistent abdominal pain, seizures

Reprinted from (48), copyright (1988) with permission from Springer Science + Business Media.

Formal mental status examination may reveal unsuspected deficits in orientation, memory, or cognition. Physical examination can demonstrate evidence of parenteral injection (e.g., venous tracks, skin-popping scars), chronic smoking (e.g., rales and rhonchi), malnutrition, infectious diseases, and traumatic sequelae. Neurologic findings (e.g., ataxia, dysarthria, pupillary changes), autonomic signs (e.g., flushing, perspiration, piloerection), and vital sign abnormalities (e.g., tachycardia, hypertension) provide valuable clues. Table 15.2 lists the signs associated with various drugs.

15.5.2.1. Case Report

A 24-year-old single woman presented with opioid dependence and amenorrhea for four months. She had been discharged from military duty, following a 1-year deployment in Iraq. While in Iraq, she developed headache, insomnia, chronic anxiety, and episodic panic attacks associated with combat-related events (e.g., mortar attacks, injury and death of other service members). During a trip to a nearby country, a friend shared her prescribed opioid medication with her. Her anxiety symptoms abated, her headaches ceased, and she was able to sleep. Back in Iraq, a military provider prescribed opioids for her during the remainder of her deployment. Upon returning to the United States and civilian life, she continued taking opioids, both prescribed and not prescribed. She also "partied" with other veterans from Iraq, leading to her unplanned pregnancy. All of her nuclear family members had a substance disorder, although three were in stable recovery and one was actively abusing "street" opioids. Subsequently, she did well on maintenance opioid medication, delivering a healthy child and complying with treatment. Treatment of her chronic anxiety, secondary mood symptoms, solo parenting, and maturation from a "child of addicts" background posed many challenges in her intermediate term care.

This case exemplified the prominence of iatrogenic (as opposed to "street") opioids in current practice. Exposure to opioids via a friend's opioid prescription, preexisting anxiety symptoms, familial–genetic factors, and casual opioid prescribing all facilitated her addiction. Sudden separation from the military, a post-deployment "party" subculture with casual sexuality, and familial predisposition also fostered her vulnerability to opioid dependence. Maintenance opioid therapy contributed to a healthy newborn and abstinence from drug seeking but was not sufficient to alleviate the psychosocial obstacles that she faced. Her struggle continued over several years, with alternating relapse and recovery efforts.

15.5.3. Analysis of the Findings

Acute drug-related problems are generally related to pharmacologic actions of the drug itself or the route of administration. These include intoxication, overdose, and medical emergencies such as agitated delirium or trauma—or, as in this case, intrauterine pregnancy. The initial problems were due to psychosocial challenges from flawed child raising, combat exposure, lax prescribing practices, and a post-deployment "party" subculture. Special clinical presentations depended on the patient's age, gender, family history, drug exposure, and the setting.

15.6. Clinical Course

The typical course of untreated, chronic drug abuse is deterioration over a period of years, often with periods of relative stabilization or brief improvement followed by further deterioration. Acute problems associated with recent drug abuse may cause the disorder to be self-limiting if the consequences motivate the user to moderate or cease drug usage. However, spontaneous abstinence from drugs occurs infrequently among those with recurrent episodes of drug abuse or with chronic drug dependence. Disability or premature death may ensue in time.

Progression over time likewise varies with the drug, route of administration, various host, and environmental factors. Other things being equal, routes with rapid drug onset (i.e., injection, smoking, snuffing) hasten the morbid course over slower routes of administration (e.g., ingestion, chewing). Drugs with shorter half-lives (e.g., heroin, lorazepam, cocaine) lead to a more rapid course than those with longer half-lives (e.g., opium, diazepam, amphetamine). More potent drugs (e.g., morphine) hasten and increase the morbid effects over weaker drugs in the same category (e.g., codeine). Some drugs produce typical medical complications (e.g., tobacco) or neuropsychiatric complications (e.g., phencyclidine) as their first manifestation, while others are more apt initially to produce psychosocial consequences (e.g., sedatives, opioids). Drugs with potent effects, rapid onset, and shorter half-lives (e.g., cocaine, heroin) lead to treatment within about 3 years of initiating their drug abuse, whereas drugs with less potent effects, slower onset, or longer half-lives (e.g., diazepam, opium) may continue 10 years or longer before treatment results (48).

Age at onset influences the course, so opioid dependence beginning at age 15 affects the patient's life course differently from opioid dependence beginning at age 35 or 55 years. Younger individuals have not yet had the opportunity to complete their education, learn an occupation, become employed, marry, have children, or otherwise establish some social competency. Normal phases of psychosocial maturation lag or fail to evolve in the face of severe drug abuse. Older drug abusers

TABLE 15.8. Phases of treatment approaches in substance use disorder.

Characteristic	Early phase: problematic usage	Middle phase: chronic dependence, addiction	Late phase: deterioration
Prognosis without treatment	Some spontaneously improve, some progress to later stages	Small percentage (<10%) spontaneously improve; most progress to later stage	Virtually no spontaneous improvement; a few "plateau"; most deteriorate rapidly
Most effective treatment modalities	Mutual-help groups; marital and family therapy; pharmacotherapy for 1–2 years (e.g., antidepressants, disulfiram, anti-craving, medication); partial hospitalization (e.g., day only, evening only, weekend only)	Pharmacotherapy (e.g., buprenorphine, methadone, disulfiram, anti-craving, medication); mutual-help groups; marital and family therapy; intensive outpatient program, long-term outpatient treatment program, and halfway house	Pharmacotherapy (e.g., buprenorphine, methadone, disulfiram, anti-craving, medication)/intensive outpatient program; residential treatment: special long-term units, nursing home, quarter-way house, mutual-help groups
Prognosis with treatment	Optimal: 60–80% "significantly improved" at 1 year post-treatment	Good: 40–60% "significantly improved" at 1 year posttreatment	Fair: 10–40% improved at 1 year; high mortality and morbidity rate in remainder
Cooperation with treatment	Willing to undertake a prolonged period of abstinence, see physician regularly, and follow treatment recommendations	May enter treatment only with pressure by family, employer, court, friends, and physician	May need to be coerced by society (e.g., incarceration, legal commitment into treatment)

Reprinted from (48), copyright (1988) with permission from Springer Science + Business Media.

coming to treatment usually have more biomedical problems and social isolation; younger drug abusers experience more legal, occupational, and family problems.

Tables 15.4, 15.5, 15.6, 15.7, and 15.8 describe phases in the course of drug abuse. Course progression is not always as consistent as shown in the tables. A patient may show early changes in some areas and more advanced changes in other areas.

Treatment often, but not always, alters the natural course of drug abuse. See Table 15.8 for prognosis with and without treatment, fitting treatment to addiction phase, and typical levels of treatment compliance across phases. In general, treatment earlier in the course tends to be more effective and less costly. Later treatment, especially after occupational loss and alienation from family, is less apt to be effective. Even in advanced cases, however, treatment often reduces the patient's morbidity and may set the stage for eventual recovery. Assuming that patients cannot recover, and that chronic deterioration is inevitable, can set up a self-fulfilling prophecy.

Acute phases of recovery, precipitated by medical, psychiatric, or social crises, proceeds over several weeks. Treatment involves medical stabilization, crisis intervention, and an assessment of psychosocial resources and liabilities. The intermediate phase of recovery involves autonomic nervous system stabilization (e.g., stable vital signs, normal gastrointestinal function), resolution of emotional distress, and social reentry; it continues over several months. In successful recovery, psychological well-being, social fulfillment, and occupational stability in the final phase of recovery typically require several years.

Brief but increasingly less frequent return to drug abuse often occurs during the early months of recovery. Although pharmacologic factors greatly influence the pretreatment course, the posttreatment relapse rates for heroin, alcohol, and tobacco (in the absence of ongoing outpatient treatment) are remarkably similar, as shown in Fig. 15.1. Modern treatment methods have changed the shape of this curve appreciably by increasing the 1-year recovery rates—often as high as 35–75 % depending on the substance, the treatment, and the characteristics of the patient group.

15.7. Laboratory Findings

Laboratory tests for drug abuse are of two general kinds. One set of tests involves direct assessment of drugs, such as drug levels in body fluids. Another set of tests involves indirect biochemical, physiologic, and psychological tests to assess the extent of impairment produced by drugs, such as hypovitaminosis, secondary infections, or psychosocial dysfunction (e.g., unemployment). These tests augment but cannot substitute for a thorough history, psychiatric interview, mental status assessment, and physical examination. Collateral sources of information may include medical or other records, reports from family or friends, as well as information from other professional sources (e.g., teacher, court, probation officer). Another assessment technique is the "test of time," in which the individual is observed and reassessed over time in order to assess the severity of the condition and the potential for recovery.

Many drugs of abuse or their metabolites can be found in urine for 12–48 hours after the last dose and sometimes longer in the case of chronic use (e.g., cannabis, amphetamine, benzoylecgonine). Qualitative urine tests are useful for screening in high-risk situations, such as emergency rooms, orthopedic and psychiatric hospital admissions, and certain target groups

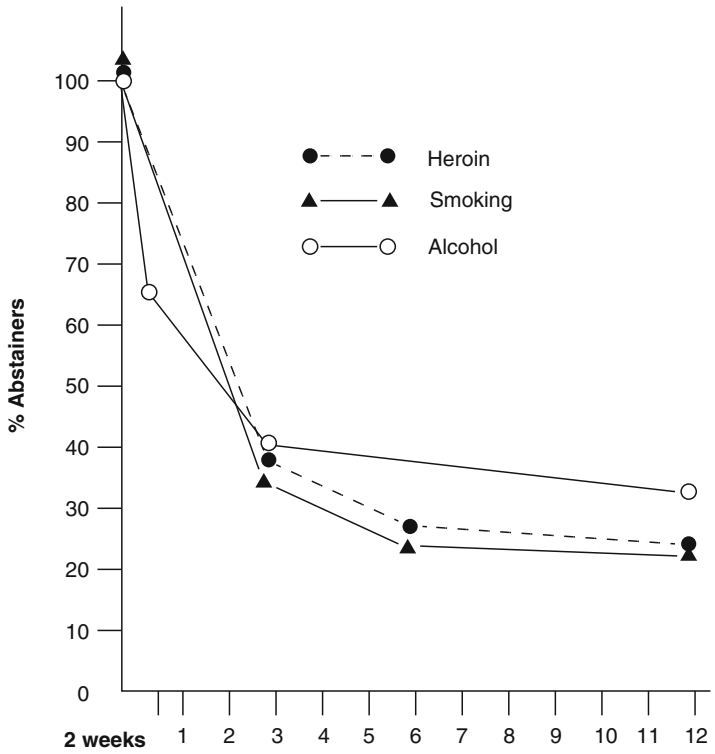

FIGURE 15.1. Relapse rate over time for heroin, smoking, and alcohol. From: Figure 15.1 reprinted from relapse rates in addiction programs, Hunt WA, Barnett LW, Branch LG, Journal Clinical Psychology 27:455–456, Copyright (1971) John Wiley and Sons.

(e.g., trauma victims, brittle diabetics, treatment failures). Quantitative blood measures are usually required only for special instances, such as management of overdose or forensic evaluation. Naloxone challenge, specific for the diagnosis of opioid dependence, consists of administering parenteral naloxone and observing for the opioid withdrawal syndrome.

Other laboratory tests not specifically measuring drugs can aid in assessing the severity of the drug abuse problem. Acute intoxication or recent withdrawal may produce abnormalities on the electroencephalogram, which can suggest specific drug effects to the experienced electroencephalographer.

Biochemical tests for renal and hepatic function reflect drug-related tissue damage to these organs. Vitamin (e.g., carotene or folic acid), serum iron, and serum protein levels can reveal nutritional neglect. With chronic drug abuse, many patients experience mild-to-moderate endocrine dysfunctions reflected in abnormal thyroid tests, electrolyte disturbances, hyperglycemia or hypoglycemia, and/or an abnormal dexamethasone suppression test. Chronic smoking can produce increased respiratory dead space, decreased vital capacity, prolonged rate of timed expiration, and abnormal blood gases. Parenteral injection of drugs can give rise to chronic viremia (hepatitis B and C, HIV), positive blood cultures, an elevated sedimentation rate, high white blood cell count, or an increased gamma globulin fraction in the serum protein. Depending on the psychiatric picture, abnormalities may occur on personality tests (e.g., the Minnesota Multiphasic Personality Inventory), intelligence tests (e.g., Wechsler Intelligence Scales), and organicity tests (e.g., Bender-Gestalt). Traumatic injuries (from fights or falls) may show up on x-rays as healing fractures of the ribs or extremities or on neuroimages as damaged or poorly perfused brain tissue. Electrophysiological measures may reveal abnormal, possibly pathognomonic abnormalities (49).

Response to treatment can be assessed by following both the first category of tests (e.g., direct drug measures) and the second category (e.g., tests of impairment or secondary complications), especially when these have been abnormal previously.

15.8. Differential Diagnosis

Differentiating drug abuse from other psychiatric disorders can be difficult. Substance abuse and psychiatric disorder coexist in one-quarter to one-third of psychiatric inpatients and in about the same or higher proportion of substance abuse patients. Drug abuse may develop as an attempt at self-treatment for a preexisting disorder (e.g., stimulant abuse for depression, sedative abuse

for anxiety or mania). Or secondary psychiatric disturbances (e.g., depression, panic attacks) may appear during the course of drug abuse or during recovery from drug abuse. Secondary sociopathy may attend the disinhibiting effects of certain drugs. Hostile-dependent behavior is a common secondary behavioral manifestation that usually clears with successful recovery.

Drug effects may mimic psychiatric disorders. For example, caffeine, cocaine, or amphetamine intoxication can produce symptoms like those of anxiety or mania. Withdrawal from these drugs may resemble depression or, less often, paranoia. Acute cannabis, phencyclidine, or hallucinogen intoxication may present clinically as acute psychosis, manic psychosis, or delirium due to a medical condition.

Drugs also may precipitate psychiatric syndromes, which persist well beyond the drug effect in the body—a phenomenon called "kindling." Acute or chronic use of cocaine, amphetamine, cannabis, phencyclidine, and the hallucinogens may bring about a lengthy illness indistinguishable from schizophrenia or bipolar illness. In some cases, the drug-precipitated disorder (once successfully treated) does not recur. In other cases, the disorder may recur even without subsequent drug abuse, as in this case.

15.8.1. Case Report

A 19-year-old college student became acutely and floridly psychotic following her first use of hashish. She failed to respond to high doses of antipsychotic medication prescribed over several weeks but did recover with a course of ECT and subsequent antipsychotic treatment. A discharge diagnosis of schizoaffective disorder was made. Over the subsequent year, her medication was reduced without incident. She later completed graduate school, worked for a few years, and married. Within weeks following the birth of her third child, at age 31, she developed insomnia, racing thoughts, euphoric mood, grandiose plans, and poor judgment (but without hallucinations or delusions). Antipsychotic medication (in low doses) along with lithium, prescribed on an outpatient basis, led to resolution of her symptoms over several weeks.

In this case it appears that drug abuse may have precipitated as well as exacerbated the first episode. The second episode, without drug abuse, was milder and responded more readily to treatment. The patient's course suggests that hashish alone did not produce the first illness but rather precipitated the illness in a person with a premorbid potential for mood disorder.

Drug effect from opioids, sedatives, stimulants, cannabis, phencyclidine, and the hallucinogens, as well as the volatile hydrocarbons, may produce an acute brain syndrome due to substances, with confusion and delirium. Chronic brain syndrome due to substances is less common but can occur. Certain volatile hydrocarbons can, with chronic use, produce dementia pictures similar to alcohol-induced dementia. Sedative and opioid abusers also may demonstrate it, probably from recurrent hypoxia secondary to respiratory depression or from head trauma due to falls or fights. Caffeine and tobacco may produce chronic brain syndromes indirectly as a result of secondary medical complications (e.g., hypertension, emphysema).

15.9. Treatment

15.9.1. Drug-Related Emergencies

Intoxication is managed simply by observing and protecting the individual until the drug is metabolized or excreted. It is important to ensure that the patient does not injure self or others while the drug is being metabolized and/or excreted. Involuntary hospitalization may be necessary for 2 or 3 days during this phase.

Overdose is managed on medical or psychiatric units, depending on the nature of the problem and the type of drug. Specific antidotes are available for three drug types liable to abuse: opioids, anticholinergics, and benzodiazepines. Naloxone for opioid overdose and physostigmine for anticholinergic overdose share two common features. First, dosage must be individualized for each patient, and second, repeated doses at 2- to 3-hour intervals are necessary because their duration of action is considerably shorter than those of many drugs of abuse (particularly when taken in large doses). Flumazenil can be used as the benzodiazepine antagonist, but it is seldom used due to potentially serious complications. Rarely, dialysis may be necessary for sedative overdose; very high blood levels, rapidly progressing stupor, and depression of vital signs comprise indications for dialysis. Acidifying the urine hastens the excretion of phencyclidine and amphetamines, while alkalinization aids excretion of some barbiturates.

Withdrawal treatment hastens recovery, reduces mortality, and aids in establishing the doctor–patient relationship. It may induce the suffering patient, still ambivalent about giving up drug dependence, to enter treatment. Opioid and sedative withdrawals are managed by using a long-acting drug that is cross-tolerant with the drug being abused. Some clinicians use antidepressant or stimulant drugs for more severe cases of stimulant withdrawal, but minimal pharmacotherapy is needed in most stimulant withdrawal. The first step consists of administering enough drug to make the patient comfortable, even to the point of mild sedation. Patients in severe withdrawal may require the first dose intravenously, since the toxic patient may not absorb well via oral ingestion or subcutaneous injection. The half-life of the drug administered should be at least as long as that

of the drug being abused and preferably longer (e.g., diazepam for lorazepam dependence, methadone for heroin dependence). Otherwise, the patient will be in and out of withdrawal, frequent doses will be necessary, and the withdrawal will be stormy and prolonged. For sedative withdrawal, some clinicians prefer to administer a shorter-acting drug initially in case the patient requires respiratory assistance with the stabilizing dose. Duration of the withdrawal is shorter for short-acting drugs and longer for longer-acting drugs. For short-acting drugs, such as lorazepam or heroin, 3- to 5-day withdrawal regimens are adequate for resolution of acute symptoms. Intermediate-acting drugs, such as clonazepam or opium, require 10–20 days depending on the degree of dependence and the patient's medical condition. Longer withdrawal regimens, lasting up to several weeks or a few months, may be needed for the long-acting drugs that accumulate in the tissues and are slowly released, such as diazepam and ethchlorvynol. Doses should be administered on a routine basis rather than as requested by the patient. For example, a 20% daily reduction would cover a 5-day withdrawal or 10% daily reduction for a 10-day withdrawal. Some mild insomnia or discomfort may still occur during withdrawal treatment. Symptom-relieving drugs (i.e., analgesics, sedatives, antiemetics) may alleviate the latter but may mask underlying medical or psychiatric disorders (48).

Methadone, a μ-opioid receptor agonist, differs from most other drugs in that the half-life (the duration of half of the absorbed dose in the body) increases with larger doses over time (50). At 5 mg administered four times a day, the half-life resembles that of morphine (3–4 hours). Repeated daily doses above 20 mg per day gradually increase the half-life to 12 hours and beyond. Non-tolerant individuals may experience respiratory depression at doses in the 30–40 mg range. Clinicians using methadone for opioid withdrawal treatment should be experienced, as fatal iatrogenic overdoses have resulted in the hands of clinicians unfamiliar with opioid withdrawal manifestations or methadone pharmacokinetics. Alpha2-adrenergic agonists (e.g., clonidine, lofexidine) are other options to alleviate opioid withdrawal by controlling autonomic symptoms. Common medical complications associated with drug abuse should be considered early during patient assessment. These include nutritional abnormalities, acute and chronic infections, and occult trauma (e.g., subdural hematoma).

Buprenorphine withdrawal also presents some unusual characteristics (36). Case reports show that withdrawal is mild and lasts only a day or two, regardless of dosage (51). This phenomenon may be due to the strong affinity and slow release of buprenorphine from the mu receptor site. Small withdrawal doses may simply prolong withdrawal.

Referral to special drug treatment programs may be necessary if those providing early medical care do not have resources and skills for further treatment. Patients commonly view such a referral as a rejection by the physician. This can be avoided by making an appointment for the patient a few weeks after the referral. The follow-up appointment assures the patient that the clinician is not abandoning him or her and provides an opportunity to assess the efficacy of the referral.

15.9.2. Assessing the Phase of Recovery

The following phases of treatment entry and recovery have been validated (52):

- Precontemplation: drug user has given no thought to stopping drug use or seeking help.
- Contemplation: drug user has considered cutting back or stopping drugs or seeking help.
- Preparation/determination: drug user has decided to cut back or stop drugs or seek help.
- Action: drug user has cut back or stopped use or sought help.
- Maintenance: former drug user maintains sobriety through pro-sobriety affiliations and activities to prevent relapse.

Discovering the drug user's preparedness for recovery is key to successful intervention. Assisting the patient through this process may require many months, although it can happen rapidly in crises.

The critical element lies in the clinician's undertaking interventions that are matched to the drug user's recovery phase. Pushing an action when the patient is in the contemplation stage will not work. At that stage, the goal is to assist the patient in moving from precontemplation to contemplation.

15.9.2.1. Case Report

The police brought a 19-year-old man to the emergency room with facial lacerations sustained in a fight at a music concert. He had consumed two pills given to him by friends, which he assumed were "herbal highs." A regular drug and alcohol user since age 15, he had recently moderated his use following the suicide death of his best friend several weeks earlier. He initially refused referral to care, as he thought his drug use was not out of control. The ER resident obtained a urine toxicology screen, called the patient's mother to pick him up, and contacted the psychiatry resident. The urine screen revealed methadone and a benzodiazepine, to the patient's surprise. In a dialogue with the patient and his mother, the psychiatry resident established that the mother had become alarmed at the patient's deterioration and considered court commitment. At the end of several hours in the ER, the patient concurred that his drug use had escalated beyond his control, and he agreed to an outpatient consultation the next day in the company of his mother.

In this case, the patient moved from precontemplation to contemplation ("I need to cut back") and then to a decision ("I will go to an evaluation with my mother"). He followed this through with an action (showing up for the evaluation). The unusual rapidity in this case was probably due to several concurrent crises: the recent death of his friend, his consuming drugs whose contents he did not know, an avoidable and disfiguring injury to his face, the unexpected urinalysis results, discovery of his mother's plans, and the resident's conveying to the patient that he had a drug abuse diagnosis (heavy pattern of use, continued use despite a series of drug-related consequences).

15.9.3. Treatment Modalities

Modalities for treatment of drug abuse are numerous and include the following: Psychotherapies and sociotherapies include individual, couple, family, and group therapies; relapse prevention therapy; motivational enhancement and verbal aversion therapies; contingency contracting therapy; social skills learning; and day, evening, or weekend program; these approaches assume sobriety, a stable residence, and some daily employment or other productive activity.

Pharmacotherapies: Several old and new medications have been used to manage addictions, not only for detoxifications but also for relapse prevention. For the treatment of severe opioid dependence, methadone and buprenorphine maintenance programs have been successful in decreasing illicit opioid consumption as well as medical, social, and legal consequences related to opioid use. Buprenorphine, a partial μ-opioid agonist and a κ-opioid antagonist approved by the FDA for treating opioid dependence can be prescribed in a primary care office setting instead of highly regulated methadone programs. Buprenorphine has less abuse potential and better safety profile than methadone. During the induction phase, buprenorphine is initiated while monitoring the patient daily for 3–7 days until a stable dose is reached. Typically, the induction doses are 2–8 mg daily, with 4–8 mg daily increases. During the maintenance phase, most patients take between 8 and 24 mg of sublingual buprenorphine. Buprenorphine can be also used as a transition medication from illicit opioid drugs to naltrexone. Naltrexone is a μ-opioid antagonist and blocks the euphoric effects of opioids. Supervision, monitoring, and contingency management are required to increase compliance with naltrexone. Monthly naltrexone injection can prevent relapse for patients recovering from opioid use disorder.

Several medications have been approved by the FDA for alcohol dependence: disulfiram, naltrexone, acamprosate, and long-acting injectable naltrexone.

No medication has been approved by the FDA for the treatment of cocaine dependence, but several medications have been reported effective in clinical trials. These agents work by increasing dopamine levels (disulfiram, amantadine, bromocriptine), enhancing GABA system (baclofen, carbamazepine, tiagabine), or decreasing adrenergic activities (propranolol) (53).

For tobacco dependence, several medications have been approved by the FDA and widely used in primary settings. These interventions include nicotine replacement therapy (transdermal nicotine patch, gum, nasal spray, nicotine inhaler, lozenge) or non-nicotine oral agents (bupropion, varenicline). Nicotine and cocaine vaccines have been under investigation.

Somatotherapies: electroacupuncture (54) has proven beneficial for opioid withdrawal and for maintenance of selected cases.

Residential treatment includes special recovery-oriented residential facilities, halfway houses, and therapeutic communities; these alternatives can be useful for the unemployed or homeless patient.

Properly speaking, mutual-help groups are not a form of treatment, although often quite therapeutic. They include Narcotics Anonymous, Alcoholics Anonymous, Al-Anon (for relatives or friends of those with substance use disorders), and other drug-specific, ethnic-specific, gender-specific, or occupation-specific groups. These groups can be useful at any phase of recovery, from precontemplation to maintenance.

If major psychiatric problems persist beyond a few to several days in association with substance use disorder, these problems will probably not resolve spontaneously. Continuation of major depression, psychosis, mania, and other major disorders beyond 2 weeks almost always calls for specific treatment and rehabilitation rather than expectant observation. If the patient responds rapidly and completely to low doses of medication, a lengthy course of medication may not be needed. Close monitoring should accompany a slow medication taper in such cases.

Minor or less disabling psychiatric syndromes are common in the early weeks of recovery. These may include adjustment reactions, a period of generalized anxiety, or a few panic attacks. If these are decreasing in severity and becoming less frequent, specific treatment may not be necessary. On the other hand, increasing, severe, or disabling symptoms generally require psychiatric treatment.

15.9.4. Treatment Goals, Outcome, and Efficacy

Treatment for drug abuse may be aimed at total abstinence, reduction of drug use, or removal of problematic aspects of continued drug use. Generally, abstinence, temporary or permanent, is the explicit goal. Simple reduction in drug dose, with continued use, is rarely effective over the long term but may result in a temporary reduction in symptoms or problems. Licit substitution of illicit opioid consumption in methadone or buprenorphine maintenance programs can appreciably help selected patients.

Treatment success is related to many factors besides treatment modalities themselves. As indicated above, matching treatment approach to the patient's recovery phase is critical. In addition, patients who are doing better at the end of 1- and 2-year follow-up studies show one or more of the following characteristics vis-à-vis treatment:

- Occupied as employees or students.
- Residence with the family or with sober persons.
- Treatment-seeking earlier rather than later in the event of relapse.
- Compliance with treatment recommendations.
- Involvement of the family in treatment.
- Continued treatment or self-help on a regular basis over 1 or more years.
- Pharmacotherapy, as warranted and appropriate to the case, by controlling drug cravings and stabilizing the central nervous system related to drug addictions.
- Treatment of comorbid psychiatric disorders: Psychiatric symptoms are much more frequent in patients with addictive disorders. Anxious and depressed addicts tend to relapse readily after addiction treatment. Proper evaluation and treatment of comorbid psychiatric disorders can contribute to relapse prevention.

Acute detoxification and medical management alone tend to have limited long-term efficacy. This is also true of residential treatment alone without subsequent outpatient care. Under such circumstances, the rate of abstinence 1 year following discharge is low. With continued outpatient care, plus case management in severe cases, the rate of abstinence at 1 year can range higher. Since those abstinent and doing well at the end of 1 year have good outcomes in most cases, the first year of outpatient care is critical.

Cost/benefit from treatment also must be considered. For decades treatment research did not take into account cost, skills of clinic staff, and applicability of treatment approaches to patients in community settings (55). In recent years a national Clinical Trials Network (CTN) has tested not only treatment efficacy but also the feasibility of drug addiction treatment in community settings (56). This CTN initiative, combined with increased understanding of addiction neurobiology (57), is forging links between professional resources and community-based, patient-centered, recovery resources (such as mutual-help groups, "drug courts," and monitored residential facilities).

Sexual Disorders: Dysfunction, Gender Identity and Paraphilias

Jon E. Grant, M.D., J.D., M.P.H. and Nancy C. Raymond, M.D.

Abstract Sexual disorders in the Diagnostic and Statistical Manual for DSM-5 are divided into three major categories: 1) sexual dysfunctions, problems in sexual desire or disturbances in the psychophysiologic changes that are part of the sexual response cycle, 2) Paraphilias, which involve recurrent intense sexual urges or fantasies, or behaviors that involve unusual objects, activities, or situations that are by and large not culturally sanctioned, and 3) gender identity disorders, which are characterized by dissatisfaction with one's biological gender and often a desire to undergo gender reassignment. In this chapter we will review the diagnostic criteria, prevalence, etiology, assessment and treatment of these disorders.

Keywords Sexual dysfunction • Paraphilias • Gender identity disorder • Sexual health • Compulsive sexual behavior

16.1. Introduction

Sexual disorders in the Diagnostic and Statistical Manual for DSM-5 (1) are divided into three major categories:

1. Sexual dysfunctions. Problems in sexual desire or disturbances in the psychophysiologic changes that are part of the sexual response cycle.
2. Paraphilias, which involve recurrent intense sexual urges or fantasies, or behaviors that involve unusual objects, activities, or situations that are by and large not culturally sanctioned.
3. Gender identity disorders, which are characterized by dissatisfaction with one's biological gender and often a desire to undergo gender reassignment.

Psychiatric research in the sexual and gender identity disorders lags behind research in many other areas of psychiatry. Less is known about the associated disorders, course, familial patterns, and etiology. Prior to summarizing the criteria, prevalence, assessment and treatment of the sexual disorders we will present a brief discussion on the determinants of sexual health.

16.2. Sexual Health Defined

The World Health Organization (WHO) and others have arrived at an understanding of the components of sexual health (2–5). According to these sources, sexual health is an approach to sexuality founded in accurate knowledge, personal awareness, and self-acceptance where one's behavior, values, and emotions are congruent and integrated within a person's wider personality structure. The definition of sexual health involves the ability to choose to be intimate with a partner, to communicate explicitly about sexual needs and desires, and to be sexually functional, to have desire, become aroused, and attain sexual fulfillment. It also involves acting intentionally and responsibly and having the ability to set appropriate sexual boundaries. Additionally, sexual health has a communal aspect reflecting not only self-acceptance and respect but also respect and appreciation for individual differences and diversity. Sexual health includes a sense of self-esteem, personal attractiveness and confidence, as well as freedom from sexual dysfunction, sexually transmitted diseases, and sexual assault and coercion. Sexual health affirms sexuality as a positive force enhancing other dimensions of one's life. In treating all of the sexual disorders described below the goal should be to assist the patient in achieving a healthy expression of their sexuality.

16.3. Sexual Dysfunction Disorders

Sexual Dysfunctions are disorders characterized by a disturbance in sexual functioning or desire (Table 16.1). DSM-5 provides subtypes and specifiers for each of the Sexual Dysfunctions. Whereas the subtypes are carried over from DSM-IV-TR, the specifiers have been expanded to more accurately reflect the variety of factors that can impact sexual functioning. The subtypes of *lifelong* and *acquired* refer to the onset of the sexual dysfunction. Lifelong refers to the failure to develop normal sexual functioning at puberty which then persists, whereas the acquired subtype refers to situations in which the person develops sexual dysfunction after having had normal functioning. Specifiers include *Situational* and *Generalized*. The Situational subtype refers to sexual dysfunction that occurs only in certain situations, with certain types of sexual stimulation, or with particular partners. The generalized type refers to sexual dysfunction that occurs independent of the situation, the partner or the type of stimulation. The Situational subtype is less likely to be due to a medication side effects or a medical condition. In addition, DSM-5 provides additional specifiers. Sexual dysfunction often occurs within a relationship and therefore *Partner factors* (e.g., a partner's erectile problems) may play a role as well as *Relationship factors* (e.g., sexual incompatibility). In these contexts, it may be difficult to determine whether the partner or relationship factor gave rise to the sexual dysfunction, results from the sexual dysfunction, or the two are interactive. Individual vulnerability factors, cultural/religious factors, and contributory medical factors are also explicitly listed in DSM-5 as contributing to or playing a role in the sexual dysfunction. These specifiers recognize that in many cases, the causes of sexual disorders are multifactorial and many variables may partially contribute to the etiology of a disorder.

16.3.1. Male Hypoactive Sexual Desire Disorder

According to the DSM-5, hypoactive sexual desire disorder is characterized by a recurrent lack of interest in or thoughts about sex (1). As with all of the other sexual dysfunction disorders, the disturbance must cause marked distress and the dysfunction should not be due to another psychiatric disorder or the physiologic effects of a substance or general medical condition. One of the complexities of making this diagnosis is that the clinician makes the judgment as to whether the man's

TABLE 16.1 Categorization of sexual dysfunctions.

Sexual dysfunction	Diagnostic criteria
Male hypoactive sexual desire disorder	Decreased interest in sex or thoughts of sex.
Female sexual interest/arousal disorder	Chronic problems with attaining or maintaining sexual desire.
Erectile disorder	Problems sustaining an erection.
Female orgasmic disorder	Chronic inability to achieve orgasm.
Delayed ejaculation	Chronic delay in achieving orgasm.
Early ejaculation	Problem of achieving an orgasm too quickly.
Genito-Pelvic pain/penetration disorder	Chronic pain associated with intercourse.

interest in sex is deficient (1). This of course assumes that the clinician has received adequate training on sexual functioning in men and women across the life cycle. If this has not been covered in the individual physician's training it places the burden on the practitioner to make sure they have educated themselves on this topic. The DSM-5 also emphasizes the importance of assessing the patient and partner for desire discrepancy since an apparent low desire in one partner may actually reflect the unusually high desire in the other partner.

DSM-5 has made significant changes in Hypoactive Sexual Desire Disorder. The current disorder only applies to men who have diminished desire for sexual activity and few if any sexual thoughts or fantasies. DSM-5 has created a new diagnosis for low sexual desire and arousal problems in women (i.e., Female Sexual Interest/Arousal Disorder). Other than the general changes to the category of Sexual Dysfunction in DSM-5, as stated above, the criteria for Male Hypoactive Sexual Desire Disorder are essentially unchanged from DSM-IV-TR.

16.3.1.1. Prevalence

Most studies that have reported on rates of hypoactive sexual desire disorder (HSDD) have used the DSM-IV-TR criteria and have found that in individuals between the ages of 18 and 59, 15.8% of men report persistent low desire (6). The prevalence of HSDD increases with aging particularly above the age of 60 (7).

16.3.1.2. Etiology

Low desire can be due to psychological factors, medical factors or some combination of factors. Often it is difficult to distinguish the etiology of the disorder. Biological factors include general medical conditions, psychiatric disorders, or disorders of the genitals in men. A multitude of medications and legal or illegal substances can also diminish sexual desire, including medications prescribed by psychiatrists: for example, serotonergic reuptake inhibitors, tricyclics, and monoamine oxidase inhibitors, antipsychotic medications, sedative hypnotics, and stimulants can all lower sexual desire (8). Other categories of medications that are particularly problematic are anti-hypertensives, including the beta-blockers and calcium channel blockers, intramuscular depo provera used for birth control, and any medications that bind testosterone (9, 10).

There are many psychosocial factors that affect desire, including discord in the relationship, psychosocial and life stressors, major life changes, such as marriage, divorce, change in job, health problems in family or children, or occupational stress (11). Finally, presence of other sexual disorders can affect desire. Clearly, any of the sexual pain disorders are likely to be associated with low desire. Discomfort with sexual orientation or gender identity disorder can all affect desire. Low desire disorders are not necessarily associated with orgasmic disorders and patients suffering from desire disorders still may be able to experience orgasm with adequate stimulation.

16.3.1.3. Assessment

Assessment of patients with low desire must include a thorough psychiatric and psychosocial history. Patients with low sexual desire should receive a general medical evaluation that includes screening for disorders such as cardiovascular disease, diabetes, or neurologic conditions that can affect sexual desire. A genital examination should be done to rule out infection, poor or excessive hygiene, or other medical abnormalities as causes of the low desire. Laboratory studies should include thyroid function tests, as either hypo- or hyperthyroidism can be associated with changes in sexual desire, hemoglobin, and testosterone levels, and any other labs as indicated by the history or physical exam (11). Low testosterone in men may be a factor that contributes to low sexual desire (12) so obtaining a level can be useful.

16.3.1.4. Treatment

While it is crucial to do a medical and sexual function work up on patients with low sexual desire, the majority of the time there are no clear biological findings. Frequently, treating or correcting the biological problem or even reducing or changing medications when indicated does not reverse the low desire. Psychotherapy by a therapist trained in treating sexual disorders is generally indicated.

Treatment of low sexual desire involves first identifying and treating any underlying medical conditions, replacing medications that may be affecting low desire, if possible, or substituting them for medications that have less effect on desire. Psychosocial issues must be addressed. For instance, presence of emotional or sexual abuse and general health issues must

be addressed. Issues of fatigue, depression and anxiety, lack of leisure time, sexual desire discrepancies, and communication difficulties are often contributing factors that need to be examined. Often for these issues couples or group psychotherapy is required. Sexual education regarding normal male sexual response cycles and variability in sexual response and practices is an important component of therapy.

There are no pharmacological treatments for low sexual desire that have well-documented efficacy (12). Testosterone supplementation may be effective to treat men with low desire who have low testosterone levels or low levels of bioavailable testosterone (13). Due to potential side effects, testosterone levels should be monitored. Unless a psychiatrist is well versed in administration and the potential side effects of these medications referral to a practitioner who has this experience is recommended.

16.3.2. Female Sexual Interest/Arousal Disorder

16.3.2.1. Criteria and Prevalence

DSM-5 has combined aspects of both Hypoactive Sexual Desire Disorder and Female Sexual Arousal Disorder to create *Female Sexual Interest/Arousal Disorder*. The disorder applies when a women has either a lack of interest in sexual activity or an inability to attain or maintain arousal. The name change reflects the common experience that desire and (at least subjective) arousal highly overlap. In some women desire precedes arousal; in other women, desire follows arousal. There are inconsistencies in how desire is defined, with some focusing on sexual behavior as an indicator of desire, with some definitions focusing on spontaneous sexual thoughts/fantasies, and others emphasizing the responsive nature of women's desire. The word "desire" in Hypoactive Sexual Desire Disorder has been changed to "interest" as desire connotes a deficiency and often implies a biological urge. The phrase "…an adequate lubrication-swelling response of sexual excitement" in DSM-IV-TR Female Sexual Arousal Disorder has been eliminated because evidence suggests that increases in vaginal blood flow during exposure to sexual stimuli may be a relatively "automatic response," and one that women may or may not be aware of. Further, there is little evidence that women with a sexual arousal disorder have impaired genital response; lubrication may or may not co-occur with subjective arousal (14, 15). For instance, a large British study of women 18 to 70 found that 17% of the women reported problems with arousal that was not associated with vaginal dryness (16). This was also true of 5% of the women in the SWAN study (17). It is interesting to note that in women subjective feelings of arousal are poorly correlated with genital response. Women can report feeling sexually aroused without significant physiological changes and may have measurable physiologic changes without reporting subjective arousal.

16.3.2.2. Etiology

In an outstanding review of sexual desire and arousal disorders published in *The New England Journal of Medicine* in 2006, Basson discusses physiologic factors that may affect genital vasocongestion in women (15). In postmenopausal women, low estrogen levels and vaginal atrophy are associated with reduced levels of vaginal congestion when a woman is not receiving sexual stimulation. However, the percent increase in response to sexual stimuli is similar either in the presence of low or high estrogen levels (18). If there is sufficient stimulation even women with estrogen deficiency may become adequately lubricated. However, in about 40% of women vaginal atrophy does adversely affect sexual functioning and sexual response (19). There is a debate about the role of oral contraceptives in affecting sexual function. Oral contraceptives increase levels of sex binding globulin, which leads to reduced free testosterone levels that could affect sexual function (20). There has been a lot of debate over the role of low testosterone in contributing to female sexual arousal disorder and the use of testosterone in the treatment is quite controversial. However, no correlation has been found between sexual arousal and serum testosterone in large population studies of women (21). There are multiple medical issues that can contribute to arousal difficulties in women, including diseases such as multiple sclerosis, renal failure, and premature menopause by chemotherapy (15). Obviously psychological and psychiatric problems can affect sexual functioning. Significant stress or discord with a partner can contribute to difficulties with arousal.

16.3.2.3. Diagnosis

A history, physical examination, including a gynecological exam, and laboratory testing need to be done to rule out medical illnesses that may be contributing to female sexual interest/arousal disorder. A careful history needs to be taken regarding potential psychological and relationship issues that may be contributing to the problem. Ideally partners would be interviewed together, as well as individually in order to understand the relational issues. The Brief Index of Sexual Functioning

Inventory is a validated 21-item self-report inventory assessing sexual interest, activity, function, and satisfaction that can be used in this circumstance (22).

Vaginal photoplethysmography is a specialized vascular test for female sexual arousal (23). A tampon sized light source and detector instrument is used to record vaginal blood flow during sexual stimulation. Duplex Doppler ultrasonography, laser Doppler, and laser oximetry are other methods for assessing female genital blood flow. It is important to note that objective vascular tests have repeatedly shown a lack of correlation with subjective awareness of vaginal vasocongestion (23).

