last decade, diagnosis of small tumors (< 2 cm in diameter) is still challenging: large pancreatic adenocarcinomas are easy to identify. As described above and shown in Fig. 2, they are usually hypoattenuating (hypodense) with ill-defined margins and tend to infiltrate posteriorly into the retroperitoneum and the adjacent vessel, preferably the mesenteric vein. Besides the molecular and cellular mechanism of invasion, such infiltrating capacity is furthermore promoted by the lack of a natural barrier between the retroperitoneum and the pancreas as it has no organ capsule. Therefore, even moderate size adenocarcinoma might infiltrate into the adjacent fat, involve the common bile duct when arising in the head, and might obstruct the pancreatic duct. In small tumors (e.g., 1–2 cm), these signs of tumor spread might not be detected at MDCT and, furthermore, isoattenuation is more frequent [22]. Such isoattenuation on both arterial and venous phase images might be found in 5–10% [7, 22]. Therefore, secondary signs of a mass must be identified, including pancreatic ductal dilatation, biliary ductal dilatation, abrupt cutoff of the pancreatic duct/common bile duct at the level of the mass (Fig. 3), an abnormal contour of the pancreas, and upstream pancreatic atrophy toward the tail [23]. Moreover, the use of thin collimation or primary reconstruction (1–1.5 mm) technique allows small lesions to be better visualized. Modern scanners, nowadays, provide a host of secondary reformatting and reconstruction possibilities of the primary data set: e.g., multiplanar 2D reconstructions or 3D reconstruction techniques. The latter has gained prominence for its ability to illustrate vascular involvement. Already in 2006, the John's Hopkins group described the routine use of multiplanar reformatting techniques and 3D reconstructions to be critical in identifying small primary tumors [7, 24]: they found the use of 3D technique most important for detailed visualization of the junction of the common bile duct and pancreatic duct and for visualizing small tumors in this location. All this applies with a high level of confidence to many aspects of differential diagnosis: Peripancreatic lymph nodes, duodenal cancers, duodenal diverticula, pancreatic anatomic anomalies (such as an annular pancreas), exophytic gastric masses, and primary retroperitoneal masses have all been confused with pancreatic adenocarcinoma on axial images. As a result, modern standardized reporting protocols in imaging of pancreatic adenocarcinoma are based on these considerations and include sophisticated reconstruction techniques [12].

One area where CT finds its limits, however, is in the differentiation of pancreatic adenocarcinoma from some cases of focal pancreatitis. Particularly, reoccurring pancreatitis can result in the appearance of a focal mass, e.g., as pseudotumor, often with pancreatic and biliary ductal obstruction, which can very much mimic the appearance of a ductal adenocarcinoma. Usually, however, abrupt occlusion of the pancreatic duct at the level of a mass is more suggestive of a malignancy, and other stigmata of chronic pancreatitis in the remainder of the gland (beaded, irregular, dilated pancreatic duct, and pancreatic parenchymal calcifications) can be suggestive of focal pancreatitis. Nevertheless, infrequently reoccuring (focal) pancreatitis and especially when the duodenal groove is involved tumor mimicry can be such that a mass in the pancreatic head might be indistinguishable between benign and malignant. Even the so-called double-duct sign should and can not be used for

differential diagnosis. Another example of tumor mimicry represents autoimmune pancreatitis when presenting as a focal mass in Type 2 and not as the relative typical sausage-like appearance [25, 26]. In both instances, a careful and thorough evaluation of the given patient's history and depiction of specific serum features associated with autoimmune pancreatitis (immunoglobulin G4 levels) might be more helpful than imaging alone (see also below at the end of this chapter). Figure 4 shows an example of autoimmune vasculitis of the celiac axis, which was mistakenly interpreted first as infiltrating pancreatic adenocarcinoma, interestingly corroborated by the underlying clinical disease pattern (back pain with somewhat sudden onset). After adequate cortisone treatment complete resolution of symptoms and morphologic findings was noted, even the patency of the previously "infiltrated" and occluded common hepatic artery was restored.

In addition to MDCT and PET-CT, MRI has become an increasingly viable option in pancreatic imaging over the last decade, and each has an important role to play: In contrast to PET MRI, probably has a greater value in primary imaging and tumor detection and differential diagnosis, particularly when a suspected pancreatic lesion is not identified at MDCT. Tiny pancreatic lesions might be more conspicuous at MRI (Fig. 5) because of its superior soft-tissue contrast [22]. In cystic pancreatic lesions, its superiority in delineation and differential diagnosis is well established [7], which is being discussed in another chapter of this book. Moreover, given the limitations of MDCT in characterizing small metastatic lesions in the liver less than 1 cm, MRI is a valuable problem-solving tool when indeterminate liver lesions are detected at MDCT. Again, this underscores its potential relevance for a complete staging protocol for presurgical workup. Similarly, PET-CT has quickly become an important test to perform in conjunction with contrast-enhanced CT for the staging of a known tumor (see below).

Unlike CT and MRI, which are anatomic imaging techniques, fluoro-2-deoxy-D-glucose (FDG) PET is a functional imaging modality that uses the radiotracer 18F-FDG. This radiotracer, a glucose analog that acts as a marker for glucose metabolism, is taken up by various tissues (cells) in the body proportional to their metabolic activity, e.g., brain, heart, kidneys. Accordingly, solid tumor with a high rate of glucose metabolism will show a significant 18F-FDG uptake, usually, much higher than surrounding tissues. Like other nuclear medicine techniques, PET studies have poor spatial resolution, making it difficult to localize sites of abnormal radiotracer uptake. As a result, most studies are now performed as integrated PET-CTs, where simultaneously acquired and overlayed coregistered CT images allow accurate localization of organ involvement sites of radiotracer uptake. There is very little debate that PET-CT (especially when performed without an associated contrast-enhanced CT) should not be used as a primary imaging modality for pancreatic adenocarcinoma. The sensitivity of PET-CT (with a noncontrast, nondiagnostic CT) is considerably lower than that of a contrast-enhanced MDCT, with a sensitivity of only 72% [27]. Moreover, even in very recent and modern PET-CT scanners, the CT part does not provide the essential high spatial MDCT ($\geq$ 256 detector rows and or dual source) equipment necessary for high-quality primary imaging as outlined above. Despite that it suffers from the inability to resolve small lesions, it

is invaluable in identifying distant metastatic disease and has been shown to change the preoperative staging and determination of resectability in a sizeable number of patients (see below). Furthermore PET-CT, however, might assume a much higher relevance for the follow-up imaging of postresection patients (see below) or in distinguishing between chronically recurrent pancreatitis and pancreatic adenocarcinoma [25]. Moreover, many patients with autoimmune pancreatitis will undergo PET-CT because of overlapping symptoms with pancreatic adenocarcinoma. However, even PET-CT cannot always differentiate between these two lesions because (autoimmune) inflammatory foci in the pancreas might also accumulate FDG to the same level as compared to pancreatic adenocarcinoma [25]. Therefore, when FDG accumulation in autoimmune pancreatitis is focal, differentiation from pancreatic cancer can be difficult. Ozaki showed FDG uptake in all of their patients with autoimmune pancreatitis but only in 73.1% of their patients with pancreatic adenocarcinoma [28]. The true morphologic uptake pattern, however, of FDG-PET might be helpful for establishing a differential diagnosis. In autoimmune pancreatitis, typically, a heterogeneous longitudinal accumulation and multiple localizations are seen, whereas in pancreatic adenocarcinoma uptake is characterized by nodular homogeneous accumulation, and, of course, solitary localization [25].

Another pancreatic neoplasm entity where MDCT finds its diagnostic limits is the differential diagnosis of cystic tumors of the pancreas. In the modern radiologic literature, there is widespread consent that MRI is far superior to any other imaging modality besides, perhaps, endoscopic ultrasound [13].

Staging

Any imaging modality for staging pancreatic adenocarcinoma is applied to characterize the patient's potential for curative resection (Figs. 6, 7 and 8). Therefore, it is of common acceptance to stage patients into having (a) resectable disease (Fig. 6), (b) borderline resectable disease (Fig. 7), (c) locally unresectable disease (Fig. 8), and (d) metastatic disease including peritoneal spread and distant organ involvement.

The American National Comprehensive Cancer Network (NCCN) has been deeply involved in this definition process. The respective NCCN guidelines, version 1.2013, have been endorsed by the International Study Group of Pancreatic Surgery and were published recently [29]. They are summarized in Table 1. Furthermore, in the 8th edition of the TNM classification system [30], tumor size now plays an intrinsic role for subtyping of T1 stages (<2 cm) as follows:

T1a = tumor size $\leq$0.5 cm in maximum dimension
T1b = tumor size 0.5–1 cm in maximum dimension
T1c = tumor size 1–2 cm in maximum dimension

Furthermore, size again plays a definitive role in discrimination between T2 stage (2–4 cm) and T3 stage (>4 cm) in the tumor's maximum dimension.

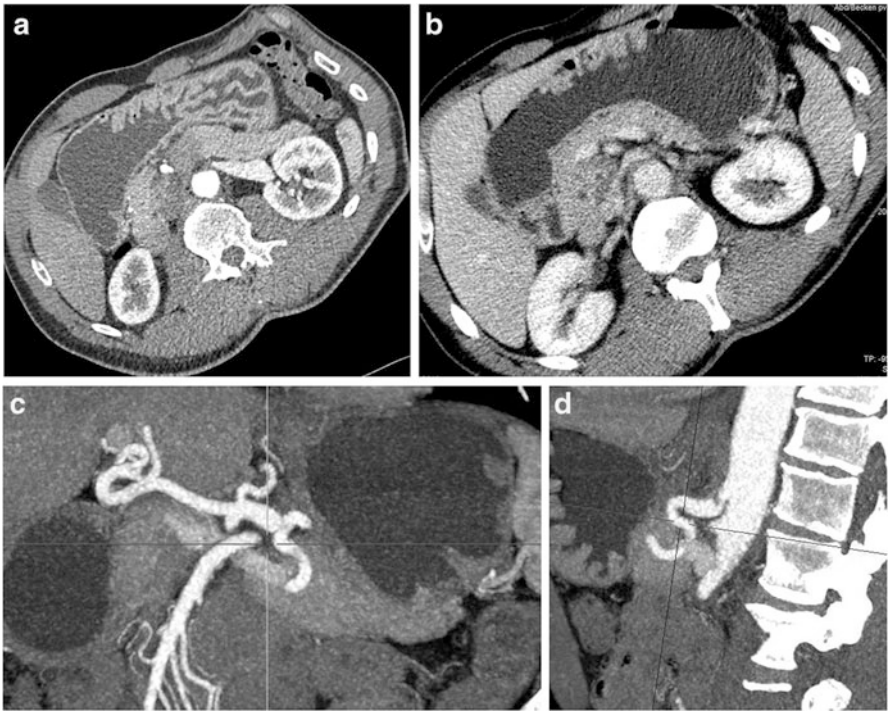

Fig. 6 Surgically resectable T2 pancreatic adenocarcinoma. (**a**) Axial plane in arterial phase at the tumor level: 2.5 cm in diameter measuring hypoattenuating mass in the dorsal aspect of the pancreatic head. (**b**) Axial plane in venous phase at the tumor level: no signs of infiltrative spread towards the superior mesenteric artery or to the superior mesenteric vein. (**c**) Coronal MIP reconstruction demonstrating complete arterial integrity. (**d**) Sagittal reconstruction demonstration potentially critical stenosis of the celiac trunk

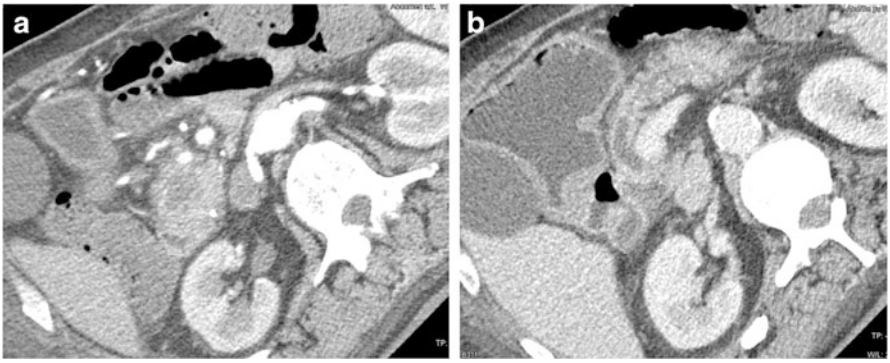

Fig. 7 borderline resectable T3 pancreatic adenocarcinoma of the head. (**a**) Axial plane in arterial phase at the tumor level showing an around 3 cm in diameter measuring tumor in the pancreatic head encasing the superior mesenteric vein by almost 360°. (**b**) Axial plane in venous phase cranial to the tumor level showing a fully open portal vein and the dilated pancreatic duct

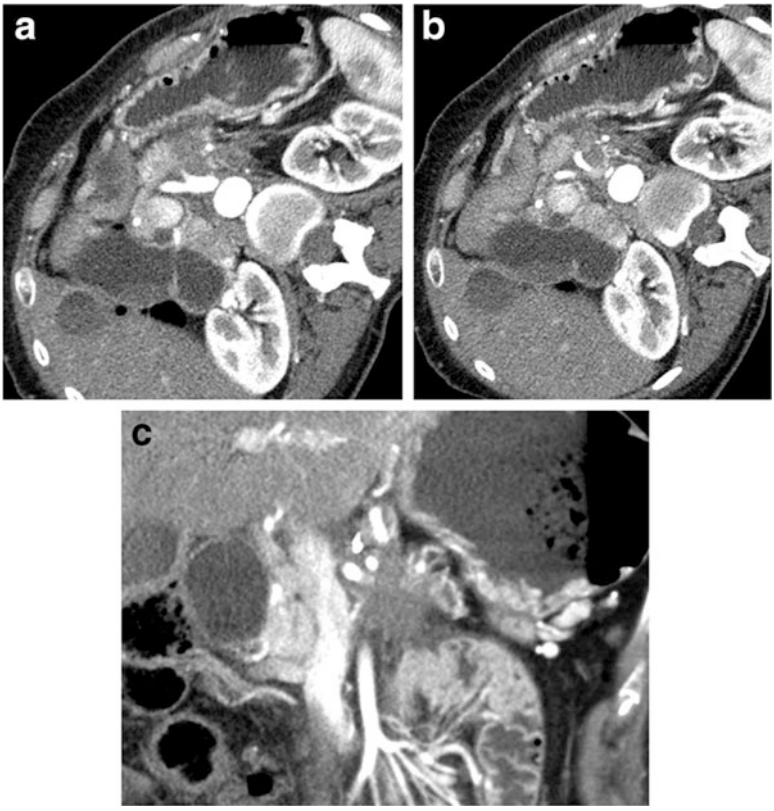

Fig. 8 Unresectable T4 pancreatic adenocarcinoma of the body. (**a**) Axial plane in arterial phase at the level of the celiac trunk showing complete encasement and hazy peritruncular hypoattenuation; (**b**) axial plane in arterial phase around 1 cm more cranial than (**a**) showing complete encasement and hazy peritruncular hypoattenuation of both the common hepatic and the splenic artery; (**c**) coronal reconstruction in arterial phase to illustrate the complete encasement of the celiac axis

In particular, this latest version of the TNM classification system [30] pays tribute to the now widely accepted fact that size is the most important prognostic factor in pancreatic adenocarcinoma alone. This relationship between tumor size and survival has been established very early [31] and was corroborated during the ongoing history of pancreatic surgery in many studies [31–36].