16.3.2.4. Treatment[1]

There are two excellent recent reviews of treatment of interest/arousal disorder in women by Basson (15) and Arlt (24). The latter focuses specifically on the use of testosterone in women. Basson concludes, "At the present time I would not recommend any pharmacotherapy pending the availability of more (and long-term) data in support of such treatment" (15). However, she does review the possible available therapies, including sildenafil, because of the involvement of nitric oxide in neurogenic vasodilatation during sexual arousal in women (15). In a small trial of women with genital arousal disorder some women reported improvement (25). However, in two larger trials in women with a combination of arousal and desire disorders there was no improvement in either desire, sensation, lubrication, or satisfaction (26). Sildenafil is off-label in women and since the teratogenic potential is unknown it can only be used in women with extreme caution.

Estrogen has been proposed as a possible treatment of low desire in women. The vaginal estradiol ring, which delivers local low-dose estrogen to the vagina seems to be a safe treatment for women with dyspareunia or lack of lubrication secondary to postmenopausal vaginal atrophy (15). The Women's Health Initiative Trial raises important questions about the safety of systemic estrogen for this purpose.

There has been much discussion and many publications regarding the use of androgen therapies to treat low desire in women. In a comprehensive review published in the *European Journal of Endocrinology*, Arlt (24) concluded:

1. Androgen replacement seems to be a promising option for the treatment of women with established causes of severe androgen deficiency, including surgical menopause or adrenal insufficiency if they concurrently suffer from symptoms of impaired mood and libido.
2. Importantly, impairment of libido is multifactorial in origin and in the majority of cases is not associated with androgen deficiency.
3. It is important to acknowledge that physiological menopause in women with intact ovaries is not associated with a sudden loss of androgen synthesis unlike the steep drop in ovarian estrogen production; therefore, postmenopausal women do not routinely require androgen replacement.
4. The slow, age-associated decline in Dehydroepiandrosterone (DHEA) and DHEA sulfate may well represent a physiological, protective mechanism, e.g., preventing increased sex steroid action in breast tissue.
5. More long-term studies in larger cohorts of women with severe androgen deficiency are needed comprehensively to assess both potential beneficial and adverse effects.

Basson and Brotto (25) also agree that low dose testosterone patch applied twice weekly administered concurrently with estrogen is helpful for women who have undergone surgically-induced menopause; however, one must be concerned about the potential androgenic side effects, including hirsutism, acne, insulin resistance that may predispose to metabolic syndrome, and a potential decrease in the high density lipoprotein (HDL) cholesterol level.

A non-pharmacologic agent that can be used to treat arousal disorder in women is the Eros-CTD (11). This is an FDA approved device designed to improve arousal by increasing blood flow to the clitoris. The woman applies a small plastic cup to the clitoris and engages a battery operated vacuum pump several times a week. Studies show no adverse events and improvement for most users in sensation, lubrication, and orgasm [reviewed in (11)].

16.3.3. Erectile Disorder

Erectile disorder applies to situations when a man is unable to attain or maintain an adequate erection. This can happen at the outset of a sexual encounter, while attempting to penetrate, or during thrusting. Some men are able to have an erection only during masturbation. If the man fails to have erections upon awakening or during masturbation, a medication side effect, a general medical condition, or a drug of abuse should be considered as a potential cause. To make the diagnosis of erectile

[1] Editor's comments: A new FDA-approved medication named Flibanserin has been introduced into the market for the treatment of female arousal disorder, recently.

disorder, there needs to be one of three problems with either attaining an erection, maintaining an erection, or absence of rigidity in erection that impact negatively on sexual activity.

16.3.3.1. Prevalence

According to a review by Beutel et al. (27), the prevalence of erectile dysfunction varies according to age. It is about 2.3% in men 30 to 39 years old and up to 5.9% in 40 to 49 year olds. The reported range in 50 to 59 year olds is 2% up to 30.8% depending on the series, and 11% to 55% for those up to age 60. Reported prevalence for those over 70 ranges from 15% to 53% and 80 and above 64% to 76%.

16.3.3.2. Etiology

There are multiple medical problems that can account for organic causes of erectile dysfunction and these medical causes should be ruled out before assuming that there is a psychological basis for the disorder. The patient should be worked up for disorders such as hypertension, heart disease, diabetes mellitus, elevated cholesterol or other lipid levels, kidney disease, hypogonadism, and possible lower urinary tract infection (27). Many of the medications used to treat the previously mentioned disorders can cause erectile dysfunction, in particular the antihypertensives and serotonin reuptake inhibitors. Psychiatric disorders such as depression and anxiety can have a marked negative effect on erectile function. Use of substances, particularly narcotics, alcohol, and marijuana, are associated with erectile dysfunction. Finally, a history of surgeries, such as prostatectomy or rectal surgery may be associated with neurologic causes of erectile dysfunction.

16.3.3.3. Diagnostic Testing

The review article by Wespes et al. (28), summarizes the major specialized diagnostic testing for erectile dysfunction. The gold standard test is the nocturnal penis tumescence and rigidity (NPRT) test that should be administered on two specific nights using the RigiScan®. The RigiScan® is a portable device that is used to assess erectile rigidity at the base and the shaft of the penis during an erection, and the duration of the erection. This device is considered to be more accurate than the older snap gauge, which was made up of cellophane strips of known tensile strength that is attached to the penis with Velcro®. During an erection the cellophane strips break. Nocturnal penile tumescence monitoring is based on the assumptions that males without erectile difficulties or with exclusively psychogenic erectile difficulties attain full erections four to six times per night during rapid eye movement sleep. However, men who have a disturbance of REM sleep or disorders such as sleep apnea may have false positive tests.

Other vascular studies include intracavernous injection of a vasoactive drug to determine if there is vascular insufficiency responsible for the erectile dysfunction (28). If the test is inconclusive, a duplex ultrasound of the penile arteries can be obtained. If the duplex examination is abnormal, penile artery arteriogram and dynamic infusion of the cavernosometry and cavernosography should be performed in patients who may be candidates for reconstructive vascular surgery. Neurologic studies can also be done to test the integrity of the neurologic system, including bulbocavernosus reflex latency and nerve conduction studies (28).

16.3.3.4. Treatment

Treatment options fall into four basic categories (28). First, healthy lifestyle changes may help reduce the comorbidity of certain medical conditions. Second, addressing organic problems, such as hormonal abnormalities or changing medications to minimize side effects is a reasonable approach. Surgical interventions include revascularization procedures, particularly for young patients with pelvic trauma. Third, psychosexual counseling and therapy can be very useful to address non-organic causes of the disorder. Finally, oral pharmacotherapy can be an option.

There are now four approved phosphodiesterase type 5 (PDE5) inhibitors (28). Treatment with these medications causes increased arterial blood flow leading to smooth muscle relaxation, vasodilatation, and penile erection. Sildenafil, tadalafil, vardenafil, and avanafil are the four medications currently approved. Side effect profile and duration of action vary between the medications and these issues should be discussed thoroughly with the patient before selecting a medication. Side effects can include orthostatic hypotension, headache, flushing, dyspepsia, change in vision or muscle pain. PDE5 inhibitors are contraindicated with organic nitrates when used to treat angina and amyl nitrate ("poppers") taken as a recreational drug. Nonarteritic anterior ischemic optic neuropathy is a rare but serious side effect so patients who have had a previous but possible transient severe loss of vision should be referred to an ophthalmologist before PDE5 inhibitors are prescribed. These medications should only be administered by psychiatrists if they are willing to do the medical workup necessary to rule out

other potentially treatable causes of the erectile dysfunction and contraindications to taking PDE5 inhibitors. These medications are also used by psychiatrists for patients who have normal erectile function until they are treated with SSRIs and then psychiatrists will prescribe these to ameliorate the SSRI side effects. However, a careful history must be taken to ensure that the patient's erectile function was normal prior to the treatment with the SSRI to ensure that there are not other medical issues that need to be addressed.

Sublingual apomorphine is a centrally acting dopamine agonist that can be used to improve erectile function; however, its use has decreased markedly now that the PDE5 inhibitors are available (28). However, apomorphine may still be used in patients who take nitrates, as the PDE5 inhibitors are contraindicated for these patients. Topical pharmacotherapy includes treatment with vasoactive drugs including 2% nitroglycerine, 15% to 20% papaverine gel, and 2% minoxidil solution or gel (28). However, adverse events such as skin and glans erythema, burning sensation, allergic reactions can be associated with all of these and should be discussed carefully with the patient prior to administration. The partner can also experience hypotension and headache due to vaginal absorption of these topical agents.

Finally, vacuum constriction devices can be used. Use of these devices requires placement of a constricting ring around the root of the penis to retain blood within the copora (28). Then the vacuum device is placed over the penis and passively pulls blood into the copora cavernosa. Second line treatments include intracavernous injections of alprostadil, intraurethral prostaglandins E_1 administration and surgical implantation of a penile prosthesis (28).

16.3.4. Female Orgasmic Disorder

Female Orgasmic Disorder describes a situation wherein a woman has recurrent delay in or absence of orgasm. Because women vary widely in their orgasmic capacity and in the type or intensity of needed stimulation, the diagnosis should be given only when the orgasmic functioning is less than would be expected given those variables. DSM-5 has made changes to Female Orgasmic Disorder: "marked infrequency" of orgasms or "reduced intensity of orgasmic sensation" can both fulfill the diagnosis. The addition of "markedly reduced intensity of orgasmic sensation" reflects the fact that orgasm is not an "all or nothing" phenomenon and that diminished intensity of orgasm may be a problem for some women. The diagnosis relies on the clinician's judgment as what sort of orgasmic capacity a woman should have at a particular age and what kind of stimulation or sexual excitement phase should bring about orgasm. Because there are no clear-cut norms, the clinician is left to making arbitrary or subjective judgments.

16.3.4.1. Prevalence

Among women presenting to sex therapy clinics for treatment, the rate of anorgasmia ranges from 24 to 37% (6). In population-based studies approximately 15.4% of premenopausal and 34.7% of postmenopausal women report difficulty achieving orgasm (14). Single women seem to have a higher prevalence of the diagnosis compared to married or cohabitating women who are in a long-term committed relationship.

16.3.4.2. Assessment and Treatment

It is important, when treating female orgasmic disorder, to determine if an arousal disorder or lack of stimulation may be the cause of the orgasmic disorder. Women with acquired or secondary orgasmic dysfunction are more likely to have co-occurring psychiatric disorders than women with lifelong orgasmic disorder (6). When treating secondary or situational anorgasmia it is important to deal with the comorbid psychiatric disorders and address the emotional or relationship discord in order to have a favorable outcome. Women who are less likely to practice masturbation are also more likely to have orgasmic disorders (6). Masturbation training using either manual or vibrator-assisted stimulation and pubococcygeal muscle training seem to be most effective for treating lifelong or primary anorgasmia (7, 29, 30). However, achieving orgasm during masturbation does not necessarily guarantee the patient will be able to have orgasm during intercourse or when stimulated by a partner. There is much debate in the literature on female sexual response as to whether orgasm during intercourse without additional clitoral stimulation is a reasonable therapeutic goal for treatment of orgasmic disorder (29). Traditional sex therapy is also used in the treatment of anorgasmia. The overall success rate has been reported to be as high as 90% or better (7, 31).

16.3.5. Delayed Ejaculation

Delayed ejaculation applies when a man has a delay in or absence of orgasm. This disorder may take several forms. For some men, only certain types of stimulation lead to orgasm. Others may experience an orgasm but only after a prolonged and

intense sexual activity or stimulation. Delayed Ejaculation is the new DSM-5 name for DSM-IV-TR Male Orgasmic Disorder. The name change reflects current terminology in the field.

16.3.5.1. Prevalence

Delayed ejaculation has been reported by 46.2% of men and increases with age from 30% for men ages 50 to 59 to 54.9% in men ages 60 to 69, and 74.3% in men ages 70 to 80 (27). Inability to reach orgasm increased from 5% for 40 to 49 years olds up to 17% for 70 to 80 year olds in one study but another reported less than 5% for those under 60, 14% for those ages 60 to 69, and 34% for 70 to 79 year olds, and 55% for those above 80 (27).

16.3.5.2. Etiology

As with other types of sexual dysfunction it is important to rule out potential medical causes of delayed ejaculation. Potential causes and treatments are reviewed by Richardson et al. (32). Possible organic causes include diabetes mellitus, peripheral vascular disease, substance use, including alcohol, cigarettes, and many drugs of abuse, spinal cord injury, retroperitoneal surgery or trauma, and other neurologic disorders, such as multiple sclerosis. Prescription medications can be a major cause, including psychiatric medications, such as selective serotonin reuptake inhibitors, tricyclic antidepressants, and antipsychotic medications.

16.3.5.3. Treatment

Most of the publications on use of medications to treat delayed ejaculation related to management of the problem when it is secondary to the use of serotonin reuptake inhibitors (32). Amantadine, cycloheptadine, and yohimbine have all been suggested for treating delayed ejaculation caused by selective serotonin reuptake inhibitors (SSRIs). There have been some single blind and double blind studies of bupropion to treat SSRI-induced sexual dysfunction (33). Results have been mixed but this agent is often tried in clinical practice. Bethanechol has been reported to be effective in treating delayed ejaculation due to tricyclic antidepressants (34), and amantadine and buspirone were reported in a prospective study of depressed men and women with generalized sexual dysfunction to reverse the sexual dysfunction side effects of SSRIs, including retarded ejaculation (35–37).

Recommendations by sex therapists to treat retarded ejaculation often include masturbatory exercises with the partner, viewing of erotica during masturbation, increasing stimulation, and working with the couple to make sure there is adequate sex play prior to intercourse. Hypnosis has been suggested as a useful adjunct to treatment.

16.3.6. Premature (Early) Ejaculation

Early ejaculation is a condition in which a man ejaculates too quickly and with minimal stimulation before, on, or shortly after penetration and before he wishes to. Early ejaculation is more common in young men, in novel sexual situations, and in men who have had a substantial interval since last orgasm. DSM-5 changed the name from premature ejaculation disorder to avoid the use of an inaccurate and stigmatizing term.

16.3.6.1. Prevalence

In the review by Beutel et al. (27), 14% of men reported periodic to frequent premature ejaculation, and 7% reported an inability to have orgasm. Early ejaculation remains relatively constant with aging. It was reported to be 13% to 14% in men ages 40 to 59, and 17% to 18% in men ages 60 to 80.

16.3.6.2. Treatment

Pharmacotherapy for early/premature ejaculation most commonly takes advantage of the side effects of the selective serotonin reuptake inhibitors. There are reports in the literature of nearly all of the SSRIs being used to treat premature ejaculation, including paroxetine, fluoxetine, sertraline, and fluvoxamine [reviewed in (38)]. There are also reports of topical anesthetics, such as lidocaine and prilocaine preparations, and PDE5 inhibitors being used to treat early/premature ejaculation [reviewed in (38)]. Psychotherapeutic approaches that have been recommended include the use of distraction and decreasing excitement and stimulation to help to delay ejaculation; however, there is not good data to show long term efficacy of these techniques (38).

16.3.7. Genito-Pelvic Pain/Penetration Disorder

16.3.7.1. Definition and Prevalence

Genito-Pelvic Pain/Penetration Disorder applies when a person has pain or discomfort, muscular tightening, or fear about pain when having sexual intercourse. This DSM-5 disorder reflects a change from DSM-IV-TR wherein two distinct disorders – Dyspareunia and Vaginismus – were used to diagnose sexual pain disorders, both now subsumed under this new category. Dyspareunia and Vaginismus were unreliable diagnoses, and it was nearly impossible in many cases for clinicians to distinguish between the two.

Dyspareunia, defined as pain during intercourse, can occur in either men or women. The estimated prevalence in men is about 1 to 1.5% [reviewed by (7)]. In contrast about 10 to 15% of women report dyspareunia and the prevalence seems to be inversely related to age, with younger women complaining of fewer problems than older women [reviewed in (7, 39)]. The prevalence of pain during sexual activity for postmenopausal women may even be higher, with 34% stating they "sometimes" or "often" have pain during sexual activity (14).

16.3.7.2. Etiology

Physical factors that can cause Genito-Pelvic Pain/Penetration Disorder in women include hymeneal scarring, pelvic inflammatory disease, and vulvar vestibulitis (7). In men, Peyronie's disease, in which there is an extreme bend in the penis, can cause dyspareunia. Other causes in men include painful retraction of the foreskin and possible physical trauma to the genitalia (39). Psychological factors such as problems in the relationship with one's partner or a history of sexual abuse can also contribute to this disorder. As with other sexual dysfunction disorders, the organic cause of the original pain may not be the only factor for maintaining the problem and so an approach that examines both the physical and psychological aspects of the disorder are important.

16.3.7.3. Treatment

There are various medical and surgical procedures for Genito-Pelvic Pain/Penetration Disorder that can address the various organic causes of this disorder. However, since in many cases there has been a long history of discomfort or pain prior to medical or surgical intervention, there is often much residual anxiety and often decreased arousal in women (7). Cognitive behavioral therapy and sex therapy treatment have both been used to treat Genito-Pelvic Pain/Penetration Disorder.

16.3.8. Vaginismus

16.3.8.1. Prevalence

Vaginismus results from an involuntary spasm of the musculature of the lower third of the vagina. Approximately 12 to 17% of women who present for treatment have this complaint (7, 39). One of the questions about diagnosis of vaginismus is how to distinguish it from dyspareunia. Often it is difficult to determine if the vaginal contraction or pain itself prevent penetration. Any vaginal pain, including pain from dyspareunia, can be accompanied by muscular contractions and it is often difficult to determine if the contraction is involuntary (40).

16.3.8.2. Treatment

Physical treatment for vaginismus includes use of vaginal dilators. Patient starts with the smallest dilator of the set and gradually increases the size of the dilator used over the course of a number of weeks. Systematic desensitization procedures may include insertion of a finger or a tampon along with psychological treatment (7). As with most cases of sexual dysfunction, treatment seems to be more effective if both partners participate and are invested in treating the condition.

16.3.9. Sexual Aversion Disorder

16.3.9.1. Definition and Clinical Characteristics

Sexual aversion is characterized by extreme aversion to and avoidance of, all (or almost all) genital sexual contact with a sexual partner. Compared to the literature on hypoactive sexual desire disorder and the other sexual dysfunctions, there is comparatively little data published on sexual aversion disorder. Theoretically, the diagnosis can be made in either men or women but the publications on the topic focus on aversion in women. Most women are brought into treatment by their husbands and it has been

suggested that men with aversion disorder do not enter into relationships so they are not likely to come to the attention of health care professionals (41). Prevalence data are not available but researchers have reported on the behavioral features of the disorder. Women with sexual aversion disorder avoid expression of affection because this might cause their partner to interpret this as a sign of willingness to engage in sexual activity. They don't go to bed at the same time as their partners, are uncomfortable with nudity, are repulsed by their partner's touch, and dissociate during sexual activity (41). Interestingly, about half of the women with sexual aversion have normal desire. They may masturbate regularly and they may have average levels of sexual fantasy (41). There are no studies documenting the efficacy of treatment but individual or couples therapy is usually the recommended treatment though women may not tolerate the traditional sex therapy approaches (Table 16.1).

16.4. Gender Identity Disorders

The DSM-5 has two sets of criteria for gender identity disorder diagnoses, gender dysphoria in children and gender dysphoria in adolescents and adults.

In response to criticisms that the term "Gender Identity Disorder" was stigmatizing, it has been replaced in DSM-5 by *Gender Dysphoria*. In addition, the previous subtype pertaining to sexual attraction was eliminated, and a new subtype categorization that does not exclude individuals with a somatic disorder of sex development was introduced.

Gender Dysphoria is characterized by persistent cross-gender identification, discomfort with one's assigned sex, and clinically significant distress or impairment. The diagnosis may be problematic in children because of the child's inability to verbalize distress, and gender identification may be transient or developmentally related. In some, the distress may reflect parental disappointments (i.e., about the child's gender) rather than the child's internal distress. In adolescents or adults, the disturbance is manifested by symptoms such as stated desire to be the other gender, frequent passing as the other gender, desire to live as the other gender, and the conviction that the person has the typical feelings and reactions of the other gender.

There is significant debate in the transgendered community and among practitioners who provide services for transgendered individuals regarding whether gender dysphoria disorders are mental disorders. Those arguing against having gender dysphoria disorder in the DSM posit that it adds to social stigmatization of a normal variant of human gender expression. Others feel quite strongly that it is only because of the formal diagnosis that those with gender dysphoria disorder are able to access healthcare and health insurance coverage to provide benefits for psychological treatments, as well as hormone and sex reassignment services. Care of transgendered individuals has been positively affected by the development of standards of care for gender dysphoria disorders developed by the Harry Benjamin International Gender Dysphoria Association (42). These guidelines provide standards for assessment and treatment of gender identity disorder in children, adolescents, and adults and will be used as the basis of the discussion that follows.

16.4.1. Prevalence

It is estimated that approximately 1 in 11,900 males and 1 in 30,400 females would be eligible for the diagnosis of gender dysphoria (43). In some patients the intensity of the gender dysphoria fluctuates below and above clinical threshold. Genetic females can function in society in an androgynous state without drawing attention to themselves. It may be that some nonpatient male transvestite female impersonators and male and female homosexuals have a form of gender dysphoria.

Little is known about the course of gender dysphoria because of the lack of studies in the area; however, it is thought to be the case that most boys or girls who express gender dysphoria as children outgrow their wish to change sex or gender (43). In clinical practice, it is certainly the case that patients who initially aspire to gender change decide not to pursue hormonal or surgical sex reassignment for a multitude of reasons. Some patients decide that the social consequences of a gender change are not acceptable and settle for some intermediate state of gender and others wish to pursue hormonal and surgical sex reassignment (43).

16.4.2. Clinical Presentation

It is important to note that the majority of children who present with gender dysphoria do not go on to be transgendered adults (43). Commonly children and adolescents present stating that they desire to be the other sex, dressing in clothes of family members of the opposite sex, playing with games and toys usually associated with the opposite gender, and preferring playmates of the opposite gender. The disorder is more commonly diagnosed in boys than girls and boys can also complain about not liking their physical sex characteristics. The majority of children and adolescents with gender dysphoria do not become transsexual although research indicates that they may eventually become homosexual (43). Gender dysphoria in boys is more closely tied to later homosexuality than to the development of adult transsexualism. Retrospective studies of

male and female homosexuals are more likely to endorse cross-dressing in childhood and adolescence than in heterosexual individuals.

Often when adult transsexuals present for treatment they have been aware of the desire to alter their gender for many years and are very impatient to get started on hormones or have surgery immediately. They often exhibit a great deal of distress about their bodies, particularly primary and secondary sex characteristics, and they report the dissatisfaction since they were children or adolescents. They may have actually experimented with cross-dressing in a subtle or overt manner. Men may wear women's underwear so as to not have the cross-dressing apparent to others. They may have already selected a name of the desired gender and are quite anxious to proceed with the sex change.

16.4.3. Assessment

When seeing a patient with gender dysphoria it is important to address the differential diagnosis. Clearly in children and adolescents it is advisable to be accepting of their gender dysphoria but also acknowledge that this may not be a long-term process. A detailed discussion of the potential benefits and side effects of treatment in childhood and adolescence is beyond the scope of this chapter; however, can be found in the Harry Benjamin International Gender Dysphoria Association Standards of Care (42). Irreversible interventions, including any surgical intervention, should not be carried out prior to adulthood.

Differential diagnosis of gender dysphoria in adults is most difficult when distinguishing from transvestic fetishism and gender dysphoria, particularly if the patient presents stating that the cross-dressing is sexually arousing. Additionally, young male homosexuals with a history of stereotypically feminine interests or behaviors and possibly cross-dressing may be mistaken for patients with gender dysphoria.

16.4.4. Treatment

According to the Standards of Care, there are five elements to the clinical work of professionals with patients with gender dysphoria. They include diagnostic assessment, psychotherapy, real-life experience, hormone therapy, and surgical therapy. Psychiatrists who work with patients with gender dysphoria may appropriately carry out any of the following responsibilities (42).

1. Accurate diagnosis of the individual's gender dysphoria disorder.
2. Accurate diagnosis of comorbid psychiatric conditions and appropriate treatment of such conditions.
3. Counsel individuals about the range of treatment options and their implications.
4. Provide psychotherapy.
5. Ascertain eligibility and readiness for hormone or surgical therapy.
6. Make formal recommendations to medical and surgical colleagues.
7. Provide relevant patient history to referral sources in the form of a letter of recommendation.
8. Maintain professional relationships with others who can provide support to those interested in gender identity treatment of gender dysphoria.
9. Educate family members, employers, and institution about gender dysphoria.
10. Be available for follow up of patients who receive treatment of gender dysphoria.

Patients with gender dysphoria may select from a whole range of options to deal with their disorder. While some are comfortable with finding a middle ground, taking hormones but not having surgery or in the case of women, having mastectomy but not penile construction, others feel it is necessary to be as completely physically like the gender of choice as possible. For most patients with gender identity disorder a period of psychotherapy is required. Real-life experience in the gender of choice is considered critical according to the Standards of Care before proceeding to hormonal or surgical treatment (42). This involves dressing, presenting, and living as an individual of the gender of choice for a period of time prior to starting on hormones or obtaining surgery. The real-life experience is critical because the consequences of the sex change may be different from what the patient imagines them to be. These issues need to be addressed prior to irreversible physical changes being made. When the psychiatrist is fully assured that the individual is psychologically stable and prepared for the next phase of treatment it is appropriate for them to send letters of recommendation to the physician prescribing hormones or to a surgeon.

16.4.5. Hormone Therapy

Hormones should only be prescribed by a practitioner who is fully versed in the potential medical consequences and is attendant to the management of these consequences, such as changes in glucose tolerance and possible development of diabetes,

effects on cardiovascular disease, venous thromboembolic disease, liver abnormalities, hyper-prolactinemia, and osteoporosis. Programs following the Standards of Care make certain that the person receiving hormones be eighteen years of age, demonstrate knowledge of what hormones medically can and cannot do and their social benefits and risks, as well as the medical benefits and risks (42). The medical and social risks should not be minimized. The person must also either have a documented real-life experience of at least three months prior to administration of hormones or a period of psychotherapy of a duration specified by the mental health professional after the initial evaluation (usually a minimum of three months) (43).

16.4.6. Surgical Treatment

There is significant research and clinical evidence that sex reassignment surgery is effective and even medically indicated for the treatment of severe gender dysphoria (43). Eligibility for a surgical sex reassignment includes being of the legal age of majority, having twelve months of continuous hormone therapy, and twelve months of successful continuous full time real-life experience. Some programs also require participation in psychotherapy but this is not an absolute requirement for eligibility. Patients must demonstrate the knowledge of the cost required, the length of hospitalization, the likely complications, and the post-surgical rehabilitation requirements of the various surgical approaches and have been made aware of different competent surgeons to perform the surgery. They must also have demonstrated that they are making progress dealing with the psychosocial aspects in the transition, including their job, informing close family members, and they must be free of significant physical, mental health, or substance abuse problems that would make surgery contraindicated. Female patients may choose to have mastectomy and hysterectomy, including a salpingo-oophorectomy. They may also have vaginectomy although if the patient plans to have phalloplasty, vaginal tissue is often used for this operation. Patients may elect to have scrotoplasty, urethroplasty, or placement of testicular prostheses. Metoidioplasty is the construction of a microphallus and is an easier surgery than phalloplasty. Female-to-male patients must explore all of these options before electing to have surgery. Male-to-female patients may have a number of genital surgeries, including orchiectomy, penectomy, vaginoplasty, clitoroplasty, and labiaplasty. Frequently male-to-female patients elect to have breast augmentation surgery. Various types of facial plastic surgery may be requested. While there are some surgeries that may modify the voice, Standards of Care suggest that more follow up research needs to be done before this procedure becomes widespread (42).

16.5. Paraphilias and Compulsive Sexual Behavior

16.5.1. Paraphilias

Paraphilic disorders are characterized by the presence of recurrent, intense sexually arousing fantasies, sexual urges, or behaviors generally involving: 1) nonhuman subjects, 2) the suffering or humiliation of oneself or one's partner, or 3) children or non-consenting persons (Table 16.2). Individuals may differ on whether the paraphilic fantasies are obligatory for arousal or used only episodically. Because not all paraphilias are considered mental disorders, DSM-5 makes a distinction between paraphilias and Paraphilic Disorders. With *Paraphilic Disorder* a paraphilia causes distress or impairment to the individual, or entails harm, or risk of harm, to self or others. A paraphilia is a necessary but insufficient condition for having a Paraphilic Disorder. Having a paraphilia does not in and of itself automatically justify or require clinical intervention.

Although often discussed in a group, there is considerable debate about which of the paraphilic disorders, if any, share a common underlying etiology. In addition, there is also debate over whether certain paraphilic disorders (e.g., sexual sadism, sexual masochism, pedophilia) should even be considered psychiatric disorders (44, 45).

Table 16.2 Paraphilic disorders.

Exhibitionistic disorder	Exposing one's genitals to strangers
Fetishistic Disorder	Sexual excitement from non-living objects
Frotteuristic Disorder	Sexual excitement from rubbing against someone
Pedophilic Disorder	Sexual interest in prepubescent children
Sexual masochistic Disorder	Finding sexual excitement in being humiliated
Sexual sadistic Disorder	Finding sexual excitement in the humiliation of others
Transvestic fetishistic Disorder	Cross-dressing (in a heterosexual male)
Voyeuristic Disorder	Observing an unsuspecting person who is partially or completely naked or having sex

16.5.1.1. Prevalence

There have been no large epidemiological studies of paraphilic disorders, and so the rates in the general community are not known. Small nonclinical studies, however, suggest that paraphilic disorders may not be rare. One anonymous study of college students found that 7% would have sex with a child if they could be assured that they would not be found out (46). In a different study of male college students, 3% reported having been sexual with a girl under the age of 12 years, 42% had been voyeurs, 2% had exposed themselves, and 35% had engaged in frotteurism (47).

16.5.1.2. Clinical Characteristics

Paraphilic disorders appear to start by late adolescence, except pedophilia which has a mean age of onset in the mid or late 20s (48). Although paraphilic disorders for most individuals begin by young adulthood, they may in fact start at any age (49). The intensity of the urges, fantasies or behaviors can differ dramatically in severity between individuals. For example, some individuals may require the paraphilic fantasy or behavior for all sexual arousal, whereas others largely engage in ordinary sexual behavior with only a fleeting urge or fantasy about the paraphilia (50).

Paraphilic disorders, although present in females (51, 52), appear to be more common in males (50). Given the paucity of research on females with paraphilic disorders, it is still unclear whether gender influences the clinical characteristics of these disorders.

Co-occurring disorders are common in individuals with paraphilic disorders, but the lifetime rates of these disorders demonstrate a large range. Lifetime mood (31% to 71%), anxiety (19% to 64%), substance use (23% to 60%), impulse control (29% to 52%), attention deficit hyperactivity (36%), and any personality (60% to 68%) disorders appear commonly in individuals with paraphilic disorders (44, 49, 53, 54). Additionally, individuals with paraphilic disorders tend to have multiple paraphilic disorders (54–57).

16.5.1.3. Etiology

Although the biology of sexual functioning and hypersexuality has long been explored (58–60), the pathology of paraphilias has been less studied. Because the orbital frontal cortex is involved in impulse control, social cognition, decision making and emotional processing, it becomes a likely candidate for understanding paraphilic behaviors. In addition, the prefrontal cortex is also involved in acquiring moral and social knowledge, and impairments in understanding moral and social values (seen in many individuals with paraphilias) may underlie these behaviors.

Current information provides only pieces of a complex puzzle. For example, frontal striatal circuits have been implicated in Tourette's disorder. Because individuals with Tourette's appear to have high rates of exhibitionism (61), these circuits may be a particularly important area for research. Pedophilia has been associated with a case of an orbitofrontal tumor, which resolved once the tumor was removed (62). A neuropsychological study of 4 individuals with pedophilia suggests that a striato-thalamo-cortical circuit may be involved in the pathophysiology of some cases of pedophilia (63).

Several neurotransmitters play a role in sexual functioning and motivation, and dysregulation of these neurotransmitters (serotonin, dopamine, norepinephrine) has been hypothesized to underlie paraphilic behaviors (64, 65). In addition, neuropeptides (e.g., gonadotropin-releasing hormone, thyroid-releasing hormone, and corticotrophin-releasing hormone), and the effects of these neuropeptides on hormones, have also been suggested as contributors to paraphilic behaviors (58). Even though several of the paraphilias combine elements of aggression and sexuality, no differences in circulating testosterone have been consistently found between sexual offenders and nonoffenders (66).

Animal models may hold some answers to etiology as pedophilia and exhibitionism have been reported in many species (67). Male gorillas may focus sexual attention on adolescent females when thwarted in attempts to mount an adult female. Male chimpanzees expose their erect penises to females as an initiating behavior leading to coitus (67).

Multiple psychological models have also been proposed for the possible etiology of paraphilic disorders. Behavioral models hypothesize that early conditioning to sexually deviant behavior results in the development of a paraphilic disorder (68). Social learning models suggest that lack of parental care, physical punishment, and frequent sexual activity within the family may predispose children to offending (69). Additionally, an addiction model has hypothesized that deviant sexual behavior acts as a drug substitute (66). Although these various models have served as paradigms to develop treatment approaches, they lack empirical evidence. How these various models interact with the various neurobiological theories has yet to be delineated.

Although various theories provide clues to the pathophysiology of paraphilic disorders, the etiology of these behaviors is most likely multifactorial (genetic, biological, developmental, social). In addition, multiple neurobiological and psychosocial dysfunctions might result in the behaviors diagnosed as paraphilias. Even among individuals with specific paraphilic disorders, there may be heterogeneity in their neurobiology. More comprehensive information of paraphilias, such as that

which could be gleaned from studies of genetics and neuroimaging, has significant potential in advancing our understanding of the etiology of these complex behaviors.

16.5.1.4. Treatment

16.5.1.4.1. Psychosocial Treatments

Cognitive behavioral therapy comprised of reducing deviant arousal and increasing appropriate arousal (e.g., desensitization, reconditioning techniques), improving ability to interact socially (e.g., social skills training, anger management), increasing victim awareness and empathy (e.g., role playing), correcting cognitive errors that allow rationalization of behavior (e.g., cognitive restructuring), and relapse prevention have demonstrated efficacy in reducing recidivism (70–72). Studies assessing this treatment approach, however, have generally focused on sex offenders, regardless of specific paraphilic disorder, and have included short treatment durations, and the studies have failed to use a no-treatment control group for comparison.

16.5.1.4.2. Pharmacotherapy

Although no consistent findings regarding testosterone levels among individuals with paraphilic disorders has been found, pharmacological agents (e.g., medroxyprogesterone acetate, cyproterone acetate) that reduce testosterone levels, via increasing testosterone reductase activity, have been used to reduce sexual urges and behaviors (73). Although promising in case reports and case series, there have been no double-blind controlled studies examining their efficacy. Similarly, case reports suggest that synthetic analogues of gonadotropin-releasing hormones reduce sexual urges and behavior in men with paraphilias by inhibiting secretion of naturally occurring gonadotropins and thereby reduce circulating levels of testosterone (74–76).

Serotonin reuptake inhibitors, pharmacologic agents that have anti-obsessional effects, have also shown promise in case reports in reducing paraphilia urges and behaviors. These medications have shown benefit for exhibitionism (77, 78), fetishism (78), sexual masochism (78), transvestic fetishism (78), and voyeurism (77, 79). There is yet no evidence that SSRIs differ in efficacy. No double-blind trials of SSRI medication have been conducted in individuals with paraphilias. When using these medications one has to be particularly careful about the anorgasmia or delayed orgasm side effect, as patients with paraphilias may find delayed orgasm actually increasing their need for intensity of stimuli during masturbation and therefore prolonging the amount of time spent engaged in masturbating to paraphilic fantasies, on the internet viewing pornography or engaged in paraphilic behavior.

16.5.2. Hypersexuality/Compulsive Sexual Behavior (Sexual Disorder NOS)

Although not recognized by the DSM-5, hypersexuality or compulsive sexual behavior is frequently discussed in the medical literature. This sexual behavior goes by a variety of names. These include hypersexuality, compulsive sexual behavior (CSB), sexual addiction, sexual compulsivity, and paraphilia-related disorder. In older literature terms such as perversion, nymphomania, Don Juanism, and hyper-eroticism have been used. A number of authors have proposed diagnostic criteria for this disorder and most are patterned after the criteria of the paraphilias (80–82). Salient features include recurrent and intense normophilic (as opposed to paraphilic) sexually arousing fantasies, sexual urges and behaviors which cause clinically significant distress in social, occupational, or other important areas of functioning. The hypersexuality must not be due to other medical conditions, substance use disorder, attributable to another Axis I disorder or developmental disorder, and must take into account norms of gender, sexual orientation, and sociocultural groups (83). Numerous behaviors have been described of those exhibiting compulsive sexual behavior, including compulsive cruising, multiple partners, compulsive masturbation, compulsive sexuality in a relationship, pornography dependence, telephone sex dependence, and cybersex dependence (83, 84).

Hyperactive sexual desire or hypersexual behavior is related to compulsive sexual behavior. Data published by Kafka (85) indicates that many of the men who present with this disorder have an average total sexual outlet (TSO) of greater than seven times per week. Total sexual outlet is defined as any sexual activity leading to orgasm, whether it be activity with a partner or masturbation behaviors. Previous publications indicate that the average TSO for adult males is 0.5 to 3 times per week, and in all the studies, a TSO of 7 or greater appears to be in the upper 3% to 8% of males (86, 87). Kafka (88) demonstrated that patients with CSB and those with paraphilias both exhibit hypersexual behavior at the same rates. In a sample of 206 males with paraphilias or CSB, 89% had a TSO of greater than 5, and 76% had a TSO of greater than 7. In this sample the age of onset of CSB was 18.7 years, with a range of 7 to 46 years. The average duration of time before the patient sought treatment was approximately 12 years.

16.5.2.1. Prevalence

There are no epidemiologic studies of the prevalence of CSB. However, Grant et al., (89) reported that 6.5% of 204 consecutive patients admitted to two inpatient psychiatry wards met criteria for CSB on a structured interview. Others have estimated the prevalence to be about 5% (90, 91). Clinical and research data indicates that CSB is predominately a male disorder. In different samples, 78% to 91% of those presenting for research studies or clinical treatment were male (90). Patients tend to present for treatment in their late thirties to early forties and come from a variety of socioeconomic backgrounds. In clinical practice, compulsive masturbation with use of internet, print, or phone pornography tends to be the most common presentation. Often male patients come in for treatment when their wife or significant other discovers and becomes disturbed by their behavior. With regard to Axis I comorbidity, mood disorders and anxiety disorders are common (91). Substance use disorders also present more frequently in those with CSB than in the general population. Patients often report strong urges to engage in the behavior, being preoccupied by thoughts and urges, attempting to resist the behavior.

16.5.2.2. Etiology

There are many theories regarding the etiology of CSB but no substantive research in the area. There are those that see the behavior as similar to addictive behavior and posit that the mechanism of drug and sexual addiction are similar (92, 93). Others see the disorders as being a type of paraphilia and assume that the etiology while unknown is similar to that of the paraphilias (94). To the extent that CSB is related to paraphilias the discussion above regarding the etiology of the paraphilias can also apply to compulsive sexual behavior. Others see CSB as a way to cope with anxiety and/or dysphoric mood (95). Atypical impulsivity (96) and hypersexuality (97) have also been suggested as causes. Our group has suggested that CSB is an urge-driven behavior and suggests that the basis of the urges and lack of frontal control over the urges that leads to CSB is similar to the abnormalities that lead to pathological gambling and other impulse control disorders (98, 99). There are multiple case reports in the literature of individuals with head injuries that develop hypersexual behavior. The majority of these lesions are in the frontal and temporal lobes (100–103).

16.5.2.3. Treatment

There is only one published placebo-controlled trial of citalopram for the treatment of compulsive sexual behavior (104). Treatment with citalopram leads to decreases in sexual desire/drive, frequency of masturbation and use of pornography (104). Both the placebo and treatment groups showed reduced sexual risk and the reduction did not differ between groups. There are multiple reports of case studies and case series of various medications suggesting efficacy in the treatment of CSB. Multiple authors have suggested selective serotonin reuptake inhibitors (SSRI) such as fluoxetine, sertraline, and paroxetine can decrease compulsive sexual behavior (105–113). The SSRI may work by decreasing urges to engage in the behavior and decreasing preoccupation. There are also case reports of tricyclic antidepressants (114) and buspirone (115, 116) being effective to help decrease anxiety and frequency of problematic behavior in those with CSB. Nefazodone has been recommended as an alternative to SSRIs since it is not as likely to cause sexual dysfunction (117) but the recent "black box" warnings about liver dysfunction have decreased the use of this medication. Earlier case reports indicate lithium carbonate and carbamazepine may be helpful in treating CSB (108, 118, 119). Atypical antipsychotic agents have been suggested as an option (106), particularly in those with any Axis I or II psychotic symptoms in addition to their compulsive sexual behavior. More recently naltrexone has been recommended for the treatment of behavioral addiction, including compulsive sexual behavior (120). High doses of 100 to 150 mg are generally needed. The use of non-steroidals is contraindicated with high dose naltrexone and liver functions must be followed carefully (121).

16.5.3. Conclusions

Paraphilic disorders and compulsive sexual behavior have historically received relatively little attention from clinicians and researchers. As such, our understanding of the basic features of these disorders is relatively primitive. Future research investigating the neurobiology of paraphilic disorders and CSB holds significant promise in advancing prevention and treatment strategies. The systematic study of treatment efficacy and tolerability is in its infancy. With no studies published yet that even approximate a controlled efficacy trial, it is not possible to make treatment recommendations. Nonetheless, specific drug and behavioral therapies appear to offer promise for the effective treatment of paraphilias and CSB. Heterogeneity of treatment samples may also complicate identification of effective treatments. At present, issues such as which medication to use and for whom, or the duration of pharmacotherapy or CBT cannot be sufficiently addressed with the available data.

Other Psychiatric Syndromes: Adjustment Disorder, Factitious Disorder, Illicit Steroid Abuse, Cultural Syndromes

William R. Yates, M.D.

Abstract Many psychiatric textbooks omit less common, yet important, clinical topics in the medical basis of psychiatry. This chapter covers four such additional areas: adjustment disorder, factitious disorder, illicit anabolic steroid abuse, and special psychiatric syndromes identified by eponyms or cultural ties.

Keywords Adjustment disorder • Factitious disorder • Anabolic steroid abuse

Adjustment disorder and factitious disorder are important, but understudied, psychiatric syndromes. Adjustment disorder is one of the most common mental disorders in primary care, the emergency room and in medical and psychiatric inpatient populations. Factitious disorder requires collaborative care between medical and psychiatric specialists for accurate assessment and management. Increased use of illicit anabolic steroids and other performance enhancing drugs has both medical and psychiatric implications. Finally, knowledge of psychiatric eponyms and cultural syndromes reminds clinicians of the importance of history and cultural awareness in the medical basis of psychiatry.

17.1. Adjustment Disorder

17.1.1. Definition

The DSM-5 criteria for adjustment disorder deal with development of various behavioral symptoms (i.e., depression, anxiety, etc.) in response to obvious stressors which are unusually severe and cause social impairment.

By definition, the distress and impairment must evolve within 3 months of the stressor. The adjustment disorder is classified as acute for symptoms lasting less than 6 months and chronic for symptoms lasting over six months. The disorder is transient, with resolution over time or with development into a more severe syndrome such as major depressive disorder (1).

The maladaptive reaction to a stressor is confirmed by either impairment in occupational or social functioning or symptoms that exceed a normal response. Additionally, the symptom complex must not meet criteria for any other specific psychiatric disorder. For example, a patient displaying a full major depressive disorder following a divorce is diagnosed with major depressive disorder and not with adjustment disorder with depressed mood. The role of the stressor in the major depressive disorder is noted with a reference to the psychosocial stressor severity rating on Axis IV.

Adults	2512	Community	Survey	0.9–2.3	[11]

17.1.2. Epidemiology

The prevalence of adjustment disorder in various populations has been the subject of limited attention. This limited attention results from several factors. Standardized interviews and operationalized criteria are recent developments. Nevertheless, several studies in various populations exist (2–11). These studies suggest that adjustment disorder is a frequent clinical condition worthy of further study. A recent survey of general practitioners in Denmark found that depression and adjustment disorder ranked as the top two mental disorders in primary care combining to account for 51% of all mental disorder diagnoses (12). Several prevalence studies of adjustment disorder are summarized in Table 17.1.

17.1.3. Clinical Picture

The clinical profile of symptoms in adjustment disorder is quite variable and is related to the developmental level and age. Adolescents appear to be more likely to develop behavioral problems with acting-out symptoms. Adults appear more likely to respond in a maladaptive fashion with depressive and anxiety symptoms.

Generally, the clinical picture reflects mild to moderate distress in the context of significant psychosocial difficulties. Symptom severity is less than most other Axis 1 disorders. Nevertheless, the symptom severity in adjustment disorder is significant enough to distinguish this population from community samples free from psychiatric illness (8).

17.1.4. Illustrative Case

Mrs. K was a 64-year-old married white woman who was admitted to the coronary care unit for congestive heart failure and atrial fibrillation. The attending physician requested a psychiatric consultation for episodes of nervousness and anxiety.

Mrs. K reported persistent anxiety since being admitted to the hospital. She felt her symptoms stemmed from confinement to her hospital room. Her usual daily activities included plenty of action and movement. Being restricted to her room made her feel trapped and out of control. She had difficulty sleeping and felt keyed up with rumination about her physical condition.

The patient denied depressed mood. There was no history of past or current panic attacks. She denied obsessions, compulsions, or phobias. She did not drink alcohol. She had no major significant psychiatric history. She did undergo a brief trial of hypnosis after a divorce. There was no history of psychotropic medication use, psychiatric hospitalization, or suicide attempts. There was no family history of psychiatric disorder.

Her medications at the time of her psychiatric evaluation included sucralfate four times daily, warfarin 5 mg daily, sublingual nitroglycerin, furosemide 40 mg daily, captopril 37.5 mg three times daily, digoxin 0.125 mg daily, metoclopropamide 10 mg four times daily, and diazepam 5 mg every 6 hours prn. Mrs. K reported that the diazepam relieved her anxiety symptoms, but she had received only one dose over the last 72 hours. Onset of her anxiety symptoms did not coincide with the initiation of any new medication during her hospital stay.

Laboratory and medical testing revealed normal thyroid function studies. Complete blood count, arterial blood gases, and general chemistry screen were within normal limits. Her electrocardiogram revealed atrial fibrillation.

On mental status examination, Mrs. K appeared well groomed and was dressed in a hospital gown. A handshake demonstrated the presence of perspiring palms. She appeared anxious in facial expression and bodily movements. She did not appear depressed. Her thoughts were logical and goal directed without a formal thought disorder. There were no hallucinations,

delusions, or suicidal or homicidal thoughts. Her insight and judgment were unimpaired. Cognitive testing revealed no abnormalities of orientation, memory, concentration, or comprehension.

The psychiatric consultant considered the following diagnoses in the differential diagnosis: generalized anxiety disorder, obsessive-compulsive personality disorder, organic anxiety syndrome secondary to medication, delirium, and adjustment disorder with anxious mood. Adjustment disorder with anxious mood was diagnosed after ruling out the other diagnostic considerations. Recommendations included a trial of diazepam 5 mg bid and an additional 5 mg prn during hospitalization. Continued diazepam treatment after discharge was felt unlikely to be necessary. A psychiatric nurse visited Mrs. K regularly during her hospitalization and provided relaxation exercises. The cardiology team was encouraged to allow ambulation and physical therapy as soon as medically possible to allow the patient to return to her active lifestyle.

The patient's anxiety responded well to the combination of diazepam and relaxation training. At discharge, the diazepam was tapered and discontinued. In a follow-up visit 3 weeks after discharge, the patient's anxiety symptoms had essentially resolved.

17.1.5. Clinical Course

Symptom duration of less than 6 months reflects a generally good prognosis for adjustment disorder. Outcome studies of adults with adjustment disorder have found over 70% without significant impairment or psychiatric illness 5 years after the index diagnosis (13). This follow-up study found that those with a psychiatric disorder were likely to have antisocial personality, alcoholism, or a major depressive disorder. However, the generally favorable prognosis is tempered by an estimated 4% suicide rate in this study population.

Presence of an adjustment disorder diagnosis has been linked to completed suicide in United States Army personnel (14). A Danish study estimated that a diagnosis of adjustment disorder at psychiatric treatment facilities increased the risk of later suicide by a factor of twelve (15).

Patients admitted to a psychiatric hospital with a diagnosis of adjustment disorder with depressed mood appear to have a more favorable prognosis than those with other mood disorders. Adjustment disorder in one study of inpatients predicted a lower rate of psychiatric hospital readmission (16).

The prognosis of adjustment disorder appears less optimistic in the adolescent population. Andreasen and Hoerick's study (13) found that only 44% of adolescents were well 5 years after an index diagnosis of adjustment disorder. The most frequent follow-up psychiatric diagnoses in the adolescent populations included major depressive disorder, antisocial personality disorder, alcoholism, drug abuse, schizophrenia, and bipolar disorder. The 5-year follow-up of adolescent adjustment disorder also found a 2% suicide rate. However, the process of suicidal ideation is generally shorter in adjustment disorder compared to other mood disorders (17).

One study of youth with new-onset insulin dependent diabetes mellitus found a high rate of new psychiatric disorders in a 5 year follow-up (18). Forty eight percent of those with adjustment disorder subjects had a new psychiatric illness diagnosed compared to only a 16% rate in controls.

Masterson (19) also documented the poor prognosis in adolescents with adjustment disorder. Sixty-two percent of adolescents displayed moderate to severe impairment 5 years after an index diagnosis. The prognosis for adjustment disorder in adolescents appears to be especially poor when there is a disturbance of conduct (20). Psychiatric comorbidity may significantly contribute to poor prognosis in children with adjustment disorder (21)

17.1.6. Etiology

The cause of adjustment disorder stems from the interaction between a stressor and the adaptive mechanisms of the individual. The type of stressor responsible for the initiation of an adjustment disorder can be quite variable and mimics the types of stressors commonly seen in everyday life. In a series of adult patients receiving psychiatric care with a diagnosis of adjustment disorder, the most common types of precipitants included marital problems, divorce or separation, a move to a new location, financial problems, and school or work problems (13). The type of stressor precipitating symptoms reflects the clinical setting of contact. For psychiatric consultations in the general hospital, a frequent precipitant is acute and chronic medical illness.

The severity of the stressor appears also to play a role in the etiology of adjustment disorder. The risk of developing psychiatric symptoms appears to increase with increased stressor severity. However, the response does need to meet the maladaptive and excessive responses criteria noted in the adjustment disorder.

The individual's pattern of response to stress has some stability over time. Therefore, individuals with previous maladaptive responses are more likely to display repeated maladaptive responses. The reason some individuals are more vulnerable

to stressors is not completely known. Genetic and environmental factors probably influence individual risks for maladaptive response to stressors (22).

One case-control study investigated the role of baseline temperament and character as risk for development of adjustment disorder (23). This study was limited to a sample of male Republic of Korea conscripts. However, individuals who developed an adjustment disorder in this group had higher measures of harm avoidance and lower measures of self-directedness, cooperativeness and self-transcendence. This study suggests some psychological features may reduce the risk of an adjustment disorder in response to a significant stressful life event.

Support for the validity of the adjustment disorder diagnosis is beginning to emerge in brain research. A quantitative EEG study of a series of subjects with adjustment disorder with depressed mood found significant differences compared to a series of subjects with major depressive disorder (24). Subjects with adjustment disorder with depressed mood showed lower levels of EEG absolute power and coherence disruption compared to those with major depressive disorder. This finding is consistent with adjustment disorder with depressed mood being an important but less severe form of mood disorder.

17.1.7. Differential Diagnosis

The differential diagnosis for adjustment disorder focuses on the primary complaint. For example, differential diagnoses in a patient with marked anxiety prior to a surgical procedure would include adjustment disorder with anxious mood, generalized anxiety, panic disorder, simple phobia, anxiety due to a general medical condition, or a mood, substance abuse, or personality disorder. Generally, it is best to begin the differential diagnosis with attention to the predominant symptom and include disorders likely to produce the target symptom in the differential diagnosis.

Adjustment disorder is not diagnosed when the target symptoms are only one instance of a pattern of overreaction. Personality disorders encompass behaviors or traits that are personal characteristics stable for long time periods. Under stress, these traits may increase target symptoms or behaviors similar to those of an adjustment disorder. The differentiation of adjustment disorder and personality disorder is difficult during time-limited assessments of new patients.

Another stress-related diagnostic category in DSM-5 is the category of psychological factors affecting other medical conditions. In this disorder, the focus of attention is worsening of a physical condition due to a psychosocial stressor. Adjustment disorder with physical complaints is diagnosed when no physical cause of the complaints is identified. In contrast, a patient with rheumatoid arthritis experiencing increased pain following the death of a relative exemplifies psychological factors affecting physical condition.

A final stress-related category in DSM-5 is the category posttraumatic stress disorder (PTSD). This category differs from adjustment disorder in several ways. In PTSD, the stressor must be of sufficient severity to be considered an “event that is outside the range of usual human experience and that would be markedly distressing to almost anyone” (1). Note that this category places a greater emphasis on the extreme nature of the stressor compared with the adjustment disorder. Additionally, in PTSD, the traumatic event must be persistently re-experienced with avoidance and arousal symptoms. With PTSD there is no limit on symptom duration. The onset of symptoms can be delayed for more than 6 months.

Mood or anxiety disorders are frequent differential diagnosis concerns in patients displaying symptoms related to an identifiable stressor. It is important to question for the presence of major depression, dysthymia, panic disorder, and generalized anxiety disorder in patients seen for conditions in which adjustment disorder is being considered. Clinical factors appear to distinguish adjustment disorder with depressed mood from major depression (25). In a general hospital psychiatry series, major depression was linked to older age, widowed marital status, and living alone (26). Psychosocial stressors can exacerbate nearly any chronic psychiatric disorder, and the resultant increase in symptoms may appear to be due to an adjustment disorder. The key to differential diagnosis between adjustment disorders and an anxiety or a mood disorder is to elicit sufficient information to confirm whether a full anxiety or mood disorder is present.

17.1.8. Treatment

Treatment recommendations for adjustment disorder are based primarily on clinical experience. Few treatment studies focus on adjustment disorder. Although the often transient nature of the condition suggests that treatment has limited importance, treatment can significantly reduce distress. Additionally, identification and treatment may prevent development of a more chronic condition.

Identification of the individual causes of adjustment reactions is the beginning of treatment planning. For patients demonstrating acute anxiety or depressive symptoms, it is beneficial to question the patient about the most distressing source of stress. This precipitating stressor may be a misunderstanding or an overestimation of danger or risk. Simple acknowledgment of the stressor sources, along with education and support, provides the basis for beginning intervention.

It is helpful to consider the individual's usual coping strategies for dealing with stressors. Facilitating the use of past successful strategies can prevent the need for new strategies. For example, allowing hospitalized patients to contact trusted friends, family, or clergy and discuss their condition and receive support may be quite beneficial.

Psychotherapy principles for adjustment disorder focus more on crisis-intervention principles than on a particular psychotherapy model. A BICEPS (brevity, immediacy, centrality, expectancy, proximity, and simplicity) model successfully limits the functional impairment following exposure to significant military stressors (27). This model uses a brief intervention approach beginning as soon as possible following stressor exposure. Patients receive notice that they are expected to return quickly to their previous level of function. The intervention occurs without transfer to another location. Attention focuses on symptom reduction without attention to underlying personality or neurotic issues.

This strategy has implications for general hospital patients experiencing adjustment disorders in the hospital setting. Symptom identification begins as soon as possible with brief intervention strategies following immediately after symptom identification. Treatment occurs on the medical ward rather than on transfer to the psychiatric unit. Physicians can encourage and expect quick symptom resolution. Psychotherapy strategies remain basic, using approaches such as relaxation training.

A Cochrane Review examined the all psychotherapy research trials in adjustment disorder (28). This review focused on the effect of interventions on facilitation of return to work. This is an important issue as work impairment is a key component of the burden in adjustment disorder. The review found limited support for both cognitive behavior therapy and problem solving therapy in reducing the level of work disability in adjustment disorder. The authors of the review noted guideline development for treatment of adjustment disorder is limited due to the paucity of studies and small number of participants in adjustment disorder.

Medication approaches for adjustment disorder target the primary presenting complaint (29). The majority of adjustment disorder diagnoses are sub-classified with anxious, depressed, or mixed emotional features. Many adjustment disorders respond to support and the passage of time-some more severe and persistent syndromes merit consideration for medication trials. Treatment studies have suggested adjustment disorder with depressed mood responds as well as major depressive disorder to a trial of antidepressant medication (30). Patients in primary care suffering from adjustment disorders appear to respond well to antidepressant therapy (31). However, large placebo controlled studies of the efficacy of antidepressant treatment in adjustment disorder are generally lacking. A recent review noted insufficient evidence to support routine antidepressant use in adjustment disorder with depression or anxiety (32).

In the case study, short-term benzodiazepine administration alleviated a significant adjustment disorder with anxious mood. Benzodiazepines have the advantage of rapid onset of anxiolytic effect. Concern about long-term dependence and withdrawal symptoms minimizes when the course of treatment is 6 weeks or less. Rational strategies for benzodiazepine use in adjustment disorder include alprazolam, 0.75 to 3 mg, in three divided doses, lorazepam, 1.5 to 6 mg, in three divided doses, clonazepam 0.5 to 1 mg in two divided doses, or diazepam, 10 to 30 mg, in a single or divided dose. Doses can be titrated to the symptom level. In hospitalized patients, it is better to use regularly scheduled administration rather than rely on an as-needed or prn administration schedule. Physicians should notify patients that the medication is for short-term use and that the development of tolerance and dependence will be medically monitored.

17.1.9. Prevention

Adjustment disorders in the medical setting often arise out of fear or anxiety about medical illnesses, hospitalization, and medical procedures. Miscommunication between medical personnel and the hospitalized patient can contribute to the development of adjustment disorders. Clear communication about the diagnosis, prognosis, and treatment plan can prevent significant adjustment disorder problems. Physicians, nurses, and ancillary medical staff efforts at education and support for the acutely and chronically hospitalized patient are important. Anticipatory education decreases adjustment symptomatology and increases patient satisfaction with medical care.

17.2. Factitious Disorder

The voluntary production of physical or psychological symptoms or signs of illness represents the core for disorders classified as factitious disorders. The DSM-5 (1) classifies factitious disorder under the Somatic Symptom and Related Disorders. Two types of factitious disorder are listed: factitious disorder imposed on self and factitious disorder imposed on another.

The main feature of factitious disorder is the production of physical or psychological symptoms deceptively and in the absence of real illness. Production of symptoms occurs without regards to obvious external incentives.

Factitious disorder is another problem encountered in the hospital setting. Although much less common than adjustment disorder, factitious disorder presents a significant challenge for medical physicians and psychiatric consultants. Along with the challenge of documenting the voluntary production of symptoms, factitious disorder patients often evoke strong negative emotional responses in members of the health care team. The management of factitious disorder also adds to the challenging character of these disorders.

17.2.1. Definition

False clinical presentation with deceptive physical signs and symptoms is the type of factitious disorder historically known as Munchausen syndrome (33). The essential features of Munchausen's syndrome include pseudologica fantastica (pathologic lying), peregrination (traveling or wandering), and recurrent feigned or simulated illness. By definition, the physical symptoms or signs in factitious disorder are intentionally produced or feigned. The motive for this symptom production is a "psychological need to assume the sick role." Motivation by an obvious external incentive is absent. By definition, the symptoms cannot occur exclusively as part of another major mental disorder.

Another category in DSM-5 is factitious disorder with predominantly psychological signs or symptoms. The definition of this disorder is identical to that for factitious disorder with physical symptoms except for the psychological character of the intentional symptom. Factitious disorder with psychological signs or symptoms has less clinical description with mixed acceptance by psychiatrists. Some have suggested that this disorder is not a valid diagnostic entity because of unresolved issues in motivation, inclusion and exclusion criteria and outcome (34).

A form of factitious disorder in childhood exists. Referred to as Munchausen syndrome by proxy, this clinical disorder involves a parent-child interaction. For this disorder, parents fabricate symptoms or signs of illness in their children to maintain their child in a sick role. Various presentations in the pediatric setting exist (35). Parents who simulate illness in their children, commonly have a personal history of somatoform disorders and factitious disorder (36)

A recently discovered variant of factitious disorder is Munchausen by internet (37). Munchausen or factitious disorder by internet is the simulation of illness in social media forums such as on Facebook, Twitter or specific disease internet discussion forums. Individuals simulating illness in social media may be doing it to receive support and attention. Others may simulate illness on the internet to disrupt or belittle social groups. Very little research on individuals with factitious disorder by internet exists, but initial studies suggest similar features to those with factitious disorder in the healthcare setting.

17.2.2. Epidemiology

No community information exists for the general population prevalence of this disorder. Most estimates of the prevalence of this disorder originate from hospital and psychiatry consultation series. Table 17.2 notes the prevalence findings for factitious disorder in the medical setting.

17.2.3. Clinical Picture

The presenting clinical sign or symptom for factitious disorder can be quite variable. Despite this variability, certain symptoms encourage aggressive pursuit of factitious disorder in the medical differential diagnosis. These high-risk situations include recurrent skin infection, especially with fecal flora contamination; recurrent unexplained hypogylcemia in diabetics and others with access to insulin; unexplained bruises or dermatologic conditions; fever of unknown origin; and surreptitious use of prescribed and over-the-counter medication. Particular medical diagnoses such as cancer have been the focus of feigned illness. Predictably as new conditions arise and become more prevalent, factitious variants arise. For example, recent reports of factitious AIDS have developed (39). Feigned psychosis and feigned posttraumatic stress disorders exemplify factitious disorder with psychological symptoms (40, 41).

TABLE 17.2 Prevalence of factitious disorder in treatment populations.

Category	*N*	Site	Contact	Prevalence (%)	Reference
Teaching hospital	1361	Inpatient	Consult	1	[44]
Fever of unknown origin	343	Inpatient	Referral	9.3	[48]
Psychotic disorder	219	Inpatient	Series	4.2	[40]
Physician survey	105	Inpatient	Practice	1.3	[38]

In Munchausen syndrome by proxy, several similarities exist compared with adult factitious disorder (35). Common fabricated signs included bleeding, neurologic problems, rashes, glycosuria, and fever. Medical occupations are frequently noted in the mothers of these children, similar to the adult factitious disorder series.

17.2.4. Illustrative Case

Ms L was a 20-year-old single unemployed woman seen by her primary-care physician for recurrent right leg swelling. The recurrent swelling had occurred over a period of 18 months, resulting in several hospitalizations for "thrombophlebitis." The patient was taking anticoagulants. Despite anticoagulant therapy, the right leg continued to be intermittently swollen. The swelling resolved with elevation, rest, and compression stockings.

At one point during the patient's illness, while she was taking anticoagulants, an acute gastrointestinal bleed occurred. Bleeding resulted in anemia (hemoglobin level 5 mg/dl). The patient's prothrombin time was in the therapeutic range prior to the acute bleed. However, at the time of the acute bleed, the prothrombin time was elevated to greater than 30 seconds. Although the patient denied taking an excessive dose of warfarin, a pill count by the physician documented excessive daily dosing. The patient required transfusion to correct the anemia.

Ms L denied any significant psychological distress. She did not appear depressed or anxious or have any psychotic symptoms. She did not respond to the intermittent swelling with anxiety or increased concern about her condition. There was no previous psychiatric history. Ms L was an only child who lived at home with her parents. Her mother had been somewhat overbearing and dominant, to the point of completing all the patient's high school homework and paper assignments. Following graduation from high school, Ms L briefly attended a secretarial training course at a school 65 miles from home. She was unable to complete the course because of her recurrent leg difficulties. When her leg became intermittently worse, Ms L received care by her mother. Her mother constantly checked her condition and provided assistance with daily cares.

During one acute swelling episode, the patient presented to the primary-care physician's office. A physical examination was done in the usual fashion with the patient gowned. However, further examination of the proximal right leg revealed a half-inch-deep circumferential tourniquet mark.

Ms L was confronted. Her physician noted the voluntary production of leg swelling and offered to arrange a psychiatric evaluation. She was not punished or humiliated for her behavior. She refused psychiatric referral and left the physician's office without returning for any scheduled follow-up appointments.

Ms L's primary-care physician called her mother to determine the reason for noncompliance with recommendations for follow-up. She reported that Ms L had transferred her care to another physician in a town 25 miles away. Additionally, she later began work at the new physician's office as a medical transcriptionist.

17.2.5. Clinical Course

Separating factitious disorder into those with a Munchausen syndrome and those without defines two different prognostic groups. Munchausen syndrome has a very poor prognosis, with only one case report of successful treatment (42). Factitious disorder without a Munchausen's syndrome appears to have a better prognosis. Good prognosis correlates with patients who also have a major depressive disorder. Combined medical and psychiatric management also decreases the morbidity of the disorder.

Ten patients with factitious disorder with hypoglycemia have been the subject of an outcome study (43). Following identification of surreptitious insulin use, confrontation, and psychiatric treatment, only three patients showed complete resolution of their condition. Remarkably, two patients died during follow-up, presumably due to self-induced hypoglycemia.

The outcome of factitious disorder with psychological symptoms has received limited attention. In the study by Pope et al. (40) of factitious disorder with psychological symptoms, the outcome was poor. Nine patients were followed for 4 to 7 years. One had committed suicide. Seven of the remaining eight had significant histories of frequent hospitalizations. Factitious disorder with psychosis predicted a poorer outcome than true psychoses such as schizophrenia or mania.

Nineteen children with Munchausen syndrome by proxy received longitudinal study (35). Two died presumably from the effects of the factitious disorder. Eight children were removed from their parents with resolution of the feigned signs. Nine children remained with their parents after confrontation and with close supervision by social workers. Of these nine children, seven were completely well without symptoms on follow-up. Two children continued with frequent physician visits for minor complaints not considered harmful factitious problems.

17.2.6. Etiology

The etiology of factitious disorder is unknown. Most case series studies of factitious disorder show a female preponderance. A Mayo Clinic series of 93 subjects found 72% were women (43). The risk factor and personality studies in this disorder present some basis for theoretical attempts to define the etiology of the disorder. Because factitious disorder patients often have severe personality disorders, the role of personality development and deficits appears to be important. Case studies of factitious disorder have described significant drives for dependency. The production of serious medical signs and symptoms mobilizes a medical care structure that often places patients in a dependent relationship. Significant angry affect is documented in case studies of factitious disorder. Borderline personality disorder is common. Patients may receive satisfaction at deceiving their health care team and getting revenge for previous interpersonal conflicts.

A history of healthcare training or jobs is common in factitious disorder. The Mayo Clinic series found a healthcare background in 66% of women with factitious disorder but only in 12% of men. Individuals may use they medical knowledge as a gateway to presenting clinical signs and symptoms.

17.2.7. Differential Diagnosis

The primary difficulty in the differential diagnosis of factitious disorder is confirming the voluntary production of signs and symptoms. Many patients never demonstrate their factitious behavior to others. This lack of proof is often frustrating and leaves an element of diagnostic doubt.

Malingering constitutes a disorder similar to factitious disorder. Both disorders involve the voluntary production of symptoms. The primary distinction in malingering is evidence that the intent of the feigned symptoms or illness is to obtain an external incentive. This external incentive, or "secondary gain," is often financial reimbursement through disability or through liability damages. Non-monetary secondary gain also can be the motive for malingering. Non-monetary incentives include evasion of military duty, evasion of criminal charges or jail sentences, or becoming eligible for better living circumstances.

Personality disorders in the medical setting mimic some of the characteristics of factitious disorder. Borderline personality disorder patients often evoke some of the same anger and frustration in health care professionals as the factitious disorder patient. The self-mutilation behaviors found with borderline personality tend to be stereotypical-an example being repeated superficial lacerations over the forearm. Although such behavior is voluntary, the patient acknowledges the behavior as being self-inflicted.

True medical illnesses deserve careful consideration in presumed factitious disorder. Follow-up series of patients diagnosed with factitious disorder have included some who went on to have the factitious symptoms explained by medical disease (44).

Other somatoform disorders also involve unexplained somatic complaints. Somatization disorder differs from factitious disorder in the number of presenting complaints. Although multiple symptoms occur in factitious disorder, single symptoms or signs are more often the focus of attention. Somatization disorder symptoms are more likely to involve subjective pain complaints, while factitious disorder target symptoms and signs often involve objective signs, i.e., hypoglycemia, skin infection, or fever.

Psychiatric comorbidity presents an additional challenge in the assessment of factitious disorder. It is possible for the patient to have more than one psychiatric disorder including factitious disorder. Treatable psychiatric comorbid conditions should receive attention. Diagnoses in this category include mood disorders, anxiety disorders, psychotic disorders, psychiatric syndromes due to a medical condition, and substance abuse.

Careful consideration of the psychiatric and medical differential diagnoses of factitious disorder can lead to accurate diagnosis of the syndrome. Careful review of outside medical records including electronic health records may be key in coming to the correct diagnosis (45). Additionally, room surveillance in person or by video can provide relevant information.

17.2.8. Laboratory Tests

Laboratory test abnormalities may be crucial in the diagnosis of factitious disorder and Munchausen syndrome (46). This is particularly true with the surreptitious use of insulin. For patients without diabetes and without a medical cause for insulin treatment, the identification of insulin antibodies provides evidence of exogenous insulin use (47). Additionally, monitoring C-peptide levels during episodes of hypoglycemia also may confirm suspicions of surreptitious insulin use to produce factitious hypoglycemia.

Self-induced infections may produce cultures revealing multiple organisms commonly found in feces. For example, recurrent wound or skin infections growing such organisms as Escherichia coli, group D enterococcus, and Klebsiella is highly

suggestive of the use of feces to feign recurrent infections. However, fecal sources of bacteria are not the only source of possible infectious agents. Factitious infections from pure cultured bacteria also have been reported (48). Other pyogenic substances such as tetanus toxoid and milk proteins can produce a clinical picture of fever of unknown origin.

Bleeding and clotting factor studies provide assistance in evaluating the patient with unexplained bleeding problems. As in the case example, pill counting for factitious use of anticoagulants also can be helpful in confirmation of factitious disorder.

17.2.9. Treatment

The treatment of factitious disorder involves a coordinated medical and psychiatric assessment and treatment plan (49). Treatment of concurrent psychiatric disorders can assist in management. Factitious disorder is not a contraindication for somatic treatment of comorbid mood or anxiety disorders.

Early studies of the treatment and natural history of factitious disorder promoted confrontation of the patient as the key to beginning treatment. There is no consensus that confrontation, especially in a punitive fashion, is an effective treatment approach. There is no evidence that the patient must admit the self-injurious behavior has occurred in order for the clinical picture to improve.

After collecting sufficient evidence to confirm a factitious disorder diagnosis, a coordinated plan to notify the patient and provide follow-up care is needed. An example of a method of notifying the patient in a non-punitive fashion follows. This example is taken as a hypothetical approach to the illustrative case prior to the primary care physician scheduling psychiatric consultation.

Ms L, I would like to give you some information about my assessment and treatment recommendations. I know your leg swelling has caused you a significant amount of discomfort. I have tried my best to provide quality care for your condition. The observation of a tourniquet mark on your leg leads me to believe your behaviors have contributed to the problem. I understand behaviors like this have complex meanings but generally can be seen as a cry for help, for understanding, and for a needed more comprehensive evaluation of emotional factors involved in your life.

I will continue to care for your medical problems. I know that these behaviors have served some purpose for you, but as your physician, I must tell you they must now stop. I expect that with help and support you will be able to discontinue these behaviors. To provide assistance for you I will arrange for you to see a psychiatrist who will provide an expert evaluation and behavioral management plan for us. Together I believe we can provide you with a strategy to improve your physical and emotional health.

The role of psychotherapy in factitious disorder has received only minimal attention. The treatment is tailored to the individual patient and his or her individual psychiatric presentation. For patients with concurrent borderline personality disorder, cognitive therapy strategies for personality disorders exist (50). For the factitious disorder behaviors, behavioral management plans provide a method of intervention. Behavioral strategies should eliminate positive reinforcement in the home and hospital for the factitious behaviors. Behavioral strategies can allow the patient to minimize embarrassment and shame. Positive reinforcement for reducing factitious behaviors is also helpful. In Munchausen syndrome by proxy, the safety and health of the child are a priority for management. This syndrome is a form of child abuse. Notification of social services and the initiation of child abuse evaluations must begin when the syndrome becomes apparent.

17.3. Illicit Anabolic Steroid Use

Anabolic steroids (AS) are a group of natural and synthetic hormones with masculinizing as well as anabolic (tissue-building) properties. Illicit use of AS began with their discovery and synthesis in the 1940s. The illicit use of AS occurs primarily in the context of athletic competition-the goal of their use is to increase size, speed, and performance, thereby gaining a competitive edge. Illicit use is defined as use without a physicians' prescription. Illicit procurement of supplies occurs through black-market sources. Although the illicit use of AS compounds has a 50-year history, their use appears to be increasing and their effect on mental status is receiving increased attention. In 1990, AS were added to schedule III of prescription drugs covered by the Controlled Substances Act. This assignment has stimulated discussion of the addiction potential of the compounds. In this section, the scope, mental status effects, and addiction hypothesis for illicit AS use will be examined.

17.3.1. Epidemiology

Various population groups surveyed for the prevalence of illicit AS use, include high school and college students and participants in specific sports. The surveys have been predominantly self-report with limited reliability and validity testing. Despite

TABLE 17.3 Prevalence rates of AS use in various populations.

Category	*N*	Period	Males (%)	Females (%)	Reference
High school students (12th grade)	2350	Lifetime	5.0	0.5	[52]
High school students (12th grade)	3403	Lifetime	6.6	N/A	[53]
College athletes		12 months	6.2	0.6	[54]
Elite power lifters	45	Lifetime	55	N/A	[55]
Elite multiple-sport athletes	271	Lifetime	N/A	2	[56]
NCAA athlete survey	637	12 months	1.1*		[57]
Swedish adults between ages 14–64	13920	Lifetime	1.7	0.3	[58]

*Survey reported both genders combined.

this, the surveys suggest that AS use is common, begins frequently during the adolescent years, and is primarily a problem in men. Reviews of the epidemiology of AS use allow some general conclusions about the epidemiology of AS use (51). Table 17.3 summarizes several of the surveys with the best methodologies (52–58).

Anabolic steroid epidemiology is an important emerging issue in forensic psychiatry. A large urine sample study of individuals in police custody in Sweden found 33.5% of the samples being positive for anabolic steroids (59). Even 11.5% of inmates in prison tested positive demonstrating a significant contraband drug problem.

Yesalis (60) proposes that survey methods probably underestimate the prevalence rates of anabolic steroid use. Nonresponse bias is likely to play a role in underestimation due to the legal and sports sanctions attached to illicit use. The prevalence estimates of AS use double or triple when athletes estimate the use of AS in their peer group. This suggests that self-reported use of AS is a lower limit of the prevalence rates. Despite using this lower limit, estimates suggest that 250,000 adolescents in the United States are using or have used AS.

The growth of the internet appears to be a factor in anabolic steroid and other performance-enhancing drug epidemiology (61). A survey of websites focused on bodybuilding and steroids founds thousands of sites. Many promoted the use of anabolic steroids and had links to sources for mail-order performance enhancing drugs. Additionally, many of these sites minimized the health risk related to these compounds.

Several risk factors appear related to anabolic steroid use. Male gender predominates in this problem. Specific sports and specific positions within sports have higher rates of AS use.

Additional risk factors for anabolic steroid abuse and dependence include opiate abuse and dependence and cocaine abuse and dependence (62). Conduct disorder and antisocial personality disorder also appear to be risk factors (63)

One intriguing factor related to anabolic steroid risk is body-image disturbance. Individuals preoccupied with muscle size and shape appear at increased risk for initiation of anabolic steroids and later development of a dependence syndrome (63).

AS use typically occurs in 8- to 16-week cycles. AS use cycles are interspersed with periods of AS abstinence. The specific steroids ingested and durations of use are variable. The methods and patterns of use develop through user experience and are disseminated through word-of-mouth and underground publications (64). Typically, the AS use pattern involves the use of multiple compounds. Compounds can include oral as well as injectable drugs. Although AS compounds were used for therapeutic indications for many years, illicit users typically employ doses much higher than the therapeutic replacement dose. This high-dose pattern has limited the generalization of current knowledge. Medical and psychiatric effects of AS in therapeutic doses do not necessarily predict effects at supratherapeutic doses.

17.3.2. Psychiatric Effects

The apparent increased prevalence of AS use has brought the psychiatric effects of these compounds under attention. Early studies with testosterone and related steroids proposed an antidepressant effect for these compounds (65). These studies tended to be small and uncontrolled. AS treatment studies for depression decreased following the advent of tricyclic compounds. With the increased use of high-dose AS compounds in athletes, the adverse psychiatric effects of these compounds became more the focus of attention and research.

The types of psychiatric effects reported with high-dose AS use fall into three categories: mood syndromes, psychotic syndromes, and behavioral syndromes, especially the development of violent and aggressive behavior. Reviews of the psychological and behavioral aspects of use of the AS compounds describe complex psychiatric effects (66, 67). Some individuals using high doses experience minimal psychiatric effects, while others may develop full-blown mood or psychotic disorders. Individual vulnerability to the psychiatric effects may be influenced by past psychiatric history, family history of psychiatric disorder, type of steroid used, pattern of cycling, other psychoactive drug use, and other factors.

Mood syndromes of depression and mania have been reported in case series and controlled studies of AS use. During the cycling phase when AS is being used, a feeling of enhanced self-esteem and euphoria with increased energy and other mania-like features have been described (68). Depressive symptoms have been reported during on and off-cycle periods of use. Case reports of suicide in AS users also have been published (69, 70). The frequency that these mood syndromes meet criteria for a psychiatric diagnosis is unclear. Pope and Katz (71) argue for full affective syndromes in up to 12% of users, while other studies suggest that although psychiatric symptoms are common, the production of a syndrome characteristic of a full psychiatric disorder is rare (72, 73).

Psychotic symptoms reported with AS use have included ideas of reference, paranoid delusions, grandiose delusions, and visual and auditory hallucinations. These psychotic symptoms have been noted during cycles of AS use as well as during periods of withdrawal. AS compounds with a 17-alkylated structure appear to be most likely to induce psychotic symptoms. Compounds in this class include oxandrolone, methandrostenolone, and oxymethalone. In all cases reported, psychotic symptoms have responded to antipsychotic medication and remitted with prolonged abstinence from AS compounds.

The psychiatric effect of AS use best documented is aggressive behavior. The link of aggressiveness to AS use has the advantage of correlates in the nonhuman primates and other animal species. Numerous studies in mammalian species have documented the role of testosterone in the increase in aggressive behavior (74). Animal studies report that the aggressive effects of testosterone appear to be male-specific-this suggests that the presence or absence of testosterone during specific developmental periods controls later response to testosterone. Other social factors appear important in determining the pattern and severity of response in males exposed to exogenous AS. Rejeski et al. (75) studied a group of cynomolgus monkeys given equal amounts of exogenous testosterone. Increase in aggressive behaviors was seen primarily in monkeys that displayed significant aggression at baseline. This link may have significant human implications since there is some indication that AS users are more likely to have premorbid antisocial personality disorder (76).

The study of the aggressive effects of ASs in humans is limited primarily to observational studies and small experimental design studies. An AS-induced link to aggression has been used in court cases of AS-related assault and homicide. This legal approach has been labeled the "dumbbell defense." Case studies suggest that the violent behavior associated with AS use is primarily in response to some provocation, but the behavioral response is excessive and extremely deviant from what would be expected.

In addition to case reports, the psychometric effects of AS use have been the subject of investigation. Yates et al. (77) examined the role of AS use in a group of AS users and controls using the Buss-Durkee Hostility Inventory (BDHI) (78). This inventory measures several aspects of aggression and hostility. AS users reported elevated responses to scales measuring verbal aggression and direct and indirect aggression. Typical questions from elevated BDHI subscales illustrate differences between AS users and nonuser controls. (True responses scored positively.) For the assault scale, a typical question is: "Once in a while I cannot control my urge to harm others." For the indirect aggression subscale, a typical question is: "I can remember being so angry that I picked up the nearest thing and broke it." For the verbal aggression scale, a typical question is: "When I get mad, I say nasty things." These behavioral characteristics of AS users are likely to increase the risk for significant legal and interpersonal difficulties. Mean scores for AS users on the BDHI are higher than reported means for a group of psychiatric patients and a group of prison inmates (79, 80). The responses from AS users in this study showed some psychometric specificity. AS users had elevated scores on the aggression factor of the BDHI but not on a separate hostility factor.

Most studies of aggression in AS use have focused on retrospective designs, relying on the self-report of AS use to identify cases and controls. Two small prospective studies have monitored the effects of AS (81, 82). In one study, volunteers received an AS compound from the research team. Both studies confirm the aggressive effect of AS compounds. The Choi et al. study confirmed the relationship of AS use with the aggression subscale of the BDHI found in the Yates et al. study (77). Interestingly, a subject in the Su et al. study (82) asked to be placed in seclusion to prevent aggressive behaviors from getting out of control and resulting in harm to others.

One key study of the link between anabolic steroid use and violent behavior comes from the United States National Longitudinal Study of Adolescent Health (83). In this study of over 20,000 subjects, 2.6% of the male adolescents had a lifetime use of anabolic steroids. This group demonstrated higher rates of violent behavior even after controlling for significant potential confounding variables such as previous violent behavior and other drug use.

Significant questions about the exact role of AS in mental status and behavioral changes remain to be answered. Significant uncontrolled factors could affect the interaction of AS within individual users. Some of these factors include previous and family history of psychiatric disorder, individual personality traits and disorders, the concurrent effects of alcohol and other psychoactive agents, the effect of expectancy in response to use, and the environment in which mental status and behavioral changes occur.

Despite the limitations of the knowledge of the effects of AS use, several clinical implications appear warranted at this time. High-risk groups presenting with new-onset psychiatric disorders should have an AS use history obtained. Urinary AS

assays can be used to confirm the patient's history. Although AS use appears common, the majority of users have sub-clinical mental status effects. Despite this, documented significant clinical mental status and behavioral effects of AS use do appear to be present in a minority of users. Clinical suspicion regarding the mental status and behavioral effects of AS use in high-risk subjects is likely to lead to better understanding of the psychopharmacology of AS compounds.