Moreover, as a result of a very recent large retrospective study of the correlation between tumor size and survival after curative resection, especially of T3 pancreatic adenocarcinoma, Kurata suggests a further subdivision of T3 stages by applying a tumor diameter of 3 cm at imaging as cut off to discriminate between the so-called T3a and T3b stages. In his study of 755 resected patients with a T3 stage, patients with a tumor smaller as T3 ($n = 274$) had a median survival time of 30.3 months. Patients with resected tumors larger than 3 cm in maximum diameter had a median survival time of 17.5 months. This large influence on tumor-free survival was highly

statistically significant: in a univariant analysis, the p-value was 0.002; and in a multivariant analysis, it was 0.005, respectively [37]. However, it remains to be seen, whether such will find relevance for prospective revisions of the TNM classification system. Nevertheless, as a routine, the correct description of tumor dimensions in all planes is part of the routine imaging process [3, 5, 7, 12, 13, 38, 39].

When putting all these facts and study results into perspective for a modern presurgical workup, it becomes evident that adequate (= high resolution) imaging is the key for addressing patients' hopes for a potentially curative procedure or avoiding unsuccessful resection (Figs. 6, 7, and 8).

As illustrated and detailed in Table 1, determining vascular involvement is the most important component of determining resectability of pancreatic adenocarcinoma. As it has been stated before, modern state-of-the-art MDCT, definitely, plays the most important role. Hence, structurized and standardized reporting tools and templates have been developed and employed to help radiologists and surgeons to communicate adequately on all the essential details of imaging for resectability. A reporting template [12] was developed as a result of a consensus conference during the annual American Pancreatic Association meeting (Chicago 2011) based on earlier work [18, 39].

However, several facts are important to note, though, which are pertinent for gaining the entire perspective of resectability of pancreatic adenocarcinoma and are not reflected in the TNM classification specifically or in the guidelines as summarized in Table 1: (1) Arterial anatomic variants are very frequent. E.g., an aberrant branch from the SMA to the right liver lobe is not uncommon (up to 15%) and might hamper head resection. (2) Stenosis of the celiac trunk either from atherosclerosis or from the left diaphragm tendon is a relatively frequent finding in the elderly which

Table 1 NCCN guidelines on resectabilty of pancreatic adenocarcinoma, version 1.2013 [29], summarized for the pancreatic head

Localized and resectable	Borderline resectable	Unresectable
No distant metastasis	No distant metastasis	Distant metastasis
No radiographic evidence of SMV or PV distortion	Venous involvement of the SMV or PV with distortion or narrowing of the vein with suitable vessel proximal and distal, allowing for safe resection and replacement	Greater than 180° SMA encasement, any celiac abutment, IVC infiltration
Clear fat planes around CA, HA, and SMA	GA encasement up to the hepatic artery with either short segment encasement or direct abutment of the HA without extension to the CA	Unreconstructable SMV/portal vein occlusion
	Tumor abutment of the SMA not to exceed 180° of the circumference of the vessel wall	Aortic invasion or encasement

CA celiac axis, *GA* gastroduodenal artery, *HA* hepatic artery, *IVC* inferior vena cava, *PV* portal vein, *SMA* superior mesenteric artery, *SMV* superior mesenteric vein

should be known before dissecting the gastroduodenal artery and thereby avoiding liver hypoxia (Fig. 6c). (3) Anatomic variable course of the inferior mesenteric vein when not draining into the splenic vein. (4) Involvement of the common hepatic artery close to the liver hilum. Moreover, for adenocarcinoma located in the tail of the pancreas or at least distinctly left of the superior mesenteric different resection strategies might apply.

Therefore, state-of-the-art imaging for staging needs to address exact localization of the tumor, exact determination of its size in all dimensions, arterial and venous vascular mapping (as described above and Table 3), thorough analysis of fatty tissue and perivascular involvement (at CT hazy hyperattenuation of fatty tissue planes = stranding) or eventual vascular abutments and lack of anatomical integrity, exclusion of liver metastasis or to other distant organs. Based on such state-of-the-art imaging, the standardized reporting system has to address and describe all details relevant for resections strategies regardless of how borderline surgical resectability is defined [40]. In Table 2, our general recommendations for CT scanning are summarized. Table 3a, b describe our suggestions for the reporting standards for arterial and venous involvement including a description of anatomical variants. These are unanimously valid and can be universally applied notwithstanding the still existent differences at present in the definition of borderline resectable pancreatic adenocarcinoma [29] across various institutions and cancer centers, which was recently analyzed in depth by Pietryga (see Table 2 in his publication) [40].

Table 2 CT imaging strategies for detection and staging of pancreatic adenocarcinoma

CT: Technical details	Imaging purpose
Helical scan type	High resolution axial planes, secondary 2D and 3D reconstructions
1 mm or submillimeter scans	Optimized spatial and contrast resolution, 2–3 mm image reconstructions
1 mm reconstruction intervals	Optimized spatial and contrast resolution, 2–3 mm image reconstructions
Pitch factor 10–15	Fast scanning compromising between homogeneous contrast phase imaging and background noise
20–30° left oblique patient's positioning + oral warm water (0.5 l) as negative contrast agent	Optimized duodenal filling and dilatation for best delineation of ampullary region
100–125 ml i.v. iodine contrast agent (≥300 mg iodine/ml, non-ionic)	Arterial and venous phase imaging, preferably using automatic dynamic scanning (better than fixed delays)
General imaging aspects	
Morphologic evaluation of the tumor location in relationship with the three anatomic pancreatic regions (head/uncinate, body, tail)	
Hypo, iso, or hyperattenuating appearance in the three contrast phase acquisitions	
Bile duct appearance, related or not to the tumor location	
Pancreatic duct appearance, related or not to the tumor location	
Pancreatic parenchymal appearance "upstream" to tumor location	
Parenchymal calcifications, cysts	

Table 3 Evaluation of vascular invasion patterns

Anatomic details vessel type	Imaging findings confirmation/exclusion
a) Arterial vessel analysis	
General abdominal vessel anatomy	Absence or presence of variant arterial vascular anatomy: e.g., narrowing of the celiac trunk, right aberrant hepatic artery originating in the superior mesenteric artery
Celiac trunk	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase peritruncular). When present: $\geq 180^\circ$ of vessel circumference or less. Presence or absence of contour irregularity
Common hepatic artery	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase periarterial). When present: $\geq 180^\circ$ of vessel circumference or less, extension to celiac trunk, extension to right or left hepatic artery. Presence or absence of contour irregularity
Superior mesenteric artery	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase periarterial). When present: $\geq 180^\circ$ of vessel circumference or less, extension to celiac trunk, extension along main stem (branch involvement). Presence or absence of contour irregularity
Splenic artery	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase periarterial). When present: $\geq 180^\circ$ of vessel circumference or less, extension to celiac trunk, extension along main stem. Presence or absence of contour irregularity
b) Venous vessel analysis	
General abdominal vessel anatomy	Absence or presence of variant venous vascular anatomy: e.g., aberrant drainage of inferior mesenteric vein into main stem of superior mesenteric vein. Normal course of inferior vena cava. Presence or absence of venous collaterals/varices
Portal vein	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase perivenous). When present: $\geq 180^\circ$ of vessel circumference or less. Presence or absence of contour irregularity. Presence or absence of thrombus/occlusion. When present: length of thrombus/occlusion
Superior mesenteric vein	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase perivenous). When present: $\geq 180^\circ$ of vessel circumference or less. Presence or absence of contour irregularity. Presence or absence of thrombus/occlusion. When present: length of thrombus/occlusion, involvement of distal draining vessels (e.g., aberrant inferior mesentic vein, jejunal branches)

(*continued*)

Table 3 (continued)

Anatomic details vessel type	Imaging findings confirmation/exclusion
Inferior vena cava	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase perivenous). When present: $\geq 180^{\circ}$ of vessel circumference or less. Presence or absence of contour irregularity. Presence or absence of thrombus/occlusion. When present: length of thrombus/occlusion
Splenic vein	Normal course. Presence or absence of stenosis or variants. Presence or absence of solid tumor contact. Presence or absence of perivascular infiltration (stranding, hazy attenuation increase perivenous). When present: $\geq 180^{\circ}$ of vessel circumference or less. Presence or absence of contour irregularity. Presence or absence of thrombus/occlusion. When present: length of thrombus/occlusion

As stated already above, MRI has advantages in delineating small tumors because of better lesion conspicuity when applying the inherent various tissue characterization parameters in combination with diffusion-weighted imaging (DWI), which is superior to the solely anatomic imaging character of MDCT. Moreover, its higher accuracy in differentiating liver lesions attributable also to its higher soft tissue characterization potential might be used for a more complete and correct staging as compared to MDCT alone. MRI is much better at defining hepatic lesions and can characterize small hemangiomas or cysts as definitively benign, as already stated above. Metastases are typically mildly hypointense on T1-weighted images and mildly hyperintense on T2-weighted images. Containing little internal fluid, metastases can be definitively differentiated from cysts or hemangiomas by their lower T2 signal. Most lesions will show peripheral enhancement on postcontrast images, along with wedge-shaped perilesional enhancement in the arterial phase. Moreover, DWIs have been shown to be substantially more sensitive for small liver metastases compared with MDCT, as liver metastases have a significantly lower ADC value than the surrounding liver [41, 42].

PET alone is not useful in the evaluation of local resectability and locoregional staging: The poor spatial resolution of PET makes it difficult to establish the relationship of the mass relative to adjacent organs and vascular structures [43]. Moreover, high radiotracer uptake in the primary mass almost always renders subtle evaluation of the surrounding tissues near the tumor bed difficult, which in particular will make a clear definition of vascular involvement relevant for resection nearly impossible as outlined in Table 3. In addition, PET-CT has no advantage compared to regular thin slice MDCT in local lymph node staging for all of the above-mentioned reasons. The sensitivity and specificity of PET-CT for local lymph node metastases may be as low as 46% and 63%, respectively [44, 45].

Similarly, the value of PET-CT for a subtle staging work-up to rule out liver metastasis is limited: the poor resolution of PET for lesions less than 1 cm might be held responsible for this poor performance. On the other hand, PET-CT does seem to

be a very valuable adjunct to contrast-enhanced MDCT in the evaluation of distant metastatic disease, e.g., lung and bones. In particular, for bone metastasis, a sensitivity of up to 100% has been reported [46]. Hence, as a standalone examination in the evaluation of hepatic metastases, PET-CT (when performed without a diagnostic contrast-enhanced CT) has, in summary, the following and significant limitations: The sensitivity of the study for hepatic metastases overall is only about 70%, with a sensitivity for lesions less than 1 cm of only 43% (although the specificity is relatively high, ranging up to 95%) [44, 45].

Therefore, the clinical practice guidelines of the NCCN acknowledge the potential utility of PET-CT in the staging of pancreatic adenocarcinoma but state that it is not a substitute to state-of-the-art (high resolution) MDCT [47, 48].

Postsurgical Imaging, Recurrence Recognition Pattern

Imaging after surgical resection of pancreatic adenocarcinoma, usually entailing the Whipple procedure with or without preservation of the pylorus, needs to address immediate or early ruling out of postsurgical complications and, during follow-up, ruling out of recurrent disease or other late complications.

Resection of pancreatic adenocarcinoma applying the Whipple procedure was once associated with high peri- and postoperative morbidity and mortality rate [49]. However, significant improvements in surgical skills and technique and, furthermore, peri- and postoperative critical care over the last three decades have reduced the 30-day mortality rate to as low as 1% in the highest-volume centers [29, 34, 35, 50]. Even in the elderly, it can be performed with very low mortality [51].

Besides the above-cited refinements in surgical technique and increasingly sophisticated critical care, MDCT has achieved a major relevance in the early and precise identification of complications that can occur after the Whipple procedure, and it has a great potential and responsibility for directing early actions to reduce both major morbidity and mortality. Many of the below mentioned classical complications are amenable to less invasive measures applying interventional radiological procedures. These, however, are beyond the scope of this chapter.

Like in the preoperative workup schedule, standardized and refined imaging protocols are required to discriminate between normal postoperative findings and true complications, and to report or rule out correctly the host of postoperative complications that might be encountered after a Whipple procedure, including pancreatic fistula, postoperative abscesses, bile leakage, portal vein or superior mesenteric vein thrombosis, postoperative hemorrhage, pseudoaneurysm formation, ischemic hepatic complications, and during follow-up pancreatic and bile duct strictures (mostly anastomotic). Moreover, without profound knowledge of the applied surgical procedural details, not such an approach or claim can be successfully realized. Any radiologist performing post-Whipple imaging studies need to fully understand the course of preparational events and hazards during the complex surgical resection steps. Conversely, the surgical report needs to address any little detail potentially relevant for the appearance of any of the above-mentioned

complications. Today, the challenges and risks during the various steps of the Whipple procedure are well defined with respect to (a) the pancreaticojejunostomy [52–54] with its risk of leakage [55], septical complication, and hemorrhage [56]; (b) the bile duct anastomosis [54] with its risk of early leakage and delayed stricture; (c) early and late hemorrhage [56] as a result of either direct preparation, complex vascular anastomotic procedures, or occurring with a somewhat unpredictable delay as a consequence of septic erosions; (d) the gastrojejunostomy [57] regardless whether part of the classical Whipple Kausch operation removing the pylorus or the modified technique preserving the pylorus including early anastomotic leakage or delayed emptying failures; (e) portal vein or superior mesenteric vein thrombosis and arterial occlusion, respectively [58], resulting either in hepatic ischemia or delayed variceal hemorrhage.