One recent development related to the psychiatric effects of anabolic steroid use is attention to the cognitive function domain. A series of long-term anabolic steroid users completed a study of computerized neuropsychological function (84). Anabolic steroid users demonstrated significant impairment in visuospatial memory compared to controls. This study could not rule out visuospatial memory impairment as a risk factor for abuse rather than a consequence. Nevertheless, the study highlights the need for further attention to neuropsychological function in this population.

In addition to the psychiatric effects of AS compounds, the phenomenology of AS use compares in many ways with the phenomenology of DSM-IV psychoactive substance abuse and dependence. Similarities and differences in AS use compared with other drugs of abuse have implications about our understanding and treatment of AS use.

17.3.3. A New Drug of Abuse?

The underground pathway for the distribution of illicit steroids presents a law enforcement challenge. This distribution system has many similarities to illicit systems developed for drugs such as cocaine and heroin. AS compounds are often obtained from sources outside the United States and brought across the border with supplies assigned to dealers who distribute to individual users for monetary gain. Recognizing this pathway, in November of 1990 the U.S. Congress placed AS in schedule III of the Controlled Substances Act. This addition classifies AS in the same category as compounds such as acetaminophen with codeine. Illegal possession and distribution of these agents are now subject to felony arrest and prosecution.

Although AS compounds now are classified with other prescription psychoactive substances of abuse and dependence, the implication of this classification is unclear. The potential for AS use to develop into an uncontrolled habit with withdrawal and psychological and physical dependence is unknown and speculative. Kashkin and Kleber (85) have hypothesized that some individuals may be susceptible to an unrecognized sex steroid hormone-dependence disorder, and that such a disorder may be modulated through the relationship of AS to the opioid and aminergic neurotransmission network. The possible classification of AS as psychoactive substances of abuse and dependence has implications for the clinical assessment and treatment of AS users. The lines of evidence supporting this hypothesis as well as those not supporting it will be reviewed.

Support for the addiction hypothesis of ASs will be dependent on linking the phenomenology and biologic mechanisms of AS use with those of the use of existing psychoactive substances such as alcohol and cocaine. Table 17.4 presents some comparisons of these issues in addressing the AS hypothesis.

Several of the phenomenologic features of AS use mimic alcoholism and drug abuse. Use of AS compounds is primarily a male gender phenomenon. Although found in women, the male/female ratio for AS use appears to be about 10: 1. The ratio for AS users who could be considered dependent is unknown. Results from the National Institute of Mental Health's Epidemiologic Catchment Area (ECA) study suggest that the male/female ratio for alcohol abuse and dependence is 6:1 and for non-alcohol abuse and dependence is 1.6:1 (86). The age of onset for AS use is adolescence and early adulthood; this also

TABLE 17.4 Comparison of use of AS compounds with alcoholism and cocaine abuse phenomenology.

Comparison categories	Alcoholism	Cocaine abuse	AS use
Male gender predominant	Yes	Yes	Yes
Early age of onset	Yes	Yes	Yes
Linked to antisocial personality	Yes	Yes	Yes
DSM-IV abuse/dependence criteria	Yes	Yes	Yes
Polysubstance abuse common	Yes	Yes	Yes
Controlled Substance Act	No	Yes	Yes
Family history of abuse	Yes	Yes	Unknown
Used primarily for psychoactive effect	Yes	Yes	No
Seek treatment for discontinuation	Yes	Yes	Uncommon
Biologic mechanism/drug causes "high"	Yes	Yes	Unknown
Withdrawal symptoms/craving	Yes	Yes	Unknown
Animal model for self-administration	Yes	Yes	Yes

corresponds with the age of onset for alcohol and drug use. Also similar to alcoholism and cocaine abuse, antisocial personality disorder has been found at higher rates in AS users.

Several case reports highlight the possibility of a dependence syndrome associated with AS use. Individual users have reported feeling that their AS use became out of control. Despite a desire to quit AS use, some users have described continued use as a result of withdrawal dysphoria or fear of losing weight, strength, or muscle mass.

In DSM-5 substance use disorder, one or more of eleven different criteria may be present (1). DSM-5 substance use disorder severity is estimated by the number of criteria present. There are few studies of the presence of DSM-5 substance use disorder criteria in AS users. However, some studies using earlier overlapping criteria have been published.

Brower et al. (87) completed a survey of 49 AS users to determine the prevalence of DSM-IV TR dependence criteria for AS. Ninety-four percent of the users reported at least one dependence syndrome, with 57% reporting three or more dependence symptoms with AS use. The most prevalent dependence symptoms reported by the AS users were withdrawal symptoms, more substance taken than intended, large quantities of time spent in AS-related activities, and continued AS use despite AS problems. Users who reported dependence symptoms were more likely to have had more cycles of AS, used higher doses, felt they were still not big enough, and had aggressive symptoms.

There is limited evidence to support a family history of alcoholism or drug dependence in AS users and also not enough data to determine the prevalence of polysubstance abuse in AS users. Investigation of both these factors is necessary.

Despite the phenomenologic similarities, some important differences remain between alcohol, cocaine, and AS use. The primary reason for AS use is not for a psychoactive effect. Motivation varies for initiation and maintenance of AS use but primarily reflects the user's drive for development of strength, muscle mass, and improved physical appearance. Although users report increased self-esteem and energy, the compounds are not used primarily for a euphoric effect. This difference remains a significant challenge to the AS addiction hypothesis.

Biologic mechanisms for addiction with AS compounds have received limited research attention. Support for an animal model of anabolic steroid abuse and dependence is weak. Rats and mice demonstrate limited reinforcing behaviors when allowed to self-administer anabolic steroids (88). Hamsters studies suggest that some individuals will self-administer high doses of anabolic steroids. The hamster model suggests the reinforcing effect of androgens in animals is milder than for alcohol or cocaine. Further study of the physiologic and psychoactive effects of AS use will need to address the effects of high-dose use, withdrawal, and evidence for development of craving

The AS addiction hypothesis in humans continues to have weak support. Further epidemiologic, clinical, and basic science study will be necessary to more completely understand the psychopharmacology and psychiatric effects of these compounds.

17.3.4. Treatment

Case reports have documented substance-dependence treatment seeking in AS users, the extent of this treatment-seeking behavior appears small. Clancy and Yates (89) reported results from a national survey of substance-abuse treatment directors. Eighty-one percent of surveyed directors reported no patients with AS use presenting for treatment at their facilities over a 1-year period. Those reporting AS-using patients did note DSM-IV TR psychoactive substance dependence for AS.

Rates of treatment seeking in anabolic steroid users may increase as the wave of new users in the 1990s and 2000s begin to experience chronic use medical and psychiatric complications (90). Treatment may need to include interventions to normalize male hypothalamic-pituitary-gonadal axis function. Antidepressant treatment many address anabolic steroid related depression. There is some evidence opioid antagonists block anabolic steroid use in animals (91). The clinical implications of this finding is unclear.

17.4. Eponyms and Cultural Syndromes

Eponyms and cultural syndromes important in psychiatry are summarized in Tables 17.5 and 17.6 (91–100). Psychiatric diagnostic classification has moved away from the use of eponyms. However, they continue to be used in clinical settings and are part of the history of psychiatric description and classification.

TABLE 17.5 Psychiatric syndromes identified with eponyms.

Eponym	Description	Found in	Reference
Capgras delusion	One of the delusions of doubles. A belief that a person, usually a close family member, has been replaced by an imposter	Schizophrenia, mood disorders, psychosis and dementia	[92]
Clerambault's delusion	A delusion usually held by a woman that a famous or wealthy person is in love with her; also known by the term pure erotomania	Paranoid schizophrenia, paranoid disorder, and psychosis due to a general medical condition	[93]
Cotard's delusion	A delusion that all has been lost including money, possessions, and parts of the body such as the heart or other organs; the delusion may include the belief that the person is dead	Schizophrenia, psychosis due to a mood disorder or a general medical condition	[94]
Couvade syndrome	The experience of signs and symptoms of pregnancy or labor by the husband of a wife who is pregnant or in labor	No psychiatric disorder and possibly anxiety disorders	[95]
DaCosta's Syndrome	The syndrome, also known as neurocirculatory asthenia, characterized by easy fatiguability, chest pain, dyspnea, and palpitations	Many cases probably panic disorder	[96]
Fregoli's delusion	The reverse of Capgras delusion; strangers are identified as familiar friends or family members	Schizophrenia, psychosis Due to a mood disorder Dementia	[97]
Ganser's syndrome	A syndrome where responses to questions are approximate but not correct; also described as hysterical pseudodementia	Schizophrenia, bipolar disorder, psychosis due to a mood disorder, malingering	[98]
Kleine-Levin Syndrome	Periodic episodes of hypersomnia accompanied by bulimia	Thalamic lesions	[99]
Kluver-Bucy	The loss of facial recognition, rage reactions, hypersexuality, and memory deficits	Surgical removal of both temporal lobes	[100]
Othello's delusion	The delusion of infidelity by the spouse	Paranoid disorder, Schizophrenia, psychosis due to a mood disorder or a general medical condition Alcohol dependence	[101]

TABLE 17.6 Cultural psychiatric syndromes.

Cultural syndrome	Description	Culture	Reference
Amok	Unexpected rapid development of agitation; accompanied by obtaining a weapon and attacking everything in sight until apprehended	Malaysia	(102)
Dhat	Delusion that sperm is leaking from the body through urination, resulting in weakness	India	(103)
Koro	An acute anxiety state characterized by fear that the penis will retract into the abdomen, resulting in death	China and Malaysia	(104)
Latah	A syndrome of echopraxia, echolalia, and coprolalia; behaviors may involve putting one's self in dangerous situations	Malaysia described in Africa, Japan and Russia	(105)
Piblokto	Attacks of bizzare behavior, including screaming, running about, and tearing off clothing	Eskimo	(106)
Voodoo	A delusion of possession by devils or evil spirits.	Haiti and Africa	(107)
Windigo	A delusion of being possessed by a cannabalistic monster (windigo)	Canadian Indians	(108)

Some of more important culture-bound syndromes are summarized in Table 17.6. Culture-bound syndromes are present throughout the world. These categories have been the subject of review (108). Knowledge of these descriptive syndromes highlights the role of the culture or in the experience and description of symptoms related to stress and brain disorders.

ADHD and the Disruptive Behavior Disorders

Elena B. Metcalf, M.D.*

Abstract Although it has now been reclassified as a Neurodevelopmental Disorder, Attention Deficit/Hyperactivity Disorder (ADHD) frequently overlaps with the Disruptive, Impulse Control, and Conduct Disorders such as Oppositional Defiant Disorder (ODD) and Conduct Disorder (CD), forming a heterogeneous group of childhood onset behavioral disorders that have traditionally been lumped together as Disruptive Behavior Disorders (DBD). These frequently comorbid disorders cause significant disturbance and distress within the child's environment, usually school and/or family, as well as causing severe developmental and psychosocial dysfunction for the individual. ADHD is characterized by symptoms of inattention, impulsivity and hyperactivity, ODD by hostility, anger, argumentativeness, defiance, and CD by aggression, deceitfulness, and violation of rights of others. The DBDs play an enormous social role because they represent a high risk for developmental trajectories that harbor psychosocial, economic, psychiatric, and criminal morbidity across the lifespan and have significant socioeconomic and health impact on a national level (1). The DBDs may share comorbidities and some etiologic and pathophysiologic characteristics, however, their clinical manifestations, developmental trajectories, and biologic substrates are distinct.

The explosion of neurobiological literature about the Disruptive Behavior Disorders, most specifically on ADHD, reflects the complex, fluid, and often-contradictory manifestations of brain-behavior relationships. This complexity is enhanced further by the accumulating research demonstrating significant differences in manifestations according to age, cognitive status, gender, comorbidities, psychosocial context, and treatment response. There is an enormous degree of individual variation shaped by the transaction of biological and environmental factors, which again has major implications for prevention and diagnostic and therapeutic interventions. For practical purposes, the current discussion will focus on each condition separately.

18.1. Attention Deficit/Hyperactivity Disorder

18.1.1. Description

ADHD is a complex neurodevelopmental syndrome characterized by developmentally inappropriate dysregulation of attention, impulse control, and hyperactivity, which is discrepant to the developmental status and cognitive competence of the individual. Commonly seen associated symptoms are perceptual and motor coordination problems and affective dysregulation. It is the most common neurodevelopmental disorder diagnosed in children, manifesting usually in the preschool years and thought to affect up to 5.4 million children in the US (2). It is a chronic and usually lifelong condition, persists in the majority of cases into adolescence and adulthood, and is estimated to have an adult prevalence of about 4% (3). Hyperactivity and impulsivity and emotional dysregulation are the most obvious and impairing symptoms in early childhood because of their stressful effects on family,

social, and preschool functioning. As the individual matures, hyperactivity usually diminishes, but internal restlessness, impatience, impulsivity, and attentional problems, as well as distractibility and forgetfulness, persist and impede development on all functional levels. There is often a striking discrepancy between cognitive potential and emotional and behavioral immaturity, which leads to peer rejection and poor self-esteem, which are major predictors of negative social outcome. The significance of the syndrome lies in the fact that not only do the ADHD symptoms by themselves block individual self-realization, but, in the majority of cases, they are associated with comorbid disorders. Depending on personality and psychosocial factors, they can lead to lifelong maladaptations and economic, social, and emotional adversity. The economic impact associated with ADHD in adults is calculated to be between $87 and $138 billion/year through reduced productivity and salary loss alone (4).

Because of its high prevalence and because of the evidence that early diagnosis and treatment clearly diminish the adverse impacts of ADHD (5), the American Academy of Child and Adolescent Psychiatry (AACAP) has recommended that all children presenting for mental health and behavioral disorders be screened for ADHD (6). And because the vast majority of children with ADHD are treated by primary care physicians rather than psychiatrists, the American Academy of Pediatrics (AAP) has developed guidelines for diagnosis and treatment of ADHD in the primary care setting (7).

The core features of ADHD are considered to be deficits of "executive function", i.e., dysfunctions of working memory and response inhibition to inappropriate actions, thoughts, and feelings; impaired attention, planning, impulse control, mental flexibility, and activity regulation (8). These deficiencies unfold throughout the lifespan with shifting symptomatology and consequences depending on age, gender, cognitive and comorbid status, and social context. ADHD is characterized by a high rate of comorbidities with other neuropsychological disorders such as language or learning disabilities, as well as with psychiatric disorders, which results not only in more severe and complex lifetime impairment for the individual, but increases the enormous burden of ADHD for society as a whole (3, 9). Besides the obvious effects on educational, vocational, and psychosocial outcomes, ADHD is also associated with increased medical morbidity and costs in accidents, hospitalizations, substance abuse, and teen pregnancy (10). Nationally, $21–$44 billion are spent each year in incremental health care costs for children with ADHD, with an additional $15–$25 billion in excess educational costs (4). Depending on personality and psychosocial factors, only a minority of persons diagnosed with ADHD in childhood show a benign life trajectory. Despite this bleak picture, there are many individuals who have managed to achieve star status despite or perhaps even because of the vagaries associated with this condition. Leonardo DaVinci, Wolfgang Amadeus Mozart, Benjamin Franklin, Thomas Edison, Albert Einstein, Abraham Lincoln, John F. Kennedy, and champion swimmer Michael Phelps, to name just a few of a long list of iconic figures, have been described with symptoms of ADHD. Clearly the factors that shape positive as well as negative outcome need as much exploration as the syndrome itself.

Historically, a clinical picture compatible with ADHD has been described for millennia and undergone a series of labels based on etiologic and functional conceptualizations. From Hippocrates, who in 500 BC described the symptoms as the result of an imbalance of humors, to the description by Still in 1902 of a genetic "moral defect" of inhibition (11), to its reframing as a disorder of attention as the core deficit, the syndrome continues to be conceptually a moving target. This is exceptionally true for the current state of affairs, where the understanding of ADHD as an executive function disorder has been broadened to contemplate a more global disorder of neurodevelopment. It is moreover becoming increasingly evident that what we clinically call ADHD is in fact the manifestations of many different disorders of multiple underlying neurobiological pathways.

ADHD is a perfect example of the nature–nurture controversy. On the one hand, it is a validated psychiatric diagnosis (12), on the other, it continues to be controversial because its symptoms are qualitatively within the spectrum of normal human behavior and temperament and attain pathological significance only at their extremes (13). Although diagnosis continues to be based on clinical indicators of impairment, ADHD is associated with objective neuropsychological deficits, changes in brain volume, and increased slow wave electroencephalograms (14). It is controversial because as a developmental disorder it evolves transactionally from conception within a social as well as biological context, so that ADHD symptoms may both cause and be manifestations of social, medical, emotional, and other neurodevelopmental conditions. It is diagnostically further complicated by the fact that the symptoms show a great deal of intraindividual variation and inconsistency and are experienced and described more by relevant persons in the child's (or adult's) environment than subjectively experienced by the child him/herself. In other words, the objective symptoms, the subjective bias of the "eye of the beholder" (teacher, parent, spouse, etc.), and the cultural and specific context that defines abnormality and impairment must be taken into consideration.

18.1.2. ADHD Criteria in DSM-5

There has been an explosion of information about psychosocial, biologic, and neuropsychological correlates of ADHD and other neuropsychiatric disorders gained in the last 15 years. Although there is now an FDA approved brain-wave test for ADHD, it remains defined and diagnosed by behavioral manifestations rather than laboratory tests. There are some variations among diagnostic systems defining ADHD, including the World Health Organization International Classification of Diseases (ICD 10), and DAMP (Disorder of Attention, Motor control and Perception, a system used primarily in Scandinavia) (15). However, The Diagnostic and Statistical Manual of Mental Disorders (DSM) classification system (16) is the prevalent system in the US and in

international research. The DSM diagnostic criteria for ADHD represent a somewhat surgical approach to dissecting the actual clinical phenomenology of ADHD from its complex manifestations and context. The DSM-5 Criteria are based on extensive field trials of ADHD symptoms, in which two behavioral dimensions may be identified, one associated with inattention and cognitive disorganization, and the other with impulsivity and hyperactivity, occurring alone or in combination.

There are several areas of discussion associated with criteria ABCD, regarding the age of onset, the occurrence across contexts, and the exclusionary criteria (17).

Criterion A: The minimum number of symptoms necessary for diagnosing older adolescents (>17 years) and adults has been decreased from 6 to 5, reflecting typical evolution of the disorder with age and development.

Criterion B: Age of onset has been increased to 12 years, a change from the previous DSM version, which stipulated onset prior to age four. This change conveys the importance of clinical presentation in childhood, while reflecting the difficulties in establishing precise age of onset retrospectively. While children who are disruptive, impulsive, and hyperactive are usually identified in their preschool years, diagnosis of children with predominantly inattentive symptoms may be delayed because inattention and cognitive disorganization may not be noticed in the preschool and early elementary years. These symptoms often become impairing only when academic and organizational demands accelerate in the later school grades or even in adulthood.

Criterion C: Cross-situational impairment is required for diagnosis but may not be consistently observed; for instance, behavioral dysregulation, oppositionality, and aggression may be obvious at home from toddlerhood, but may be well controlled in a structured and developmentally effective preschool or daycare environment. Children with ADHD have low adaptability and are often exquisitely sensitive to the "goodness of fit" with their physical environment, teachers, parents, siblings, and peers, which may be reflected in the often highly disparate behavior ratings one finds between teachers and parents, and between teachers from one grade to the next (18, 19).

Criterion D refers to the requirement for clear evidence of functional impairment. The core impairments in ADHD are academic underachievement and poor peer relationships due to peer rejection. The presence and degree of functional impairment is clinically more relevant than the absolute number of ADHD symptoms, and has higher predictive significance for outcome (20). Gordon and colleagues (20), in an analysis of four longitudinal epidemiologic studies of ADHD, pointed out that in all four studies, the link between impairment and symptoms was weak, with DSM symptoms predicting at most 25% of the variance of impairment. Accordingly, prevalence rates were found to diminish when impairment criteria were applied. On the other hand, ADHD with significant impairment may be underdiagnosed if impairment is ignored and symptom counts do not meet threshold levels, which is frequently the case for adolescent and adult ADHD (20).

Criterion E: The exclusionary criteria have been revised to permit codiagnosis of ADHD with Autism Spectrum Disorders. Close attention must be paid to differential diagnosis given the frequent overlap of impulsivity, hyperactivity, and attentional dysregulation in other neurodevelopmental, mood, anxiety, and impulse-control disorders (21), and the frequent comorbidity of mood disorders with ADHD (9). This overlap will be discussed further in the section about comorbidities.

The DSM-5 symptom checklists are prefaced with the requirement that the behaviors interfere with functioning and development. The adequacy of the family, social, and school environment as well as age and cognitive-adaptive status of the child therefore need to be taken into consideration in order to assess how the child's ADHD symptoms are related to the environment, and if behavioral or academic expectations are appropriate for the age and development of the child. This is especially relevant when preschoolers and toddlers present with difficult behavior. Neurodevelopmental delays in toddlers and preschoolers are frequently associated with behavioral dysregulation, poor frustration tolerance, impulsivity, and avoidance behaviors and may mimic early signs of ADHD (22). On the other hand, inexperienced, stressed, emotionally dysregulated, or isolated parents may misinterpret the normal developmental agenda of increased autonomy and exploratory drive in young children as hyperactivity and ADHD (23). The parental expectations, socioemotional health, and possible observation bias of the caretakers must therefore be considered, and observations of less involved individuals included in the behavioral assessment of very young children. It is important to remember that there is an increased frequency of socioeconomic adversity and neuropsychiatric disorders in other family members of children with ADHD, which increases the risk for maladaptation and persistence of disruptive symptoms from early into later childhood and adolescence, and for the development of behavioral and emotional comorbidities (24).

18.1.2.1. Inattentive vs. Hyperactive-Impulsive Symptom Spectrum

Considerable clinical and neuropsychological differences exist between the inattentive and hyperactive presentations, indicating the heterogeneity underlying the diagnosis. Differences are found with respect to gender distribution, functional impairments, comorbidities, and pharmacologic response (25, 26). Hyperactivity is the symptom driving behavioral impairment and comorbidity with ODD, whereas attention problems drive academic impairment (27, 28). The combined type has the worst of both worlds, showing both academic impairment and ODD symptoms in about 50%, and is the most common presentation in both genders (28). The hyperactive-impulsive presentation is usually not associated with academic problems, and in fact is correlated with above average academic performance in a significant proportion (27). However, about 30% of children are behaviorally at risk because of associated ODD symptoms (27).

The predominantly inattentive form of ADHD (ADHD-I) is characterized largely by symptoms of cognitive dysfunction, underarousal, poor working memory, slow cognitive tempo, forgetfulness, and avoidance of mental effort (29). These children are usually older at diagnosis, more likely to be female, and are more likely to have comorbid internalizing rather than externalizing disorders, learning disabilities, and speech and language problems (26, 29). Children demonstrating predominantly inattentive behavior are socially impaired because of withdrawn behavior rather than impulsive intrusiveness. There is low comorbidity between inattentive ADHD and ODD symptoms. Community samples have found that a higher proportion of girls have the inattentive subtype than the other two subtypes (1:2), and in referred samples, inattention is found twice as frequently in girls than boys (30). Because inattentive children are not disruptive, problems may go unnoticed; they are underreferred, and often only identified when comorbidities or academic problems emerge.

18.1.3. Epidemiology

18.1.3.1. Prevalence

ADHD is the most commonly diagnosed neurobehavioral disorder of childhood. Prevalence rates vary from 3 to 12% in large epidemiologic studies, with 6.7–7.5% appearing to be the most consistent range. The most recent National Survey of Children's Health, conducted by the CDC in 2007, and based on telephone interviews with over 100,000 families, reported 9.5% (5.4 million) US children, age 4–17, that had ever had a diagnosis of ADHD. The rate in boys was reported to be 13.2%, versus 5.6% in girls. The rates increased with age: 6.6% in children less than 11 years; 11.2% in children 11–14 years old, and 13.6% in 15–17 year olds. There were large prevalence differences by state, with the lowest rate (5.6%) in Nevada, and the highest (15.6%) in North Carolina. There was no significant difference between white and black respondents (9.9% vs. 10.1%, respectively), however rates in multiracial children (14.2%) were higher than for other racial groups. Hispanics reported rates almost half those of non-Hispanics (5.6% vs. 10.5%) (2).

A 2007 systematic review and metaregression analysis of 102 studies from all world regions (31) found a pooled international prevalence rate of 5.29%. ADHD has been identified as a clinical diagnostic entity in all countries studied, but rates vary according to diagnostic criteria, source of information, requirement of impairment for diagnosis, and geographic origin of the study. Rates based on geographic location of the population were only significantly different between the US and Africa. The fact that ADHD rates are higher in inner cities and populations below the poverty level indicates the contribution of psychosocial adversity to syndrome development, which was already demonstrated by Rutter in the Isle of Wight studies in the 1970s (32). Epidemiologic data clearly associate socioeconomic and demographic factors with the diagnosis of ADHD, i.e., family characteristics such as less likely to live with father, more likely to be poor, school characteristics such as older teachers, and higher expectations for school performance (33).

It is important to stress that Checklist studies lead to false elevations of prevalence rates and can only be used as an estimate of deviance from the norm in a particular population. Checklist studies do not rate the prevalence of ADHD using diagnostic criteria. Instead, rating scales only establish a level of statistical deviance from the normative population. Population prevalence rates established by checklist criteria are often far higher than prevalence rates reported for more stringent diagnostic criteria (20).

18.1.3.2. Gender

Historically, most of the clinical description, epidemiology, and prevalence literature has been focused on latency age boys. ADHD in boys manifests with more disruptive and externalizing behaviors than girls, so that the rate of referral and diagnosis in boys has been much higher, possibly skewing epidemiologic as well as clinical data. Girls with ADHD are underreferred, which is strikingly illustrated by the fact that prevalence rates for ADHD in community samples show a >2:1 male:female ratio, but the ratio of boys to girls referred to clinics may be as high as 10:1 (28). This referral and treatment discrepancy is highly significant because girls with ADHD are just as much at risk for adverse long-term functional outcomes as boys with ADHD as they progress into adolescence and adulthood (34). Although for most aspects of female ADHD, it is not gender, but ADHD, that accounts for functional impairment, the clinical picture differs somewhat from that of boys with ADHD in that ADHD girls have less disruptive and externalizing behaviors and higher rates of internalizing symptoms and more cognitive impairment than boys. Both genders appear to be equally vulnerable to ADHD risk conferred by psychosocial adversity (30, 34). However, boys may be more vulnerable to involvement with deviant peers (35).

In the Massachusetts General Hospital Study of Gender Differences (36), a longitudinal study following both clinic and community cohorts, the predominant subtype for both genders in both community and referred settings was the combined subtype. However, the inattentive subtype was identified in twice as many girls as boys in the clinic population. In both community and referred subjects, boys and girls showed significant and comparable impairments in psychosocial, educational, and emotional

domains. At 5-year follow-up at an average age of about 17 years, the girls with ADHD had rates of antisocial, anxiety, mood, and substance abuse disorders comparable to boys with ADHD, and significantly higher than female controls. A nonsignificant trend to eating disorders also appeared in this population in adolescence. Girls with ADHD in this study differed from boys in one surprising aspect, namely that in adolescence they showed a higher vulnerability to substance abuse than boys with ADHD, even though they had less impairments earlier on. A longitudinal study of girls with ADHD followed from childhood to adolescence found disruptive-oppositional ADHD symptoms and peer rejection in girls to be predictive of later substance abuse and internalizing disorders (37). Girls with ADHD are at high risk for early sexual activity and unplanned pregnancy. Longitudinal studies into adulthood confirm that the persistence of ADHD symptoms and continued strong association with depression and anxiety is similar for both genders, with a higher risk for substance abuse disorders and antisocial personality disorders in men (38).

18.1.3.3. Age

18.1.3.3.1. Infants

Most studies of ADHD are limited to children in middle childhood (6–12 years). However, data are becoming available about the developmental precursors of psychopathology from infancy and toddlerhood, although the DSM classification system is poorly suited for these age groups. Neuroimaging studies suggest that structural variations may be present in infancy that are associated with later executive functioning impairment (39). Models of temperament conceptually overlap the dimensions of behavioral and affective self-regulation associated with ADHD, and the "difficult-temperament" infant may represent a bridge between infant risk and development of ADHD (40).

Auerbach (41) examined temperament differences and neurodevelopmental immaturity in male newborns at familial risk for ADHD using factors derived from the Brazelton Neonatal Behavior Assessment Scale (NBAS) (42). Newborns at risk for ADHD showed risk factors not only on indices associated with temperament, namely poor state organization (irritability, problems self-quieting), but also on measures of motor maturity and autonomic stability. At 7 months of age, a subcohort of this genetically at-risk group showed decreased interest in block play, higher activity, and increased anger reactivity. These authors assert that symptoms are subtle, possibly nonspecific, and their predictive value for later ADHD or psychopathology could be a function of the interaction with caretaking environments.

Other studies have found disorganized, insecure attachment, emotional dysregulation, and sleep problems in infancy correlated with hyperactivity, ADHD, and conduct disorders at early school age (23, 43, 44). The infant behaviors may be mediated by negative parenting and/or parental psychopathology, specifically maternal depression. Hostile parenting by mothers of sons appears to be a risk factor for later ODD and conduct disorder, whereas maternal depression is more strongly associated with ADHD (45, 46). A construct of parental–child interaction that may be a mediating factor for these effects is the presence and quality of parental, i.e., maternal responsiveness. Parental responsiveness can be operationalized and indicates the parent's sensitivity and adaptation to the child's signals, states, and needs. Maternal responsiveness may not protect against the development of ADHD, however, it does appear to protect against the codevelopment of ODD/CD (45). Maternal responsiveness is also strongly associated with language development in early childhood, which, in turn affects behavior regulation (47). In fact, distractibility in early childhood as a precursor of hyperactivity in middle childhood may be determined more by caregiving and contextual factors than biological and temperamental factors (48).

This reality was aptly summarized by Erickson, who observed: "The infant age of development is based on establishment of basic trust derived from earliest experience and is dependent on the quality of the maternal relationship" (49). And to follow with Michael Rutter: "The impression of lasting effects stems from the very high probability that a poor early upbringing will be followed by a poor later upbringing. The persistence of behavioral sequelae is largely a consequence of the persistence of the damaging experiences" (50).

18.1.3.3.2. Preschoolers

ADHD may be suspected when developmentally appropriate activity and impulsivity characteristic for toddlers and early preschoolers becomes extreme or persists beyond the toddler and early preschool period. However, in about 50% of cases considered to be at risk for ADHD, symptoms do not persist, and only 5–10% of preschoolers with concerns about inattention actually continue on to develop ADHD (51). Prevalence rates for ADHD in preschoolers are quite inconsistent, depending on methods and clinic vs. community populations. The range is from about 2% in primary care pediatrics to 5.7% in community to 59% in psychiatric referral clinics (52). There is often a significant discrepancy between parent and teacher evaluations. For example, in one Japanese study, parents reported a prevalence of 31.1% of ADHD symptoms, while teachers thought only 4.3% of these children met diagnostic criteria (53). In the Canadian nationwide survey of children 0–7 years, children's behavior was rated by their mothers at 2 and again at 7 years, with 7% of children showing persistence of hyperactivity at 7 years. The persistence was associated with male gender, maternal prenatal smoking, maternal depression, and hostile parenting (54).

At this age persistent behavioral ADHD symptoms may indicate a host of disparate problems, from medical problems, such as gastro-esophageal reflux, to environmental disruption and parenting effects, to the emotional and cognitive response to developmental frustration, to autism spectrum disorders (ASD). Disrupted sleep patterns or reduced sleep quality are associated with overactivity, anger, aggression, impulsivity, tantrums, and annoying behaviors, and these problems often resolve when the underlying sleep problem is corrected (55). Toddlers and preschoolers with language delay are often very frustrated, distractible, disruptive, emotionally dysregulated, and physically expressive. Language may improve dramatically with skilled speech-language therapy and results in equally dramatic emotional and behavioral stabilizations. In contrast, impulsive, hyperactive, inattentive, and distractible behaviors are common in preschoolers with autism spectrum disorders, but it is the lack of communicative and social intent and stereotypical behaviors that should raise concerns that one may be dealing primarily with an ASD rather than ADHD. Furthermore, cognitive deficits may underlie and mimic ADHD symptoms (22). Preschoolers usually love the individual attention and activities of testing situations as long as they are able to understand and perform the requested tasks. They may do fine behaviorally and be attentive as long as they are not requested to perform tasks that are difficult for them. However, when increased task complexity such as in imitative drawing or block activities, language testing, and other cognitive challenges results in avoidance behavior, distractibility, and inattentiveness, verbal and nonverbal cognitive deficits should be ruled out.

Preschoolers with ADHD show deficits and differences from control children in intellectual, sensory, and motor performance that go beyond the core symptoms of ADHD (22). Although similar deficits have been found in school-age children with ADHD, there is a paucity of data about developmental delays in preschoolers with ADHD. However, it is important to remember that ADHD, ASD, cognitive-adaptive, and language disorders have common interfaces at this age, and may only reveal their separate identities and diagnoses with time and with appropriate interventions.

18.1.3.3.3. Middle Childhood

By middle childhood the behavioral, cognitive, and emotional streams become more separable and diagnostically recognizable. Academic underachievement and problems with social competence and acceptance emerge as the most salient impairments. Awareness of being different begins to affect the child's self-esteem, especially as it is often the result of peer rejection or name-calling. Behavioral dysregulation persists, but dysfunctions in cognition, sensory and motor, and affective domains become more evident (17, 56).

There are many ways in which ADHD children differ from their unaffected peers. Causal connections, story comprehension, and time perception are deficient compared to controls (57, 58). Children with ADHD show restricted cognitive flexibility (59), which may manifest as stubbornness, oppositionality, or avoidance behavior. Cognitive disorganization, impaired working memory, poor reading comprehension, and procrastination emerge in middle childhood, and affect academic performance and especially homework activities (17). They have difficulty starting and completing tasks and have difficulty self-monitoring (60). They are often clumsy with complex fine motor tasks (61), and in visual-motor integration, which manifests in poor handwriting and impairment in written schoolwork. Adaptive function in daily living skills, such as maintaining personal hygiene or taking on household responsibilities, is immature relative to cognitive levels (62). Although they are inattentive and distractible with chores, homework and even on the sportsfield, they may spend hours transfixed watching television or playing computer and video games. They are emotionally and behaviorally very context dependent (57), for instance may do very well with one teacher, but may be oppositional and resistant to another. They are emotionally dysregulated, attention seeking, difficult to satisfy, tend to overreact to current and anticipated experience, and are especially intolerant of disappointment and negative experience (63).

A frequent complaint of parents is emotional and behavioral immaturity, such as silliness and inappropriateness, a preference for playmates, activities, and toys that are considerably below age and cognitive level, and a remarkable lack of insight into their own behavior, while being extremely sensitive to rejection and criticism.

However, it is very important to acknowledge that their emotions go both ways: they are also often very affectionate, enthusiastic, generous, forgiving, eager to please, very responsive to individual attention especially from other adults, and are often deeply hurt and baffled by the rejection they experience from their peers.

Academic failure due to core ADHD symptoms and associated cognitive, language, and learning disabilities, which are found in 30–50% (9), lead to poor self-esteem and acting-out behavior, conflictual family, and peer relationships and increase the risk for depression. Peer rejection may happen already to hyperactive, intrusive, impulsive preschoolers, but becomes much more evident and perceived by middle childhood, where it quickly leads to loss of self-esteem and confidence. Half of children with ADHD suffer from peer rejection, which appears to be the primary mediator for the relationship between ADHD and depression in both younger and older children with ADHD, and is a powerful predictive factor for depression in adult ADHD, particularly in women (64). Academic performance in fact may not be an issue in a bright child with ADHD, but whose impulsive and unmodulated social approach may lead to significant impairment in family and peer relationships from early childhood. Academic underachievement and peer rejection in association with ADHD convey separate but additive risk for developing of internalizing and externalizing behaviors, substance abuse disorders, and school and occupational failure in adolescence and adulthood (65).

Erik Erikson refers to middle childhood as the stage that is determined developmentally by the conflict between industry and inferiority: "the child's danger, at this stage, lies in a sense of inadequacy and inferiority. If he despairs of his tools and skills or of his status among his tool partners, he may be discouraged from the identification with them and with a section of the tool world" (49).

18.1.3.3.4. Adolescence

In the transition from childhood to adulthood, powerful changes occur in physical development, sexuality, peer and family relationships, and cognitive, moral, and emotional development. In previously emotionally healthy children, this transition is not as tempestuous as lore would have it. However, adolescence increases the risk for emergence or consolidation of previously latent, cognitive, behavioral, and emotional problems, which appears to be driven by genetic-biologic factors and shaped by family and peer relationships and academic performance. The persistence of ADHD into adolescence is also strongly associated with familial occurrence, psychosocial adversity, and preexisting psychiatric comorbidity (24, 66). Impairing symptoms continue into adolescence in 60–85% with only a small minority showing remission. Hyperactivity decreases, but inattentiveness and impulsivity persist (56). Comorbidities with anxiety disorders, depression, and dysthymia increase from the already high rate of about 30% in middle childhood to 35 and 50% respectively by mid-adolescence. Adolescent-onset mania may be suspected in depressed children with chronic irritability and explosiveness (9). Quality of life is affected in all domains: 50–70% of children with ADHD have few or no friends, the school dropout rate is estimated at 32–40%, and the college completion rate 5–10% (10, 67, 68). Adolescents with ADHD are at a twofold to fourfold risk compared with normative peers to be involved in automobile accidents (69); other risk-taking behaviors are increased, such as unprotected sex, with an increased teen pregnancy and STD rate in some studies (10). Eating disorders present a risk in girls with ADHD who are experiencing academic and peer problems, probably as a result of seeking peer acceptance and impulsive behavior (64). ADHD has also been correlated with bulimia in obese adolescents of both genders, independently of mood disorders (70).

The increased rate of psychiatric disorders in adolescence is multifactorial, driven on the one hand by familial predisposition, physical change, and environmental stressors and on the other by adolescent-specific cognitive and affective development, increased introspection, and self-appraisal (71). Sociocultural factors play a strong role in shaping the course of adolescence, so that coping mechanisms as well as issues such as school attendance and dropout rates, adolescent sexual behavior, substance use, and problems with the criminal justice system, must be considered in context, rather than solely being the results of individual pathology.

18.1.3.3.5. Adults

Although this discussion about ADHD is restricted to children, mention of adult ADHD is appropriate, since a significant portion of the parents of children with ADHD themselves have ADHD and associated comorbidities. Frequently it is the child's evaluation and treatment that leads to the parents' realization of their own disability, and frequently the first step in treating the child is addressing the parents' problems. Although adults may not meet full symptom criteria, it appears that impairing ADHD symptomatology persists into adulthood in about 65% of childhood diagnosed ADHD (4). There also is a subgroup of adults whose symptoms did not appear or result in impairment until later childhood who nevertheless meet all other diagnostic criteria and show significant impairment (72). The adult prevalence is estimated to be between 4–5% (3, 4).

The majority of adults have significant psychosocial dysfunction, including lower educational and occupational status, have fewer friends, sire more children in early adulthood, and have higher divorce rates than controls (1, 10, 72, 73). They are at substantially higher risk for antisocial personality disorders, and mood and anxiety disorders, and for behavior leading to arrest. In fact, reported prevalence of ADHD among incarcerated males may be as high as 40%, and is highly associated with learning disabilities and affective disorders (74).

18.1.4. Comorbidity

Comorbidities with at least one neurodevelopmental or psychiatric disorder occur in at least 80% of persons with ADHD, and 60% have two or more comorbidities (9). The greater the number of comorbidities, the more severely the cognitive and psychosocial functions of the individual are affected (75). Awareness of this high likelihood of comorbidity, and diagnosis and interventions has the same urgency as treatment of ADHD in order to decrease the severe psychosocial stressors that are the inevitable consequences for the child and his/her family (76). There is virtually no research literature that explicitly describes the development and course of children with "pure" ADHD, which clearly exist and could in fact represent a specific subcategory of ADHD that deserves investigation.

18.1.4.1. ADHD and Other Neurodevelopmental Disorders

Children with ADHD are different cognitively as well as affectively from children without ADHD. About 30–50% of children with ADHD have other neurodevelopmental disorders such as dyslexia and language disorders. It appears that such co-occurrences are not based on single factor linear causality, such as attentional dysfunction leading to impaired perceptual processing which then leads to reading disorders. It appears instead that they may be etiologically multifactorial, in that disparate conditions share genetic and cognitive traits that account for their co-occurrence (77). The surprisingly high rate of 25–40% comorbidity of ADHD with dyslexia is an example of such a putative genetic pleiotropy, in which one gene may exert effects on different cognitive functions.

Speech-language delay and disorders occur in 30–50% of children with ADHD (78), and frequently precede the development of reading disorders. The etiologic complexity of these comorbidities is illustrated by the fact that both language and reading development are strongly affected by environmental-caretaker factors as well as genetic factors (79). Language disorders that persist into adolescence are in and of themselves associated with higher degrees of cognitive, behavioral, and emotional disturbances (80), as is the nonverbal learning disability or right hemisphere syndrome, which is frequently associated with ADHD and is characterized by average language ability but difficulty with social cognition, and deficits in visual-integrative, mathematics, and graphomotor competence (81).

Children with Autism Spectrum Disorders have a 20–50% rate of comorbid ADHD as well as the characteristic social-communication deficits (82). Developmental coordination disorder is identified in about 50% of children with ADHD, and indicates more severe cognitive involvement as well as psychopathology. Conversely, virtually all children with movement problems are at risk for problems in attention, learning, and psychosocial adjustment (83). About 55% of children with Tourette's syndrome have comorbid ADHD (84).

Children with mental retardation have similar prevalence rates of ADHD as children with typical intelligence. However, the concurrence of ADHD increases the severity of functional cognitive impairment (82).

18.1.4.2. Psychiatric Comorbidity

18.1.4.2.1. Mood and Anxiety Disorders

Mood and anxiety disorders frequently have symptoms of inattention, impulsivity, and hyperactivity that may be misdiagnosed as ADHD. However, at least 25% of children with ADHD are thought to have comorbid anxiety and close to 50% may have mood disorders, including dysthymia and Major Depression (9). Community and psychiatric referral cohorts show the same rate of comorbidities, and in both, the prevalence of comorbidities increase markedly with age. The Massachusetts Longitudinal studies of children with ADHD found that 29% of 11 year olds with ADHD met criteria for depression, which increased to 45% by mid-adolescence, compared to 2–5% of controls. The association of Bipolar Disorder to ADHD is as yet somewhat unclear, but it is thought that early hyperactivity may actually represent a developmental precursor to mania for a significant number of children with ADHD. In the Massachusetts cohort, 11% were found to have mania at baseline, characterized by severe chronic irritability, aggression, and explosiveness, which increased to 12% after 4 years. Lifetime prevalence of ADHD in bipolar adults is estimated at 9.5%, with onset of mood symptoms an average of 4 years earlier (13.9 vs. 18 years old) than in patients with bipolar disorder alone (85). Anxiety disorders were found in 28% at baseline of 11 years, and increased to 35% in middle adolescence, compared to 5% and 9% respectively in normals. Characteristically, anxiety (generalized anxiety, separation anxiety) and depression are found concurrently in ADHD. The severity and degree of impairment is mediated by a number of comorbid conditions, family-genetic factors, and age of onset (86), i.e., the earlier the onset, the more severe the manifestations.

An interesting diagnostic dilemma exists between ADHD and Posttraumatic Stress Disorder, especially in communities that experience high levels of community or domestic violence. Clinicians must be attentive to significant overlap of ADHD symptoms with PTSD arousal symptoms (PTSD criteria E for older children or criteria D for children under 6): irritable behavior, angry outbursts, reckless behavior, hypervigilance, exaggerated startle response, concentration problems, and sleep disturbance. It is often difficult to elicit a clear history of trauma; whereas parents and schools are likely to report behavior problems. The two disorders are phenomenologically, diagnostically, and neurobiologically independent disorders, which can coexist and combine to exacerbate stress-reactivity (87).

18.1.4.2.2. Risk Factors in Psychiatric Comorbidity

As with other neurobehavioral disorders, the development of depression and anxiety in childhood and adolescence is associated with genetic, prenatal, and early infant and childhood biological and experiential factors (86, 88). It is in this context quite striking that the role of mothers in the development of behavioral disorders is well researched, whereas the presence and role of

fathers as contributing to or protective of mental disorders has received little attention until recently (89). The importance of prenatal and early childhood environmental/psychosocial contributions to childhood mental health and developmental disorders cannot be stressed enough, since prevention and early intervention are realistic goals for many of the identified risk factors (90).

Prenatal maternal stress, substance use, anxiety, and depression are associated with risk to the cognitive and affective-behavioral development in their children, mediated by alterations in the maternal HPA and, in the case of substance use, on the direct effects of teratogens on the developing brain. Postnatal environment, which includes psychosocial adversity (low income, social isolation, marital stress, absent fathers, intrafamily hostility), parental psychopathology, and caretaking behaviors are risk factors for the development of externalizing and internalizing disorders in the offspring.

However, anxiety disorders in parents have a higher specificity for development of anxiety in their children (86) than other disorders, which is mediated by overprotective, controlling, and negative parenting. Child factors that are associated with the development of anxiety are biobehavioral dysregulation in infancy, overreactivity and developmental delays in the preschool period (91), and resulting vicious cycles of anxiety, impaired peer relationships, and further developmental and academic failure. Development and persistence of depression is less specific to the particular parental psychopathology, but associated with similar prenatal and postnatal risk factors as well as with the presence of depression in the mother during later childhood (46). The cumulative effects of poor peer relationships and academic impairments represent the specific risk factors for the development of depression in ADHD (64, 86).

18.1.4.2.3. ADHD and Oppositional Defiant Disorder

ODD can be identified in about 40–60% of children with ADHD, predominantly combined type, in about 30% with the predominantly hyperactive type and is rarely reported in ADHD-Inattentive type (9). Children with ODD are disobedient toward authority figures, often easily angered, negative, vindictive, very controlling, and easily provoked by their peers. Children with depression, bipolar, and anxiety disorders may demonstrate similar symptoms. Such symptoms may occur as a reaction to stress or abuse. Despite severely oppositional behavior toward adults, behavior toward peers may be quite peaceful. Symptoms may emerge as early as in toddlerhood to preschool age and are strongly associated with maternal depression, decreased maternal responsivity, and negative parenting practices in early childhood (23, 46). In preschoolers, ODD behavior may be severe at home, often especially toward the mother and siblings, but not evident in a well-managed structured preschool environment. When ODD persists into later childhood and adolescence, a high rate of active maternal depression, helplessness and overreactivity (92–94), and paternal negativity are contributing factors (86), and oppositional behavior spills over into the school setting. Fathers of children with ODD have an increased rate of substance abuse, negative parenting, a childhood history of ADHD, and current anxiety disorder (94). ODD is associated with intense family conflict (95), that is especially virulent in adolescence and potentiates the negative effects of core ADHD behaviors (96, 97). ODD may be comorbid with Conduct Disorder as well as ADHD, but ODD does not develop into later Conduct Disorder if the latter was not already present in earlier childhood (92). Conduct disorder is clearly separable from both ADHD and ODD, and will be discussed separately.

18.1.4.2.4. ADHD-Plus

Symptoms of ADHD can be found as a specific manifestation of neurological involvement or as secondary symptoms of systemic disorders. First, identifying an underlying medical condition is imperative for appropriate etiological treatment. Secondly, if ADHD is a manifestation of or occurs comorbidly in chronic systemic or neurologic illness, pharmacologic treatment may considerably improve quality of life. ADHD symptoms, in association with cognitive and learning disorders are frequent in: posttraumatic and postinfectious encephalopathy, fetal alcohol exposure, chronic lead poisoning, cerebral palsy, prematurity, neuromuscular disorders, especially myotonic dystrophy, neurofibromatosis, fragile X, Turner, Klinefelter, and Williams Syndromes, seizure disorders, congenital brain anomalies, metabolic disorders, as well as in a host of less prevalent neurogenetic syndromes (98).

Any chronic illness, anemia, asthma, allergies, heart conditions, renal disease, metabolic dysregulation such as in diabetes or thyroid disease, chronic gastrointestinal problems, nutritional deficiencies, and other disorders causing chronic fatigue, inattentiveness, and behavioral symptoms such as restlessness may mimic ADHD and should be considered in the presence of leading physical symptoms. Chronic hypoxia, as in congenital heart disease (CHD) and Sleep Disordered Breathing, have actually been shown to be causal for ADHD (99). Studies have shown clinically significant improvement in attentional symptoms as measured by continuous performance tests following tonsillectomy (100).

Furthermore, many medications have side effects that may affect attention and cognitive processing in some children, most significantly antipsychotics, anticonvulsants, steroids, antihypertensives, bronchodilators, and antihistamines.

18.1.5. Neuropsychology

Neuropsychological theories regarding a hyperactive, impulsive, and inattentive childhood behavioral syndrome have a long-standing history dating to the latter part of the nineteenth and early part of the 20th century (12, 101). Neuropsychological dysfunction in ADHD has since been increasingly well-characterized and documented. In the 1990s, the availability of enhanced brain imaging and measurement techniques served as a catalyst to rapid advancements in the field, with much of the research over the last decades focusing on the delineation of executive functioning and inhibitory deficits in the disorder (8, 102, 103). As seen from a neuropsychological perspective, many functional processes fall under the rubric of executive functions, including set shifting, planning, inhibition, and working memory. Primarily concerned with goal-directed and problem-solving behavior, executive functions are thought to play a role in a wide range of adaptive and goal-directed behaviors, including context-specific action selection (102, 104). Problems with behavioral inhibition, conceptualized as the ability to strategically or effortfully inhibit an automatic or on-going response, have been suggested by Barkley (8) to be the primary deficit in ADHD, with inhibitory impairments leading to inadequate time for execution of other executive functions—particularly, working memory, self-regulation (e.g., of affect, motivation, and arousal), internalization of speech, and reconstitution (analysis and synthesis).

Research to date has widely supported the presence of both behavioral inhibition and executive functioning deficits in the combined subtype of the disorder (105–107). A meta-analysis by Willcutt and colleagues identified difficulties with response inhibition, vigilance, working memory, and planning to be the most robust ADHD-related impairments. Imaging studies have linked executive and inhibitory impairments to dysfunction in multiple distributed prefrontal-striatal neural networks, particularly right prefrontal cortex (especially the inferior frontal gyrus), anterior cingulate, caudate, and thalamus (108–110). However, whether response inhibition deficits—or even executive functioning or prefrontal cortex deficits more broadly—constitute the core or primary deficit in ADHD remains under considerable debate (111, 112). For instance, attention and arousal factors (e.g., variable performance and slower responding) are likely to also contribute to response inhibition deficits (113). In addition, meta-analytic studies suggest that despite findings of moderate group deficits on executive measures, many children with ADHD do not demonstrate executive impairments on any given measure. Nigg and colleagues, for instance, found that although approximately 80% of children with ADHD exhibit impairments on at least one executive functioning measure, no more than 50% of children with ADHD demonstrated impairments on any one particular executive measure and only ten percent of children had generalized/global impairments across executive functioning measures (i.e., on five or more executive functioning measures) (114). The implicit conclusion from such findings is that children with ADHD likely comprise a heterogeneous group consisting of etiologically distinct subtypes, with multiple or distinct etiological pathways that lead to similar behavioral (i.e., descriptive)-level phenotypes (as documented by the DSM-5).

The considerable neuropsychological heterogeneity among children diagnosed with ADHD has moved the field towards a search for "endophenotypes" to bridge ADHD behavioral symptoms, neuropsychological impairments, and underlying genetic or neurobiological etiologies and to explain differences in symptom clusters, comorbid diagnoses, and patterns of neuropsychological and cognitive deficits (114, 115). This approach aims to identify possible pathways to disorder—including potentially numerous genetic and environmental influences—and attempts to improve upon the DSM's behaviorally-based taxonomy by increasing specificity of the ADHD construct. This alteration in focus has produced a resurgence of interest in alternate theories of ADHD, especially those that posit neuropsychologically distinct subtypes with multiple pathways to disorder (116–118). For instance, Sergeant and colleagues' cognitive-energetic state regulation theory of ADHD (119) posits arousal (i.e., phasic alertness), activation (i.e., response readiness), and effort impairments—linked to right-lateralized noradrenergic and left-lateralized dopaminergic neural networks, respectively—to constitute the primary deficits in ADHD, with specific impairments possible in one or more of these three energetic "pools". Other prominent theories of ADHD argue the disorder to result from temporal processing deficits (120, 121), abnormalities in reinforcement-response mechanism (e.g., reward circuitry) (122), or interactions between altered reinforcement-response mechanisms and environmental factors such as social-learning, environmental conditioning, and altered appetitive or motivational systems (123) that produce "delay aversion" (124, 125).

A few additional points are relevant to current neuropsychological findings in ADHD. Patterns of impairment in the inattentive subtype of the disorder remain relatively underspecified, with the limited existing studies finding no convincing evidence for subtype differences (126). This research may, however, be confounded by the DSM taxonomy, which lumps together children without hyperactivity (many of whom are actually underactive) and those whose hyperactivity problems are "subthreshold" for the combined subtype of the disorder. This distinction is important, since some evidence suggests that children with "sluggish cognitive tempo" (e.g., inconsistent alertness and underactivity) may represent an etiologically distinct neuropsychological subtype of ADHD (127). Also as yet relatively underspecified are neuropsychological pathways towards comorbidity in ADHD. Temperamental vulnerabilities (e.g., negative emotionality), for instance, may predict development of comorbid oppositional or antisocial behavior disorders in ADHD independently of cognitive deficits (117, 118). Likewise, ADHD-related

neurocognitive impairments may predispose children towards the development of comorbid learning disabilities (128, 129). Finally, identification of the developmental trajectory of neurocognitive impairments remains in its early stages, but studies to date support the presence of impairments identifiable as early as preschool (116, 130) that persist into adulthood, despite the waning of behavioral symptoms such as hyperactivity and impulsivity (131–133).

18.1.6. Pathophysiology

The dominant hypothesis for the pathophysiology of ADHD is that of prefrontal cortical dysfunction, which is mediated by abnormalities of catecholaminergic neurotransmission in the catecholamine-rich fronto-striatal-cerebellar networks, which are the putative neural substrates for inhibitory and attentional control. The hypothesis is supported by the treatment effectiveness of stimulants, which increase the availability of extracellular catecholamines by inhibiting their reuptake from the synaptic cleft into the presynaptic terminals. Further, an increasing number of neuroimaging studies have captured structural and functional abnormalities in fronto-cortical and fronto-subcortical networks that persist in to adulthood. For example, a study of medication naïve young adults with a childhood ADHD diagnosis showed dysfunction in latero-fronto-striato-parietal regions relative to controls during sustained attention, as well as in ventromedial orbitofrontal regions during reward, suggesting dysfunctions in cognitive-attentional as well as motivational neural networks (134). The brain deficits in ADHD appear to be multisystemic, and are likely the result of differential disruptions that may occur during the development of the brain in fronto-striatal-cerebellar-parietal circuits, and may account for the inconsistency of clinical as well as of neuropsychological, morphological, and neuroimaging findings. As Casey points out, "cognitive (and neural) processes are intrinsically linked deficits in one system, and are likely to affect others in secondary ways, especially in a dynamically changing system such as the developing child with ADHD" (135).

18.1.6.1. Neuroimaging

Anatomic evidence for involvement of the frontal-striatal-cerebellar circuits is based on volumetric studies which demonstrate differences of the cerebellar vermis, caudate, putamen, and globus pallidus morphology in ADHD subjects compared to controls, as well as frontal lobe differences, with smaller volumes described of medial frontal areas including the cingulate, prefrontal, premotor, and motor cortex (136). In contrast to finding volumetric changes in discrete regions, Castellanos (137) found cerebrum and cerebellum as a whole to be smaller in all mapped regions in children and adolescents with combined type ADHD, rather than showing localized changes in fronto-striatal volumes. These differences were not affected by symptom severity, physical growth, handedness, or cognitive-comorbid parameters and remained consistent over different ages, except for a "normalization" of caudate size in adolescent probands, which was speculated to reflect the decrease in motor activity with adolescence in normal as well as hyperactivity-impulsivity in ADHD children. Significantly, morphologic changes were the same for children on stimulants as for untreated children. fMRI studies demonstrate activation differences in attention processing tasks in striatal-frontal networks (138), and in inhibitory-control tasks of cingulate, ventrolateral, and dorsolateral prefrontal cortex between ADHD and controls, but, comparable to Castellanos' findings, no differences were identified between treated and stimulant-naive ADHD subjects. (110, 139). Acute methylphenidate challenge enhances brain activity on fMRI, but this response to methylphenidate is inconsistent, not reflected in clinical test performance, and does not correspond to the fMRI activation patterns between ADHD probands and controls (138).

Affective response and mood disturbances in ADHD are thought to be correlated with volumetric differences in amygdalar regions found in children with combined ADHD and are interpreted to represent alterations in interconnectivity between amygdalar nuclei and the Prefrontal Cortex (PFC). Differences in hippocampal volume are speculated to account for differences in delay aversion and stimulus-seeking behavior (140). Further evidence for frontal involvement are EEG studies demonstrating cortical slowing (141, 142), and enhancement of Theta activity in frontal quadrants in ADHD, with males having more generalized and females having localized frontal changes (143). These EEG changes are the basis of the FDA approved Neuropsychiatric EEG-Based Assessment aid, which computes the ratio of theta and beta brain waves over a 15-minute period (144). In a blinded, prospective, multicenter study, EEG identified ADHD with 87% sensitivity and 94% specificity. Because EEG cannot identify comorbidities or alternative diagnoses, it is not recommended as a substitute for clinical evaluation (145).

It is unclear how specific neuroimaging findings are to ADHD and how much they overlap with other forms of neuropathology. It appears likely that structural-functional relationships are bidirectional, and affected by developmental and environmental factors (136). Given the clinical as well as neuropsychological heterogeneity of ADHD more definite conclusions require investigation of population samples that are defined by phenotypical homogeneity with regard to cognitive, behavioral, comorbid, and medication response characteristics.

18.1.6.2. Neuromodulators

ADHD symptoms appear to be mediated by alterations of the availability and effect of the catecholamines dopamine, and norepinephrine, which activate the circuitry and projections between the prefrontal cortex (PFC), basal ganglia, and cerebellum. Moderate levels of these catecholamines enhance, and high levels inhibit PFC function. Localization and effect of dopamine is dependent on the type of dopamine receptors that are activated, of which D-1, D-2, and D-4 receptors are the major groups. D-1-type receptors are concentrated in the PFC and their stimulation has a "U" shaped effect on PFC function, e.g., enhances working memory and attention regulation at lower levels of dopamine, but impairs it at high levels, such as with stress. Much less is known about dopamine-2-type receptor dysfunction, which appears to be associated with schizophrenia, and while there is some evidence for genotypic overlap of ADHD and schizotypy, the role of D-2 activity in ADHD remains to be clarified. D4 receptors are actually activated by norepinephrine rather than dopamine and appear to inhibit GABAergic (inhibitory) activity in PFC pyramidal cells; stimulation of D4 receptors consequently increases pyramidal cell firing. It appears that D4-receptor dysfunction, which results in increased GABA activity in the PFC with decreased pyramidal cell firing, may be associated with ADHD (146–148).

Norepinephrine receptor activity may enhance or impair PFC depending on receptor type. Activation of the postsynaptic alpha-2A receptor has enhancing effects and its agonist guanfacine improves executive functions in the PFC. Stress increases norepinephrine release at alpha-1 receptors, which has detrimental effects on PFC function. High alpha-1 activity may be associated with mania and schizophrenia, worsening with stimulants, and is blocked pharmacologically by antipsychotics (149).

18.1.7. Etiology

The many changes the concept of ADHD has undergone over time reflect different ideas about its causes. There is a point of view that considers what is called ADHD not to be a neuropathologically defined entity, but a mental construct for behavioral dysfunctional symptoms that represent a final common pathway of etiologically heterogeneous conditions. A monocausal model has given way to a transactional developmental model, in which individual factors (i.e., genetic vulnerabilities, temperament, and intelligence) interact with biologic and psychosocial factors throughout the lifespan. Recent research has returned focus on and specified the significance of the physical and social environment during gestation, infancy, and early childhood in shaping the neurodevelopmental substrate out of which mental and physical health as well as pathology, evolve (23, 90). This research gives support to the feasibility of prevention or at least mitigation of physical as well as mental disorders.

18.1.7.1. Genetics

Given the transactional conception of ADHD, the vulnerability to develop the behavioral and cognitive features associated with ADHD is highly familial. Based on epidemiologic, family, twin, adoption, and case–control studies, the heritability is considered to be between 60 and 80% (149, 150). The phenotype of ADHD is highly variable, and implies complex interactions of multiple genetic, biologic, and environmental factors. ADHD is most likely a polygenic condition, which implies the interaction of multiple alleles in the expression of ADHD, and a high if less expressive presence of such alleles in the nonafflicted population, which increases the difficulty of identifying pathogenic polymorphisms. Studies relating neuropsychological and behavioral markers to known candidate genes have led to inconsistent results (149, 150). Consequently, clinical, neuropsychological, epidemiological, and pharmacological patterns are sought as identifiers of distinct heritable subtypes that then can be researched systematically with molecular genetic methods (150, 151). Chromosomal regions containing potential ADHD predisposing loci, including 5p, 6q, 7p, 11q, 16p, and 17p, have been identified through family-based linkage studies (152). However, data associating ADHD with identifiable susceptibility genes is contradictory and still far from providing any clinically applicable consequences.

Because of the marked therapeutic effect of stimulants in ADHD, which is attributed to the inhibition of dopamine transporter (DAT) and increase of functional availability of extracellular dopamine, molecular genetic investigations have largely focused on identifying candidate genes associated with alterations of dopamine transporter and receptor (DRD) mechanisms. For example, associations were found with DAT1, DRD4, synaptosomal-associated protein of 25 kDa (SNAP25), brain serotonin transporter (5HTT), serotonin receptor 1B (HTR1B), and dopamine-beta-hydroxylase (DBH) (153). Meta-analysis examining 5 top candidate genes, all implicated in synaptic transmission and plasticity [brain-derived neurotrophic factor (BDNF), HTR1B, norepinephrine transporter gene (SLC6A2), SLC6A4, and SNAP25] found only the SNAP25 variant showing an association with ADHD. SNAP25 decreases Ca^{2+} responsiveness at glutamatergic synapses (150). A meta-analysis of 113 genetic studies by Bobb, Castellanos, and colleagues (154) supports a definite but modest role for dopamine D4 and D5 receptors, and dopamine and serotonin transporter genes in ADHD. An association of the DRD4 7- repeat allele with ADHD has been replicated

and a longitudinal study has confirmed this association in ADHD with higher cognitive function and better long-term outcome than other forms of ADHD (155).

A different approach to genetic specification suggests differentiating the phenotypes of ADHD by using dimensional as well as categorical diagnostic criteria as well as refining the subtypes as a workable path to identifying associations with susceptibility genes, for instance in differentiating susceptibility genes for different comorbidities with ADHD (156). This approach is related to the concept of "endophenotype," which has resurfaced as a way to organize and classify the mediators of genetic-phenotype relationships into operational subtypes, such as through specific neuropsychological profiles or biological markers that themselves are heritable (157). However attempts to prove that specific neuropsychological deficits play this role in children with ADHD and their unaffected family members have been unsuccessful or limited at best (115).

An example of the genotype-phenotype linkage approach is Barkley and colleagues' study of the clinical phenotypes associated with identified susceptibility genes in children with ADHD and controls enrolled in the Rochester Longitudinal Study (158). The investigation included a wide spectrum of behavioral and neuropsychological measures and identified a group of children with ADHD that demonstrated numerous behavioral main effects associated with a heterozygous DAT1 polymorphism. This group was distinguished by more severe and pervasive behavioral problems and consequences, whose effect size increased from childhood into adulthood, whereas neuropsychological tests of executive function did not associate with susceptibility genes or with distinguishing behavioral symptoms (158). Barkley makes an argument for studying the "extended phenotype" of ADHD, which he describes as the distal effect of the genotype on social relations, family, and occupational performance. Barkley conceptualizes this "extended phenotype" as being a genetically and biographically relevant endophenotype, determining the life trajectory with at least as much validity as endophenotypes identified by specific neuropsychological constellations.

In summary, the molecular genetics of ADHD supports polymorphisms in dopaminergic transporter and receptor genes, but also implies involvement of other neurotransmitter systems. Phenomenologically defined "endophenotypes" are sought as heritable mediators between genotype and phenotype to explain the heterogeneity of ADHD, but so far are only theoretical constructs. The available data does not support a unitary cause for ADHD but indicates significant polygenetic heterogeneity (159).

18.1.7.2. Physical Environmental Factors

There are many studies demonstrating the effect of early environmental adversity and influences on developmental outcome (23, 90). ADHD symptoms are frequently embedded in a spectrum of cognitive, behavioral, and physical sequelae that are strongly mediated by psychosocial and genetic variables. The following section briefly outlines the most salient environmental factors that have been etiologically associated with ADHD. Based on current knowledge, many cases of ADHD and associated neurodevelopmental disorders could be prevented or mitigated with individual as well as public health interventions.

Factors that are unequivocally associated with the etiology of ADHD are maternal smoking and alcohol use during pregnancy as well as exposure to other environmental toxins, nutritional deficiencies, prematurity, and maternal stress. However, any agent that crosses the blood-brain barrier may affect neurodevelopment. Exposure levels that have no effects in adults may have a significant impact on the developing brain. Direct behavioral effects of single agents are difficult to disentangle from the interaction with genetic, other environmental, and socio-familial factors that are frequently involved (160).

18.1.7.2.1. Prenatal Smoking

Epidemiologic and animal studies provide strong support that in-utero exposures to maternal smoking and alcohol are associated with increased risk for persistent behavioral and cognitive effects in the offspring. Smoking occurs in up to 25% of US pregnancies and increases the risk for ADHD by a factor of 2.5–3.5, when corrected for other biological and psychosocial variables (161). Most epidemiologic studies have focused on ADHD-combined type and externalizing disorders and found a strong association with prenatal smoking and nicotine exposure (162), but a careful case-control study of 100 middle-class children with ADHD-Inattentive type found an odds-ratio of 3.44 for ADHD if mothers smoked more than 10 cigarettes/day compared to mothers who did not smoke. Smoking was also associated with lower IQ scores and an increased rate of anxiety disorders in this nonreferred cohort. There was a higher prevalence of mothers with ADHD in the smoking group, demonstrating the cumulative risk of environmental and genetic factors (163).

Smoking has developmental and morphologic effects through multiple pathways, including increased CO, decreased oxygenation, cadmium accumulation, vasoconstrictive, and nicotinergic effects. The effect on the brain occurs through nicotinic effects on cholinergic neurotransmission, and on neuronal migration, replication, and differentiation early in brain development (164). Smoking alters the maternal HPA-axis and increases fetal cortisol exposure, which affects neurotransmission in cortical, hippocampal, and limbic systems, and has been shown to increase fetal ACTH, which has long-term effects on stress reactivity and behavior of the offspring (165). Increased prenatal cortisol exposure is associated with long-lasting behavioral effects that

include not only ADHD but anxiety and depression (166). Genetically mediated susceptibility to the effects of prenatal smoking has been demonstrated by the increased prevalence and severity of ADHD in children with both DAT1 and DAT4 polymorphisms who were exposed to prenatal smoking as compared to exposed children with either or no polymorphism (167).

18.1.7.2.2. Prenatal Alcohol Exposure

The teratogenetic effects on multiple organ systems of prenatal alcohol exposure, which is estimated to occur in 20–30% of pregnancies in the US, are well known (168). It is estimated that 2–5% of younger school children in the United States and Western Europe have Fetal Alcohol Spectrum Disorder (a composite of full-blown Fetal Alcohol Syndrome, Alcohol Related Neurodevelopmental Disorder, and Alcohol Related Birth Defects) (169). Alcohol affects neuronal migration, myelination, and neuronogenesis. Direct behavioral teratogenicity is demonstrated in animal studies showing specific attentional dysfunction with fetal alcohol exposure. Indirect effects are through dysregulation of the maternal HPA-axis and cortisol levels with effects on fetal brain development and function (170–172).

ADHD has been reported in 50–80% of individuals with prenatal alcohol exposure, and usually occurs within a spectrum of significant cognitive and behavioral deficits (173). The neuropsychological profile of FASD is subtly different than in ADHD without alcohol exposure in terms of executive functioning, spatial working memory, encoding, and set-shifting (174, 175). Further clarification of the neurodevelopmental differences between FASD and ADHD may have treatment implications, as stimulants are often less effective in treating attention and impulse control problems in alcohol exposed children (176).

In maternal Alcohol Use Disorder (AUD), the effects of polysubstance use, especially smoking, dose-response effects, genetic susceptibility, cognitive impairment, and nutritional and environmental factors mediate the behavioral outcomes, so that the behavioral risk conferred by the prenatal exposure alone is difficult to determine. Psychosocial confounders, particularly maternal psychopathology and male gender of the child, account for a much higher proportion of the behavioral variance than alcohol itself (168). However, even minimal amounts of prenatal alcohol exposure within an adverse social environment potentiate the behavioral risk when compared to controls. Aggressive and hyperactive behaviors are seen at 7 years of age after as little as 0.5 oz/week of fetal alcohol exposure when other factors are accounted for (168). In a "Children of Twins" study, comparing the offspring of twin pairs that were discordant for alcohol use, Knopik concludes that genetic factors (i.e., maternal ADHD, which leads to maternal AUD) act independently of alcohol exposure, and represent a cumulative risk for ADHD with alcohol exposure (177).

18.1.7.2.3. Environmental Pollutants

The neurotoxic effects of lead and mercury are well researched and include hyperactivity and attentional deficits. Exposure of the developing brain to cadmium (through prenatal and secondary smoking, industrial waste, and diet), manganese (as supplement, in soy products, and as octane enhancer in gasoline), PCBs (the latter affecting thyroid function), and agricultural and household pesticides causes neurobehavioral deficits including hyperactivity and attentional dysfunction, which have been demonstrated in epidemiologic samples as well as in animal studies. Research on the developmental effects of the thousands of other common environmental pollutants is lacking. Environmental pollutants, genetic susceptibility, nutritional deficits, and psychosocial risk factors frequently occur simultaneously and may enhance or modify their interactions, so that it is extremely difficult to determine the effect of single factors (90, 178).

18.1.7.2.4. Nutritional and Micronutrient Deficiencies

Nutritional and micronutrient deficiencies in infants, children, and women of childbearing age have a profound impact on global health and are not restricted to the developing world. Brain, behavior, and cognitive development are affected by both protein-energy malnutrition (PEM) and micronutrient deficiencies during the course of early brain development and are etiologically associated with deficits in cognitive function and ADHD (179, 180). Globally, about 25% of children have stunted growth due to malnutrition, and in the US clinical malnutrition affects about 10% of poor children (181, 182). In a longitudinal study of a Barbadian birth cohort, Galler and Ramsay reported a 60% incidence of persistent ADHD in children followed to at least age 18 years who had protein-energy malnutrition only in the first year of life, but not later, compared to a 15% incidence in controls (183). However, in the developed world, children with systemic disorders that affect feeding or absorption of nutrients, for instance cerebral palsy or celiac disease, may also suffer nutritional deficits that may cause neurodevelopmental compromise. Maintaining appropriate and adequate nutrition during periods of rapid brain growth and neuromotor development is therefore crucial in infants with nutritional deficiencies of all causes.

Iron deficiency is the most common micronutrient deficiency worldwide affecting 1.2 billion people and is most prevalent in infants, children, and women of childbearing age. It is also common in the US: 13% of 1-year-olds, 5% of 2-year-olds, and

9–11% of adolescent and young adult women are shown to have iron deficiency, of which only 2–5% had iron deficiency anemia (184). Multiple studies show attentional, memory, and learning impairment in anemic and nonanemic iron deficiency in infancy, childhood, and adolescence. Iron fulfills multiple roles in brain function, including mitochondrial electron transport, neurotransmitter synthesis, and cortical, and hippocampal development. Iron deficiency in infancy has lasting effects throughout childhood and adolescence, but correction during infancy improves cognitive and behavioral effects. Correction of iron deficiency diagnosed in school-age and older children has also been shown to normalize the cognitive-behavioral effects (185).

Long-Chain-Polyunsaturated essential fatty acids, specifically Omega-3 FAs, have been studied not only in terms of cardiac and immunologic effects but also for their role in brain development and function. Omega-3 FAs are structural elements of cell membranes, neurotransmitters and substrates of signaling molecules, and modulators in the regulation of gene expression and have played a central role in the evolution of the brain (186). Omega-3 FAs cannot be synthesized by the body and are derived entirely from the diet. Marginal or deficient Omega-3 status during pregnancy and in early infancy has been associated with increased susceptibility to bipolar disorder and depression (187). The increased risk for ADHD and schizophrenia in persons born prematurely is thought to be the result of delayed grey matter maturation associated with decreased Omega-3 fatty acid accrual (187). Abnormalities of fatty acid metabolism have been shown in subgroups of children with ADHD who demonstrated symptoms of fatty acid dysfunction, i.e., increased thirst and dry skin (188).

18.1.7.2.5. Other Dietary Factors

18.1.7.2.5.1. Obesity Risks

The well-known worldwide increase in obesity, especially relevant in pregnant women, is associated with an increase in gestational diabetes and metabolic syndrome, which is associated with increased and lasting risk for metabolic and neurologic problems in the offspring. At this time there is no evidence for a direct causal relationship between obesity during pregnancy and ADHD.

Increasing evidence, however, points to a significant association between ADHD and obesity (189). Three mechanisms underlying the association between ADHD and obesity have been proposed: (1) obesity and/or factors associated with it (such as sleep-disordered breathing and deficits in arousal/alertness) manifest as ADHD-like symptoms; (2) ADHD and obesity share common genetics and neurobiological dysfunctions, involving the dopaminergic and, possibly, other systems (e.g., brain-derived neurotropic factor, melanocortin-4-receptor); and (3) impulsivity and inattention of ADHD contribute to weight gain via dysregulated eating patterns. This association was confirmed in a recent study by Cortese et al., which found men diagnosed as children with ADHD were twice as likely to be obese in a 33-year follow-up study compared to men who were not diagnosed with the condition (190).

18.1.7.2.5.2. Food Reactivity and ADHD

Ever since Feingold published his observations in 1977 that a salicylate-free diet originally intended to treat salicylate-induced asthma also improved symptoms of hyperactivity (191), the discussion of a possible dietary role in behavioral disturbance and specifically in ADHD has been highly partisan, with objectivity becoming a victim of beliefs and biases on both sides of the issue. Recent meta-analyses reviewing 35 years of data have done little to clarify the issues (192). Diets purported to reduce symptoms associated with ADHD include sugar-restricted, additive/preservative free, allergen-free (elimination) diets, and a non-Western "healthy" diet high in fiber, folate, and omega-3 fatty acids. Controlled studies failed to confirm the effectiveness of the Feingold additive and salicylate-free diet. Nevertheless, a small subgroup of children do seem to respond adversely to additives and preservatives administered as a challenge, suggesting that combination antigen and additive-free diet may be appropriate for children with sensitivities to food antigens or allergens and to dyes (about 8% of children with ADHD) (192, 193). Atopic children with ADHD have a significantly higher response rate to elimination diets than nonatopic children. Foods most commonly implicated include dairy, wheat, egg, chocolate, nuts, and citrus fruits. Skin tests for allergic reactivity are not reliable, and behavioral improvements may lag 2 weeks after elimination of the offending food (193).

Meta-analysis of 16 studies concluded that sugar does not usually affect the behavior or cognitive performance of children, nor does aspartame or saccharine, although, as was the case with food dyes, there may be a small group of "sugar-responders" for whom aggressive or hyperactive behavior correlate with daily sugar intake. Reactive hypoglycemia is a plausible cause of transient increase in beta activity in fronto-temporal areas, associated with exacerbation of ADHD symptoms, and can be ameliorated by a low glycemic-index diet (193).

The Australian Raine study examined the relationship between dietary patterns and ADHD in a population-based cohort of live births followed until age 14. This study found an association between ADHD and higher intake of fat, sugar, and sodium (the typical "Western" diet), while diets rich in fish, fruits, vegetables, and whole grains ("healthy" diet) were not associated with ADHD diagnosis (194).

The pathophysiological mechanisms underlying behavioral food reactivity are not known. The role of diet and nutrition certainly is not settled at this point and deserves further exploration.

18.1.7.3. Prematurity

The occurrence of premature delivery is itself highly complex and multifactorial. Multiple physical and environmental factors place enormous demands on the premature brain, and even in the absence of significant neurologic or physical sequelae, many children remain small, have mild neurologic dysfunctions or dyspraxia, and "soft" morbidities that nonetheless may have significant effects on cognitive and especially psychosocial function (195). In addition, family factors, such as parental anxiety and overprotectiveness may affect cognitive and emotional development. Children born with low birth weights are at an increased risk for ADHD and other behavioral, psychiatric, and cognitive disorders. Neuronal cell death associated with multiple assaults on the immature brain, as well as reduced essential fatty acid availability, may be some of the causative factors involved. Other factors may be increased maternal stress and cortisol levels. The risk for ADHD was found to be increased by a factor of 2.46 in a meta-analysis of premature outcomes (196), and longitudinal studies found an incidence of ADHD of at least 23% of otherwise neurologically and cognitively intact very low birth weight (VLBW) children at follow-up, although even weights of less than 2,500 g already present an independent risk for ADHD (196). Psychosocial factors mediate the severity of the developmental sequelae on behavior and cognition. Lawson carefully examined focused attention at 7 months of age in neurologically intact VLBW infants and found correlations of focused (as compared to casual) attention with cognitive as well as hyperactivity measures at 5 years of age, with risk mediated by male gender, gestational age, and maternal education (197). Other longitudinal studies have shown strong relationships between VLBW, cognitive deficits, emotional dysregulation, and lower SES at 2 years (198), and internalizing problems, peer rejection, and inattention in late adolescence (199).

In summary, prematurity and low birth weight are associated with an increased risk for ADHD and behavioral-psychiatric disorders in neurologically and cognitively intact children. Risk is mediated by gender, age, and SES/maternal education. Early anticipatory guidance should start in infancy to mitigate psychiatric and behavioral morbidity.

18.1.7.4. Chronic Hypoxia

Chronic, even mild degrees of oxygen desaturation may cause cognitive and attentional dysfunction. Cyanotic Congenital Heart Disease (CHD) and Sleep Disordered Breathing are both relatively common. The evidence is robust that the hypoxia associated with both is causative for ADHD (99). Cyanotic CHD is well known to be associated with neurodevelopmental delays. Sleep disordered breathing, such as in adenoidal hyperplasia or respiratory allergies, causes significant oxygen desaturation, ADHD, and decreased IQ. Seemingly innocuous and mundane factors such as infant seating and carriers may restrict respiratory activity and should be seen as potential sources of harmful oxygen desaturation (99).

18.1.7.5. Psychosocial Factors

As already discussed, psychosocial factors play a pervasive role in the development of ADHD. The stage is set already before birth, in that maternal mental health and stress have direct and indirect physical effects on the fetus, which may last into adulthood. After birth, the responsiveness of the primary caretakers to the infant appears to be the crucial factor that shapes and gives direction to the development of attention, perception, cognition, attachment, emotionality, and beginning sense of self of the infant. This process is beautifully described by Daniel Stern (200) and continues to be validated by infant research. Maternal responsiveness may be fragile or inconsistent: depression, anxiety, ADHD, substance abuse, multiple children, and economic pressures may interfere with the intent or ability to provide the emotional and cognitive stimulation and reciprocity necessary for normal development. Attention deficit may in fact, in some cases, be a deficit of attention. Child factors that may inhibit maternal reciprocity are also significant, such as poor maternal-child temperamental "fit," child illness with increased internal distractibility due to pain or discomfort, sensory overreactivity, etc. Other family environmental factors that contribute to later comorbidities with depression and oppositional defiant behavior may be paternal psychopathology, hostile parenting, and a chaotic family environment. Boys are rated by their parents as being more intentional and in control of their disruptive behavior than girls, and are at higher risk for being the object of hostile parenting and harsh discipline, which may be a factor leading to increased oppositionality in boys already present by preschool age (201). Low SES and family stressors are high risk factors for development of antisocial behavior in hyperactive boys, and predictive of negative adolescent peer group affiliation (gangs) already by kindergarten age (202).

The Fragile Families and Child Wellbeing Study, a multicenter study of almost 3,000 children followed from birth to 3 years, examined the cumulative effect of maternal mental health, substance use, and domestic violence at 1 year after the child's birth on child behavior at 3 years as measured by the Child Behavior Checklist (CBCL) (203). 50% of mothers had at least one adversity factor. Prevalence of child aggression, anxiety, and attention problems were between 18 and 20% in children whose mothers were depressed, anxious, or abused and increased highly significantly with cumulative maternal problems, with anxiety showing the greatest increase. Prevalence rates for all problems were much higher in families below the poverty line and lower SES

than higher SES. However, the effect of increased maternal problems on the children was the same across SES groups (203). This study demonstrates the high correlation with and cumulative effect of maternal and child problems. Unfortunately, there is no information about the factors that were associated with positive child outcomes (about 75%) in this study.

18.1.7.6. Electronic Media

TV viewing during infancy and toddlerhood has been shown in several studies to be associated with significantly increased risk for ADHD by school age (204, 205). TV watching in infants, whose brains are undergoing rapid synaptogenesis, and have high plasticity relative to experience and stimulation, may interfere with normal perceptual and cognitive development, especially in the presence of perceptual or cognitive vulnerabilities. It is also known that adult TV watching decreases the attention given to the child. This may play a significant role in environmental and social deprivation for children whose mothers are depressed and isolated (206). In older children, an association between time spent playing video games, school performance, and symptoms of ADHD inattentive type has been found (207). Swing and colleagues (208) used a longitudinal design to show that the amount of time spent watching TV or playing video games was positively related to greater attention problems. This was true even when earlier attention problems and gender were statistically controlled, ruling out the possibility that the association between screen media use and attention problems is merely the result of children with attention problems being especially attracted to screen media. Screen time was associated with attention problems in both middle childhood and late adolescent/early adult samples (208).