Normal Postsurgical Morphologic Features

The timing of postsurgical MDCT study with regard to the postsurgery course largely determines the morphologic appearance of the postoperative abdominal findings and it can vary substantially (Fig. 9). Nevertheless, and regardless of whether the study is performed in the very early postoperative period or as part of the routine surveillance program, the three anastomoses of the Whipple operation must be carefully evaluated:

1. Pancreaticojejunostomy: A jejunal loop is pulled up transmesenterically and anastomosed to the right of the pancreatic remnant. Often, the pancreatic duct can be visualized from the pancreatic tail toward the anastomosis. In an early postsurgical phase, collapsed loops of bowel adjacent to the pancreaticojejunostomy might be misinterpreted as hematoma. In later follow-up imaging studies, such collapsed bowel loops can mimic tumor recurrence. Similarly, the morphologic appearance of the anastomosis can present as a "bulge" of the jejunum into the residual part of the pancreas, which again can be misinterpreted as tumor recurrence. Multiplanar reformation or 3D postprocessing can be particularly valuable in visualizing these confounding issues related to the pancreaticojejunostomy. In an acute or early postsurgery situation, the blind end of the jejunal loop might assume a hazy appearance from swelling. Its anatomic position is not much variable and should be identified somewhere behind the left liver lobe toward the remnant of the stomach in the classic Whipple Kausch operation or near the pylorojejunostomy in its modified version with a preserved pylorus.
2. Bile duct anastomosis (hepaticojejunostomy or choledochojejunostomy): For the anastomosis between the bile duct system and the intestinum, the same loop as for the pancreaticojejunostomy is used but further "downstream." The anastomotic morphology can be difficult to interpret in the axial plane. In a normal postoperative situation, usually, gas is present in the bile duct(s). Such pneumobilia can be considered as a sign of well-functioning anastomosis when gas can freely move up and down through. Most often, the gas in the intrahepatic bile ducts can be

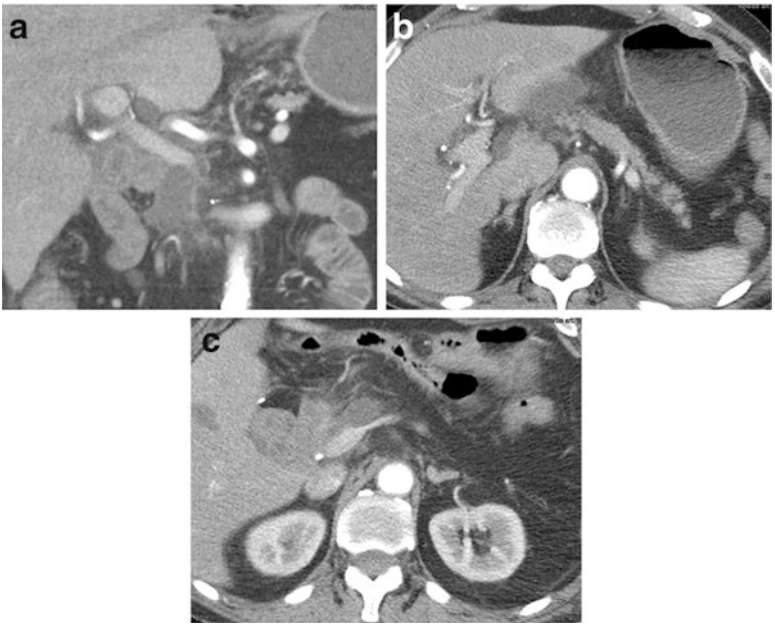

Fig. 9 Normal postoperative MDCT study day 8 after Whipple operation with preserved pylorus. (**a**) Coronal view in arterial phase (2 mm reformat): note the anatomy with a jejunal loop for both the pancreaticojejunostomy and the biliary-enteric anastomosis. The hepatic ligament shows the typical postsurgical hazy appearance resulting from the detailed preparational steps. In the surgical bed, there is a small unsuspicious fluid collection. Both anastomoses show mild swelling and hazy environments. Portal vein and proper hepatic artery are well perfused. (**b**) Axial view in arterial phase (2 mm): the pancreaticojejunostomy shows mild swelling, no signs of leakage, abscess or hemorrhage. (**c**) Axial view in arterial phase (2 mm): the hepaticojejunostomy shows mild swelling, no signs of leakage, abscess, or hemorrhage. Superior mesenteric and splenic vein well perfused. Minor local fluid collection ventral to the confluens

traced centrally toward the anastomosis. The bowel loops of the hepaticojejunostomy are rarely distended, and, like described already for the pancreaticojejunostomy, such collapsed loops of jejunum in the right upper quadrant and the near the anastomosis should not be mistaken for tumor recurrence when imaging is done during later follow-up.

3. Gastrojejunostomy: In the modified Whipple operation, the jejunum is anastomosed to the pylorus, which nowadays is mostly the case. The exact position of this anastomosis varies depending on the institution and its surgical tradition and technique. This anastomosis should be best evaluated by applying oral contrast agent. For this, warm still water and chemical intestinal spasmolysis are preferred to achieve the best morphologic situation possible.

In early postoperative imaging minor fluid collections, anastomotic edema and fat stranding in the mesentery and in the fat planes surrounding the major

abdominal vessels are common imaging features and should not be misinterpreted as a residual tumor or an abnormal inflammatory process. Often termed as induration, reflecting hazy hyperattenuation zones surrounding the superior mesenteric vein and superior mesenteric artery such reaction is very typical as a result of the detailed surgical resection steps, e.g., vessel preparation and lymph node dissection. Sometimes it can be very focal and masslike in appearance, and should not be misinterpreted as a residual tumor. However, for a correct diagnosis, full information as to the resection status is mandatory. The first postoperative imaging procedure forms the baseline for any follow-up studies, which should show resolution or stability of these immediate postoperative findings (see also below). It is also common and acceptable to visualize multiple prominent lymph nodes in the central mesentery and the sites of surgical maneuver and exploration, sometimes measuring more than 1 cm in size, and these lymph nodes are almost always reactive in the acute setting. Again, close attention should be paid to these lymph nodes on subsequent follow-up studies to ensure that they either remain stable or resolve. Because of anastomotic edema, thickening at the gastrojejunostomy is a common finding. For the same reason, dilatation of the pancreatic duct might be observed secondary to edema at the pancreaticojejunostomy. And mild intrahepatic biliary dilatation should not be misinterpreted as an early biliary-enteric stricture because this finding usually reflects mild postoperative edema at the hepaticojejunostomy and will typically resolve during the later course.

Pathologic Postsurgical Findings, Complications

Leakage of the Hepaticojejunostomy or Choledochojejunostomy

Although leakage of the biliary-enteric anastomosis of the Whipple operation is a relatively rare complication ranging from 2% in high volume centers [59, 60] to 8% in smaller series [61], it might have dreadful consequences and might further perpetrate other complications associated with high morbidity and mortality [59]. Bile leaks typically appear within the first week after surgery as bilirubin-rich drainage fluid in the surgical drains. Associated clinical signs include fever, leukocytosis, and increased CRP levels. Patients with a bile leak frequently develop other complications, including a pancreatic fistula, wound infection, delayed gastric emptying, and sepsis. A severity grading system has been proposed by the International Study Group of Liver Surgery [62]: bile leakage was defined as bilirubin concentration in the drain fluid at least three times the serum bilirubin concentration on or after postoperative day 3, or as the need for radiologic or operative intervention resulting from biliary collections or bile leakage peritonitis. The severity of bile leakage was classified according to its relevance for patients' clinical management. Grade A bile leakage does not require any change in patients' clinical management. A Grade B bile leakage requires active therapeutic intervention but is manageable without relaparotomy, whereas in Grade C, bile leakage relaparotomy or a prolonged

percutaneous transhepatic drainage is required [59, 63], which, however, can be successfully performed ever after failed surgical repair attempts [63]. As a consequence of findings in a high-volume center and revising the results of 715 operations, Burkhart proposes a slightly different grading system: Grade A bile leaks are those managed with prolonged drainage by operatively placed drains, grade B bile leaks with percutaneous abdominal drainage, and grade C bile leaks with insertion of a percutaneous transhepatic biliary drainage, respectively. Such is the routine in our institution [51].

In some patients, the diagnosis of a bile leak is suggested by the presence of a focal fluid collection or biloma close to the biliary-enteric anastomosis at MDCT. However, confirmation should be based on the above-mentioned biochemical findings.

Pancreatic Fistula

Pancreatic fistula as a result of failure of the pancreaticojejunostomy is considered as one of the most frequent causes of serious postoperative morbidity after the Whipple procedure: The reported rate of pancreatic fistula may be anywhere between 6% and 14% depending on the exact definition of a fistula as discussed below, and the mortality rate ranges from 1.4% to 3.7% [64]. In 2016, the International Study Group of Pancreatic Fistula classification has become the gold standard in defining postoperative pancreatic fistula in clinical practice. According to this, a clinically relevant postoperative pancreatic fistula is defined as a drain output of any measurable volume of fluid with an amylase level >3 times the upper limit of institutional normal serum amylase activity, associated with a clinically relevant development/condition related directly to the postoperative pancreatic fistula. Consequently, grade A postoperative pancreatic fistula is defined and called a "biochemical leak," because it has no clinical importance and is no longer referred to a true pancreatic fistula. Postoperative pancreatic fistula grades B and C are defined as follows: Grade B requires a change in the postoperative management; drains are either left in place >3 weeks or repositioned through endoscopic or percutaneous procedures. Grade C postoperative pancreatic fistula reflects those postoperative pancreatic fistulas that require reoperation or lead to single or multiple organ failures and/or mortality attributable to the pancreatic fistula [55].

Moreover, a pancreatic fistula is associated with a number of other direct or indirect complications, including pancreatitis, abscess formation, hemorrhage, delayed gastric emptying, and sepsis [64]. The development of an abscess or sepsis in conjunction with a pancreatic fistula can have a mortality rate ranging from 20% to 40% [65]. Although the drain output is the key to diagnosis, as stated before, MDCT can be helpful in identifying pancreatic fistula: The presence of a focal fluid collection or hemorrhage adjacent to the pancreaticojejunostomy is strongly suggestive, particularly if the collection appears to be in contiguity with the pancreatic duct or anastomotic suture line.

Leaks from the Gastrojejunostomy

Unlike pancreatic fistula, which is a relatively common complication of the Whipple procedure, leaks from the gastrojejunostomy are much rarer, and this complication has not been well characterized in the surgical literature. However, in a series of 3000 patients who underwent either a classic or pylorus-sparing Whipple procedure for a number of different indications, Winter found a gastrojejunostomy leak only in 0.4% [66]. When these leaks occur, though, they are associated with significant morbidity; 12 of the 13 patients in this series ultimately required surgical intervention, and four of the 13 patients died as a result of the complication. Because of the rarity of this leakage, information from the radiology literature regarding the typical imaging manifestations is very sparse. A relatively clear suspicion arises when a fluid collection directly adjacent to the gastrojejunostomy is seen. In such a rare finding, a positive oral contrast material might have an advantage over the usually applied negative oral contrast using warm water. Then, direct extravasation of the positive contrast material at the anastomosis is strongly suggestive of such leakage from the gastrojejunostomy.

Abscesses

The incidence of an intraabdominal abscess after the Whipple procedure, regardless of the underlying cause, ranges up to 6% [67]. Intraabdominal abscesses can arise secondary to an underlying pancreatic fistula, superinfection of an acute postoperative fluid collection, leakage from the hepaticojejunostomy, or leakage from the gastrojejunostomy or duodenojejunostomy, as already stated above. Hence, MDCT in early postoperative phase is most often performed to search for fluid collections suspicious for postsurgical abscesses. Diagnosis of an abscess should be based on (a) presence of an at least mildly attenuating fluid collection with Hounsfield units above 10, (b) contrast uptake of a rim-like delineation wall, and (c) adequate clinical suspicion including respective laboratory findings.

Postoperative Hemorrhage

Although not very frequent (up to 14%), postoperative hemorrhage after the Whipple procedure might present as a dreadful complication, with a mortality rate up to 40% [68, 69]. There are two distinct groups of patients based on the timely appearance. Early postoperative hemorrhage occurs within the first 24 h after surgery and often results from active bleeding from a leaking stump of the gastroduodenal artery mainly because of inadequate ligation during surgery. Late postoperative hemorrhage occurs mostly between 5 and 15 days and is usually secondary to erosions of the mesenteric vasculature as a result of inflammatory complications from leakages, perhaps around 60%, and sepsis [68, 70]. The

International Study Group of Pancreatic Surgery (ISGPS) developed an objective, generally applicable definition of postpancreatectomy hemorrhage: Postpancreatectomy hemorrhage is defined by three parameters: onset, location, and severity. The onset is either early ($<$ or $=$ 24 h after the end of the index operation) or late ($>$24 h). The location is either intraluminal or extraluminal. The severity of bleeding may be either mild or severe. Three different grades (grades A, B, and C) are defined according to the time of onset, site of bleeding, severity, and clinical impact [56]. Intraluminal hemorrhage will usually present with hematemesis or melena, whereas extraluminal hemorrhage is suspected when blood appears in abdominal drains or when hemoglobin levels are acutely dropping. Extraluminal intraabdominal hemorrhage is much more common than intraluminal hemorrhage by a ratio of 2:1 [71]. The initial presence of blood from either intraluminal or extraluminal source has been termed "sentinel" bleeding and requires urgent measures as has been nicely demonstrated in a large and very recent series of Ansari [69]. In very acute clinical settings of unstable patients, CT may not be a consideration but rather angiography and interventional radiology. When hemorrhage from the stump of the gastroduodenal artery then is detected, immediate surgery is preferred, as interventional measures might become very cumbersome and time-consuming, such as trying to implant stent grafts to seal off the bleeding stump. Placing a small blocking balloon catheter into the celiac axis may be very helpful under such conditions. In patients who are stable, MDCT is extremely helpful. Arterial phase imaging should identify the active extravasation sites or pseudoaneurysm formation. Besides adequate phase, correct timing of intravenous contrast medium injection nor further preparational steps should be applied in the interest of time.

Postoperative Pancreatitis

The presence of postoperative pancreatitis can have significant prognostic implications, including a higher risk of pancreatic fistula and, for poorly understood reasons, a higher risk of delayed gastric emptying (see below). As fat stranding and inflammatory changes in the mesentery, around the major abdominal vessels and surrounding the residual pancreatic tissue are common findings, differentiating pancreatitis from normal postoperative inflammation can be difficult, particularly in cases of mild pancreatitis. The true incidence of post-Whipple pancreatitis is unknown, but given that CT can detect only severe cases, the incidence is likely higher than the 27% (10/37) reported by Räty [72]. Nevertheless, in severe cases, MDCT confirms the diagnosis of postoperative pancreatitis when severe peripancreatic inflammatory changes, low attenuation fluid collection with direct contact with the pancreatic remnant, and hypoattenuating fatty infiltration are present. Moreover, a disproportionate amount of fluid in the pararenal spaces can be another clue suggesting pancreatitis [58].