18.1.8. Evaluation

Since the majority of children with ADHD are treated by their primary care physicians, the American Academy of Pediatrics has issued guidelines for evaluation and management of ADHD which are virtually congruent with the preliminary guidelines by the American Academy of Child and Adolescent Psychiatry (6, 7).

Screening for ADHD should be a part of any child's mental health assessment. Any child presenting with symptoms of impulsivity, hyperactivity, and attentional dysfunction should have a thorough evaluation for ADHD. Assessment needs to be based on DSM-criteria and includes information from parents or caregivers, classroom teacher, or other school professionals, regarding the core symptoms of ADHD in various settings, the age of onset, duration of symptoms, and degree of functional impairment. Since ADHD increases and becomes more virulent with psychosocial adversity and comorbidities, information about preceding and ongoing social/familial stressors and family and emotional functioning should be obtained.

18.1.8.1. The Diagnostic Interview

The diagnostic interview with the parents as well as interview with the child, and, if possible, observation in a challenging situation, are central to the evaluation. The parents and child should be interviewed separately in order to allow free expression of concerns, avoid further injury to self-esteem, and divulge confidential information from both. A thorough medical history including prenatal and perinatal and family history is important for the consideration of etiologic factors, rule out medical conditions, and to assess risk for specific comorbidities. Developmental, educational, and daycare information, as well as social history, provide essential contextual information.

The interview with the verbal child/adolescent may lead to sometimes unexpected insight into the child's emotional state, and perception of self, peer, and family relationships and should serve to rule out significant social, thought, or emotional problems.

The physical and neurological examination should be made with respect to ruling out associated or underlying medical conditions, which are, in effect, infrequent. However, in about 50% of children with ADHD one finds indication of mild neurological dysfunction, such as abnormal neurologic soft signs, decreased muscle tone, motor planning problems, and sensory differences, which may significantly affect fine and gross motor activities. These findings are important for treatment planning. Laboratory evaluations are not useful unless clinically indicated.

A short developmental screening session with preschoolers often is a window into behavioral, cognitive, and emotional vulnerabilities. Avoidance, inattention, distractibility, or oppositionality on developmental testing are often signs of developmental incompetence rather than of a primary attention deficit.

18.1.8.2. Behavior Rating Scales

The diagnostic interviews should be augmented with information from school, teachers, and other caregivers and should include standardized ADHD specific rating scales from parents and teachers (ADHD IV, SNAP-IV-R, Vanderbilt ADHD Rating Scales, AcTers, Conners' Rating Scales-Revised), and broadband behavior rating scales that screen for associated behavioral-emotional

dysfunction in the home and school environment (BASC, CBCL Parent, caregiver-teacher report forms). Adolescent self-reports are available for the major screening systems (209). Several of these scales are free and in the public domain and can be downloaded (209). Children with ADHD usually have better behavioral control in structured situations, so that there may be significant differences between classroom, playground, and home behavior. Discrepancies between teacher and parent behavior ratings are common and do not necessarily challenge the diagnosis, but show that different aspects of the underlying condition manifest in different environments. Emotional-behavioral issues may be more pronounced at home, whereas inattention/distractibility is more evident in school. Children with ADHD may be likened to the proverbial "canaries in the coal mine" and quickly display problems with environmental "fit". Children with LD without ADHD usually are not disruptive or inattentive outside of the challenging situations.

Behavior rating scales are important adjuncts in the evaluation process for ADHD but should not be used as the basis for making the diagnosis. It should also be remembered that they reflect subjective evaluations of the child and may be colored by the emotional state, expectations, and experience of the evaluator.

18.1.8.3. Developmental/Psychological Assessments

Since ADHD is defined as a significant discrepancy of attention, impulsivity, and activity relative to developmental age, screening and if indicated evaluation of cognitive-adaptive status, communication-language, visual-motor integration, social-adaptive, as well as hearing and vision should be performed in the child suspected of having ADHD.

A formal psychoeducational evaluation assessing intelligence, memory, executive function, visual-motor integration, and achievement with standard methods may be necessary in the academically or behaviorally underperforming school-age child to rule out learning discrepancies relative to cognitive potential, which may also include giftedness. A psychoeducational evaluation can be performed free of charge by the school system for any child in a given district, provided that there is an indication. Specific speech-language and occupational therapy evaluations may be indicated to rule out a language disorder, which co-occurs in approximately 25% of children with ADHD.

In older students and adults, evaluations become more problematical because of the need to have childhood behavior information (possibly from the patient's parent or sibling) as well as current behavioral descriptors, such as from the spouse or employer.

The evaluation should explicitly identify vulnerabilities and impairments, i.e., academic, social, emotional, behavioral, and comorbidities. However, in addition to impairments, it is important to identify strengths, competencies, talents, and other self-esteem and resilience building factors that may be integrated into the comprehensive treatment plan.

18.1.9. Treatment

ADHD is a chronic disorder, therefore quality of life considerations of the child within his or her family, school, and peer context should be at the center of treatment planning. Similarly to other chronic conditions, a holistic approach needs to include lifestyle as well as medication management. Short-term and long-term treatment goals need to be specified relative to specific target symptoms, and academic and social goals need to be balanced. Educating the child and the family, engaging them as partners, and addressing both child and family generated problems is the first step. It is important to remember that at least 25% of children with ADHD also have a parent with ADHD, and that other mental disorders are increased in these families. Quite frequently, the diagnosis of the child leads to the parent's recognition of their own impairment and seeking treatment for themselves. Comorbidities need to be treated with the same urgency as ADHD, with stabilization of any acute conditions such as manic episodes, given priority.

The treatment plan should consider medication and/ or behavioral therapy as appropriate. Target outcomes should be defined and if not achieved within a given period of time, the diagnosis, comorbidities, compliance, and treatment appropriateness should be re-evaluated. A systematic follow-up needs to be pursued, and target outcomes and adverse effects should be monitored with information gathered from teachers, parents, and the patient.

18.1.9.1. Behavioral and Educational Treatments

Medication management is at the center of ADHD treatment, but supportive interventions should be considered in any child at risk for or with manifestations of ADHD. Intensive behavior management interventions within the school and home setting are shown to be sufficient in decreasing core symptoms in milder cases of ADHD, and should be considered in such cases before pharmacological treatment is begun. Consistent behavior management decreases dosage requirements when medication proves necessary (210), although short-term treatment does not appear to offer any benefit beyond that obtained by optimal medication management (211).

Behavioral treatments are especially relevant in preschool ADHD, where skilled early behavioral intervention may redirect an otherwise high-risk developmental trajectory and medication treatment may not be desired, effective, or associated with unacceptable side effects (212). Behavior management in older children does not change the core symptoms of ADHD, but it changes parenting style and effectiveness. Parenting-family training can give parents the skills to be active and authoritative agents in their children's development and behavior and to avoid the combination of helpless defeatism, hostile parenting, and chaotic overreactivity that gives rise to and maintains externalizing behavior (213, 214).

Parent training and /or developmental preschools may be available through the State Early Intervention or school systems and should be vigorously sought at the earliest possible moment. Providers who deal with young children need to be knowledgeable about state and community resources. Early Head Start, a good daycare, or preschool may provide an emotionally neutral environment, which may relieve stress for the child as well as the family and improve family interactions.

Educational interventions: School children with ADHD without learning disabilities are eligible for individualized accommodations under section 504 of the 1973 Rehabilitation Act which is a civil rights law that prohibits discrimination against individuals with disabilities and emphasizes regular class placement with behavioral and pedagogic modifications. It is unfunded but federally mandated. Children with ADHD and comorbid learning disabilities are eligible for special education and an Individualized Education Plan (IEP) under the federally funded Individuals with Disabilities Education Act, which is mandated to provide more extensive services to children with disorders of learning and encompasses modification under section 504.

Tutoring may be extremely helpful in children with specific LD and ADHD. Being able to read at grade level by third grade is associated with increased resilience in light of other developmental risk factors. ADHD behavior that is highly associated with a learning disability may resolve if the LD is successfully addressed. Social skills interventions for ADHD may be provided within the school setting but usually are obtained privately. Social skills and behavior management training in the context of ADHD summer camps improve core ADHD symptoms as well as social coping and insight and are available in some communities as academic laboratory settings. It is quite obvious that behavior management interventions require more financial and personal cost than medication management. Health insurance frequently does not pay for the intensive parenting counseling that is initially required, and parents must be willing to develop the skills, change their own behavior, and adopt a long-term perspective for success. Behavior management is similar to medication management in that it is effective only as long as it is utilized, i.e., it has no curative potential, but it does, however, teach self-control, social skills, and coping strategies (215).

18.1.9.2. Pharmacologic Treatment

18.1.9.2.1. Stimulants

In 1937 Bradley reported that amphetamine dramatically improved behavior, emotionality, and academic performance in institutionalized children with normal cognition but severely disruptive behavior (216). Amphetamines (AMP) were not routinely used in ADHD until the less potent stimulant methylphenidate (Ritalin) became available in the 1960s. Since then methylphenidate (MPH) has become the most frequently utilized and studied psychotropic agent in children, and stimulants have become the gold standard for treatment effectiveness in ADHD (217). Stimulants are by far the most popular medications for ADHD because of their large margin of safety, effectiveness, short half-lives with easily observed treatment response, and ease of administration. Side effects are low, and there is little attenuation over time.

Improvement of prefrontal cognitive tasks in "normal" as well as ADHD subjects with low doses of methylphenidate is the basis for improvement of clinical symptoms. Stimulants affect norepinephrine and dopamine release predominantly in the prefrontal cortex and fronto-striatal circuits by inhibiting the reuptake, and enhancing the release of these catecholamines at the synaptic cleft, as well as by blocking the dopamine transporter and enhancing extracellular dopamine (147).

Given the neuropathological heterogeneity of ADHD, the effectiveness of stimulants on the core symptoms in the majority of cases is surprisingly simple. Stimulants improve cognitive and academic performance as well as the core symptoms of impulsivity, hyperactivity, and attentional dysregulation. Stimulants are effective in improving ODD and CD symptoms even in the absence of ADHD symptoms (147). Stimulants are effective in all ages starting with preschoolers (218). The effects are similar in children and adults with and without ADHD and are therefore neither diagnostic nor specific. Treatment has been shown to have major effects on quality of life: Stimulant treatment is associated with less grade retention, lower school dropout rates, less absenteeism, lower rates of substance abuse, and improved reading scores (5). Hundreds of randomized short-term trials have shown stimulants to be effective in 50–75% of children with ADHD with relatively few side effects. However, the application of the outcomes of clinical research trials vs. the outcome in community settings is problematic, because clinical research trials have a strong sample bias compared to community conditions, excluding many factors that confound community treatment such as comorbid conditions and poor compliance. The distinction between *efficacy*, as used in controlled clinical research trials, vs. *effectiveness* of a treatment, i.e., the treatment response under usual clinical conditions, should therefore be kept in mind. Quality of life measures should also be considered when assessing treatment response (219).

Compared to the abundance of short-term randomized trials of stimulants, mostly of methylphenidate, comparatively few long-term studies have been completed. The benchmark of long-term clinical trials has been the Multimodal Treatments Study of Children with ADHD (MTA) (220), a multicenter randomized prospective study which compared community (including pharmacological) treatment, intensive pharmacological (mostly methylphenidate), and behavioral treatments alone and in combination with pharmacological treatment, over the course of 14 months in 579 children. The study found that compared to behavioral and community treatments, pharmacological treatment alone was superior to all other conditions in treating core ADHD symptoms. However, combination treatment was more effective than pharmacologic treatment alone in improving associated oppositional/aggressive and internalizing symptoms, especially comorbid anxiety, teacher-rated social skills, parent-child relations, and reading achievement (220). While there has been an explosion of research in neurodevelopmental disorders, mostly in the realm of genetics and neuroimaging, this study remains the foundation of clinical practice.

The community counterpart to the MTA has been the medication arm of the Rochester Epidemiology Project (5, 11). The long-term safety and effectiveness of stimulant treatment in a community setting was investigated in 283 children with research identified ADHD, whose treatment data were available from a median age of 9 years, with a median duration of 33 months and range from school entry until high school graduation. Seventy-three percent showed a favorable response rate to stimulants. About 22% of children had side effects with a higher rate of side effects for dextroamphetamine than MPH (5).

Treatment effects have been studied predominantly in latency age boys, but similar effectiveness in girls, adolescents, and adults has been demonstrated (5, 220). Effects are also similar across subtypes in most studies, with some showing greater responsiveness of the inattentive subtype to lower doses. However, outcomes are not always consistent: other studies show improved hyperactivity and impulsivity with less response of attention problems. The Preschool ADHD Treatments Study (PATS), a combination of blinded randomized and open label study of 1 year's duration in children, age 3–5 years, demonstrated that stimulants are also efficacious in preschoolers, who tended to require lower doses and had an increased incidence of side effects (218).

18.1.9.2.1.1. Stimulant Forms

Methylphenidate, its D-isomer (dexmethylphenidate, Focalin), mixed amphetamine salts (MAS-Adderall) and D-Amphetamine are the most frequently used stimulants and are available in short acting (4 hour), intermediate (8 hour), and sustained release (12 hour) forms. Amphetamines are about twice as potent as methylphenidate. The effect size of stimulants, i.e., the difference between drug and placebo effects, is 0.8–1 and provides a comparison measure between different medications for ADHD. Dosage and frequency requirements are highly individualistic and depend only in part on the size and weight of the child. It is therefore recommended to start low and titrate upward depending on treatment goals. Dosage for MPH preparations range from 0.3 to 2 mg/kg/day, with half of that for Focalin (D-isomer of MPH) and amphetamine preparations (221).

When beginning stimulant treatment, it is important to consider the target symptoms, i.e., under what conditions does the child need medication and for how long (school, homework, sports, etc.)? Timing is important also in observing the child for effects and side effects at peak level as well as possible withdrawal/rebound symptoms at trough, and allows for adjustment of medication to daily routines, meals, and bedtimes.

Short-acting MPH/MAS/D-amphetamine onset is after about 30 minutes and duration of effect is about 3–5 hours. Short-acting methylphenidate is now available in liquid form for children who have difficulty swallowing pills. Intermediate preparations (Metadate CD, Ritalin LA) onset is after about 1 hour and duration about 8 hours. Sustained release preparations (OROS-Methylphenidate/Adderall XR MAS/lisdexamphetamine) have an onset of about 1 hour, with a duration effect of up to 12 hours. Intermediate and long-acting preparations vary with respect to the immediate release component, which is 50% and 25% respectively, and may need an initial low-dose short-acting "booster". The type of delivery system, whether beaded in capsules, in a wax matrix or osmotic release form, affect absorption and availability. Once per day sustained release dosing is desirable because it improves compliance, is less conspicuous, has less abuse potential, and the effect is smoother with less "roller coaster" response from changes in levels (222–224).

A MPH dermal patch (multipolymeric adhesive system, Daytrana), releasing 10–30 mg of MPH over a 9 hour period, is approved for children 6–12 years and can be practical in children who are not able to take oral medications. It has been found safe and effective in short-term studies (225). There are anecdotal reports of local and systemic sensitization, however, which is a risk with all topical medications. Heat sensitivity of the patch needs to be considered.

Dosage requirements of stimulants vary with the individual as well as with the context. Children with prenatal substance exposures often require higher stimulant doses and are more difficult to manage medically. Behavioral interventions modify medication effects. Pelham has observed that stimulant effectiveness plateaus at lower doses under conditions of consistent behavior management and a structured environment, whereas higher doses are more likely to be required in less optimal circumstances (210).

Maintenance of a structured, daytime routine with adequate nutrition and sleep, as well as physical exercise, (which in some studies has shown to improve executive function), provides the physical requirements to optimize medication effects.

18.1.9.2.1.2. Stimulants in Comorbid Conditions

Stimulants are effective for ADHD symptoms in multiple comorbid conditions including sequelae of brain injury and other static encephalopathies; in ADHD symptoms associated with Autism Spectrum Disorders; and in mental retardation with ADHD. Careful stimulant treatment may be very effective and is not contraindicated in well-controlled seizure disorders with comorbid ADHD (226). In ADHD with comorbid tic disorders, stimulants are not a contraindication when carefully monitored (227), but should be discontinued if tics worsen or do not stabilize with alpha-adrenergic agonists (clonidine, guanfacine) (228), which have shown effectiveness in tic disorders.

Stimulants may not be as effective in treating core symptoms of ADHD when there are significant comorbidities with anxiety or mood disorders. Under these conditions, single or combination treatments with atomoxetine have been shown to be effective in some patients (229). Alternatively, SSRIs, buproprion, or tricyclic antidepressants may be helpful. The tricyclics have significant alpha-adrenergic effects but require very close monitoring because of cardiac toxicity. Stimulants should not be used in severe anxiety disorders. There is some indication that stimulants may precipitate manic episodes in previously not identified bipolar disorder, but may be used in ADHD/bipolar co-occurrence after mood stabilization (230).

18.1.9.2.1.3. Stimulant Side Effects

Stimulants have a high margin of safety. Most side effects are a result of CNS-action of stimulants and therefore behavioral or emotional. However, stomach and headache are frequent, usually mild, and of short duration. Absorption is affected by calcium and citric acid, but not by other foods, so that stomach aches can be ameliorated when stimulants are taken with a meal. Appetite suppression is frequent and chronic, but can be compensated with a good breakfast, dinner, and bedtime snack. Children should have a snack when levels are declining after short or intermediate dosages in order to prevent the convergence of hunger and rebound/withdrawal symptoms. Sleep problems are often associated with ADHD, but stimulants may also interfere with sleep if given too late in the day. Sleep hygiene, melatonin or clonidine, and a carbohydrate- rich bedtime snack may help with sleep onset. Lack of adequate and restful sleep may worsen ADHD symptoms and emotional reactivity.

Stimulants are activating and therefore may increase anxiety. Rarely stimulants may precipitate a psychotic reaction (231). Social withdrawal, emotional and activity constriction, and obsessive-compulsive behavior may be a sign of overmedication and should lead to dosage adjustment. In some children, increasing hyperactivity may be a sign of overmedication rather than undermedication. "Roller coaster" and withdrawal effects are seen more often on short-acting than intermediate or long-acting stimulants. They are usually of short duration and consist of whininess, sadness, and irritability. A nutritious snack and "quiet time" or physical activity usually can bridge this period. However, some children may withdraw or rebound with significant aggression, which may necessitate a stimulant switch or alternate medication or augmentation with an alpha-adrenergic agonist (clonidine, guanfacine). It is important to observe behavioral changes with regard to expected peak or declining levels.

Transient tics may occur as a result of stimulant treatment and usually resolve after change in dosage, discontinuation, or change to alternative drugs (228). Contrary to public opinion, stimulants do not promote substance abuse and in fact, show a protective effect to nonalcohol substance use when compared to persons with ADHD who have not been treated (232).

Occasionally stimulants cause increased diuresis and enuresis due to a minor diuretic effect. Priapism can occur. Bone-marrow suppression and leukopenia occur very rarely. There are no established recommendations regarding monitoring of CBC.

18.1.9.2.1.3.1. Cardiac Effects

Stimulants do have cardiovascular effects, and may decrease heart rate and increase diastolic and systolic blood pressure at standard therapeutic doses (233). Although cases of sudden cardiac death have been reported, increased risk is not supported by clinical data (234): sudden death on Adderall is calculated as 0.5:100,000 patient years as compared to 1.3–8.5:100,000 patient years in the general pediatric population. Sudden death in children is most often caused by fatal arrhythmias due to congenital heart diseases, such as long QT syndrome and hypertrophic cardiomyopathy. Five of the 12 reported cases of sudden cardiac death while taking stimulants had unrecognized underlying structural heart disease. While screening for a family history of sudden cardiac death is prudent, the American Academy of Pediatrics and American Academy of Child and Adolescent Psychiatry no longer recommend the routine use of EKG before beginning stimulant therapy (235). The combination of the cardiotropic alpha-adrenergic drugs and stimulants should be carefully monitored for hypotension and arrhythmias or bradycardia.

Tricyclic antidepressants and MAO inhibitors should not be given with MPH because the latter increases TCA levels, increasing the risk of cardiotoxicity or hypertension. Stimulants are contraindicated in significant arrhythmias, hypertension, liver disease, severe anxiety, and drug-seeking behavior (234).

18.1.9.2.1.3.2. Stimulants and Growth

The effect of stimulants on growth has been a topic of controversy for some time. Although the Preschool ADHD Treatment Study, which monitored children over 12 months of stimulant treatment, found that linear growth decelerated by 20% of

expected growth in 1 year, with a moderate effect on weight (236), studies in older children show insignificant decreases in growth velocity and weight gain on MPH and MAS as well as on long-acting stimulants in school-age children (237). No information is currently available on the long-term growth trajectories of children started on stimulants as preschoolers; stimulant use in preschoolers needs precise justification. Depending on symptom severity, continuous year-round dosage may be warranted, but in cases of growth plateau, drug holidays can provide crucial opportunities for catch up growth. Although growth suppression is independent of weight loss, in very young children, careful management of dosing times to provide for adequate mealtimes is important to allow adequate nutrition.

18.1.9.2.2. Nonstimulant Medications

Fifty to seventy percent of children respond to stimulants, but alternate medications and nonpharmacological and supportive interventions are necessary for the other 30–50% who do not.

18.1.9.2.2.1. Atomoxetine

Atomoxetine (Strattera) is a norepinephrine reuptake inhibitor. Its benefits include no abuse potential, no motor or tic activation, and it does not interfere with sleep. However its effect size is significantly less than that of stimulants at 0.6–0.72. Full effect is reached after 4–6 weeks (and possibly longer) of therapy. Dose is 0.5 mg/kg/day in one or two divided doses, effects last for 24 hours, which is very useful for children who have significant attentional problems in the morning. Atomoxetine may be more effective in treating core symptoms of ADHD in stimulant naive children rather than in those previously on stimulants. It may be used in conjunction with a stimulant when longer duration without sleep deprivation is needed. Atomoxetine is showing some advantage in children with ADHD and comorbid anxiety or depression; however, comedication with a stimulant may be necessary to improve core symptoms. Side effects are appetite suppression, GI upset, somnolence, occasional irritability, and aggression. Cardiac side effects, i.e., increased blood pressure and tachycardia have been reported. Suicidal ideations have been reported in 5/1357 children on atomoxetine, leading to a Federal Drug Administration black box warning (238).

18.1.9.2.2.2. Modafinil

Modafinil (Provigil) (221), originally indicated for narcolepsy, is not FDA approved for treatment of ADHD. Its mechanism of action is thought to be through diffuse cortical activation via adrenergic systems as well as through thalamic and reticular activation system attenuation. It also has a low abuse potential. It has an effect size of 0.7 after titration to a full dose after 7–9 days to an average dose of 300–400 mg/day. Side effects are headache, appetite suppression, nervousness, and sleep disturbance.

18.1.9.2.2.3. Alpha-2 Adrenergic Agonists

The antihypertensive drugs clonidine and guanfacine (221) inhibit catecholamine release, affect basal adrenergic tone, and improve prefrontal cortex function. They may be used alone or in conjunction with stimulants and are effective in impulsivity, hyperactivity, aggression, especially in young children, and in treating ADHD associated sleep disorders (239). Guanfacine is effective in tic disorders with ADHD, alone or in combination with stimulants (228). Behavioral effectiveness may not be observable for 4–6 weeks. Side effects of sedation and irritability may be significant initially, more so with clonidine than guanfacine. The potential for hypotension and bradycardia require EKG and blood pressure monitoring. Both medications are available in long-acting formulations (marketed as Intuniv and Kapvay) for once-daily dosing.

18.1.9.2.2.4. Antidepressants

The tricyclic antidepressants desipramine and nortriptyline have excellent effectiveness in improving the core symptoms of ADHD, and ADHD with comorbid tic disorders due to their noradrenergic effects (148). However, they have a narrow margin of safety because of their significant accumulation in cardiac as well as brain tissue, with a significant risk of cardiotoxicity resulting in conduction abnormalities, increased heart rate, and increased blood pressure. Effects are observed after about 4 weeks, dosages must be carefully titrated, and blood levels and cardiac response monitored with frequent EKGs. TCAs have significant anticholinergic side effects, often cause weight gain and gastrointestinal problems. Their use for ADHD has decreased sharply after reports of sudden cardiac death in several children (240).

Bupropion is an antidepressant with noradrenergic and dopaminergic neurotransmission effects. Several double-blind controlled studies have showed some efficacy in treating children and adolescents for ADHD, though results were less robust than those typically seen with stimulants (241–245). Caution should be used in those at risk for seizures.

18.1.9.3. Nonpharmacologic Treatments of Core ADHD Symptoms

Nonpharmacological treatments may need to be considered when medication response is associated with significant side effects, lack of improvement, or when pharmacologic treatment is undesirable for other reasons. Nonpharmacological treatments that have been subjected to accepted research trials are biofeedback paradigms and dietary interventions in selected populations. These interventions may be effective by themselves or within a multimodal treatment context. Many alternative and complementary treatments of ADHD that reflect cultural as well as scientific approaches are in use and cannot be discussed here. Given the fact that there are many pathways that lead to ADHD, heterogeneity of effective interventions is conceivable. A critical but open mind should be maintained toward novel approaches.

18.1.9.3.1. Biofeedback Modalities

Neurofeedback is a method of self-regulation that has been widely clinically utilized in combination with or as an "alternative" to pharmacologic treatment, especially in Australia and Europe. Neurofeedback is based on the pathophysiological model of cortical hypoarousal, which is demonstrated in neuroimaging modalities and may also be observed in quantitative EEG studies by the relative dominance of slow (theta) waves over alpha and beta waves in the frontal and prefrontal cortex in the majority of patients with ADHD (142, 143). Suppression of slow and increased production of faster brain-wave activity is achieved by operant conditioning using differing EEG feedback protocols that are determined by ADHD subtype. Thirty to fifty sessions are usually required. The results of several controlled group studies indicate that EEG biofeedback may be effective in treating the core behavioral symptoms as well as successful on the continuance performance test (CPT), cognitive, emotional, and academic performance in ADHD, either alone or in conjunction with stimulants. Improvements in these parameters has allowed reduction of stimulant doses and has persisted up to 1 year after conclusion of the NF treatment and after complete discontinuation of stimulant treatment (246). Randomized double-blind placebo controlled studies have shown similar results on behavioral and neuropsychologic parameters as well as activation of cortical areas known to be underactive in ADHD. Strehl and colleagues reported a controlled study of EEG-biofeedback in self-regulation of Slow Cortical Potentials with persistent improvement in ADHD core symptoms as well as neuropsychological parameters (247). However, methodological questions remain whether the actual agents of change are the biofeedback paradigm or contextual factors (142).

Significant improvement of hyperactivity with Actigraph-biofeedback has also been reported (248). The interactive metronome (249), a biofeedback paradigm based on synchronization of hand and foot movements with auditory stimuli, originally used in enhancing performance in sports, and widely used in movement disorders, has been shown to improve attentional and academic performance in one double-blind placebo controlled study (249).

18.1.9.3.2. Elimination Diets and Dietary Supplements

Based on the research of the last 35 years, it is difficult to dismiss summarily the findings that some children with ADHD respond favorably to individualized elimination diets (192). Behavioral improvement is more likely with appropriate elimination diets in individuals with atopic histories, family history of migraine, and a family history of food reactivity (192); younger children also seem to be more responsive. Specific target behaviors may include sleep and mood disturbances in addition to typical ADHD symptoms. Proven or suspected antigens as well as food colorings and preservatives should be eliminated for at least 3 months with monitoring of target behaviors. Challenges should then be tried for the individual suspected foods. A partial blinding may be carried out by not informing teachers or therapists. Nutritional counseling and referral to support groups is often advisable. The family must understand that dietary management requires a great deal of commitment on a long-term basis. Dietary management should be under the direction of a knowledgeable physician.

Children with ADHD have been found to have low levels of long-chain polyunsaturated fatty acids in their plasma and red blood cells, compared with controls (192). The double-blind placebo controlled Oxford-Durham study found that Omega 3:6-essential fatty acids (EFA) supplementation improved manifestations of ADHD as well as reading and spelling in children with Developmental Coordination Disorder, reading disorders, and associated ADHD symptoms, without affecting motor coordination (250). Other studies have failed to show any benefit from Omega-3 supplementation (251). For review see (252).

Low serum ferritin has been correlated with baseline inattention, hyperactivity, and impulsivity, and also with the dose of amphetamine required to optimize clinical response, indicating that iron supplementation may be worthy of further exploration. Some studies have also shown benefit in ADHD from zinc supplementation (192).

18.1.9.4. Prevention

Considering the vast implications of ADHD for the individual as well as for society, and the fact that a good deal is known about risk factors for ADHD, it is surprising that very little emphasis is placed on prevention. Addressing the socioeconomic adversity within which ADHD and other neurobehavioral disorders flourish is a challenge to public health and political institutions.

However, the practitioner in primary care as well as the mental health provider who deals with children, parents, and women of childbearing age has the opportunity and obligation to inform about prevention, early intervention, and steps that can be taken to modify known genetic and environmental risk factors, as well as to treat manifest developmental and mental disorders. Prevention should address prepregnancy and pregnancy physical health, optimize chronic illness management, stress avoidance of toxins (i.e., smoking, lead, alcohol, mercury), and emphasize optimal nutrition. Essential fatty acids (EFAs) occupy a special role because they are essential for fetal neurodevelopment, may be protective for mood disorders, but are seriously deficient in the average American diet, which provides only 20–60% of the recommended daily dose. Mental health factors frequently are interactive with physical factors, and depression, isolation, and psychosocial stress contribute to adverse pregnancy outcome and fetal neurodevelopmental problems. Postnatal preventive measures again include optimal nutrition for the infant, child, and lactating mother, and enabling and maximizing caretaker-child responsiveness and interaction. This includes early recognition and treatment of postpartum depression and of the overall high incidence (20%) of maternal depression. Anticipatory guidance includes supporting the parent's understanding of the infants and child's developmental needs and capabilities, and addressing ADHD in parents and other family members. Early interventions for developmental and behavioral problems should be encouraged rather than adopting a "wait and see" attitude. Avoiding active and passive TV and video exposure during the first 2 years and limiting it afterwards, as recommended by the American Academy of Pediatrics, promoting social and physical activity, and providing parental and caretaker responsiveness may not eliminate ADHD, but provide the background for optimal emotional and cognitive development within the constraints of genetic predispositions, and mitigate the risk for development of psychiatric comorbidities.

In the child that is at high risk for or has manifest ADHD, supportive interventions are important for improving self-esteem and peer and family relationships, which can buffer the negative effects of ADHD on psychosocial functioning. Peer friendships, extracurricular activities (sports, arts, scouting, etc.), social-altruistic engagement, and parent involvement in school activities improve self-esteem and self-concept. An adult mentor outside of the nuclear family ("Big Brother/Sister", teacher, godparent, etc.) can be crucial especially for adolescents and especially in families that have multiple risk factors (253). Family activities and rituals, as well as stable daily routines help to provide the external emotional and temporal stability that is often very fragile in children with ADHD.

18.2. Oppositional Defiant Disorder (ODD)

ODD is one of the most commonly encountered clinical disorders in children and adolescents, characterized by a persistent pattern of angry or irritable mood, argumentative or defiant behavior, and vindictiveness that exceeds behavioral expectations for the individual's developmental level, gender, and culture. The severity of the disorder is linked to the pervasiveness of the behaviors across multiple settings.

18.2.1. Epidemiology

Prevalence studies have indicated a rate of 1–16%, depending on criteria and assessment methods used, with an average of 3.3%. There is a slight predominance in boys, with a male-female ratio of 1.4:1 prior to adolescence. Prevalence is consistent across cultural and ethnic groups, and onset is usually by age 8 (254).

18.2.2. Etiology

There is no unifying theory of etiology for ODD. High levels of emotional reactivity and poor frustration tolerance are temperamental factors associated with development of ODD. Harsh, inconsistent, and neglectful parenting practices are often implicated in causal theories. Neurobiological markers have not successfully distinguished ODD from Conduct Disorder. Baseline underarousal has consistently been found in youth with ODD, and exogenous biological factors may be implicated. Attachment theorists have suggested that oppositional behavior can develop in the face of an unresponsive parent. Aggressive children underutilize pertinent social cues, misattribute hostile intent to peers, generate fewer solutions to problems, and expect to be rewarded for aggressive responses. Although environmental factors such as poverty, lack of structure, and community violence have been posited as contributing factors; in fact, socio-economic status appears to be responsible for <1% of variance. However, intrafamilial social processes such as lack of parental supervision, lack of positive parental involvement, inconsistent discipline practices, and outright child abuse have been consistently implicated in the pathogenesis of disruptive behaviors (255).

18.2.3. Comorbidities

About 14% of children, adolescents, and adults with ODD also meet criteria for ADHD; 14% have a comorbid anxiety disorder, and 9% have comorbid depression (256). Persons with predominantly angry/irritable mood symptoms are at increased risk for mood disorders, while predominantly defiant/vindictive individuals frequently progress to conduct disorder. Learning disabilities, language disorders, and substance use disorders are also considered common comorbidities, although specific numbers are lacking. Oppositional behavior is sometimes used to manage anxiety, and is also frequently observed in autism spectrum disorders (255).

18.2.4. Prognosis

Approximately 67% of children will no longer meet criteria for diagnosis after 3 years. Early onset of symptoms is associated with worse prognosis, and 30% of these children progress to conduct disorder. Comorbidity with ADHD confers worse prognosis, with a greater range and persistence of problem behaviors, higher rates of peer rejection, and worse academic performance.

18.2.5. Treatment

18.2.5.1. Parent Training

The greatest degree of evidence supports parent management strategies targeting social skills, conflict resolution, and anger management, and training to improve parents' ability to handle disruptive behavior (257). The basic principles include: (1) reduce positive reinforcement of disruptive behavior; (2) increase reinforcement of prosocial and compliant behavior; (3) apply consequences for disruptive behavior; (4) make parental response predictable, contingent, and immediate. These interventions address the coercive response to parental demands and ways parents unwittingly reinforce the child's noncompliance (258).

18.2.5.2. Other therapies

Evidence supports programs such as Head Start, home visitation to high-risk families, and school-based programs as having a modest preventative effect for ODD (255). For severe cases, day treatment and residential treatment facilities may be necessary, always giving preference for the least restrictive treatment setting. Short-term, "inoculation" interventions (such as "boot camps") have not been shown to be effective and can even reinforce a fear-aggression reaction if children are exposed to frightening situations without providing behavioral alternatives (255).

18.2.5.3. Role of Medication in ODD

In the event of comorbid ADHD, treatment with stimulants or nonstimulants may improve oppositional behavior. Both typical and atypical antipsychotics have been shown to be helpful for treating aggression (259).

18.3. Intermittent Explosive Disorder

Intermittent Explosive Disorder, or IED, consists of a pattern of aggressive outbursts that typically last for only a few minutes and can involve either frequent (i.e., twice weekly) verbal or nondestructive physical aggression, or at least three outbursts of aggression that result in property destruction or physical injury over the course of a year. The outbursts are impulsive (rather than premeditated), usually come "out of the blue" or in response to a minor provocation, and appear grossly out of proportion to the alleged trigger (260).

Five to seven percent of the US population is estimated to display recurrent, problematic, impulsive aggression (261). Age of onset is typically in adolescence, and the course of the disorder tends to be relatively stable for up to two decades. Research has identified serotonergic abnormalities, especially in the anterior cingulate and orbitofrontal cortex, with higher amplitude amygdala response to anger stimuli on fMRI than in controls (260). There appears to be a higher prevalence in first-degree relatives (32%) and twins, suggesting a substantial genetic influence for impulsive aggression (262). Significant psychological correlates have also been found, with affected individuals demonstrating elevated relational aggression, more hostile attribution bias, greater affective lability and affective intensity, and a greater degree of immature defense mechanisms such as acting out, dissociation, projection, and rationalization. A history of trauma, especially in childhood, is frequently elicited (260).

The disorder is frequently comorbid with mood, anxiety, substance use, and personality disorders, as well as being frequently seen in individuals with ADHD (17.2%), ODD (21.6%), or Conduct Disorder (19.3%) (260). An IED diagnosis is not compatible, however, with a diagnosis of Disruptive mood dysregulation disorder, which always has onset in childhood and is characterized by a persistently negative mood state, not just during aggressive outbursts.

Preliminary medication trials with fluoxetine, divalproex, or oxcarbazepine have all been shown to reduce impulsive aggression, as has CBT, although additional research is needed regarding treatment of this disorder (260).

18.4. Conduct Disorder

18.4.1. Definition

Conduct disorder consists of a constellation of symptoms whereby rights of others are repeatedly violated. This comprises serious aggressive and antisocial behaviors such as bullying, initiating physical fights, physical cruelty to people and animals, fire setting and deliberately destroying others' properties, stealing, and serious violations of parental and school rules. This disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

18.4.2. Epidemiology

Three to five percent of preadolescent boys and 6–8% of adolescent boys meet criteria for conduct disorder. Boys outnumber girls 4:1 prior to adolescence to about 2:1 in adolescence (263). The Ontario Child Health Study indicated that for ages 4–16 years, 5.5% suffered from conduct disorder. Life-course persistent (LCP) versus adolescence-limited antisocial behavior are two examples of developmental pathways to antisocial or violent behavior.

LCP accounts for 5–8% of the offender populations which have an early onset involving serious crime and continue into adulthood. Twenty-five percent of adolescence-limited offenders continue their delinquent behavior into adulthood. These late starters may offend with peers but behave well in school and at home (264).

DSM-5 distinguishes between three subtypes of conduct disorder based on the age of onset. In childhood onset type, there is onset of at least one criterion characteristic of conduct disorder prior to age 10 years. These children begin showing mild conduct problems as early as preschool or early elementary school and their behavioral problems tend to increase in rate and severity throughout childhood and into adolescence.

The second type is the adolescence-onset conduct disorder in which there is absence of any criterion characteristic of conduct disorder prior to age 10 years. These youth do not show any significant behavioral problems in childhood. It is with the onset of adolescence that they begin to exhibit significant antisocial and delinquent behaviors.

Unspecified onset can be used when criteria for conduct disorder are met, but there is not enough information to determine if symptom onset was before or after 10 years of age.

Additional specifiers indicate a lack of prosocial emotions, such as remorse or guilt, lack of empathy, lack of concern about performance, and shallow or deficient affect.

18.4.3. Genetics

The Iowa Adoption cohorts have demonstrated that the degree of adoptee aggressiveness and conduct disorder has a significant genetic component. Cadoret et al. (265) followed the lead that the neurotransmitter serotonin or polymorphisms in the serotonin transporter gene (5HTT) were important sources of variability in "externalizing" behaviors such as aggression, conduct disorder, and attention deficit hyperactivity disorder. They genotyped a subgroup of adoptees ($n=87$) at high risk of these disorders with respect to the serotonin-transporter-linked promoter region (5HT-TLPR) polymorphism and used ordinal logistic regression to conduct an associated study. One type of interaction with the long variant of 5HT-TLPR increased externalizing behaviors in individuals with antisocial biologic parentage. A second interaction with one or more 5HT-TLPR short variants appeared to increase externalizing behaviors in conjunction with a genetic diathesis for alcoholism. It was also demonstrated that male individuals with a short variant were more likely to have higher symptom counts for conduct disorder, aggression, and ADHD. Their results supported the hypothesis that gene-biological family history interactions are involved in the externalizing behaviors studied.

Dick and colleagues (266) did a genome-wide screen for genes influencing conduct disorder. Their results suggest that regions on chromosomes 19 and 2 may contain genes conferring risk to conduct disorder. Interestingly the same region on chromosome 2 has also been linked to alcohol dependence in this sample (266). Childhood conduct disorder is known to be associated with the susceptibility for future alcohol problems. These findings suggest that some of the genes contributing to alcohol dependence in adulthood may also contribute to conduct disorder in childhood.

18.4.4. Risk Factors

There are several risk factors that contribute to the outcome of conduct disorder (267). Genes and intergenerational transmission and familial aggregation of antisocial behavior play a part in the development of conduct disorder. Studies have shown that there is an aggregation of disruptive and antisocial behaviors in families. It has also been demonstrated that a history of parental antisocial behavior disorder is associated with a preadolescent onset of conduct disorder. Cortisol levels were lower among sons of fathers with a childhood history of conduct disorder that progressed to antisocial personality disorder than those without a history. Testosterone has also been associated with aggression, including the early onset of aggression (267).

There is a link between underarousal of the autonomic nervous system and conduct disorder. Evidence has shown an association between low heart rate and conduct disorder and higher heart rate and anxiety, also seen in girls. A higher skin conductance has been found in individuals who avoid criminal behavior despite a paternal history of criminality. It has been hypothesized that these are markers of anxiety that play a role in inhibiting children from engaging in disruptive or criminal behavior (267).

Maternal smoking has also been linked to conduct disorder in boys, particularly with onset before puberty. Parent substance abuse, pregnancy, and birth complications have also been linked to disruptive behavior disorders. High levels of environmental toxins, such as lead, have been associated with greater parent and teacher ratings of aggressiveness, delinquency scores, and greater somatic complaints.

It has been seen that by adolescence, delinquent peers contribute greatly to the spread of delinquency and antisocial behaviors. Youth with conduct disorder are frequently rejected by prosocial peers and they tend to become more attached to youth with longer criminal histories. Males are more likely to be arrested for violent crimes and females for truancy, prostitution, running away, or underage drinking (264).