Portal Vein and Superior Mesenteric Vein Thrombosis

During the last 10 years, a new category of borderline resectable tumors has emerged, including tumors that involve $\leq 180^{\circ}$ of the circumference of the superior mesenteric artery, abut or encase the hepatic artery for a short segment, or narrow or occlude the superior mesenteric or portal vein for a short segment. Adequate surgical options now exist for vascular reconstruction for patients with such conditions, as summarized in Table 1 and resulting from several consensus initiatives [29, 38, 73, 74]. This is also reflected, to some extent, in the latest (8th) edition of the TNM classification [30]. As a result, the complexity and incidence of surgical venous reconstructions have markedly increased, and it is not rare for patients to undergo venous resections with either primary anastomosis or the insertion of a venous interposition graft even in the elderly [51]. The development of mesenteric venous thrombosis can have disastrous consequences, including intestinal ischemia, uncontrolled ascites, hepatic ischemia, and death [75, 76]. Thererfore, for the diagnosis of superior mesenteric and/or portal vein thrombosis, MDCT needs to be carried out very carefully with special attention to the adequate timing of the intravenous contrast material. Eventually, special venous phase imaging with automated dynamic scanning might become necessary. The coronal reconstructions as 2D or MIP projections are very important for accurate diagnosis, particularly for thrombus detection in the superior mesenteric vein. The latter should be carefully evaluated along its course to rule out short-segment filling defects which can be difficult to visualize on the axial source images.

Hepatic Infarction

At postsurgical MDCT hepatic infarction is relatively ease to detect or rule out, provided that adequate phase correct dynamic imaging is performed. The underlying arterial occlusion should be detected similarly to the previously mentioned venous thrombosis on high-quality coronal images, including 2D and MIP projection. Infarcted hepatic tissue, usually, presents as a demarcated and zonal hypoattenuation parenchymal area both in arterial and venous phases. It is a relatively rare complication because of dual blood supply to the liver. Nevertheless, it is a well-known complication of the Whipple procedure. Most patients have an underlying abnormality in their mesenteric arterial vasculature, eventually overlooked at imaging for primary staging (see above), or as a result of severe atherosclerotic disease, median arcuate ligament syndrome, fibromuscular dysplasia, or previously unknown mesenteric vasculitis. These patients are uniquely vulnerable to postoperative variations and decreases in blood flow as a result of hypotension, sepsis, and more [77]. Another surgical complication that can overlook on the preoperative imaging or at the time of surgery [77]. The consequences of hepatic infarction can be severe, with a mortality rate approaching 50% after hepatobiliary surgery. In cases of common (or proper) hepatic artery injury or thrombosis, the most common result is infarction

of the left hepatic lobe, with subsequent development of biliary necrosis, hepatic superinfection, and hepatic abscesses.

Delayed Gastric Emptying

A common complication of the Whipple procedure, the exact incidence of delayed gastric emptying is unclear, largely because of the lack of a consensus definition [57]. Depending on the exact definition used, the incidence may be as high as 49% [57]. The International Study Group of Pancreatic Surgery (ISGPS) developed an objective and generally applicable definition with grades of delayed gastric emptying based primarily on severity and clinical impact. Three different grades (A, B, and C) were defined based on the impact on the clinical course and on postoperative management [57]. Although not a diagnosis primarily as result of imaging, the presence of a severely distended stomach filled with oral contrast material can be highly suggestive in the suspected clinical setting. Fluoroscopic oral contrast studies of gastric emptying rather than CT alone may be helpful in better confirming this diagnosis. Clinically, delayed gastric emptying is often diagnosed on the basis of a persistent need for a nasogastric tube after surgery or the need to reinsert a nasogastric tube several days after surgery. The exact cause of this complication is unknown but is likely related to localized disturbance of the autonomic innervation of the stomach near the operative bed. Interestingly, the likelihood of delayed gastric emptying is thought to be perpetrated by other previous postsurgical complications, including the development of an abscess, pancreatic fistula, and severe intraoperative blood loss [78].

Late Complications

Anastomotic Strictures

Anastomotic strictures can be identified at both the pancreaticojejunostomy and hepaticojejunostomy. Patients with biliary strictures present with cholangitis and jaundice, whereas patients with pancreaticojejunostomy strictures present with diarrhea, steatorrhea, abdominal pain, and pancreatic insufficiency. CT has a valuable role in the diagnosis of anastomotic strictures at these two sites because any change in the size of the pancreatic duct or intrahepatic bile ducts should be looked on with suspicion. However, change in duct size should result in a careful evaluation of the anastomotic site for any signs of local tumor recurrence resulting in ductal obstruction.

Tumor Recurrence

Although the vast majority of patients with disease recurrence present with distant metastatic disease, up to 40% of patients present with isolated local recurrence. Typically, this is not a complication during the first months after surgery. Roeder

reported a median time to local recurrence of 20 months after initial treatment [79]. The presence of a positive margin after surgery, possibly seen in more than half of patients operated [80, 81], undoubtedly increases the risk of local recurrence [82], particularly in view of the recent advances in surgical techniques as extensively discussed above [29] with respect to the definitions of borderline resectable adenocarcinoma of the pancreas. There is not much information in the radiology literature so far detailing and describing local tumor recurrence patterns after pancreaticoduodenectomy, nor have the most common sites of local recurrence been adequately demonstrated and reported. One reason for lack of high quality follow-up imaging study may be that recurrence of pancreatic cancer was not treated, but in recent years radiochemotherapy and, in rare cases, surgery for local recurrence has been advocated [83]. A major problem in patients with pancreatic cancer is that extensive postoperative changes with scar tissue formation as well as lymph node enlargement are present after surgical therapy that may be mistaken for disease recurrence as already discussed above. One study was able to demonstrate, though, that a specific pattern of regrowth on regular follow-up MDCT might be identified after the Whipple operation for pancreatic adenocarcinoma. The mean follow-up interval was 3.9 $\pm$ 1.8 months, with a mean relapse-free interval of 12.9 $\pm$ 10.4 months. The predominant site of recurrence was local (65%), followed by lymph node (17%), liver metastasis (11%), and peritoneal carcinosis (7%). Local recurrence was identified at the superior mesenteric artery ($n = 28$), the hepatic artery ($n = 8$), in an area defined by the surrounding vessels: celiac trunk, portal vein, inferior vena cava ($n = 22$), and in a space limited by the mesenteric artery, portal vein and inferior vena cava ($n = 17$). Lymph node recurrence occurred in the mesenteric root and left lateral to the aorta [84]. The most important imaging finding was focal increase of hypoattenuating tissue strands alongside of the major vessels and within or near the previous resection margins in the mesentery. This corresponds with findings of careful and standardized microscopic exploration of the resection margins in resected specimen [80]. The superior mesenteric artery is the leading structure for recurrence [84]. As another result of this study, early detection of local tumor recurrence bears the potential of another surgical exploration with a secondary curative intent.

Conclusion

Early tumor detection, profound and precise differential diagnostic strategies, correct staging and adequate peri- and posttherapeutic imaging schedules must play a very important role in present and future treatment of pancreatic adenocarcinom. Early tumor detection is one of the key factors for a potential cure by surgical resection. Major advances in MDCT (multidetector computed tomography), including 2D and 3D reconstruction, are highly useful in improving staging and postsurgical care. For tumor detection, MDCT is applied in the dual phase technique using the different attenuation pattern of tumorous tissue versus normal pancreatic tissue, the former being specifically characterized by hypoattenuation both during the arterial and

venous phase acquisition. Such hypoattenuation is the imaging surrogate of the desmoplastic tissue character of pancreatic adenocarcinoma, which develops as a consequence of very specific biochemical and micromolecular behavior of pancreatic tumor cells. CT finds its limits when such hypoattenuation is lacking in small tumors. Then, MRI might be superior to MDCT. PET-CT is particularly helpful in differentiating between malignant and benign in complex clinical problems, such as discriminating between autoimmune pancreatitis and pancreatic adenocarcinoma, identifying the distant metastatic disease in the pretheraupeutic staging workup, and, furthermore, discriminating between benign fibrotic tissue and tumor recurrence in the follow-up after surgical resection. In the regular diagnostic workup, otherwise, it does not assume a major role.

Abstract

Magnetic resonance imaging (MRI) has conventionally taken a secondary role to CT in the staging of pancreatic adenocarcinoma. It has been used for the evaluation of the pancreas in equivocal CT findings, in patients who are unable to have iodinated contrast media or to avoid using ionizing radiation.

However, MRI is particularly useful for the assessment of small pancreatic lesions, differentiating benign from malignant pancreatic lesions, and the assessment of cystic pancreatic masses, and has an invaluable role in the preoperative assessment prior to enucleation surgery. This chapter will cover the MRI sequences used for the diagnosis and staging of pancreatic neoplasms, the advantages and disadvantages of MRI, and will describe the mimics of pancreatic cancer, and other pancreatic neoplasms.

Keywords

MRI pancreatic carcinoma · Diffusion weighted imaging pancreatic carcinoma · MRI staging pancreatic carcinoma · MRI mimics pancreatic carcinoma · MRI technique for imaging pancreatic carcinoma

Introduction

Magnetic resonance imaging (MRI) of the pancreas has conventionally taken a secondary role in the diagnosis and staging of pancreatic malignancy.

The multidetector computed tomography (MDCT) pancreatic protocol has been extensively validated for the use of pancreatic staging for pancreatic carcinoma [1] and is the mainstay for the diagnosis and evaluation of surgical resectability. This is due to the superior spatial resolution of CT and the ability to multiplanar reformat the images for accurate tumor and vessel assessment.

However, due to its superior soft tissue contrast resolution, MRI has significant advantages over CT in the detection of small noncontour deforming pancreatic lesions, characterization and differentiation between benign and malignant lesions, and the detection and characterization of liver and peritoneal metastasis [2].

With increasing advancement in MRI technology, comparisons between CT and MRI have shown a similar ability in prediction of vessel and tumor involvement [3–5].

MRI Technique

The multipulse capability of MRI enables detection and characterization of pancreatic and liver lesions with a high degree of accuracy. Each individual sequence obtained provides tissue specific information of a lesion. The information gathered from all the sequences aids in the characterization of lesions where CT and conventional ultrasound cannot. This is particularly useful when endoscopic ultrasound with fine needle aspiration of the pancreas is not available or cannot be performed.

There are standard sequences used for the assessment of the pancreas, with occasional variations depending on the clinical question, and the age and capability of the MRI scanner available.

The standard sequences are outlined below.

T1 Weighted Gradient Recalled Echo (GRE)

The axial T1 weighted GRE sequence provides excellent delineation of the pancreatic contour demonstrating good anatomical detail. This is due to the inherent high signal of the pancreas on the T1 weighted sequences due to the presence of acinar cells with the pancreas, and the high content of paramagnetic ions such as manganese [6]. The pancreas is clearly outlined against the higher T weighted signal peripancreatic fat.

Fat suppressed T1 weighted sequences suppresses the macroscopic fat. The peripancreatic fat therefore becomes dark, thus increasing the conspicuity of the inherently high signal pancreas. This sequence is used for the post-contrast scans due to the high lesion contrast [7].

Most pancreatic abnormalities are low signal on the T1 weighted sequence including pancreatic lesions and pancreatitis, and therefore visible within the high signal pancreas. This enables the detection of small lesions (less than 2 cm) which can be beyond the resolution of CT. Difficulty may ensue when there is a pancreatic carcinoma within acute or chronic pancreatitis, as both pathologies return a low T1 weighted signal.

The T1 weighted sequences without fat suppression, where the surrounding peripancreatic fat is of higher signal to the pancreas is used to assess tumor infiltration into the fat and adjacent vessels.

T2 Weighted Sequences

On the T2 weighted fast or turbo spin echo (FSE/TSE) sequence, the normal pancreas is not as clearly defined as it has an intermediate signal intensity, only slightly higher than surrounding muscle. Solid pancreatic lesions are of low signal on this sequence making conspicuity with the pancreas difficult.

On fat suppressed images, there is little contrast differentiation between normal pancreas and surrounding peri-pancreatic fat.

However, fluid is bright on T2 weighted sequences. Thus, cystic lesions can be confidently identified within the pancreas, as can the outline of the pancreatic and biliary ductal system.

The presence of necrosis or cystic degeneration of a solid lesion is also more clearly identified on this sequence due to the internal fluid content.

On the T2 weighted sequences, the peri-pancreatic tissue is of a higher signal than the adjacent pancreas. This provides good delineation of the peri-pancreatic fat adjacent to pancreatic contour, enabling assessment of peri-pancreatic inflammation, peri-pancreatic tumor infiltration, and identification of lymph nodes.

Diffusion Weighted Sequences

The diffusion weighted sequence (DWI) is becoming an established sequence for the assessment of the pancreas due to its ability to provide information on the cellular density of tissue.

In normal tissue, water molecules diffuse freely in relation to molecular interactions and the cellular environment (Brownian motion). However, in the presence of pathology, this diffusion is restricted due to changes at the cellular level such as edema, fibrosis, or increased cellular density [8].

The diffusion weighted sequence is sensitive to molecular motion as it applies two "diffusion gradients" around the 180° refocusing pulse. Molecules that are restricted in their movement (due to cellular change) receive both gradient excitations and therefore receive no net change to their phase, and therefore return a high signal. Molecules that are unrestricted in their movement (normal tissue) do not receive both gradients excitations as they are motion, and therefore experience a phase loss and return a low signal.

The timing and application of these diffusion gradients determine the sensitivity to diffusion and is indicated by the use of "b-values," with increasing b-values indicating increasing sensitivity to diffusion.

A diffusion sequence will routinely begin with a b-factor of "b-0" to establish a baseline image and then with b-values of increasing value tailored to examine a particular tissue type. On images with a high "b" value, there is loss of anatomical detail of the solid organs, resulting in lesions with restricted diffusion appearing conspicuous.

The diffusion sequence in its natural form contains T2 contrast due to the repetition and echo time used in these sequences. The T2 contamination, termed "T2 shine through," can be misinterpreted as an indication of pathology if not fully understood and recognized. To correct this shine through, the calculation of apparent diffusion coefficients, or "ADC map" as it is better known, is required.

The ADC map is calculated using a logarithmic algorithm involving the b-0 and the second, or the multiple b-values acquired. Through the application of this algorithm, the effects of T2 shine through are removed, leaving a corrected image set. This ADC map is opposite to the initial uncorrected image set in signal properties: areas of restricted diffusion which have a high signal on the uncorrected

raw image set will have a low signal on the ADC map [9–11]. Quantification can be assessed on the ADC map using regions of interest.

As a result of the varied cellular densities of normal pancreas and pancreatic pathology, DWI can potentially be useful in the identification and characterization of pancreatic lesions.

Dynamic Contrast Scans

Dynamic contrast enhanced T1 weighted fat suppressed gradient recalled echo (GRE) sequences are performed following intravenous gadolinium contrast administration. The contrast enhanced sequences require patient cooperation with at least 4 to 5 breath-holds of at least 11 s in length.

An extracellular gadolinium agent is conventionally used for assessment of the pancreas. This behaves similarly to contrast agents in CT by diffusing rapidly from the intravascular space into the extracellular space. These are excreted by glomerular filtration via the kidneys.