Potential links have been identified between temperament, antisocial behavior, and conduct disorder. Two temperamental types have been found. Type 1 is the callous unempathetic type, which appears to be unrelated to parenting and family context. Type 2 is the reactive, externalizing, antisocial child and is often associated with conduct disorder and negative parenting (268).

A modest to moderate link has been suggested between empathy and prosocial behavior. Boys and girls with conduct disorder are lower in empathy and the identification of interpersonal cues than those without conduct disorder.

Low IQ is associated with low achievement and school failure, both of which are related to later antisocial behavior. High verbal IQ was related to a decrease in conduct disorder symptoms over time only for boys in a clinic-referred sample without a parent with antisocial personality disorder (267).

Reading disorder may be associated with abnormal language processing within the left temporal cortex and has been linked to conduct disorder (267).

There has been a strong association between poverty and crime and disruptive behaviors. Disruptive behaviors among both boys and girls have been linked with poor and disadvantaged neighborhoods. Several other community factors are predictive of later violence such as availability of drugs, exposure to violence, and low SES. Youth in late adolescence with conduct disorder reported experiencing greater stress and engaging in more maladaptive coping strategies (267).

18.4.5. Protective Factors

Findings have indicated that outcomes are mediated by the interaction between protective elements and risk factors. Protection against antisocial behaviors is determined by high IQ, easy temperament, the ability to relate well to others, good work habits at school, areas of competence outside school, and a good relationship with at least one parent or other important adult. A school atmosphere that fosters success, responsibility, and self-discipline as well as selection of a nondelinquent peer is vital in protecting against continuing criminal activity (269).

18.4.6. Neurobiological Findings

Many previous brain-imaging studies in adults with antisocial behavior have shown functional and morphologic brain abnormalities. Sterzer et al. (270) used functional magnetic resonance imaging to test whether the impaired emotional responsiveness of adolescents with antisocial conduct disorder would be reflected by abnormal neural responses to negative affective stimuli. They compared brain activations in response to passive viewing of affect-laden pictures in conduct disorder patients to those in normal control subjects. The main effects for negative-neutral affective valence included activations in the amygdala and hippocampus, ventral extrastriate visual cortex, and the intraparietal sulcus bilaterally.

Kruesi et al. (271) compared regional brain volumes from magnetic resonance imaging scans from 10 youths with early onset conduct disorder and 10 healthy controls to determine whether prefrontal or temporal lobe brain volumes differed in the two groups. Results showed that subjects with conduct disorder had significantly reduced right temporal lobe and right temporal gray matter volumes. The prefrontal volumes in subjects with conduct disorder were 16% smaller than in controls, but the

difference did not reach statistical significance. It was also seen that early onset conduct disorder without substance abuse comorbidity was also significantly associated with small right temporal gray matter volumes.

Bussing et al. (272) conducted a study to examine a community sample of 12 children with combined subtype ADHD (ages 8–12 years, 7 with conduct disorder) and 19 healthy controls matched for age, gender, handedness, and poverty. Measurements of the left and total posterior, superior, and inferior lobes of the cerebellar vermis indicated smaller volumes for both pure ADHD and comorbid children compared to the controls. The results suggested ADHD and ADHD comorbid with conduct disorder have similar cerebellar morphology.

18.4.7. Treatment

It has been seen that no single intervention is effective against severe conduct disorder. Each dysfunctional domain needs to be targeted by multimodal interventions and this treatment must be delivered long enough to make a difference. Programs such as Head Start may help prevent delinquency in conduct disorder in preschool-aged children where poverty, perinatal complications, maternal attachment problems, temperamental traits, and parental education are risk factors. Such programs provide children with stimulation, parents with education, and parental support in crisis (269).

In the treatment of conduct disorder in school-aged children, both parenting skills training and training for the child are effective. The intervention should be aimed for the child, the family, as well as the school.

Adolescence is a time when internal self-regulation assumes more importance. Henggeler's Mutisystemic Therapy treats adolescents with conduct disorder in their psychosocial environment and family interventions (269). Augmentation of treatment is done by targeting social skills, conflict resolution, and anger management.

The childhood-onset group of conduct disorder has a history of behavior problems early in development and is at risk for the most severe and aggressive pattern of behaviors in adolescence and adulthood. Early interventions that are comprehensive and target multiple risk factors are found to be more effective. Families and Schools Together (FAST Track) Program involves multiple component interventions such as: (1) Parenting interventions that teach parents appropriate behavior management skills, (2) helping children develop anger control and problem-solving skills using a cognitive behavior intervention, (3) helping teachers use more effective behavior management using classroom interventions, (4) academic tutoring, and (5) home visits to support family functioning (263).

18.4.7.1. Pharmacotherapy

Medications are recommended only for treatment of target symptoms and comorbid disorders. Mood stabilizers, typical and atypical antipsychotics, alpha agonists, and the stimulants have been found to be useful in the treatment of children and adolescents with conduct disorder. Findling et al found that aggressive children with conduct disorder may benefit from quetiapine (273). Lithium was found to be safe and efficacious for the short-term treatment of aggressive inpatient children and adolescents with conduct disorder. Haloperidol was also found to be useful but lithium was better tolerated than haloperidol (267).

Risperidone and methylphenidate were also found to be superior to placebo in treating conduct disorder. Although no studies have demonstrated their superior efficacy in conduct disorder, antidepressants, lithium carbonate, carbamazepine, and propranolol are used in clinical practice. Clonidine and guanfacine are often used for their effect on reducing aggression and impulsivity (267). Donovan et al. found divalproex to be an efficacious treatment for explosive temper and mood lability in conduct disorder (274).

There are clear indications for hospitalization in children and adolescents who exhibit potential for imminent risk to self or others and show aggressive behavior or imminent deterioration in medical status (269). Inpatient, partial-hospitalization and residential treatment should include therapeutic milieu, family involvement, individual and group therapy, vocational training, treatment of comorbid disorders, and ongoing coordination with school, social services, and the juvenile justice system.

18.5. Summary

The explosion of neurobiological literature on ADHD and the Disruptive Behavior Disorders reflects the complex, fluid, and often-contradictory manifestations of brain–behavior relationships. This complexity is enhanced further by the accumulating research demonstrating significant differences in manifestations according to age, cognitive status, gender, comorbidities, psychosocial context, and treatment response. There is an enormous degree of individual variation shaped by the transaction of biological and environmental factors, which again has major implications for prevention and diagnostic and therapeutic interventions. ADHD has a high, though polygenic, heritability, with clinical expression strongly mediated by environmental and

familial factors. ADHD and CD appear to be genetically distinct, whereas ODD evolves within the context of ADHD. ADHD demonstrates extremely high affiliations with other neurodevelopmental and mental disorders. Research has expanded the conceptualization of ADHD as a primary disorder of frontal-striatal cognitive systems to include affective and motor regulatory pathways and to question the validity and utility of "executive function" deficits as the sole core dysfunctions. ADHD manifests from early childhood and persists in most cases throughout the lifespan. Evaluation and management of the individual needs to acknowledge the co-occurrence of ADHD with learning disorders, anxiety, and mood disorders, which are the basis for the high degree of psychosocial morbidity. Despite the etiological, neuropsychological, and clinical complexity, psychostimulant treatment can help to attenuate some of the most detrimental psychosocial effects that occur when left untreated. Alternative drugs are available in patients who cannot use stimulants, and behavioral and psychosocial interventions should be included as supportive treatments, especially in young children. Prevention and early intervention are feasible, given that there are clear causal relationships, such as toxic exposures (prenatal exposure to smoking, alcohol, lead, etc.), parental psychopathology, and environmental and lifestyle stressors that can be eliminated or modified if appropriate intervention is sought and available.

Mood Disorders in Children and Adolescents

Kathryn R. Cullen, M.D. and Ana Bortnova, B.A.*

Abstract Mood disorders are chronic, often debilitating illnesses that affect people of all ages. In children and adolescents, these disorders can be particularly difficult to address, as presentation, diagnosis, and treatment are often complicated and outcomes are uncertain. There are many proposed etiologies for the development of these disorders, including biological and psychosocial factors. Although research on treatment of depression in children and in adolescents lags behind that in adults, some evidence has emerged to support the use of validated treatments for mood disorders in youth. Research is needed to better understand the developmental etiology and mechanisms in pediatric mood disorders, which will guide advancement in pharmacologic and psychotherapeutic treatment for children and adolescents suffering from mood disorders.

Keywords Major depressive disorder • Bipolar disorder • Mood disorder • Children • Adolescents

Mood disorders in children and adolescents are serious, complicated disorders that impact psychological, social, and biological well-being. With significant morbidity and mortality, lengthy course, and risk for recurrence in adulthood (1, 2) these disorders can impair growth and development if not properly addressed. Mood disorders often interfere with family and peer relationships and with educational performance (3–5). These youngsters are also at increased risk for substance abuse, legal difficulties, and hospitalizations (6–8). Depressed children and adolescents are at increased risk for both suicide attempts and completed suicides (9, 10). The impact that mood disorders can have on children and adolescents requires measures aimed at the early detection and treatment. Thus, a basic understanding of mood disorders, their etiologies, and their treatments is essential to clinicians treating children and adolescents.

19.1. Diagnosing Mood Disorders in Children and Adolescents

The Diagnostic and Statistical Manual of Mental Disorders 5 (DSM-5) provides diagnostic criteria for each mood disorder. When applying these criteria to a patient it is crucial to consider the age of the patient, as methods of diagnosis may vary with age. For the most complete diagnosis, information should be obtained from various sources, such as the child's family, teachers, and physicians (11).

19.1.1. Major Depressive Disorder

The DSM-5 criteria for major depressive disorder include presence of either depressed/irritable mood or anhedonia as well as other depressive symptoms (failure to meet expected growth rate, insomnia, hypersomnia, changes in weight or appetite, lack of energy, thoughts of death or suicidal ideations, poor concentration, etc.) for two weeks (12, 13).

These symptoms must not be due to the effects of medication, alcohol or drug use, or a general medical condition. A major depressive episode is considered to have ended when the symptoms have diminished below the threshold for diagnosis or have been resolved completely for at least three consecutive months (12). In a departure from DSM-IV, the case of bereavement is no longer an exclusion for the diagnosis of MDD.

19.1.2. Persistent Depressive Disorder

Persistent depressive disorder, previously known as dysthymia, in children and adolescents is defined as the presence of a persistent depressed or irritable mood that occurs for most of the day, for a majority of days, and it is present for at least one year (12). The symptoms must result in clinically significant distress or impairment in functioning or require markedly increased effort to maintain a previous level of functioning. In addition, a major depressive episode may not be present during the initial year of symptoms.

19.1.3. Bipolar Disorders

For a diagnosis of a manic episode, DSM-5 requires presence of an irritable or elevated mood as well as increased energy and three or more of several other symptoms (grandiosity, pressured speech, flight of ideas, distractibility, decreased need for sleep, impulsivity) that last for one week. These symptoms cause social impairment and the episode should not be due to an abuse of a drug or a medical condition or treatment (12). Recent work examined six commonly-used research diagnostic interview instruments in the application of DSM 5 criteria for pediatric bipolar disorder, and found significant differences in the criteria and descriptive text for a manic episode. Galanter and colleagues noted that instruments varied with respect to whether symptoms must represent a change from the child's usual state, and whether B-criteria are required to co-occur with A-criteria (14). This issue may help explain some of the inconsistencies in findings across studies in pediatric bipolar disorder, and represents an important problem for the field to address moving forward.

Bipolar II disorder is characterized by one or more major depressive episodes accompanied by at least one hypomanic episode (similar to a manic episode but lasting at least four days) (12). Hypomanic episodes should include a minimum of three of the above-mentioned seven manic symptoms. A hypomanic episode is not severe enough to require hospitalization and does not cause a marked impairment in social or other important areas of functioning (11).

Cyclothymic disorder is a chronic and fluctuating mood disorder of milder clinical symptomatology and is characterized by multiple periods of mild hypomanic symptoms alternating with periods of mild depression (12). Hypomanic and depressive symptoms are both insufficient in number, severity, duration, and pervasiveness to meet full criteria for mania or depression. Symptoms must be present for at least one year and without a symptom-free interval longer than two months.

Children and adolescents who exhibit manic symptoms with mixed features who do not meet full criteria for the disorder (typically due to failure to meet the duration criteria for individual episodes) are frequently diagnosed as Bipolar Disorder, Not Elsewhere Defined. Notable efforts to examine pediatric bipolar disorder such as the Course and Outcome of Bipolar Youth (COBY) project have proposed criteria for diagnosing Bipolar NED. These include individuals who do not meet the DSM-5 criteria for BP-I or BP-II but have had a distinct period of abnormally elevated, expansive, or irritable mood plus the following: 1) two DSM-5 manic symptoms (three if the mood is irritability only) that were clearly associated with the onset of abnormal mood, 2) a clear change in functioning, 3) mood and symptom duration of a minimum of 4 hours within a 24-hour period for a day to be considered meeting the diagnostic threshold, and 4) a minimum of 4 days (not necessarily consecutive) meeting the mood, symptom, duration, and functional change criteria over the subject's lifetime, which could be two episodes lasting two days, four episodes lasting one day, or another variation (15). Recent work has suggested that the symptomatology and functioning of this group of children is very similar to children who meet criteria for Bipolar Disorder types I or II, supporting the hypothesis that these illnesses are on the same spectrum (16).

The diagnostic criteria for bipolar disorder used for adults may not always be reliable in diagnosing mania in children and adolescents (17), and the diagnosis of bipolar disorder in children has been especially controversial (18, 19). Unlike adults, children and adolescents often present with a delay in initial manic symptoms, or may actually begin with a subclinical presentation (7). In addition, children and adolescents often have an atypical presentation, including psychotic symptoms, suicide

attempts, inappropriate sexual behavior, behavioral symptoms and a "stormy" first year of illness (20, 21). The establishment of more developmentally appropriate diagnostic criteria has been suggested to provide more validity (22).

19.2. Etiology, Pathogenesis and Neurobiological Findings

19.2.1. Hormones

Several biological/hormonal factors have been implicated in the development of depression, i.e. growth hormone, cortisol, ACTH, prolactin, thyroid hormones, and melatonin. Also, differences in treatment responses to various medications with respect to age, suggest neurobiological mechanisms are involved in the course of the disease. However, the roles that such neurobiological factors play in the etiology of pediatric and adolescent mood disorders are not well understood.

Studies of depressed children have demonstrated hyposecretion of growth hormone after various chemical challenges, including insulin and growth hormone releasing hormone (GHRH) (23, 24). This dysregulation of growth hormone secretion is hypothesized to either reflect changes in the central noradrenergic receptors or be the result of alterations in transmitters, such as somatomedin or somatostatin. Growth hormone suppression has even been reported in children and adolescents who have never experienced an episode of major depression, but have a strong family history of mood disorders (25). Conversely, some studies in children (26) and adolescents (27, 28) have reported a relative hypersecretion of growth hormone during sleep. It has been suggested that this nocturnal hypersecretion may be affected by stressful life events (29). However, other studies have failed to replicate this finding (30). One case-controlled study comparing 44 adolescents with major depression and 37 non-depressed control subjects found no differences in nocturnal growth hormone secretion. However, when subjects in the depression group were divided into suicidal and non-suicidal groups, a significant blunting of nocturnal growth hormone secretion was present in the suicidal group compared with the nonsuicidal group (31).

Another study (32) examined the growth hormone response to growth hormone-releasing hormone (GHRH) in 82 depressed children compared to 55 controls, matched for age, gender, and pubertal status. The mean growth hormone response to the GHRH was significantly lower in the depressed group. However the mechanism behind this phenomenon is still unclear. The authors of this study discovered low growth hormone states persist, even after clinical recovery, which suggested growth hormone may function as a "trait marker" for depressive disorders (32).

Cortisol has also been implicated in the etiology of depression. The Hypothalamic-Pituitary-Adrenal (HPA) axis is involved in neuroendocrine and behavioral responses to stress, and is influenced by developmental factors and levels of social interaction (33). Animal studies of HPA axis reactivity can invoke the experience of social stress and can lead to behaviors similar to those seen in depression and anxiety in humans (34).

Studies of the HPA axis in depressed adults have found elevated cortisol levels (35). However, the relationship between HPA axis dysfunction and depression is less clear in children and adolescents. Some studies have reported no significant difference in baseline plasma cortisol secretion between depressed outpatient children (36) and adolescents (36) with non-depressed controls. Ryan et al. (1994) found lower cortisol levels in children suffering from early-onset major depressive disorder compared with nondepressed controls after an infusion of L-5-hydroxytryptophan, a serotonin precursor, suggesting an abnormality in cortisol regulatory mechanisms in some depressed children and adolescents (37). Other studies found severely depressed and suicidal children and adolescents manifest cortisol hypersecretion (38, 39). In a longitudinal study of adolescent depression, Rao and colleagues measured urinary cortisol in 55 adolescents with MDD during the index episode. Higher cortisol levels were associated with a longer time to recovery, and, in combination with recent stressful events, predicted recurrence. Social support moderated the effect of cortisol on the index episode and was protective against risk of recurrence (40). Depressed preschool-aged children also had cortisol irregularities when subjected to separation or frustrating stimuli (41). Explanations offered for the diverse findings in HPA axis reactivity in depressed children and adolescents include age, different maturation levels, decreased prevalence of melancholic symptoms, and more rapid adaptation to stress in depressed youth (42).

Corticotropin-releasing hormone (CRH) levels have also been an important area of study, as cortisol secretion abnormalities have been linked to alterations in endogenous CRH secretion (43). Adult studies have consistently demonstrated elevated baseline cortisol and blunted corticotropin secretion after CRH infusion (44). However, a comparison of pre-pubertal children with major depressive disorder and non-depressed control subjects did not find significant differences in baseline or post-CRH stimulation levels of either cortisol or ACTH (44).

Pineal gland irregularities and prolactin secretion may be altered in mood disorders. Studies in depressed adults found blunted prolactin secretion after administration of serotonin precursors and agonists (45). Waterman et al. (46) did not find a significant difference in basal 24-hour prolactin concentrations in adolescents with major depression compared with control subjects. A study exploring nocturnal secretion of various hormones in depressed children confirmed these findings and also found no significant difference in prolactin secretion between depressed children and controls (30).

Common thyroid abnormalities have been found in depressed adults, but many of these abnormalities did not result in overt thyroid disease (47). Thyroid aberrations in depressed adults include elevated basal thyroxine (T4), reduced triidothyroxine (T3) and thyroid-stimulating hormone (TSH), and blunted TSH response to thyrotropin-releasing hormone (47). However, thyroid studies in depressed children and adolescents are inconclusive.

One study (48) examined thyroid hormone concentrations in depressed adolescents and concluded that free T4 concentrations were lowered in depressed adolescents, which suggested a relationship between negative behaviors and dysfunction of the hypothalamic-pituitary adrenal axis. A similar study by the same group (48) explored thyroid function in depressed children and reported reduced basal T4, T3, and TSH values (48). However, reduced levels of T4 and TSH were only found in the male subjects. To date, no studies have evaluated TRH challenges in depressed and normal control adolescents.

19.2.2. Melatonin

A few studies have investigated the role of melatonin in pediatric MDD. A small study (49) found lowered nocturnal serum melatonin levels in depressed boys aged 7–13 years. Another study found depressed children and adolescents produced higher levels of overnight urine melatonin than those without primary major depression (50). A study exploring pineal gland function by measuring serum melatonin levels during both wakefulness and sleep in depressed children and adolescents found nocturnal serum melatonin levels significantly increased in subjects with major depression, and also demonstrated a significantly higher melatonin profile in those subjects with co-occurring psychotic symptoms (51). More recently, a study investigated circadian profiles in young people during the early stages of affective disorders in order to assess the progression of abnormalities. Maismith and colleagues reported that although there was no difference in the timing onset of melatonin across illness stages, it was noted that patients with established disorders, as opposed to earlier and attenuated syndromes, had more marked reductions in melatonin secretion, and that lower levels were associated with subjective sleepiness and poorer performance on neuropsychological tests of verbal memory (52).

19.2.3. Neurochemical Findings

19.2.3.1. Major Depressive Disorder

Norepinephrine and serotonin are the neurochemicals associated with the regulation of mood and the pathophysiology of depression. In addition, the neurotransmitter acetylcholine is believed to be involved in mood disorders, as drugs which increase its levels reportedly induce depressive symptoms in nondepressed adults and exacerbate depressive symptoms in patients with depression (53). The exact role of acetylcholine in mood disorders in children and adolescents is still unclear.

Antidepressants appear to function by restoring healthy functioning to dysregulated neurotransmitter systems in the brain (54). While serotonergic system dysregulation is demonstrated across the lifespan in depression, the nature of these neurotransmitter dysregulations appear to differ in children, adolescents, and adults. This is demonstrated in several ways, such as the difference of response to medications such as tricyclic antidepressants, which appear to be more effective in older populations (55).

19.2.3.2. Bipolar disorder

Manic symptoms such as flight of ideas, irritability, distractibility, and high energy have been linked to increased neuronal excitability from decreased activity of the Na^+-K^+-ATPase pump in bipolar disorder (56). Depressive symptoms in bipolar disorder are hypothesized to be secondary to a larger decrease in pump activity and a resultant decrease in neurotransmitter release (56). Guanine nucleotide binding proteins (57) have also been postulated to play an important role in the molecular etiology of bipolar disorder (58). This hypothesis is based on the finding that lithium attenuates the functioning of G-protein and dampens the oscillatory system, which promotes mood stabilization (59).

19.2.4. Sleep Abnormalities

Sleep abnormalities in depression have been studied in both pediatric and adult populations. However, results vary with age. Depressed children and adolescents frequently report sleep disturbances (60), but to date, EEG findings have not paralleled those in depressed adults. Studies in adults with major depression have consistently demonstrated increased rapid eye movement (REM) density in early REM periods, decreased delta (slow-wave) sleep; disturbed sleep continuity, and shortened REM

latency (61). Studies of depressed adolescents have reported prolonged sleep latency, reduced REM latency, and decreased sleep, but no differences in delta sleep (60, 62–65). Greater sleep changes in inpatient adolescents and in those with psychosis, suicidality, and endogenous major depressive disorder subtypes have been observed (62, 64, 66). A review of sleep studies of depressed children (55) found only one study that reported recordable sleep abnormalities in depressed children. This study reported decreased REM latency and increased sleep latency in an inpatient sample (67).

Sleep abnormalities may be a marker to signal future trajectories for mood disorder. Rao and colleagues conducted a sleep study in 28 adolescents with unipolar depression and evaluated them 7 years later (68), and examined whether sleep patterns could predict course of illness. Adolescents whose course of illness in the 7 year follow-up period was consistent with unipolar depression showed lower REM latency, higher REM density, and more REM sleep in the early part of the night compared to those who converted to bipolar and to normal controls who remained free of psychopathology at follow-up. Depressed adolescents who later developed bipolar disorder were distinguished by having more stage 1 sleep and diminished stage 4 sleep than the other groups. Additionally, a longitudinal study in adolescents at risk for depression by virtue of having a parent with depression showed that compared with normal controls, adolescents at high risk for depression had shorter latency to rapid eye movement (REM) sleep, increased phasic REM sleep, and more REM sleep at baseline (69). Shorter REM latency, higher REM density and elevated nocturnal urinary free cortisol (measured at baseline) were associated with the development of depression during the 5-year follow-up.

19.2.5. Genetic Factors

19.2.5.1. Major Depressive Disorder

Depressed children and adolescents commonly have family members affected by mood disorders. The reported lifetime risk of major depressive disorder in children of depressed parents ranges from 15% (70) to 45% (71). Twin studies have supported the presence of a genetic factor in the etiology of depression, with higher concordance rates for depression in monozygotic (54%) versus dizygotic (24%) twins (72). Recurrence and an early-onset of symptoms have been suggested as characteristics most associated with familial risk (72). In fact, lifetime rates of mood disorders in first-degree relatives of depressed inpatient adolescents are significantly higher than in the general population (73). In addition, first degree-relatives of depressed suicidal adolescents may have increased lifetime rates of suicidal behavior (74). Several studies report children of depressed parents are at high risk to develop depression, and have increased risk for other psychopathology, including anxiety and disruptive disorders (11).

Relatives of patients with bipolar disorder are also at risk for major depression, as relatives of bipolar probands have higher rates of unipolar depression as well as bipolar disorder (75). In addition, a familial relationship has been suggested between major depression and bipolar type II disorder. However large-scale studies to explore this relationship to date are lacking (72).

Familial studies report a strong risk for the development of depression in the children of depressed parents, particularly if the history of depression extends to previous generations (76). There is evidence to suggest a genetic component to the development of major depression (77). However, recent studies suggest environmental stressors may be an important factor in the development of depression in genetically-predisposed individuals (78–80).

Genetic research has increasingly sought to examine not only how genes are associated with various mental health disorders, but how genetic and environmental factors interact to shape an individual's outcomes. This theory, known as gene-environment interaction (G X E), suggests that the effect of the environment on an individual's outcome depends on their genes and vice versa (296). One of the most studied genes in the depression literature is the serotonin-linked polymorphism, 5-HTTLPR. In a seminal paper, Caspi et al. (298) reported that individuals with the short allele of the gene were more likely to develop depression in the face of stressful life events than individuals with two long alleles of the gene. More recently, Vrshek-Schallhorn et al. (297) studied this gene and life events in adolescents and young adults, and found that there was a significant G X E effect for interpersonal life stressors as opposed to non-interpersonal life stressors for carriers of the short (S) genotype of 5-HTTLPR. Similar investigations have been conducted examining different polymorphisms of the brain-derived neurotrophic factor (BDNF); for example Cruz-Fuentes and colleagues recently reported that early life adversity raises risk for depression only in those with the val-val allele for this gene (300). Other studies have looked at various other genes and their prevalence in individuals with MDD. Periera et al. (299) examined the genetic variation of the AKT1 and AKT1P genes, which play an important role in down-stream signaling pathways relevant to serotonin systems and mood, in late-onset depression. They found that there is a strong association for one of the polymorphisms of the AKT1 gene with late onset depression (LOD). However, these genes have not yet been examined in early-onset depression. More recently, the field has increasingly recognized that MDD is a complex, polygenetic

disorder, and there has been interest in examining the entire genome to identify risk for MDD. Unfortunately, however, studies utilizing genome-wide association techniques of large samples have failed to yield supporting evidence for the candidate gene studies (i.e. 5HTTLPR, BDNF), and have yet to reveal any conclusive information on the genetics of MDD (301).

19.2.5.2. Bipolar Disorder

With an estimated heritability of 85–89%, bipolar disorder has a strong genetic component (75). Family studies of adolescent-onset bipolar patients found bipolar disorder was increased among first-degree relatives (81). In addition, an early onset of disease predicts a higher prevalence of illness in family members (82). Post et al. (302), who studied this relationship between family members and early onset of bipolar disorder, found that individuals in the United States, compared to Europe, had a higher likelihood of having two parents with bipolar disorder and therefore were more likely to develop bipolar disorder at an earlier age.

Similar to unipolar depression, the genetic basis for bipolar disorder is likely to be the cumulative effect of many genes (83), which leave a person susceptible to environmental influences and stressors which can lead to the development of bipolar disorder. Although different genes may be involved from family to family, the same phenotypic mood disorder may result (83).

Several candidate genes have been investigated and replicated in bipolar disorder, including *SLC6A4/5-HTT* [*serotonin transporter gene*], *BDNF* [*brain-derived neurotrophic factor*], *DAOA* [*D-amino acid oxidase activator*], *DTNBP1* [*dysbindin*], *NRG1* [*neuregulin 1*], *DISC1* [*disrupted in schizophrenia 1*]) (303). Additionally, genome-wide association studies have indicated polymorphisms in two genes (*CACNA1C [calcium channel, voltage-dependent, L type, alpha 1C subunit]*, and *ANK3* [*ankyrin 3*]). Therefore, in contrast to MDD, recent progress has been made in bipolar genetic research, identifying several common, single nucleotide polymorphisms that have survived significance testing in genome-wide analyses (304). However, these discoveries have not yet been translated to clinical practice (e.g. genetic testing to determine risk for bipolar disorder in the clinic.)

19.2.6. Neuroimaging Abnormalities

19.2.6.1. Major Depressive Disorder

The past two decades have seen a major advance in the understanding of depression through the use of brain imaging research. Various modalities including structural, functional, and magnetic resonance spectroscopy, and imaging studies in depressed adults have implicated a network of brain regions referred to as fronto-limbic neural circuitry (84). This network encompasses both dorsal and ventral frontal areas, the anterior cingulate cortex, the amygdala, the hippocampus, and the insula, which are known to mediate processes relevant to emotion and mood (85). The areas in this network are known to undergo significant change and development throughout adolescence (86, 87). Although lagging significantly behind research in adult depression, some important strides have been made using neuroimaging techniques in pediatric depression. These studies have generally supported adult work implicating fronto-limbic neural circuitry, and they suggest that the pathophysiology of depression may involve an abnormality in the development of these networks (88).

19.2.6.2. Bipolar Disorder

Similar to the research in MDD, neuroimaging studies in pediatric bipolar disorder have generally implicated fronto-limbic neural circuitry (89, 90). Emerging longitudinal research examining youth with bipolar disorder has begun to suggest progressive changes that occur across development, including loss in gray matter volume in prefrontal, anterior cingulate, and subgenual cortical regions (91). Whereas increased amygdala volumes has been an important finding in adults with bipolar disorder, the opposite pattern has been found in children (92–94), and recent work has suggested that amygdala volume is reduced at the onset of illness and increases with age (95).

19.3. Psychological Theories of Mood Disorders

19.3.1. Learned Helplessness

Seligman and Peterson's (97) learned helplessness model theorizes that depression is connected to the experience of uncontrollable life events. These uncontrollable life events lead the person to perceive his or her behavior as independent from these events. Thus, the person essentially "gives up." This idea of helplessness is associated with motivational, cognitive, and emotional deficits in human responsiveness.

19.3.2. Cognitive Models

Cognitive models provide a theory that account for the thoughts, or cognitions associated with depression. In Beck's (98) model, distorted, negative thoughts characteristic of depressed individuals are seen as underlying depression.

19.3.3. Social and Environmental Factors in the Development of Mood Disorders

Social and environmental factors may have a role in the development and maintenance of mood disorders. Children and adolescents with mood disorders typically have poor relationships with parents, siblings, and peers (96). In the family, factors such as lack of parental affect, irritability directed toward the child, and child abuse may also contribute to increased vulnerability to depression in the child (99). In regards to mania, when child rearing practices of manic parents were examined, many had poor parenting techniques (100). The episodic nature of the unreasonable behavior of these manic parents may be harmful to the normal development of children, especially children with mood disorders (17).

19.3.4. Attachment theory

In his attachment theory, Bowlby emphasized the importance of early relationships with caregivers for development and relationships formed later in life (101). Mary Ainsworth developed the Strange Situation, a paradigm designed to allow characterization of parent-child relationships as either secure or insecure attachment (102). Disruptions in attachment have important implications for the later development of psychopathology (103).

19.4. Epidemiology

19.4.1. Depressive Disorders

It is estimated that approximately 2.5% of children and 8.3% of adolescents in the United States have depressive disorders (1). However, no large-scale epidemiological studies have been done on the prevalence of major depressive disorder in prepubertal children to date (11). In specialized populations, depression was reported in 7% of children admitted to pediatric hospitals for medical reasons (104) and in 40% of children in pediatric neurology clinics presenting with headaches (105). In prepubertal children, depression occurs at approximately the same rate in both sexes (2). However, after puberty there is a marked difference in the sexes, with females presenting with major depression twice as frequently as males. The lifetime prevalence rate of depressive disorders in adolescents has been estimated to range from 15 to 20%, which is comparable to the lifetime rate of major depressive disorder in adults (106). An epidemiological study reported prevalence rates of persistent depressive disorder of 1.6% to 8.0% in adolescents (107).

19.4.2. Bipolar Disorders

Bipolar disorder does not occur as often in the general population as major depressive disorder or persistent depressive disorder. The lifetime prevalence of bipolar disorder approaches approximately 1% by adolescence (7). Geller et al. (1998) reported the mean age of childhood-onset bipolar disorder as approximately eight years (108). Burke et al. (109) found the age of onset to be slightly older at 15 to 19 years. Patients with early-onset bipolar disorder have higher rates of psychotic features and a more severe course of illness than those with an older age of onset (110–112). Children and adolescents with bipolar disorder have a more prolonged course and have decreased response to treatment (8, 111).

19.5. Clinical Presentations and Phenomenology

19.5.1. Depressive Disorders

Young children, unable to express emotions like adults, present with more somatic complaints, psychomotor agitation, and mood-congruent hallucinations (11). With increasing age, these symptoms lessen, but self-esteem may worsen. Adolescents, as a result, can present with antisocial behavior, substance use, restlessness, "grouchiness," aggression, social withdrawal, family and school problems, wanting to leave home, or feelings of not being approved of or understood. Later in adolescence, the phenomenology of major depression more closely approximates adult major depression (113). It has been suggested that

symptoms of "endogenicity" – melancholia, psychosis, suicide attempts, lethality of suicide attempts, and functional impairment – increase with age (1).

19.5.2. Bipolar Disorders

Bipolar disorder also presents with variability at different stages of development. Younger, pre-school aged children often present with explosive and unmanageable temper tantrums, sexual joking, and nightmares with violent imagery (1). As children become school-aged, they begin to display pressured speech and increased motor and goal-directed activity, involvement in pleasurable activities with a high level of danger, hypersexuality, disordered sleep patterns with high activity levels in the bedroom before sleep (114). However, at this age, manic episodes may not be the discrete periods often seen in adults, and often have a chronic, non-episodic, and rapid-cycling presentation (115, 116). Irritable, unpredictable and labile moods are common in adolescents and may be more common than euphoria in this age group (11).

19.6. Gender Differences in Mood Disorders

19.6.1. Depressive Disorders

An interesting phenomenon noticed in depression after puberty is the dramatic shift of occurrence, leading to a female-to-male ratio of depression of 2:1 (2). Biologically, several changes have been implicated in the gender differences observed in depressed adolescents; however, evidence-based literature in this area is quite limited. One theory involves the increased oxytocin production observed in post-pubertal females (117). Changes in hormones such as progesterone, estrogen, and cortisol have also been implicated in the differences observed between the genders in depression. There is also evidence in the adult literature to suggest that gender may affect response to medications, specifically SSRIs (118), but studies to date in this area have been inconclusive (119) and largely unexplored in pediatric populations.

19.6.2. Bipolar Disorders

Gender differences in bipolar disorder are even less studied. There is no evidence to date to suggest a gender difference in the development and treatment of bipolar disorder in children and adolescents. Pre-pubertal onset mania may be more common in males than in females, particularly in hospitalized patients (108).

19.7. Differential Diagnoses/Comorbidities

19.7.1. Major Depressive Disorder

The most frequent comorbid diagnoses with major depressive disorder are persistent depressive disorder (30%-80%), anxiety disorders (30%-80%), disruptive disorders (10%-80%), and substance abuse disorders (20%-30%) (11). In general, comorbidities with major depressive disorder are associated with a more severe and persistent course of depression (1). Thus, it is important to assess comorbid psychiatric diagnoses as they may influence treatment and have an impact on the course of depression. The comorbidity of MDD and anxiety disorders can have important clinical implications; individuals with both disorders may have increased risk for substance abuse, suicidality, poor response to psychotherapy, and psychosocial problems. Anxiety disorders comorbid with MDD present differently at different stages throughout childhood. Separation anxiety is most common in children whereas generalized anxiety disorder is most common in adolescents (120).

Conduct disorders are also common in children. They may be present in 15–30% of depressed children and adolescents (121). More than 50% of children and adolescents with a mood disorder have conduct disorder or oppositional defiant disorder (11). Symptoms of conduct disorder such as irritability, oppositional defiance and social withdrawal may mask MDD symptoms (120). Youth with both MDD and conduct disorders are at increased risk for suicide (122). Although comorbid conduct disorder and MDD in childhood is not associated with increased risk of MDD in adulthood (120), depressed patients with comorbid conduct disorders had worse short-term outcome, fewer melancholic symptoms, fewer recurrences of depression, a lower familial aggregation of mood disorders, a higher incidence of adult criminality, more suicide attempts, higher levels of family criticism, and an increased response to placebo than patients with only MDD (11).

Substance abuse is also a common comorbid diagnosis in adolescents with MDD (1). Rao et al. found depressed adolescents had an earlier onset of substance use disorders and greater psychosocial impairment than control subjects (123).

Comorbid obsessive-compulsive disorder (OCD) occurs in 10–30% of children and adolescents with MDD. Severe OCD symptoms require treatment. However, they should be addressed after the treatment of the depressive symptoms, as mood disorders can interfere with a patient's motivation and compliance with behavioral therapy programs (120).

Several diagnoses included in the differential diagnosis of MDD should be ruled out. For instance, adjustment disorder with depressed mood is a possibility in a school-age child with a depressed affect. In this diagnosis, several depressive symptoms are present, but there are not enough present to warrant a diagnosis of MDD, and the duration is less than 6 months (96). Another important diagnostic consideration (especially in adolescents) is substance-induced mood disorder with depressive features. This diagnosis is made when the depressed mood is due to the physiological side effects of a medication, drug of abuse, exposure to a toxin, or other somatic treatment (11). A substance-induced depression can be distinguished from a major depressive disorder by the onset, course, and clinical presentation of the disorder (123). It is also important to consider all medical conditions that may produce psychiatric syndromes similar to MDD or DD (96).

19.7.2. Bipolar Disorder

A diagnosis of mania should not be made until the child or adolescent is observed in a drug-free state. Medications reported to induce manic states include amphetamines, corticosteroids, sympathomimetics, isoniazid, and antidepressants (17). Hyperthyroidism may present with a manic-like state (17). Neurological conditions also may cause a manic syndrome such as head trauma, multiple sclerosis, stroke, and seizure disorders with a left temporal focus (17). Space occupying lesions such as meningiomas, gliomas, and metastatic lesions in the thalamus have been implicated (124).

There are also psychiatric disorders that can co-occur with or be incorrectly diagnosed as mania. For instance, Attention-Deficit/hyperactivity disorder (ADHD) and Bipolar Disorder are difficult to differentiate in children and adolescents (125). Specifically, psychomotor agitation, distractibility, aggression, poor school performance, restless sleep, and sexually inappropriate behavior are symptoms of both ADHD and Bipolar Disorder. Manic children, however, have more affect and are euphoric or irritable. Children with ADHD have low self-esteem and a much longer duration of symptoms (17). It has been suggested that childhood-onset bipolar disorder is frequently comorbid with ADHD (126). Whereas hyperactivity, impulsivity and attention impairments are present in both groups, the presence of episodes of prolonged elevated mood and of a decreased need for sleep differentiates juvenile-onset Bipolar Disorder from ADHD (127).

Conduct disorder is also frequently comorbid with Bipolar Disorder (128). Many children with mania have unruly, disruptive behavior suggestive of a conduct disorder. However, children with a "pure" conduct disorder do not have pressured speech, flight of ideas, or delusions of grandeur (17). Children and adolescents with bipolar disorder sometimes become involved with the use of alcohol or drugs in an attempt to treat symptoms of their mood disorder. Most adolescents have easy access to drugs and alcohol (17).

Schizophrenia may also be confused as a manic episode because of the presence of delusions and hallucinations in both disorders (17). Psychotic symptoms are common in prepubertal manic children (114). Usually the course of illness can help distinguish these diagnoses: the onset of schizophrenia is typically insidious and the onset of a manic episode is usually acute (17).

Sexual abuse is also important as a differential diagnosis in childhood because manic hypersexuality is often manifested in children by self-stimulatory behaviors, including masturbation in public (11). Therefore, it is important to evaluate for sexual abuse and exposure to inappropriate adult sexual behaviors when considering the diagnosis of bipolar mania (124).

19.8. Treatment

The treatment approach to child and adolescent mood disorders should be biopsychosocial and include psychotherapy, medication, educational assessment and planning, and social skills training (13). Treatment setting is also a consideration. It must be determined if the patient may be treated appropriately on an outpatient basis. Hospitalization may be required to protect the child or adolescent from either his/her own dangerous behaviors or to protect him/her from a volatile and unsafe home environment. Aggression, deterioration in symptoms or functional status, and family unrest are the major predictors of inpatient hospitalization of children and adolescents (129, 130).

19.8.1. Biological and Pharmacological Treatments

19.8.1.1. Major Depressive Disorder

19.8.1.1.1. Selective Serotonin Reuptake Inhibitors

There are seven randomized controlled trials exploring the use of selective serotonin reuptake inhibitors (SSRIs) in the acute treatment of MDD in children and adolescents. These include three randomized controlled trials of fluoxetine in children and adolescents ages 7–18, depending on the study (131, 132); one randomized, controlled study of paroxetine, placebo, and imipramine in adolescents ages 12–18 (133); one multicenter randomized, double-blind, placebo-controlled trial of sertraline in children and adolescents ages 6–17 (134); a randomized, placebo-controlled trial of citalopram in children and adolescents ages 7–17 (135), a double-blind, randomized, placebo-controlled trial of escitalopram in children and adolescents ages 6–17 (136) which demonstrated significant improvement in adolescents only, and a follow-up trial of escitalopram in adolescents 12–17 (137). Only two SSRIs are currently approved by the FDA to treat pediatric depression: Fluoxetine is approved to treat depression in children eight years of age and older, and escitalopram is approved to treat depression in adolescents 12 years of age and older. Medications such as fluvoxamine have proven themselves safe and effective in treating other childhood disorders, i.e. obsessive-compulsive disorder. However, studies proving these medications safe and effective in childhood depression are lacking.