Peak pancreatic parenchymal enhancement occurs at 35 s post-contrast resulting in intense homogenous pancreatic enhancement where lesion conspicuity is at its greatest. The pancreas then becomes isointense to the liver on the portal venous and delayed phases, with loss of contrast enhancement by 3 min. The pancreas is imaged 35 s (pancreatic parenchymal phase), 70 s (portal venous) and delayed phase scans, usually 1 and 3 min.

The contrast enhanced images also provides evaluation of the adjacent vessels for vascular staging.

Magnetic Resonance Cholangiopancreatography (MRCP)

MRCP is a fluid targeted sequence depicting the biliary and pancreatic ductal system. Two types of MRCP technique are utilized.

A thick slab single-shot turbo spin echo T2 sequence can be obtained in any plane with a single short breath hold. This provides an excellent overall view of the entire biliary and pancreatic ductal system.

The multisection thin slab single shot spin echo sequence requires breath-hold and therefore patient cooperation. This sequence provides more detailed view of the pancreatic duct providing thin slice sequential images.

To visualize the biliary tract and pancreatic duct without fluid from the surrounding stomach and duodenum obscuring the view, the patient is starved for at least 4–6 h and given a T2 negative oral contrast agent such as pineapple juice immediately before the scan. This effectively nulls the signal from the stomach and duodenum. On the MRCP sequences, the solid organ detail is not present, providing a clear view of the ductal system such as in ERCP.

The dorsal pancreatic duct is normally 2 to 3 mm in diameter, increasing caliber from the tail of the pancreas to head. Although there are several tiny side branches

arising from the pancreatic duct, these are not normally identified on MRCP unless pathologically dilated.

Cystic lesions and ductal abnormalities can clearly be identified on MRCP [12].

The presence of ductal narrowing may indicate the presence of a small pancreatic lesion and may be the only sign visible on imaging. Intraductal filling defects such as stones which are low signal compared to the high signal duct in patients with chronic pancreatitis are also clearly depicted as an alternative cause of ductal dilatation [13].

Secretin MRCP

Dynamic assessment of the pancreatic duct is possible with the administration of the enzyme secretin. This is an amino acid polypeptide hormone which is usually secreted by the duodenal mucosa in response to a meal when the intraluminal acidity increases. The synthetic version is administered by slow intravenous injection over 1 min in order to avoid side effects such as abdominal pain. The enzyme stimulates the production of pancreatic enzymes and increases the tone of the sphincter of Oddi, resulting in an increase in the caliber of the pancreatic duct. The increase in caliber can be seen by 1 min post-intravenous administration of secretin and reaches a maximum by 3–5 min, returning to normal by 5 min post-intravenous administration.

This sequence is used as an adjunct to conventional MRCP. The standard MRCP sequences are obtained followed by the dynamic images using coronal single shot turbo spin echo sequences every 30 s for 10 min postinjection. Although secretin MRCP is not used in diagnosis or staging of pancreatic adenocarcinoma, the transient increase in pancreatic duct diameter (usually by 1 mm or more) improves the depiction of the ductal anatomy and allows differentiation of a side branch IPMN from a mucinous tumor with a high degree of accuracy [14]. This will be discussed later on in the chapter.

This sequence can also be useful in the assessment of patency of the postoperative pancreaticoenteric ductal anastomosis.

Advantages and Disadvantages of MRI

MRI does not employ the use of ionizing radiation as in other imaging modalities, which allows investigation to be performed with no known biological harm to the patient. This is useful for pregnant patients and for patients who have multiple interval scans of the pancreas.

The main disadvantage of MRI is the length of the examination and the requirement for patients to take multiple breath-holds in order to obtain high-resolution diagnostic images.

The length of a typical MRI examination of the pancreas is around 30 min which can be a limiting factor for patients who are claustrophobic, in pain, or acutely unwell. Movement or breathing during the acquisition of the sequences can result in

significant degradation of imaging quality, thus reducing the diagnostic accuracy of the investigation.

Fast sequences can be utilized for patients who are unable to hold their breath, but to the detriment of diagnostic quality.

MRI Safety

MRI is particularly useful in imaging patients where administration of nonionic iodinated CT contrast media is contraindicated such as patients with a known allergy to CT contrast. The incidence of acute adverse severe reactions associated with MR gadolinium-based contrast agents varies between 0.17% and 2.4% [15]. This is significantly lower than the rate of adverse effects associated with nonionic iodinated contrast media [16, 17] and should be considered if the patient has an allergy to CT contrast. However, studies have shown that a previous reaction to CT contrast media does increase the risk for hypersensitivity reactions to gadolinium [18].

Risk factors for immediate hypersensitivity reactions to gadolinium contrast are noted in female patients, patients with underlying allergic diseases, multiple exposures, and those with a previous hypersensitivity to MR contrast media [19]. Patients with previous hypersensitivity to gadolinium are about eight times more likely to experience a reaction which can be of a greater severity than the initial contrast reaction [20].

Corticosteroid treatment has been used a premedication to reduce the incidence and severity of hypersensitivity reactions and is effective in preventing mild reactions [21]. However, patients who have had severe reactions are still at an increased risk despite premedication [22].

The administration of limited duration corticosteroids itself poses a risk particularly in patients with infection, diabetes, and hypertension.

Nephrogenic Systemic Fibrosis

In patients with renal failure, imaging with MRI and gadolinium contrast was previously considered to be a safe alternative to nonionic CT contrast media.

However, over the last decade, a condition called nephrogenic systemic fibrosis (NSF) has come to light. NSF is a fibrotic condition caused by the deposition of gadolinium within tissues of patients with end-stage renal failure [23].

The stability of the gadolinium chelate is directly linked with the development NSF. Plasma elimination of gadolinium from the body is approximately 2 h in patients with preserved renal function. However, in patients with renal failure, plasma elimination is lengthened. This increases the risk of displacement of the gadolinium ion from its chelating ligand and the formation of gadolinium-phosphate complexes which precipitate in tissues resulting in a fibrotic response [24, 25]. The exact parameter leading to lack of stability of the gadolinium chelate is not definitively known, with a lack of consensus in the literature [26].

Due to the accumulation of fibrosis in skin and visceral tissues, skin thickening, particularly involving the extremities, is noted with the development of joint contractures and loss of mobility [27]. Fibrosis involving the liver, lungs, muscle, and heart has also been recognized [28]. In some patients, this disease can be aggressive, leading to severe disability or death.

NSF has been seen in patients with chronic renal failure with an eGFR less than 30 mL/min, resulting in an incidence of NSF in 3–5% in these patients [29, 30]. Patients with hyperphosphatemia, acidosis, or pro-inflammatory states are also at increased risk [31].

Recommendations have been published by the European Society of Uroradiology (ESUR), American College of Radiology (ACR), and Food and Drug Administration (FDA) on the use of gadolinium contrast. Some gadolinium agents are contraindicated in patients with acute and chronic renal failure (CKD 4–5) as they have the highest association with NSF: gadopentate (Magnevist), gadodiamide (Ominiscan), and gadoversetamide (optiMARK). The other gadolinium agents are recommended to be used in caution in patient with low eGFR (<30 mL/min), and multiple administration of gadolinium to be avoided within a 7-day period.

Other recommendations vary between ESUR and ACR on the use of other gadolinium agents, and the timing of dialysis post-gadolinium administration [32].

Current guidelines for patients undergoing MRI with contrast include assessment of the eGFR in patients over 60 years, a history of renal disease, hypertension, or diabetes.

Referral to these guidelines online is suggested for the most up-to-date information in the relevant country of residence.

Diagnosis and Staging of Pancreatic Adenocarcinoma

Tumor Diagnosis

On T1 weighted sequences, pancreatic adenocarcinoma is demonstrated as an ill-defined hypointense mass within the high T1 signal pancreatic parenchyma. Thus, small lesions beyond the resolution of CT or iso-attenuating lesions on CT are better defined on this sequence [33]. This is potentially useful when EUS is not available or cannot be performed.

Tumor infiltration into the peri-pancreatic tissue is depicted as a low signal mass among the high signal fat on the nonfat saturated T1 weighted sequence. This is usually depicted as nodular infiltration into the fat or along the peri-pancreatic vessels, or vascular encasement.

On the T2 weighted sequences, pancreatic adenocarcinoma is isointense to mildly hyperintense compared to background pancreas due to its fibrotic nature. This makes identification of the lesion within the pancreatic parenchyma difficult. The presence of necrosis or cystic degeneration may help visualization as this will return a high signal compared to background pancreas. Assessment of the dilated pancreatic duct and its transition point is an important secondary sign of the presence of a mass lesion, and is well visualized on this sequence and on MRCP.

Administration of intravenous gadolinium contrast increases the conspicuity of tumors and improves the detection rate of small tumors (less than 2 cm) [34, 35].

After administration of intravenous gadolinium contrast, pancreatic adenocarcinoma demonstrates decreased enhancement compared to the pancreas on the pancreatic parenchymal phase image (35 s), with mild progressive enhancement into the delayed sequences. This is due to the desmoplastic nature of the lesion [36]. However, the tumor remains lower signal than the surrounding enhancing pancreas. This is differentiated from inflammatory lesions which demonstrate increased enhancement compared to the pancreas on the delayed contrast enhanced scans.

Diffusion sequences have been shown to be useful in the identification of the pancreatic adenocarcinoma from background pancreas by visual assessment on the DW images and by quantification on the ADC map [37–40]. Pancreatic adenocarcinoma is bright on the high "b" value DW images compared to the background pancreas and returns a lower ADC value on quantitative analysis.

Small pancreatic tumors have been shown to demonstrate restricted diffusion, as shown in cases of neuroendocrine tumors [41].

In patients with chronic pancreatitis, identification of adenocarcinoma may not be reliable. The inherent high signal of the pancreas on the T1 weighted sequence is lost in both pathologies, making differentiation on this sequence difficult. Chronic pancreatitis may also appear hyperintense on the high b value DW images making visual assessment on this sequence misleading [42]. However, ADC values have been shown to differ with adenocarcinoma returning a lower ADC value than chronic pancreatitis, and can be useful if there is a high index of suspicion of adenocarcinoma within chronic pancreatitis.

Although diffusion weighted imaging may be useful in differentiating benign from malignant mass lesions [37, 38], to date, there are only a few studies looking at characterization of different solid pancreatic lesions using DWI. Studies have shown there is a wide overlap in ADC quantification in differing solid pancreatic lesions making accurate characterization difficult [40, 43]. Studies have also looked DWI of adenocarcinoma with different histopathological grades, but the findings are still unclear if DWI can be helpful here [8].

Occasionally the primary malignancy can be difficult to appreciate on imaging. The secondary signs of pancreatic adenocarcinoma include pancreatic duct dilatation, atrophy of the pancreas distal to the tumor, and dilated collateral vessels due to venous invasion of the tumor. These signs can be the only indication of the presence of a mass (Fig. 1).

Vascular Resectability

The extent of vascular involvement by pancreatic adenocarcinoma is best depicted on post-contrast multidetector CT imaging with 3-D reformats. Gadolinium-enhanced MRI is inferior to multidetector CT in terms of spatial resolution and 1.5 T MRI does not provide isotropic imaging in order to obtain 3-D reformatting.

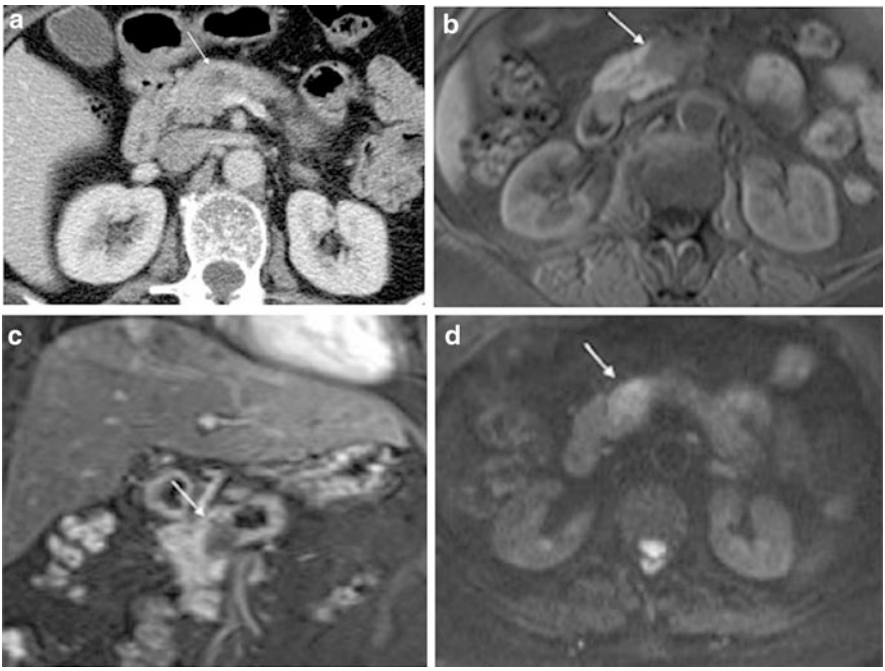

Fig. 1 CT and MR findings of a pancreatic adenocarcinoma in the neck of pancreas. (**a**) Axial contrast enhanced CT demonstrating a nonspecific hypo/ iso-dense swelling of the head of pancreas with no defined mass (*white arrow*). (**b**) Axial T1w noncontrast image demonstrating a hypointense mass (*white arrow*) within the pancreas. (**c**) Post-contrast coronal T1w fat saturated image demonstrating a hypoenhancing mass with a normally enhancing pancreatic head. (**d**) Diffusion weighted images at a high "b" value demonstrating restricted diffusion (*white arrow*) (Images courtesy of Dr. R Albazaz, Leeds Teaching Hospital NHS trust)

However, with the advent of 3.0 T MRI scanners, 3-D gradient echo images have become available enabling reconstructions of 1–1.5 mm slice thickness in order to obtain accurate vascular assessment. Here, MRI with MR angiography has shown to have similar sensitivities of determining resectability compared to multidetector CT (approximately 90%) [44]. Assessment for vascular staging is the same for CT staging and is described in the chapter ▶ "Pancreatic Adenocarcinoma: CT and PET/CT" (Fig. 2).

Assessment for Enucleation of Pancreatic Lesions

Enucleation surgery has been performed for small cystic tumors, neuroendocrine lesions, and IPMN.

MRI is particularly useful in the surgical assessment of the lesions. The combination of the T1 and T2 weighted images allows accurate assessment of the distance

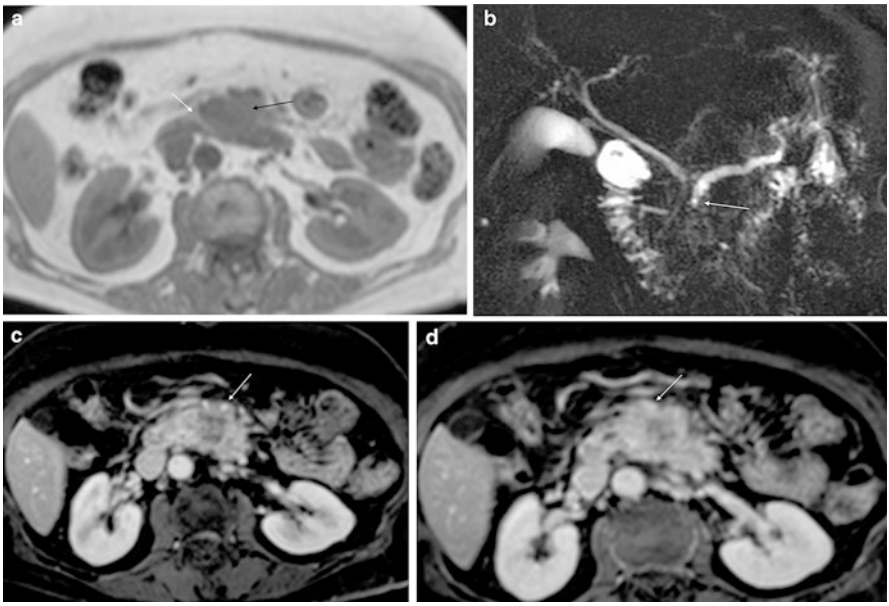

Fig. 2 MR images demonstrating an uncinate process mass with vascular compromise. (**a**) Axial T1 in-phase scan demonstrating the low signal uncinate process mass (*black arrow*) with rim of normal high T1 signal pancreas (*white arrow*). (**b**) MRCP sequence demonstrating a dilated pancreatic duct with sharp cutoff at the uncinated process of pancreas (*white arrow*). (**d**) Axial T1 fat saturated post-contrast portal venous phase scan demonstrating the hypoenhancing uncinate process tumor with involvement of the posterior wall of the superior mesenteric vein (*white arrow*)

of the pancreatic lesion from the pancreatic duct to avoid involvement of the duct during surgery.

Nodal Disease

Accurate nodal staging has been shown not to be reliable on cross-sectional imaging. Where size criteria were historically used to differentiate benign from malignant nodes, this has shown not to be accurate [45] with presence of micro-metastases occurring in normal appearing lymph nodes. Nodes are more difficult to see on MRI sequences than CT, but the presence of necrosis within a node does significantly increase the suspicion of malignant infiltration.

Liver Metastases

MRI is able to detect liver lesions with a high degree of sensitivity (81–92%) compared to multidetector CT (70–87%) [46]. The addition of diffusion weighted

sequences has led to the ability to detect very tiny liver lesions not seen on other modalities or on other MR sequences [47, 48].

Characterization and detection of liver lesions is significantly increased with the use of hepatocyte specific contrast agents (gadoxetate disodium, *Primovist*, *Bayer*, *Germany* or gadobenate dimeglumine, *MultiHance*, *Bracco*, *Princeton*, *NJ*). This type of contrast agent is taken up by the hepatocytes and is excreted via hepatobiliary system.

The enhancement of liver on the dynamic contrast arterial, portal venous, 1 and 5 min delayed phase scans is similar to the other extracellular gadolinium contrast agents. Specific liver uptake of the contrast by hepatocytes results in optimal contrast enhancement of the liver on the delayed phase scans (20–40 min for gadoxetate disodium, and 60 min for gadobenate dimeglumine). Smaller liver lesions are clearly delineated against the uniformly enhancing background pancreas. Due to the excretion of contrast by the hepatobiliary system, the biliary tract is also well visualized on the delayed scans.

Liver metastasis secondary to pancreatic adenocarcinoma tends to be hypovascular. The lesions are hypointense on T1 weighted sequences, iso- to moderately hyperintense on T2 weighted sequences, and can have a target appearance. They demonstrate irregular rim enhancement post-contrast (Fig. 3).

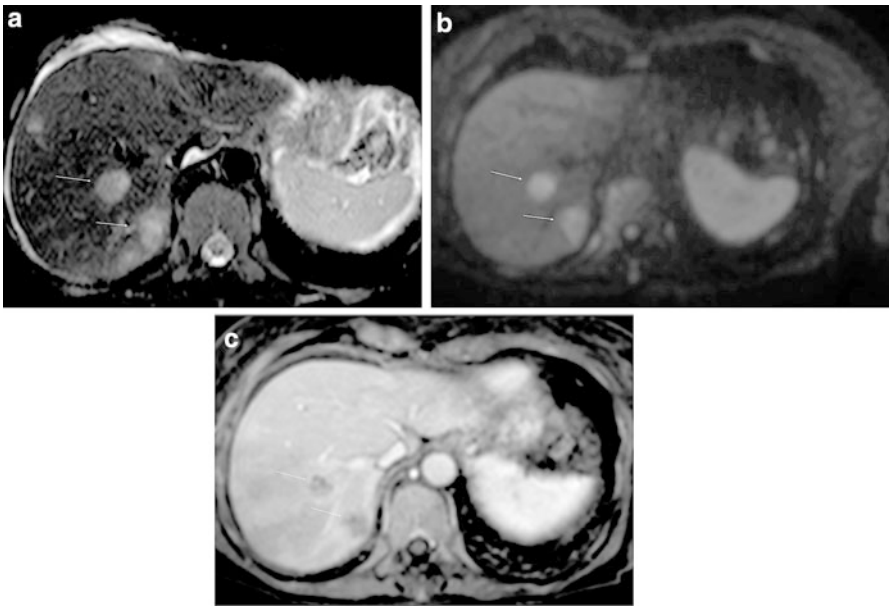

Fig. 3 Selected images demonstrating liver metastases secondary to pancreatic adenocarcinoma. (**a**) Axial T2 weighted images of the liver demonstrating several liver metastases with a target-like appearance. Two of the lesions have been arrowed with a *white arrow*. There is also ascites in the upper abdomen. (**b**) DWI images demonstrating restricted diffusion of these visualized two lesions on this slice (*white arrow*). (**c**) Axial T1 weighted fat saturated post-contrast scans demonstrating irregular rim enhancement of these metastases (*white arrow*)

Wedge-shaped perilesional transient enhancement on the arterial phase is seen typically with pancreatic adenocarcinoma metastases, and not seen in neuroendocrine liver metastases. Pancreatic adenocarcinoma liver metastases in the periphery of the liver tend to be hypervascular and maybe only seen transiently on the arterial phase scan [49].

Tumor Assessment Post-neo-Adjuvant Chemotherapy

Patients with borderline resectable disease who have been treated with chemotherapy to downstage the tumor have repeat imaging prior to surgical consideration. In both CT and MRI imaging, the posttreatment fibrosis results in over-staging of local disease with both CT and MRI demonstrating a reduced sensitivity and specificity in predicting vascular involvement and resectability post-chemotherapy [50].

Mimics of Pancreatic Adenocarcinoma

Fatty Changes

Fatty replacement within the pancreas is usually diffuse, but not so rarely, can be focal and typically present in the anterior aspect of the pancreatic head. This can mimic a mass on CT or ultrasound. Due to the availability of fat and nonfat suppressed sequences, MRI is of choice for definitive diagnosis.

On the T1 weighted sequence, the fatty lesion is typically iso- or hyperintense to the pancreas. On the T1 fat saturated sequences, the area of fat will suppress appearing low signal compared to the remainder of the pancreas [51]. Post-contrast, there is homogenous enhancement of the pancreas, thus differentiating focal fatty change from adenocarcinoma.

Mass-Forming Pancreatitis

Focal pancreatitis and pancreatic adenocarcinoma can be difficult to differentiate on imaging and may lead to unnecessary surgical resection. In the absence of tissue confirmation by EUS FNA, MRI can be useful in differentiating the two pathologies.

Focal pancreatitis is usually more defined than pancreatic adenocarcinoma but also returns a low signal on T1 weighted sequence. As with adenocarcinoma, pancreatitis demonstrates reduced enhancement compared to the background pancreas, but demonstrates progressive enhancement on the delayed contrast images, more so than adenocarcinoma, and can enhance to a greater extent than the normal pancreatic tissue. Subtle findings also include preservation of pancreatic architecture if the inflammation is not marked, whereas this architecture is destroyed in adenocarcinoma.

However, it can be impossible to differentiate the two pathologies on imaging, and follow-up imaging in about 4–6 weeks is advised if the clinical features favor pancreatitis.

Mass-forming autoimmune pancreatitis (AIP) is another mimic of adenocarcinoma on both imaging and histology. Homogenous enhancement of mass-forming AIP on the arterial and portal venous phase sequences differentiate this from pancreatic adenocarcinoma, as well as the preserved architecture of the pancreas. The duct penetration sign, where the main pancreatic duct penetrates the mass is a specific finding in an inflammatory pancreatic mass lesion. This appearance is different to pancreatic adenocarcinoma where there is an abrupt cutoff of the pancreatic duct at the site of the mass (Fig. 4).

Lower ADC values in mass-forming AIP have also been shown to be useful in differentiating the two pathologies, but this finding has not always been consistent in the literature with substantial overlap in the ADC values [52]. Other features of AIP are the halo sign, with a thin rim of fluid around the pancreas and evidence of autoimmune disease in other organs.

Other Solid Pancreatic Tumors

Solid Pseudopapillary Tumor

Solid pseudopapillary tumor of the pancreas represents 1–2% of pancreatic tumors. These are of low-grade malignant potential and predominantly occur in younger women. They are usually large (mean 9 cm), located within the tail and are well demarcated with a thick solid capsule which enhances post-contrast. On the dynamic contrast enhanced scans, there is variable enhancement ranging from a hypervascular mass with washout to slow enhancement on the arterial phase with progressive enhancement to into the delayed phase [53]. The mass tends to displace surrounding structures rather than invading them. Due to hemorrhage, the lesion can exhibit solid and cystic components, and as a consequence demonstrate high signal on the T1w sequence and appear cystic on the T2w sequence, differentiating this from pancreatic adenocarcinoma [54].

Pancreatic Neuroendocrine Tumors (NET)

Functioning NET are identified primarily from symptoms due to the secretion of hormones rather than identification of a mass on imaging. These lesions tend to be small at diagnosis (less than 3 cm) and can be elusive on cross-sectional imaging.

These lesions are well defined, low signal on the T1 weighted sequences, but demonstrate higher signal on the T2 weighted sequences compared to the

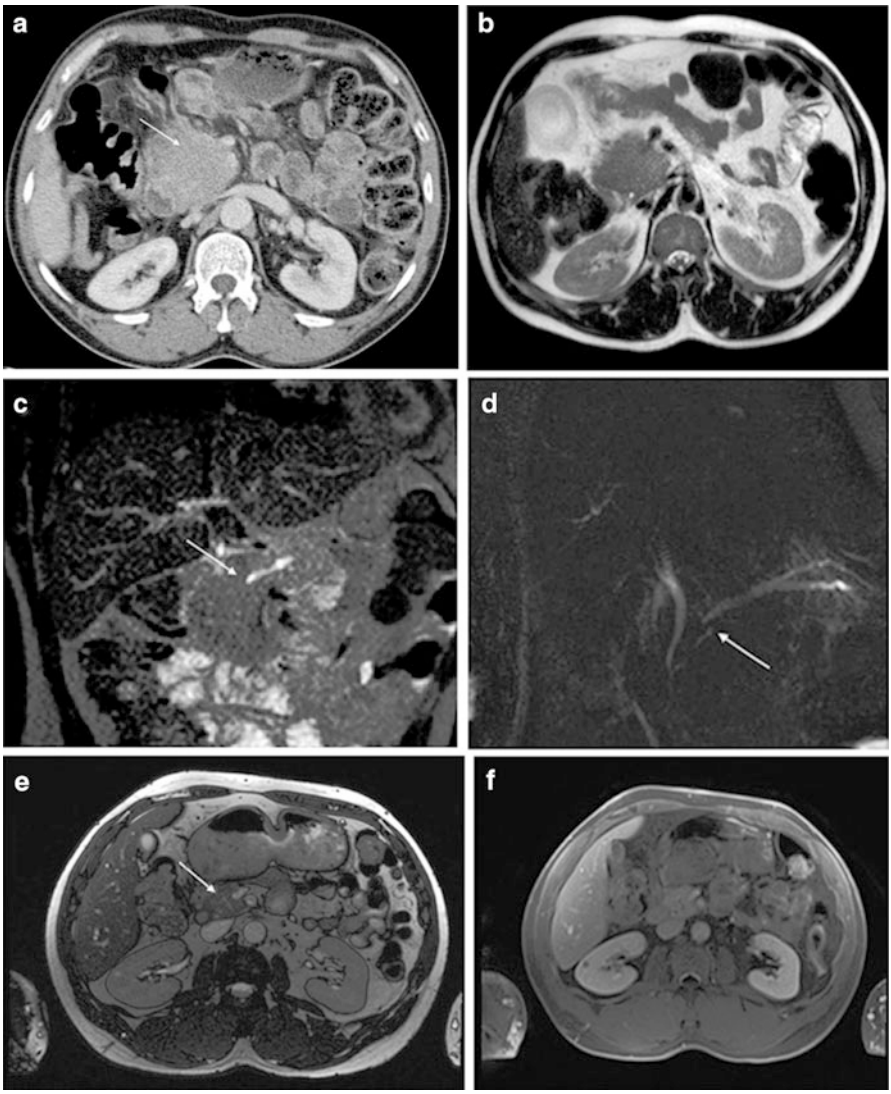

Fig. 4 Selective images of a mass forming AIP pre and posttreatment. (**a**) Axial contrast enhanced CT scan demonstrating a slightly hypodense expanded pancreatic head (*white arrow*) in keeping with a mass. (**b**) Axial T2 weighted sequence of the head of pancreas which is slightly higher signal than muscle. (**c**) Coronal T2 weighted sequence demonstrating the high signal pancreatic duct penetrating the mass (*white arrow*). (**e**) Axial T2 weighted scan of the pancreatic head which appears normal in size with a normal pancreatic duct (*white arrow*), 4 weeks post-steroid treatment. (**f**) Axial portal venous phase scan of a normally enhancing pancreatic head (Images courtesy of Dr. R Albazaz, Leeds Teaching Hospital NHS trust)

background pancreas and can appear cystic with a thickened wall. They are hypervascular demonstrating intense arterial enhancement post-contrast. They can also demonstrate ring enhancement. Malignant endocrine neoplasms tend to demonstrate restricted diffusion, but the ADC values do to vary due to tumor differentiation, hemorrhage, and necrosis [55] (Fig. 5).