The SSRIs are metabolized in the liver by the cytochrome P450 isoenzyme system and differentially inhibit the cytochrome P450 isoenzymes, which can lead to drug-drug interactions with medications metabolized by the same isoenzyme (138). There is little information on the impact of age on absorption, metabolism, therapeutic levels, or possible drug interactions of SSRIs.

The AACAP guidelines recommend continued treatment with SSRI for 6–12 months after achieving an acceptable clinical response (139, 306). At this point, continuing antidepressant treatment as maintenance therapy may be required for patients with multiple or severe episodes of depression or patients at high risk for recurrence. Frequency of follow-up would be determined by factors such as stability of home environment, existence of comorbid conditions, and clinical status. Patients with recurrent episodes accompanied by psychosis, severe suicidality, or treatment resistance may even require lifelong treatment (139).

Common side effects for SSRIs include: gastrointestinal upset, decreased appetite, headache, restlessness, insomnia, and fatigue. These effects are usually dose-dependant and do not appear to be long-term (140). Recently concern about the use of SSRIs during pregnancy has been raised regarding the development of Persistent Pulmonary Hypertension of the Newborn (PPHN) in infants exposed to SSRIs late in pregnancy (141). Additionally, congenital malformations, particularly ventricular septal defects, may be linked to SSRIs, particularly paroxetine (142).

The possibility that SSRIs and antidepressant medication in general may increase suicide risk has also been raised. This concern surfaced after an FDA meta-analysis of 95 adverse event cases across 23 pediatric trials of antidepressants (140). While no individual trial demonstrated a statistically significant risk of suicidality, many trials had a relative risk of greater than or equal to two, increasing the concern of researchers. Suicidal behavior occurred most often in patients with a history of suicide attempts or ideation. In response to these concerns, the FDA has published a "black box" warning for all antidepressants, indicating a possible increased risk of suicidality in children and adolescents given antidepressant medications. The FDA has also requested all antidepressant medications be packaged in specific quantities. Patients should receive a medication guide with each prescription, alerting them to the increased risk of suicidal thinking and behavior (11).

The recent Treatment for Adolescents with Depression Study (TADS) addressed the concern of increased suicidality with SSRI medication for the treatment of depression in adolescents (143). In this study of 439 adolescents ages 12–17, the number of adolescents reporting suicidal ideation declined from 29% at baseline to 10.3% after 12 weeks. The treatment group receiving both treatment with fluoxetine and cognitive behavioral therapy proved to be statistically superior to placebo with respect to reducing reports of suicidal ideation. Recent toxicological and epidemiologic evidence also suggest a declining rate of suicide among children and adolescents, coinciding with increasing rates of antidepressant use in this population (140).

Another concern regarding the use of SSRIs in children and adolescents with major depression is the risk of "switching" to a manic episode. Recent literature suggests that children ages 10–14 on antidepressant medication are at highest risk for conversion to a manic episode (144), but further research suggests that children on SSRIs may be at lower risk for a manic switch compared to those on other antidepressants such as tricyclic antidepressants. However, further analysis of this data suggests pre-pubertal children (ages 5–14) are at higher risk of new-onset mania on SSRI treatment than older adolescents and adults (ages 15–29 years) (145). Other suggested risk factors for switching to a manic episode include family history of bipolar disorder and multigenerational mood disorders (140).

19.8.1.1.2. Tricyclic Antidepressants

Tricyclic antidepressants (TCAs), previously a mainstay of treatment for MDD, have been well studied and often utilized in adult patients. Studies of TCAs in adults with major depressive disorder have established their efficacy in acute (146) and maintenance treatment (147). Yet, literature reviews and a meta-analysis of 12 randomized controlled trials of TCAs in patients aged 6–18 years (148) have not supported efficacy in children and adolescents (149).

A literature search on the cardiovascular effects of TCAs in children and adolescents (150) found TCA use was associated with several cardiovascular events. Adverse reactions ranged from minor increases in systolic and diastolic blood pressures and heart rate to sudden death. Electrocardiographic changes were noted, but most were not age-related and were associated with higher serum-levels of medication. The American Association of Poison Control Centers Toxic Exposure Surveillance System reviewed all 168 cases of sudden death in children and adolescents in which there was a mention of the TCA desipramine, or four structurally similar TCAs, amitriptyline, imipramine, nortriptyline, and doxepin from 1983 to 2002 (151). The case fatality rate was significantly higher for children and adolescents on desipramine compared to all other TCAs. The authors recognize that the explanation for relatively higher rate of toxicity with desipramine compared to the other studied tricyclic antidepressants is largely unclear. They do, however, suggest that pharmacodynamic factors may be implicated (151).

19.8.1.1.3. Monoamine Oxidase Inhibitors

Historically, monoamine oxidase inhibitors (MAOIs) have been a second-line treatment for depression in adults (152) but they may be more effective than TCAs for depression with atypical features, i.e. increased sleep, increased eating, and weight gain (153). However, the dietary limitations and risk of tyramine-induced interactions have limited their use in children and adolescents (154).

To date, there are few studies of MAOIs in adolescents. In a chart review, Ryan et al. (155) assessed the efficacy of MAOIs in 23 depressed adolescents. Twenty-one of these subjects had not responded to heterocyclic antidepressants. Seventy percent of the adolescents reviewed in Ryan's study had a "good" or "fair" response to MAOIs alone or in combination with heterocyclic antidepressants. However, dietary noncompliance was a significant problem in 80% of the subjects. Because of the relatively high risk of noncompliance with a tyramine-free diet, the risks of MAOI treatment may outweigh the potential therapeutic benefits in unreliable adolescents or families (155). Newer MAOIs, such as moclobemide have benefits over the older, nonselective monoamine oxidase inhibitors. First, they do not appear to impair cognitive function in young adults as do older antidepressants (156). This is a significant advantage for school-age children. Second, these newer medications may not require the dietary restrictions of the older, nonselective inhibitors. Unfortunately, studies utilizing these medications in depressed children and adolescents are still lacking (152). In fact, no studies have been published testing any MAOIs in over two decades. In general, these agents tend to be used in responsible adolescents with treatment-resistant depression.

19.8.1.1.4. Other Antidepressants

Bupropion is thought to derive most of its antidepressant properties from its effect on the noradrenergic system and specifically its modulation of the reuptake of norepinephrine and dopamine in the CNS. Bupropion undergoes biotransformation to three pharmacologically-active metabolites. One in particular, hydroxybupropion, is associated with increased side effects, mainly dermatological and gastrointestinal (157). These side effects may worsen if bupropion is combined with other medications, such as fluoxetine. Concerns about seizures in adults with eating disorders have limited the use of bupropion. However, the incidence of seizures is low in adults when bupropion is given in limited doses. When the dose is under 450 mg/day in adults, seizures occur in approximately 4 per 1000 patients (158). With respect to pediatric data, several cases of presumed "serum-sickness" have been reported in patients on bupropion with a history of comorbid ADHD or bipolar disorder who subsequently developed depression (159). One controlled trial has been conducted in adolescents with depression and ADHD reported that sustained-release bupropion was associated with significant improvements over placebo in both depression and ADHD symptoms (160). Additionally, an open-label trial of sustained-release bupropion for adolescents with substance use disorders, ADHD and a mood disorder, found significant reductions in symptoms and functioning for all three disorders (161).

Venlafaxine inhibits reuptake of both serotonin and norepinephrine from the synaptic cleft. Like SSRIs, venlafaxine lacks significant affinity for muscarinic, cholinergic, histaminic, or α_1-adrenergic receptors (11). Venlafaxine is one of the few newer antidepressants to have pharmacokinetic data for children and adolescents (162). An initial double blind, placebo-controlled study of 33 children and adolescents aged 8–17 did not find improvement of depressive symptoms (163). The authors of this study suggest that cognitive behavioral therapy (CBT), which was administered to all subjects, may have masked the effects of venlafaxine versus placebo. A subsequent report described two randomized controlled trials in

169 children and adolescents with depression ages 7 to 17 years with venlafaxine ER for 8 weeks. Although neither study showed greater improvement in depressive symptoms than placebo, a post-hoc analysis revealed that the medication was superior to placebo among adolescents aged 12–17 but not among children aged 7–11 (164).

Trazodone and nefazodone have little published literature supporting their use in depressed children and adolescents. Trazodone derives most of its antidepressant properties from its action as a serotonin receptor antagonist (152). Two major side effects – priapism and sedation – have limited its use in children and adolescents. Nefazodone works at both sites of the serotonin (5-hydroxytryptamine [5-HT]) receptors. It blocks the 5-HT_2 receptor as a postsynaptic serotonin antagonist and inhibits presynaptic serotonin reuptake. In an 8-week open-label trial of nefazodone in 28 depressed children and adolescents (aged 7–17) nefazodone was generally well-tolerated (165). Nefazodone was also clinically effective for depressive symptomatology, although efficacy was not the major focus of the study. Nefazodone also carries an FDA black-box warning for hepatotoxicity. Therefore, patients on nefazodone should closely be monitored for this rare, yet severe event.

19.8.1.2. Electroconvulsive Therapy

Treatment with electroconvulsive therapy (ECT) may be considered in children and adolescents who do not adequately respond to multiple antidepressant medications and cognitive behavioral therapy, particularly if there is a family history of depression found only to be responsive to ECT (11). To use ECT in children and adolescents, two additional child and adolescent psychiatrists, in addition to the primary treating psychiatrist, need to agree that this level of treatment is indicated.

19.8.1.3. Transcranial Magnetic Stimulation

A few studies have begun to investigate repetitive trans-cranial magnetic stimulation (rTMS) for treatment-resistant depression in adolescents. This technique induces weak electric currents using a rapidly changing magnetic field. Over time, this intervention can change the excitability and inhibition of neural networks. Treatment effects are believed to reflect changes in synaptic plasticity akin to long-term potentiation and long-term depression (166). Two small pilot, open labeled studies have been conducted in treatment-resistant depression, which have both reported significant improvement in symptoms and good tolerability of the treatment. (167, 168). When these patients were re-assessed three months (168) and three years (169) later, the clinical improvements were maintained, and there was no evidence for long-term cognitive deterioration. These studies have prompted interest in further research investigating this treatment methodology using larger samples and controlled designs.

19.8.1.4. Bright Light Therapy

Bright light therapy (BLT) has been investigated as a treatment for depression symptoms in adolescents with both seasonal and non-seasonal depression. First, a placebo-controlled trial of light therapy for the treatment of pediatric seasonal affective disorder reported significant improvement in depression symptoms in the BLT group compared with placebo (170). In a later study, a randomized crossover trial was conducted using bright light therapy (BLT) as a mono-therapy for non-seasonal depression in 28 adolescents. This study found significant reductions in depression scores and elevation of evening melatonin levels to be associated with BLT (171). This group also examined BLT as an add-on therapy to fluoxetine and psychotherapy, and found a significant improvement in depression symptoms but no change in evening melatonin levels (172).

19.8.1.5. Vitamin D

Emerging research has examined the relationship between Vitamin D deficiency and depression. Vitamin D has components that overlap with the physiology of depression therefore affecting mood when the vitamin is low in the body. Vitamin D has been linked to sleep and circadian rhythms which, when disrupted, can exacerbate depressive symptoms (173). A recent meta-analysis of studies in adults confirmed an association in which depressed patients tend to have lower vitamin D levels, and that individuals with low vitamin D are at higher risk for depression (174). However, a recent case series in adults which also found lower vitamin D levels in adults with depression did not show improvement in depression symptoms as a result of vitamin D replacement (175). A Swedish study of 54 adolescents (ages 10–19) conducted in 2011 investigated the correlation between Vitamin D and well-being over the course of three months (176). Researchers found a significant decrease in depressive symptoms and an increase in well-being after taking a Vitamin D supplement. Controlled trials are needed to further assess whether Vitamin D assessment and treatment should be incorporated into routine care and treatment of adolescent depression.

19.8.1.6. Psychotherapeutic Treatment Options for Depression

The psychotherapeutic treatment options available for children with Major Depressive Disorder (MDD) and Persistent Depressive Disorder (PDD) are similar to those available to adults, but tailored to children. A biopsychosocial approach is the best for children and adolescents with MDD. This approach combines medication management, psychotherapy, social skills training, and educational assessment and planning (96). A combination of various short-term therapeutic techniques may be the most efficacious treatment option for the child or adolescent with a depressive disorder (177).

19.8.1.6.1. Cognitive Behavioral Therapy (CBT)

CBT is an effective treatment for depressed children and adolescents. It addresses the cognitive biases which maintain depression (11). CBT is based on the cognitive theory that individuals trigger and maintain depression by specific dysfunctional cognitive constructs (178). In CBT the child is the focus of treatment and has an active collaboration with the therapist to address the emotional processing of distressing issues and to develop coping strategies. Parents may be involved as "co-therapists" to reinforce the newly learned behaviors.

A study comparing 12–16 weeks of individual CBT, nondirective supportive psychotherapy, and systematic behavior family therapy in a group of 107 clinically referred, depressed adolescents found CBT was the most efficacious. CBT had the most rapid reduction in interviewer-rated and self-reported depression and the greatest increases in parent-rated treatment credibility (179). Wood et al. (180) studied the effectiveness of brief individual CBT and relaxation training for clinically depressed adolescent outpatients. A combination of cognitive, social problem solving, and symptom-focused interventions was associated with significant reductions in dysphoria and improved general adjustment. Patients who received CBT were more likely to remit from their depressive disorder than control patients.

As more studies are conducted on efficacy of CBT, its effectiveness for the prevention of depression in a high risk population (i.e. children of depressed parents) needs evaluation (181). A large multi-center controlled trial to assess the effect of CBT to prevent depression and anxiety in offspring of parents with depression and anxiety is currently underway (182).

19.8.1.6.2. Dialectical Behavioral Therapy (DBT)

Dialectic behavioral therapy (DBT) was developed out of cognitive behavioral therapy originally designed to treat symptoms associated with borderline personality disorder (BPD) in adults (183). There has been strong interest in adapting DBT for adolescents with depressive symptoms (184). A study of 12 adolescents tested the effectiveness of DBT on suicidal thoughts and depression over the course of one year (185). Researchers found a reduction in depressive symptoms and improved quality of life, which was associated with a reduction in self-injurious behavior and suicidal thoughts. Sunseri (2004) and Rathus and Miller (2004) also found positive effects including reduction in depression symptoms and self-injurious behaviors in suicidal adolescents (186, 187).

19.8.1.6.3. Family Therapy

Although there is only limited empirical research on its use, family therapy may provide helpful support for the depressed child or adolescent. Emphasis is on understanding a child's symptoms as they relate to the entire family unit (188). Observational studies suggest there is an association between the problems families encounter with a depressed child or adolescent and problems existing within the family. Such problems could include existing mental illness (other than the child's) in the family or strained relations due to the difficulties of interacting with a depressed child or adolescent (189). Research to explore the efficacy of other forms of family involvement for the treatment of adolescents and children with depression is being conducted. One such study conducted by Sanford et al. (2006) on family psychoeducation (FPE) found FPE influences processes which are thought to affect the course of adolescent depression (190). Its use increased parent-adolescent relationships and improved social functioning. FPE might have potential to reduce recurrence of subsequent major depressive episodes.

19.8.1.6.4. Attachment-Based Family Therapy

Attachment-based family therapy (AFBT) is a brief, manualized treatment for adolescent depression that focuses on repairing relationships between adolescents and parents, addressing attachment failures and rebuilding trust. Early evidence has suggested that this approach is effective in reducing depression symptoms including suicidal ideation in adolescents (191, 192). Recent work has suggested putative mechanisms underlying the benefits of this treatment. Increases in maternal autonomy-granting during ABFT was associated with improved perceptions of parental care and decreases in attachment-related

anxiety and avoidance. Decreases in adolescents' perceived parental control were associated with reductions in adolescents' depressive symptoms (193).

19.8.1.6.5. Group Therapy

Some consider group therapy the treatment of choice for adolescent depression because the developmental tasks of adolescence include emotional separation and individuation from parents and identification with a peer group (194). Fine et al. (195) compared two forms of short-term group therapy for depressed adolescents: a therapeutic support group (TSG) and a social skills group (SSG). Subjects in the TSG shared common problems, developed new ways to cope with stressful situations, and provided mutual support. Subjects in the TSG improved significantly more than those in the SSG. Adolescents treated in the TSG had significantly greater reductions in their depressive symptoms and increases in self-concept. However, these group differences were no longer evident at 9-month follow-up.

19.8.1.6.6. Psychodynamic Psychotherapy

Psychodynamic psychotherapy for adolescent depression emphasizes the importance of object loss and self-critical internal representations. Goals of therapy include a reduction in the use of maladaptive defense mechanisms, resolution of past psychological trauma, and greater acceptance of the realistic limitations of one's family and one's own abilities. The aim of psychodynamic psychotherapy is not only to relieve the symptoms of depression, but also to ensure maintenance of improvement and prevention of relapse through modification of the individual's adaptive style and personality organization (11).

19.8.1.6.7. Interpersonal Psychotherapy

Interpersonal Psychotherapy for Depressed Adolescents (IPT-A) is based on psychodynamic theory and it is derived from Interpersonal Psychotherapy originally developed for adult patients, but was modified for use in adolescents (196). IPT is focused on the current relationships of the patient. IPT is based on the principle that regardless of the underlying cause of the depression, the onset of symptoms occurs within an interpersonal context: depression can negatively impact interpersonal relationships, and problems in relationships can have negative effects on mood (197, 198). The goal of IPT is to improve relationships and develop better communication and interpersonal problem-solving skills (197, 198). IPT-A is delivered over the course of 12–16 weeks, which is divided into the initial phase, the middle phase and the termination phase. The initial phase includes explaining the theory and goals of IPT-A, identifying the interpersonal problem areas and developing a treatment plan with the patient (197, 198). The adolescent and therapist begin working on the conflicts during the middle phase. This includes communication analysis, decision analysis, and role playing (197, 198). During the termination phase, the therapist reviews the adolescent's depressive symptoms and changes that have occurred in communication and relationship skills, and discusses the management of future depressive recurrences (197, 198). Mufson and Fairbanks (199) conducted a study with depressed adolescents who each received 12 weeks of modified interpersonal psychotherapy in an open clinical trial then completed a follow up evaluation. Of 10 depressed adolescents who participated in the follow-up evaluation, only 1 met criteria for a mood disorder at the end of the trial. Most reported few depressive symptoms and had maintained improvement in social functioning, despite experiencing a significant number of negative life events. Improvements that occurred during the 12-week open clinical trial were maintained for the next year (199). A controlled trial was conducted in 63 adolescents and their families who were randomized to receive either IPT or treatment as usual delivered by school-based mental health clinicians (200). This study found that IPT was superior to treatment as usual for reducing depression symptoms. Furthermore, adolescents who reported higher levels of conflict with mothers and of social dysfunction with friends were particularly responsive to IPT as opposed to treatment as usual (201). Such findings have important implications for developing strategies for personalizing treatment based on individual characteristics.

19.8.1.7. Combined Treatments for Depression

Several large, controlled studies have now investigated whether a combination of treatments might be more helpful than single approaches for adolescents with MDD. All reports to date have examined adding CBT to a medication strategy.

The Treatment for Adolescents with Depression Study (TADS) was a 12-week, multisite, double-blind, placebo-controlled study of 493 adolescents (ages 12–17 years) with a diagnosis of major depressive disorder. There were four treatment groups: (a) fluoxetine only, (b) CBT only, (c) CBT plus fluoxetine, and (d) placebo. The combination treatment group had a 71% response rate, compared with 61% response rate for fluoxetine alone, 43% response rate for CBT alone, and 34.8% response for placebo. The combination of CBT and fluoxetine had a response rate twice that of placebo (122): a statistically significant difference. In addition, the combination of fluoxetine and CBT was superior to either fluoxetine alone ($P = .02$) or CBT alone ($P = .001$). After 12 weeks, the placebo condition ended but the active treatment groups continued open-label through 36 weeks.

The participants were then followed up naturalistically at one and five years following discontinuation of active treatment. At week 36, the estimated remission rates for intention-to-treat cases were 60% for the combination group, 55% for the fluoxetine group, and 64% for the cognitive-behavioral therapy group (202). One year following discontinuation of the TADS treatments, the benefit of all active treatment (week 36) persisted during followup on all measures of depression and suicidality (203). Almost half of the original sample was assessed for the five year follow-up. At that time, 96% of the participants had recovered from their index episode; of those almost half had a recurrence during the follow-up period (204).

The Treatment of Resistant Depression in Adolescents (TORDIA) was a 12-week, multisite, double-blind study of 334 adolescents (ages 12–18) with SSRI-resistant MDD (205). The adolescents were randomized into one of four treatment conditions: (a) switching to another SSRI, (b) switching to venlafaxine, (c) switching to another SSRI and adding CBT, or (d) switching to venlafaxine and adding CBT. Both combination treatment groups showed better responses than the medication-only groups. There were no clear advantages to either a second SSRI or venlafaxine, but venlafaxine was associated with greater side effects (increase in diastolic blood pressure and pulse, skin problems). The TORDIA results support the combination of using CBT and medication, however, the response rates for the combined treatment were 54.8% while just switching to either an SSRI or non-SSRI also yielded a fairly high response rate of 40.5%. This indicates a need for further research.

The Adolescent Depression and Antidepressant and Psychotherapy Trial (ADAPT) was a 12 week, multisite, pragmatic randomized controlled superiority trial of 208 adolescents ages 11–17 with moderate-to-severe MDD who did not respond to a brief initial intervention based on principles of routine clinical care for at least two sessions (206). Adolescents were randomized to start an SSRI or start a combination of an SSRI and CBT for 12 weeks. At week 12, 86 of the 208 (43%) adolescents reported being much or very much improved. In contrast to TADS and TORDIA, there was no significant difference in treatment effectiveness for the combined treatment (SSRI plus CBT) over just the SSRI alone (206). Predictors of a poor treatment response included baseline severity, obsessive-compulsive disorder and suicidal ideation, together with presence of at least one disappointing life event during the treatment (207). Predictors of suicide attempts during the treatment included baseline high suicidality, nonsuicidal self-injury, and poor family function. Predictors of nonsuicidal self-injury during the treatment included baseline nonsuicidal self-injury, hopelessness, anxiety disorder, and being younger and female (208).

19.8.1.8. Summary of Treatments for Depression

Recent practice parameters published by the American Academy of Child and Adolescent Psychiatry suggest starting with basic psychosocial interventions for youths with milder and/or simpler forms of illness, and recommending pharmacotherapy and/or specific therapy types (e.g. CBT or IPT) for those youths who do not respond to supportive psychotherapy or who have more complicated depressions (209). With regards to duration of pharmacotherapy, discontinuation could be considered six to twelve months after symptom resolution and medication should be gradually tapered (209, 210). These parameters noted that in order to prevent recurrence, some youths should be maintained with treatment for longer periods of time, and given the lack of research to date to guide clinicians in this area, clinicians are encouraged to trust their judgment and to consider individual factors such as clinical status, functioning, support systems, environmental stressors, and comorbidities (209).

19.8.2. Bipolar Disorder Treatment

In recent years, a substantial amount of progress has been made in testing interventions for youth with bipolar disorder, especially in regards to psychopharmacological interventions, and specifically for treating manic symptoms. Although previous guidelines had suggested that lithium or valproate should be used as first line agents for non-psychotic mania in pediatric bipolar patients (211), more recent review of the evidence has indicated that for youth, second-generation atypical antipsychotic medications have stronger evidence for effectiveness (212). Increasing evidence is available to suggest that pediatric bipolar disorder is a chronic illness and that children and adolescents frequently do not fully respond to a single intervention; rather, the majority of children will require multiple mood-stabilizing agents (213) and will benefit optimally from combined treatment with psychosocial individual and family interventions (214).

19.8.2.1. Pharmacotherapy

19.8.2.1.1. Lithium

Lithium was the first FDA-approved mood stabilizer for children and adolescents older than twelve years of age. Support for lithium in children and adolescents with bipolar disorder comes from several case reports (215). A large open trial (n = 100) suggested the benefit of lithium for treating acute mania in children and adolescents with bipolar disorder (216). However, a subsequent discontinuation study did not detect a significant superiority of lithium over placebo for preventing

relapse (217). In a small (n = 30) double-blind, placebo-controlled trial, Geller and colleagues reported that lithium was not significantly superior to placebo for treating mania in children and adolescents (218). More recently, Findling and colleagues published a report on 41 children and adolescents with bipolar disorder that had at least a partial response to an 8 week open-labeled trial of lithium and who continued long-term (mean 15 weeks) with lithium. This study reported that patients who initially responded to lithium maintained their response during the continuation phase, but that those who initially had a partial response did not improve during the continuation phase, even though adjunctive medications could be prescribed (219).

Lithium dosing is more complicated in children than in adults, as it is reported to have a shorter half-life and higher total clearance in children (220). The therapeutic range for lithium blood levels ranges from 0.6–1.2 mEq/L and is dependent on the individual's lithium excretion rate. Lithium levels should be monitored to avoid lithium toxicity. There are two major approaches to calculating a safe, effective dosage of lithium for children and adolescents with bipolar disorder: a weight-based method (215) and a kinetics-based method (221). The weight-based approach, applicable to 6 to 12-year-old children, recommends a dosage of 30 mg/kg/day in three divided doses and produces a therapeutic lithium level within 5 days (215). The kinetics-based model uses a single 600 mg lithium test dose to predict serum lithium levels in children (221).

Due to chronicity and unpredictability of symptoms in child and adolescent patients with bipolar disorder, the optimal duration of antimanic treatment is difficult to establish (11). However, evidence supports long-term maintenance therapy with lithium, as discontinuation of lithium has been associated with an increased risk of relapse (8, 222). Furthermore, restabilizing patients on lithium, once therapy has been discontinued or interrupted, can be difficult (223, 224).

Children treated with lithium should be carefully monitored for adverse effects on the renal and thyroid systems. Serum electrolyte levels should be obtained at regular intervals (225, 226). Some studies of lithium found an association with cognitive impairment, including confusion and forgetfulness, at even low lithium plasma levels (227). Other common lithium side effects in children, obtained from case reports, systematic reporting, and various efficacy studies, include weight gain, polydipsia, headache, tremor, acne, hypothyroidism, and GI complaints (nausea and diarrhea) (217). Renal, ocular, thyroid, neurological, dermatological, and cardiovascular side effects are less common (11). In addition, there has been concern regarding lithium therapy in sexually active adolescent females, as this medication has been associated with various congenital abnormalities, particularly Ebstein's anomaly, a malformation of the tricuspid valve.

19.8.2.1.2. Anticonvulsants

Anticonvulsant medications have been used in the acute and prophylactic treatment of bipolar disorder, particularly in the management of mixed states and rapid-cycling bipolar disorder.

Although valproate is commonly used in the acute treatment of children and adolescents with bipolar disorder, there is limited evidence to support its use. Valproate monotherapy had produced response rates of 53–80% in three open-label studies (228–230). However, a small (n = 15), double blind placebo-controlled trial failed to demonstrate effectiveness of valproate extended-release over placebo for children and adolescents aged 10–17 with bipolar disorder (231).

There are several safety concerns with valproate in children and adolescents; including hepatic failure, pancreatitis, and birth defects in the offspring of women on valproate therapy. Rare, yet potentially fatal hepatotoxicity appears to occur almost exclusively in children younger than two years of age and is more common among those on a combination of anticonvulsants (232). The North American Antiepileptic Drug Pregnancy Registry suggests a 10.7% rate of major congenital malformations (compared to a 2.9% rate in the general population), including neural tube defects and cardiac defects (pulmonary atresia) in the offspring of women who used valproate during pregnancy (233). Valproate has also been associated with hyperammonemic encephalopathy (particularly in patients with urea cycle disorders) (234), benign thrombocytopenia (235), and weight gain . Other side effects include sedation, nausea/vomiting, tremor, hyperglycemia, and alopecia (236).

Additionally, there has been concern of a possible valproate-induced metabolic syndrome, characterized by obesity, hyperinsulinemia, lipid abnormalities, polycystic ovaries, and hyperandrogenism, particularly in younger women exposed peripubertally. A proposed mechanism for development of this Polycystic Ovarian Syndrome (PCOS) in this population is that valproate-induced hyperinsulinemia leads to increased androgen levels and eventually PCOS. In a cohort of Finnish women taking valproate for seizures, 80% of those who began valproate before age 20 had polycystic ovaries or an elevated serum testosterone concentration, as compared to 27% of women taking other antiepileptics. Valproate has been associated with polycystic ovaries and elevated serum testosterone in women (237). Isojarvi et al. (1998) found the severity of this metabolic syndrome was reduced when valproate was replaced with lamotrigine in 16 women (suggesting a partial reversibility) (238). The generalizability of these findings to psychiatric populations is unclear as current reports are confined to women with epilepsy.

Carbamazepine is currently FDA-approved for the treatment of seizures in children and adolescents. Although double-blind, placebo-controlled studies in adults have shown efficacy for carbamazepine in acute mania (239), no controlled studied have shown carbamazepine to be effective as monotherapy in children and adolescents with bipolar disorder. In an open-label study that compared carbamazepine, valproate and lithium for children with bipolar disorder, both medications had similar effect

sizes [with valproate showing a non-significantly larger effect (228)]. In an open-labeled study of 27 children with bipolar mania treated with extended-release carbamazepine, Joshi and colleagues reported significant but modest improvement in manic symptoms, with failure to completely resolve manic symptoms at the end of the trial (240).

Many of the reports that support carbamazepine use in children and adolescents with bipolar disorder are in those with comorbid ADHD or conduct disorder (some of whom also had neurological disorders). Carbamazepine was effective in seven manic adolescents who did not response to lithium (241). It was a safe and effective treatment for acute mania and long-term maintenance treatment in three patients with juvenile-onset bipolar I disorder (242). However, other studies did not find carbamazepine more effective than placebo (228).

Carbamazepine is usually initiated at a low dose and is adjusted up based on tolerability to achieve blood levels ranging from 6–12 mcg/mL (242, 243). This typically corresponds to a maintenance dose of 10–20 mg/kg/day, given in divided doses, which could be as high as 1200 mg/day in adolescents (244, 245). Carbamazepine affects hepatic cytochrome P450, which results in carbamazepine inducing its own metabolism as well as that of other hepatically metabolized medications. This could result in lower than expected blood levels. Plasma levels should be checked after achieving a steady-state plasma concentration, particularly if carbamazepine is used with medications which utilize the cytochrome P450 system.

There is currently a black box warning for carbamazepine, as it has the potential to cause blood dyscrasias. Aplastic anemia, agranulocytosis (246) and leukopenia (247) have been reported with carbamazepine. Thus, complete blood cell counts with differential and reticulocyte counts should be monitored throughout carbamazepine therapy. Caution should also be used when prescribing carbamazepine to adolescent females, as relationships between carbamazepine and craniofacial defects, neural tube defects, and cardiac malformations have been reported (248). Other potential side effects include drowsiness, loss of coordination, vertigo, inappropriate antidiuretic hormone secretion, and cognitive/behavioral effects such as impaired performance in learning and memory tasks, irritability, agitation, insomnia, and emotional lability.

Oxcarbazepine, an analog of carbamazepine, has similar efficacy but has a lower risk of side effects. Thus, no blood level monitoring is required. As oxcarbazepine is a weaker inducer of Cytochrome P-450, it does not have as great an effect on drug-drug interactions as carbamazepine (249). Although case studies have supported oxcarbazepine use in bipolar disorder in children and adolescents (250, 251), a large, double blind placebo-controlled trial in 116 children and adolescents with bipolar disorder did not show that oxcarbazepine was superior to placebo for treating manic symptoms (252). Important adverse reactions reported with oxcarbazepine include drug-induced hyponatremia and dermatological/hypersensitivity reactions (253). In addition, oxcarbazepine may reduce contraceptive efficacy by altering plasma estrogen concentrations. Thus birth control options should be evaluated when treating bipolar females of child-bearing age (254).

Lamotrigine and topiramate are both approved for the treatment of epilepsy in adults and are used to treat children with atypical seizures. These medications are also currently being evaluated for use in bipolar disorder in children and adolescents. Several recent open-label trials found lamotrigine effective either as a monotherapy or as an adjunctive treatment (255–259). However, no results from controlled studies have yet been published for youth with bipolar. Further, an age-related association with Stevens-Johnson syndrome and other potentially-life threatening rashes (260) may limit its use in children and adolescents. Preliminary data of topiramate in bipolar youth found improvement of YMRS scores, but this was not statistically significant (261). The possibility of decreased sodium bicarbonate, leading to hyperchloremic metabolic acidosis in youths treated with topiramate for seizure disorder has been reported (262). Other possible adverse reactions from topiramate include impaired sweat production and cognitive impairment (263, 264).

19.8.2.1.3. Atypical Antipsychotics

Several case reports of children and adolescents who were unresponsive to other mood stabilizing medications found clozapine was effective in alleviating manic symptoms (265, 266). Furthermore, an open trial in hospitalized adolescents who had failed prior treatment on antimanic or other antipsychotic agents reported significant improvement in mood symptoms after several weeks of clozapine as either a monotherapy or as an adjunctive therapy. The most common side effects of clozapine were sedation and weight gain. Weekly blood draws are required when initiating treatment to monitor for clozapine-induced agranulocytosis, which hinders widespread use in children and adolescents.

Initial reports from case studies and chart reviews on the effects of olanzapine for children and adolescents with bipolar disorder were promising (267–269). Confirming this, a randomized controlled trial testing the efficacy of olanzapine to treat acute mania in 161 adolescents 13 to 17 years old showed response superior to placebo after one week and remission superior to placebo after 3 weeks (270). Olanzapine is now approved to treat bipolar manic and mixed episodes in adolescents aged 13–17. Common side effects of olanzapine are weight gain, somnolence, agitation and insomnia.

Risperidone has been well-established as an effective treatment for adults with bipolar disorder presenting with acute mania. An open-label study of twenty-two children and adolescents found a 70% response rate after eight weeks of treatment (271). A chart review of risperidone use in children and adolescents found an average weight gain of 1.2 kg per month, over

six months (272). A three week, double-blind controlled trial testing the efficacy of high-dose (3–6 mg/day) versus low-dose (0.5–2.5 mg/day) versus placebo in 169 children with bipolar disorder ages 10–17 years found significant clinical improvement in both treatment groups, and that the lower-dose group had a better side effect profile (273). A double-blind controlled trial comparing risperidone and valproate in 66 children and adolescents with bipolar disorder found that risperidone led to more rapid and greater reduction of both manic and depressive symptoms than valproate and that risperidone also had lower rates of adverse events and attrition than valproate (274). Risperidone is now FDA-approved for the treatment of bipolar disorder in children and adolescents aged 10–17.

A double-blind, placebo-controlled study of thirty hospitalized adolescents with either manic or mixed symptoms found quetiapine was as an effective adjunctive treatment when added to divalproex therapy (275). More recently, another double-blind placebo controlled study of 266 children and adolescents aged 10–17 years with bipolar disorder found that quetiapine dosed at both 400 mg/day and 600 mg per day was superior to placebo (276). Common side effects for quetiapine are somnolence, dizziness, dry mouth, elevated liver transaminases and constipation. Quetiapine is now FDA-approved as a mono-therapeutic agent and as an adjunctive agent for the treatment of bipolar disorder in children ages 10–17.

Several open-labeled trials have suggested that aripiprazole may be a safe and effective treatment option for pediatric bipolar disorder (277–279). A large, placebo-controlled trial in children and adolescents with bipolar disorder supported the efficacy of aripiprazole for the treatment of acute mania (280). Subsequently, a controlled study examining the long-term efficacy of aripiprazole as a maintenance treatment reported that after clinical stabilization with aripiprazole, children randomized to the placebo group (n = 30) experienced relapse significantly sooner than those randomized to maintenance treatment with aripiprazole (281). Aripiprazole is now FDA-approved both as an adjunctive treatment along with lithium or valproate and as a mono-therapeutic agent for the treatment of manic and mixed episodes in children and adolescents aged 10–17.

Two open-labeled trials have supported the possible efficacy and safety of ziprasidone for the treatment of bipolar disorder in children and adolescents (282, 283). A 4-week, placebo controlled trial conducted in 237 adolescents with bipolar disorder suggested that this medication was significantly more effective than placebo and well-tolerated. The results have not yet been published but are available on the FDA website (284). Ziprasidone is not currently FDA-approved for the treatment of bipolar disorder in children or adolescents.

All children and adolescents on atypical antipsychotics should be monitored for neuroleptic malignant syndrome, tardive dyskinesia, diabetes, and weight gain. They should also be alerted to the potential development of metabolic syndrome. In a comparative study, Ratzoni et al. (2002) treated fifty adolescents with risperidone ($n = 21$), olanzapine ($n = 21$), or haloperidol ($n = 8$). After twelve weeks, olanzapine was associated with the greatest relative average weight gain of 11.1%. The relative average weight gains on risperidone and haloperidol treatments were 6.6% and 1.5%, respectively (285).

Patients and their parents should be counseled about the risks and benefits of therapy before initiating treatment with an antipsychotic. Patients should also be encouraged to exercise and eat healthy food. In addition to monitoring their weight, fasting plasma glucose and lipid profile should be followed throughout therapy (286).

19.8.2.2. Electroconvulsive Therapy

Electroconvulsive therapy (ECT) has been an effective treatment for acute mania in adults (287). Studies in adolescents estimate a 75–100% response rate in mood disorders (288). However, ECT has been infrequently utilized, at least in part because of stigma associated with its use. Potential side effects of ECT include mild cognitive impairment, transient effects on short-term memory, anxiety reactions, disinhibitions, and altered seizure threshold (289). Current practice parameters suggest ECT be considered after a failure to respond to two or more trials of pharmacotherapy or when symptoms preclude waiting for a response to medication (288).

19.8.2.3. Treating Depression in Bipolar Children and Adolescents

While the vast majority of clinical research has focused on treating the manic symptoms of bipolar patients, treatment of children and adolescents with bipolar disorder also requires careful monitoring and treatment of depressive symptoms and episodes. Only a few prospective studies have directly addressed bipolar depression in youth. In an open-labeled trial of lithium monotherapy in 22 youth with bipolar depression, Patel and colleagues reported an effect size of 1.7 (290). In an open-label study, 46 youth with bipolar depression were treated with lamotrigine in combination with an atypical antipsychotic, and then given lamotrigine monotherapy in a 6 week maintenance phase. This study reported lamotrigine was well-tolerated and was associated with further reduction in depression symptoms (258). Another open-label study of lamotrigine monotherapy or adjunctive therapy for youth with bipolar depression found a large effect size for reducing depression symptoms (259). The only randomized, placebo-controlled trial that has been conducted in bipolar youth was a negative study. Quetiapine was not

found to be more effective than placebo for reducing depression symptoms in bipolar youth (291). The practice of using antidepressants to address depressive symptoms in bipolar patients has been controversial. Because antidepressants have been reported to elicit manic conversion, current guidelines suggest that adequate mood stabilization should be achieved before initiating antidepressant therapy (140).

19.8.2.4. Psychotherapeutic Treatment Options

Psychosocial treatments are a mainstay of therapy between acute episodes and are aimed at reducing morbidity and preventing relapse. A review of controlled trials conducted in adults suggested that psychotherapy treatments, when added to psychopharmacological interventions, reduce the risk of relapse of mood episodes and enhance social functioning (292). Although less work has been done with pediatric bipolar disorder, two randomized controlled trials have been conducted testing psychosocial interventions for youth with bipolar disorder. In a 2-year study, Milowitz and colleagues showed that as an adjunctive treatment to pharmacotherapy, patients that received family-focused therapy had better trajectories of depression symptoms in comparison to a psychoeducation control group (293). Another study showed that in addition to treatment as usual, a psychoeducation intervention was superior to wait-list control for improving mood symptoms for pediatric mood disorders (294). An additional factor to be considered in treatment is that bipolar disorder is often comorbid with other conditions such as disruptive behavior disorders, substance abuse, and learning disabilities. Each of these comorbid conditions will require specifically targeted psychotherapeutic interventions (295).

19.9. Summary

Mood disorders are major psychiatric disorders that occur at an increasing rate in children and adolescents. Historically, mood disorders have been undertreated and underrecognized in this population. Recent studies found that these disorders impact psychosocial functioning and impede developmental well-being. The high rates of comorbid anxiety disorders with major depressive and persistent depressive disorders make them more difficult to recognize and treat. Likewise, the similar presentation of ADHD and bipolar disorder hinders proper treatment. A careful assessment by clinicians and researchers will lead to earlier recognition and treatment. Continued research on the neurodevelopmental underpinnings of mood disorders in children and adolescents should provide the foundation for advancement in clinical practices.

In recent years, emerging evidence has begun to support validated evidence-based treatments for children and adolescents with mood disorders. For children and adolescents with depression treatment with SSRIs in combination with psychotherapy such as CBT, IPT, and group therapy adapted for use with younger patients are indicated (305). For children and adolescents with bipolar disorder, a range of psychopharmacologic options are now available, with increasing evidence supporting second-generation atypical antipsychotics as efficacious especially for pediatric mania (305). Emerging evidence suggests that family therapy may be useful in addition to mood-stabilizing agents. Research that focuses on developing empirically supported guidelines for psychosocial, pharmacological, and environmental therapy for children and adolescents with mood disorders is needed.