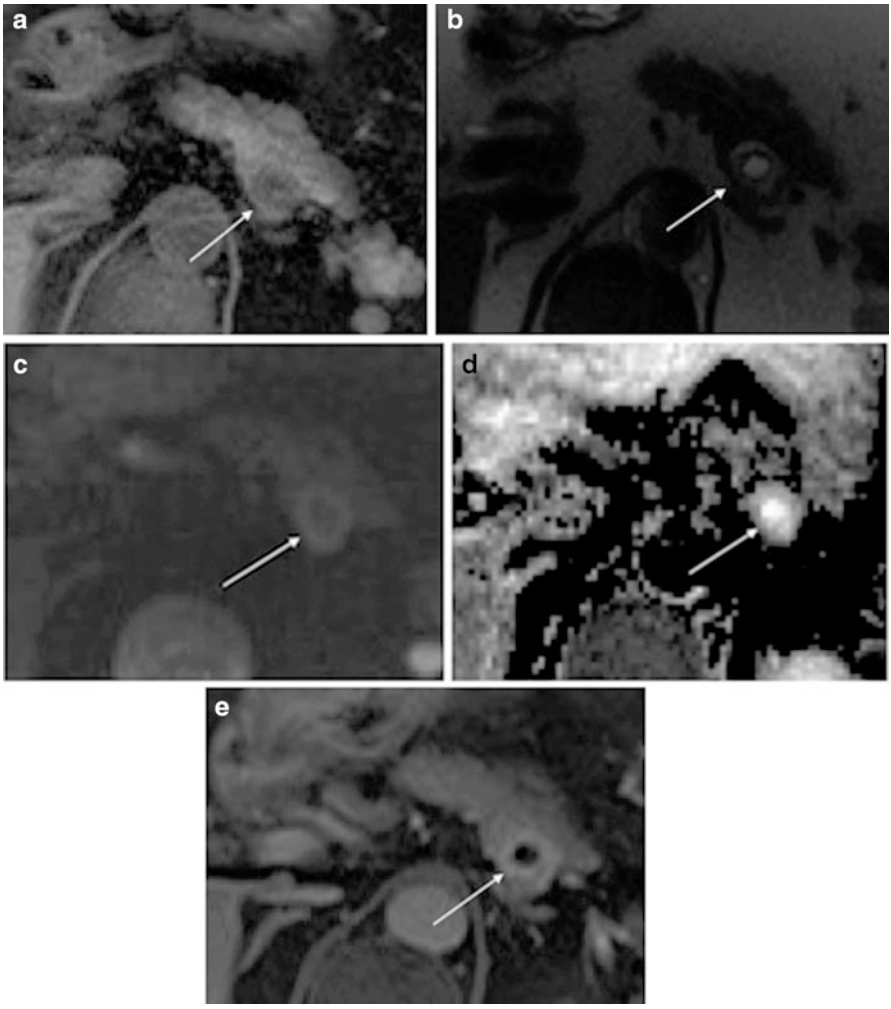

Fig. 5 Selected images of a NET of the posterior body of pancreas with cystic degeneration. (**a**) Axial T1 fat saturated images demonstrating the low signal lesion within the high signal pancreas (*white arrow*). (**b**) Axial T2 image demonstrates the lesion returning a high signal. (**c**) DWI images with restricted diffusion of the rim of the lesion (*white arrow*). (**d**) ADC map with low signal rim in keeping with restricted diffusion (*white arrow*). (**e**) Axial post-contrast portal venous image demonstrating rim enhancement of the NET (*white arrow*) (Images courtesy of Dr. R Albazaz, Leeds Teaching Hospital NHS trust)

Nonfunctional endocrine tumors tend to be much larger in size at presentation due to the lack of hormone secretion and symptoms. These lesions exhibit calcification, cystic/necrotic degeneration, and vascular invasion. The vascular invasion tends to be fingerlike intravascular solid tumor thrombus within the affected vessels, a feature not usually seen in patients with adenocarcinoma. Enhancement is varied due to the necrosis and calcification, but the solid areas are typically hypervascular [56, 57].

Lymphoma

Primary pancreatic lymphoma is rare and seen usually in immunocompromised patients. This is commonly the B cell type of non-Hodgkin's lymphoma and can either be a focal well-circumscribed lesion or a diffuse infiltration of the pancreas.

The focal type of lymphoma typically localizes at the pancreatic head with no significant dilatation of the main pancreatic duct. There can be encasement of the vessels but vascular distortion is not seen.

The diffuse form of pancreatic lymphoma can mimic acute pancreatitis.

The imaging characteristics are nonspecific, demonstrating low signal on T1 and intermediate signal on T2 weighted images, and demonstrating faint contrast enhancement [58].

Metastases to the Pancreas

Metastasis to the pancreas is relatively rare. Renal cell carcinoma metastases have a predilection for the pancreas (30%). Other malignancies include bronchogenic carcinoma (23%), breast, and colon. Renal cell carcinoma metastases are hypervascular on the arterial phase. Otherwise, metastases have variable heterogeneous enhancement and can be difficult to differentiate from adenocarcinoma [59]. However, the patient will have a history of current or previous malignancy, and the lesions may be multiple, which is not typically seen in adenocarcinoma.

Cystic Lesions of the Pancreas

The majority of cystic lesions within the pancreas are discovered incidentally on imaging, either ultrasound, CT or MRI. The incidence of these cysts is increasing, and may be in part due to the availability of high-end ultrasound, CT, and MRI scanners, and a general increase in diagnostic imaging of the population. Only rarely, are these pancreatic cystic abnormalities malignant mucinous lesions.

Serous Cystic Lesions

Serous cystadenoma of the pancreas is considered to be a benign entity, seen in older female patients with only very rare cases of malignant degeneration.

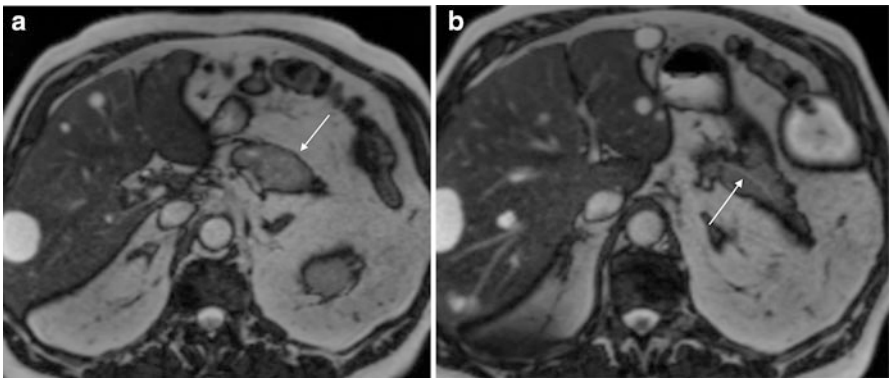

Fig. 6 Selected images demonstrating a serous cystic lesion in the tail of pancreas. (**a**) Axial T2 weighted image demonstrating a mass with several small cysts and a central low signal scar (*white arrow*). (**b**) Axial T2 weighted image demonstrating a normal caliber distal pancreatic duct (*white arrow*) and no pancreatic atrophy

These lesions typically contain multiple tiny cysts (less than 2 cm) with a central stellate calcified scar giving a honeycomb appearance. On CT, these can look solid and can mimic pancreatic adenocarcinoma. On MRI, the multiple cysts are clearly delineated on the T2w sequences where fluid is bright, with the low signal delayed enhancing central scar enabling a confident diagnosis. There is no dilatation of the pancreatic duct and no pancreatic atrophy (Fig. 6).

Mucinous Tumors of the Pancreas

Mucinous cystic neoplasms occur more often in women, seen within the body or tail of the pancreas, and have a higher malignant potential. These lesions have a range of histology. The most recent WHO update classifies lesions from benign mucinous lesions with low to intermediate grade dysplasia (previously termed cystadenoma), to mucinous lesions with high grade dysplasia (previously termed cystadenocarcinoma), and mucinous tumors with associated invasive carcinoma.

Mucinous cysts are larger than other neoplastic cysts, lobulated and exophytic and are typically unilocular with a few septations. The lesions have thick enhancing walls with septations, calcifications, and occasionally solid papillary excretions. Again, these are usually high signal on the T2 sequences but given their mucin component, can demonstrate variability in signal characteristics, including high signal on T1 weighted images.

These are differentiated from side branch intraductal papillary mucinous neoplasms (IPMN) by lack of connection to the main pancreatic duct on the MRCP sequences [60].

Increased risk factors for adenocarcinoma or high-grade dysplasia in mucinous cystic neoplasms are the male sex, pancreatic head and neck location, larger lesions, solid components or mural nodules, and pancreatic duct dilatation [61].

Intraductal Papillary Mucinous Neoplasms (IPMN)

IPMN arise from the main pancreatic duct or the side branches. Three types of IPMN are recognized: the side-branch IPMN, main branch IPMN, and mixed type IPMN.

MRCP imaging is the most useful noninvasive imaging modality to assess for IPMN. The pancreatic duct and side branches are well delineated on the T2 weighted sequences and MRCP sequences.

Side branch IPMN are most commonly identified in the uncinate process of the pancreas and appear septated or lobulated. However, they can be found elsewhere within the pancreas and can appear as unilocular cystic foci. Although more commonly solitary, they can be multifocal in 40% of cases.

The presence of a side-branch IPMN can be reliably depicted where communication between a cystic lesion and the main pancreatic duct is shown. However, this may not be reliably identified on imaging.

Studies have shown a low risk of malignancy if there are no solid components, no dilatation of the main pancreatic duct and the cysts measure less than 3 cm [62, 63].

Worrisome features of a cystic lesion in the pancreas include a cyst of greater than 3 cm, thickened enhancing cyst wall, abrupt change in the caliber of the main pancreatic duct with distal pancreatic atrophy, nonenhanced mural nodules, and lymphadenopathy. Cysts with high risk stigmata are lesions with an enhancing solid component and a main pancreatic duct greater than 10 mm [64] (Fig. 7).

Main branch IPMN carries a higher risk of malignancy of between 23% and 57% [65] and management is often surgical. Features include dilatation of the main pancreatic duct of more than 5 mm, either diffuse or segmental dilatation in the absence of an obstructive lesion. The side branches can be dilated, and small mural nodules can be identified. The pancreatic parenchyma becomes atrophied, particularly with increasing ductal dilatation.

The main branch IPMN type is clearly depicted on the MRCP and T2 weighted sequences and accurate measurements can be performed to demonstrate the extent and caliber of dilatation and stricturing of the pancreatic duct.

The excellent soft tissue contrast between high signal fluid and low signal soft tissue on the T2 weighted sequences of MRCP enables accurate detection of solid papillary projections and mass formation within an IPMN undergoing malignant transformation.

The presence of a solid mass, dilatation of the main pancreatic duct to over 10 mm diameter, diffuse or multifocal involvement, and calcified intraluminal content are specific signs of malignancy [66].

MRI is the preferred imaging modality for the follow-up and management of IPMN due to the superior delineation of these lesions on the T2 weighted and post-contrast sequences. The lack of ionizing radiation allows for repeated interval imaging without risk of radiation burden to the patient [67, 68]. The management of cystic neoplasms is discussed in chapter ► “Management of Cystic Neoplasms of the Pancreas Including IPMNs”.

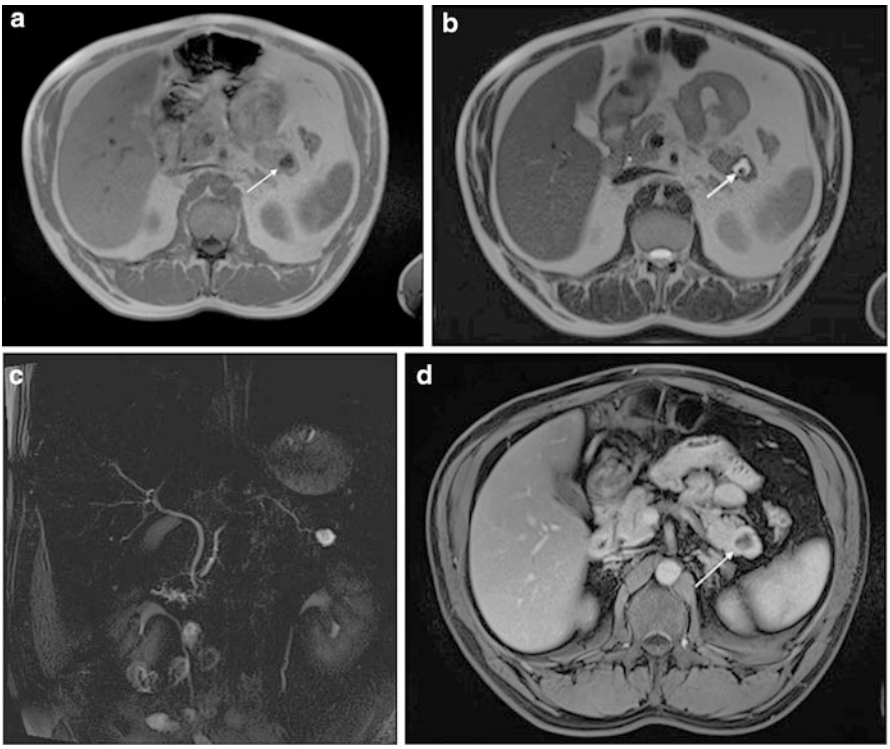

Fig. 7 Selected images of a pancreatic cyst in the tail of pancreas with a mural nodule. (**a**) Axial T1 sequence demonstrating a low signal lesion in the tail of pancreas (*white arrow*). (**b**) Axial T2 sequence demonstrating the cyst with a mural nodule (*white arrow*). (**c**) MRCP sequences demonstrating the cyst with internal mural nodule, and good overview of the pancreatic and biliary ductal system. (**d**) Axial contrast enhanced scan in portal venous phase demonstrating thick rim enhancement and mild enhancement of the mural nodule

Conclusion

With recent advances in the technology of magnetic resonance imaging, MRI is being increasingly utilized in the imaging of pancreatic lesions. It is a particularly useful problem-solving tool in the evaluation of pancreatic cysts, identification of small pancreatic lesions beyond the resolution of CT, and has increasingly potential use in differentiating benign from malignant pancreatic lesions. The ability to clearly visualize the pancreatic duct and define this from a pancreatic lesion makes MRI invaluable in the preoperative assessment prior to enucleation surgery.

For staging, with the advent of 3 T MRI, the ability of vascular staging is becoming comparable to CT. MRI with diffusion weighted imaging and gadolinium contrast has been shown to be far superior to CT in the detection of liver metastases,

and its use prior to consideration of pancreatic surgery may have a significant impact on patient outcome.

However, MRI is not without its risk, particularly for contrast enhanced scans. Patients with known relevant risk factors must be assessed prior to consideration of contrast enhanced MRI and the consequences may be severe.

EUS and Its Role in Pancreatic Cancer

Tobias Grote and Thomas Mathias Gress

Contents

Abstract

Endosocopic ultrasound (EUS) has become an indispensable tool in pancreatic diseases especially in cancer. This article provides an overview about basic principles as well as current developments in the field. It reviews recent literature regarding the use of EUS in pancreatic cancer. The key focus is on EUS-guided tissue sampling by EUS-fine-needle aspiration (EUS-FNA). Further main aspects include cystic pancreatic neoplasias, screening of individuals at risk for familial pancreatic cancer, and EUS-guided therapy.

Keywords
Pancreatic cancer · Endoscopic ultrasound (EUS) · EUS-fine-needle aspiration (EUS-FNA) · Staging · Cystic pancreatic neoplasia · EUS-guided therapy

Introduction

Endoscopic ultrasound (EUS) was developed in the late 1970s and allows to visualize the complete pancreas without interfering signals from the overlying gas, which is a main obstacle in transabdominal ultrasound. In the early 1990s EUS-guided fine-needle aspiration (EUS-FNA) added an important tool in diagnosing pancreatic cancer. In recent years EUS-FNA has also gained significance as a standard, whenever a tissue diagnosis is required, e.g., before starting palliative chemotherapy, but also before initiating neoadjuvant treatment in resectable disease. Recommendations on the role of endoscopy including EUS and EUS-FNA in the evaluation and management of patients with solid pancreatic neoplasia have recently been summarized by the ASGE Standards of Practice Committee [1].

EUS Equipment

EUS imaging can be performed with radial (360°) or linear echoendoscopes. Some aspects of the different instruments have been recently reviewed [2]. Nowadays the EUS probes are coupled to electronic ultrasound processors for the generation of electronic EUS-images, endowed with special aspects as Doppler, contrast-enhanced endoscopic ultrasound, harmonic imaging, and elastography. Frequency usually varies between 5 and 10 MHz. Small miniprobes have been developed that are introduced through the working channel of conventional endoscopes and can be advanced into the biliary or pancreatic duct. These probes use high-frequency ultrasounds (12–30 MHz); however, they are not widely used. Radial and linear echoendoscopes are both used for the evaluation of pancreatobiliary diseases and perform equally well. Some experts only use linear probes as they allow performing fine-needle aspiration in the same procedure. Recently, in a randomized tandem study, it has been suggested that linear array EUS may have advantages in detection of pancreatic lesions in high-risk individuals [3]. However, extensive personal experience and training with one or the other EUS probe certainly remains among the most important criteria for the quality of EUS results.

Visualization and Staging of Pancreatic Cancer with EUS

Usually EUS is used for the evaluation of a pancreatic tumor that has been detected or is suspected in another imaging modality such as abdominal ultrasound or CT. When it is used for pancreatic cancer screening, e.g., in research programs for

individuals at risk for familial pancreatic cancer, EUS may be the first imaging modality detecting a tumor. Pancreatic cancer can be identified by EUS as homogenous or inhomogeneous echo-poor area, sometimes with echo-rich spots or cystic components [4]. More advanced tumor stages display an even less homogeneous tissue pattern and infiltrate neighboring organs and large peripancreatic vessels. While most surgeons will rely on modern CT imaging studies as standard to assess tumor resectability, criteria have been developed to evaluate vascular involvement using EUS. These criteria comprise the lack of a hyperechoic interface between the vessel wall and the tumor, the detection of tumor material in the vessels, the visualization of collaterals due to arterial or venous thrombosis, and indirect criteria such as tumor size or the proximity to major vessels. However, the significance of these criteria remains under debate [5].

Compared with CT and MRI, EUS is the more operator-dependent modality though in the hands of an expert EUS is the most sensitive test to detect pancreatic mass lesions that are less than 2 cm in size or equivocal in other imaging modalities [6]. A systematic review of nine studies [7] reached the conclusion that EUS is more sensitive than CT for the detection of pancreatic cancer (91–100% vs. 53–91%), whereas the two modalities deliver similar results for loco-regional tumor staging. EUS is usually performed prior to ERCP and stent insertion to avoid interfering signals of the biliary stent on the accuracy of EUS staging. However, the effects of biliary stents on staging accuracy appear to be negligible [8].

EUS-Guided Tissue Sampling

A new hallmark in endoscopic ultrasound in the beginning of the 1990s was the introduction of EUS-guided tissue sampling using steel needles [9, 10]. EUS thus allows tissue acquisition for pathology diagnosis, though in resectable tumors, sampling may not be necessary before surgery [11] and is, e.g., not routinely recommended in the German S3-guidelines for pancreatic cancer [12]. However, in some situations, a nonoperative pathology diagnosis in patients with otherwise resectable lesions may be essential. For example, endoscopic tissue diagnosis is helpful for the diagnosis of conditions that may mimic neoplasms or tumors such as autoimmune pancreatitis [13] and cystic lesions [14] or to allow patient enrollment into a neoadjuvant chemotherapy protocol [15]. For EUS-guided tissue sampling, thin steel needles are introduced through the working channel of linear echoendoscopes. In order to protect the instrumentation channel, the needles are covered by a plastic and metal-reinforced sheath, which extends out of the working channel. Once a stable position is reached and the target is in focus, the needle is advanced into the lesion passing through the gastrointestinal wall. The stylet is pulled back before the tip of the needle is pushed into the lesion. A negative pressure is applied using a syringe at the end of the needle. Now the needle is moved forward and backward several times within the lesion to obtain sufficient material for cytological and histological examination [4]. EUS-guided tissue sampling can be performed by FNA (EUS-guided FNA [EUS-FNA]) or by EUS-guided fine-needle

core biopsy (EUS-FNB). EUS-FNA has a sensitivity and specificity of up to 95% and 100%, respectively [16, 17], and is the preferred and a cost-effective method for making a definitive cytology diagnosis of a pancreatic mass [18]. Reasonable sensitivities for cytological analyses is usually obtained by performing five–six needle passes [19], though even two needle passes may already yield sufficient material for cytological and histological analyses [20]. Immediate evaluation and feedback from an on-site cytopathologist during sampling increases diagnostic yield by 10–15% [21, 22], however, due to logistic and infrastructural limitations is not widely available.

Several recent trials compared the diagnostic yield of EUS-FNA versus EUS-FNB [23, 24]. Though results are inconclusive, there seems to be a trend toward EUS-FNB, as this approach preserves the tissue architecture and may achieve a higher yield. A meta-analysis, though, could not demonstrate a significant benefit for core needles regarding sample adequacy and diagnostic accuracy [25]. EUS-FNA with cytopathology usually is adequate for a diagnosis of adenocarcinoma and neuroendocrine tumors (NETs), but it may not provide sufficient material to establish diagnoses such as lymphoma, well-differentiated carcinoma, or autoimmune pancreatitis [26]. Overall, several studies indicate that EUS-FNB is not superior to EUS-FNA in the work-up of a pancreatic mass, but should be considered if EUS-FNA is nondiagnostic and a histological diagnosis is needed [27–29]. FNB may be more technically challenging in particular for sampling of pancreatic head masses since the FNB needle has a higher stiffness which is less compatible with the angulation of the endoscope required for biopsy from this location. More flexible needles have been developed recently that may allow to obtain core tissue biopsies from the pancreatic head when required to establish the histological diagnosis [30].

Potential adverse events from EUS-guided sampling of pancreatic masses include a 0.5–2% risk of pancreatitis or bleeding [16, 17, 31]. In a prospective study of 3,207 diagnostic EUS (8% pancreatobiliary tumor staging) and 224 EUS-guided FNA (48% solid pancreatic masses), a morbidity of 0.1% ($n = 3$) and 2.2% ($n = 5$), respectively, with no mortality was reported [32]. Although pancreatitis is a dreaded complication of pancreatic EUS-FNA, the incidence was low in a large multicentric survey of 4,909 EUS-guided FNAs of solid pancreatic masses, with only 14 cases of acute pancreatitis reported (0.29%) [33]. Tumor seeding with EUS-FNA has been reported, but the risk appears to be as small as 0.003–0.009% [34], and reports are currently limited to isolated cases [35, 36]. Since in addition for pancreatic head masses the potential site of seeding is included in the resection, the small risk of seeding appears to be irrelevant. Indeed, preoperative EUS-FNA has not been reported to be associated with adverse perioperative or long-term outcomes in patients undergoing resections for solid neoplasms of the pancreas [37] (Figs. 1 and 2).

Novel Developments in EUS-Guided Tissue Sampling

EUS-FNA for cytological approach is deemed time consuming and often unable to provide suitable specimens for modern molecular analyses. A recent prospective study compared the cytological analysis of 130 specimens obtained by EUS-FNA

Fig. 1 EUS-FNA with a 19G needle of an echo-poor tumor in the tail of the pancreas in a 48-year-old male patient. Histology showed a poorly differentiated pancreatic carcinoma

with a 22G needle cytological approach with a separate cohort of 130 specimens that were immediately formalin fixed to preserve microcores of tissue prior to routine histological processing [38]. This study found that direct formalin fixation significantly shortened the time required for diagnosis from 3.6 to 2.9 days ($p < 0.05$) by reducing the average time (140 vs. 33 min/case) and number of slides (9.65 vs. 4.67 slides/case) for histopathological processing. Specificity and sensitivity yielded comparable results between the two approaches (82.3% vs. 77% and 90.9% vs. 100%). Importantly, EUS-FNA histology preserved the tumor tissue architecture with neoplastic glands embedded in stroma in 67.89% of diagnostic cases compared to 27.55% with the standard cytological approach ($p < 0.001$). Furthermore, microcore samples were suitable for molecular studies including the immunohistochemical and mRNA analyses. This novel approach is suggested to be suitable for future investigational trials in pancreatic cancer patients, e.g., to obtain predictive signatures prior to a planned neoadjuvant treatment.

Another fascinating and highly promising field is the use of molecular markers, e.g., DNA-analysis or genetic analysis and quantitative studies of oncogene mutations (e.g., K-ras) in specimens obtained from EUS-FNA to differentiate malignant and benign pancreatic masses, to increase accuracy of early diagnosis or to assess prognosis of pancreatic cancer patients. Various molecular markers have been considered useful and have been tried. In a study by Tada et al. [39], the combination of cytology and analysis for mutant K-ras was shown to improve diagnostic accuracy, as cytological diagnosis of malignancy by EUS-FNA was achieved in only 62% of patients with pancreatic cancer, whereas mutant K-ras was detected in 77% of the EUS-FNA aspirates from cases with pancreatic carcinoma. When cytology and K-ras mutation detection were combined, the diagnostic accuracy increased to 81%. Importantly, K-ras mutations were absent in cases with a suspicious cytology from benign pancreatic lesions. Recent miRNome analyses show that PDAC and IPMN have differential miRNA profiles with respect to controls, with a large number of deregulated miRNAs shared by both neoplastic lesions. Overall, 30 miRNAs whose expression is significantly increased in PDAC and IPMN lesions were identified and validated in this study. The feasibility of detecting these miRNAs in

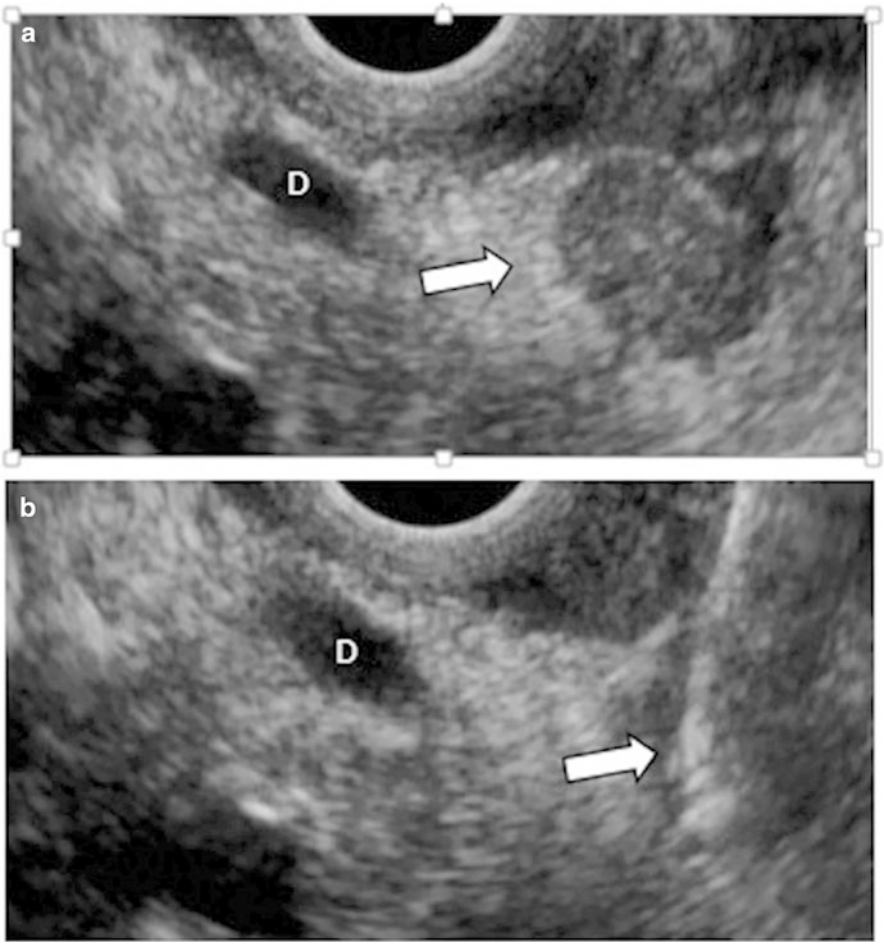

Fig. 2 (**a**) Suspected lymph node metastasis in a 56-year-old male patient with chronic pancreatitis and a mass in the head of the pancreas (D pancreatic duct, *arrow* peripancreatic lymph node) (**b**) EUS-FNA of peripancreatic lymph node (D pancreatic duct, *arrow* needle within lymph node). Histology revealed chronic inflammation but no sign of malignancy

endoscopic ultrasound-guided fine-needle aspiration samples make them good biomarker candidates for early detection of pancreatic cancer [40]. A second study demonstrated that a 2-miRNA classifier (miR-21 + miR-155) was capable of distinguishing benign from malignant pancreatic lesions in EUS-FNAs with a sensitivity of 81.5% and a specificity of 85.7% (AUC 0.930) [41]. EUS-FNA cytology genotyping using next-generation sequencing of a 160 cancer gene panel revealed a broad spectrum of pathogenic alterations that showed a high degree of concordance to paired surgical resection specimens. This fidelity suggests that sequencing analysis of gene panels in EUS-FNA may be used for molecular stratification of pancreatic tumors as the basis to personalize therapeutic decisions [42]. Yet, most of these

studies are still based on relatively small numbers of patients and on research conditions and are not yet widely applicable. Thus, encouraging and fascinating these and similar results cannot be extrapolated to everyday clinical practice yet and require further validation by studies incorporating larger patient numbers.

EUS for Cystic Pancreatic Neoplasias (CPNs)

Pancreatic cysts detected by imaging in asymptomatic patients may correspond to a variety of pathologies ranging from benign cysts (pseudocysts, serous cystic adenomas (SCA), true cysts) and premalignant or malignant cystic neoplasias (mucinous cystic neoplasms (MCNs), intraductal papillary mucinous neoplasms (IPMNs), solid pseudopapillary neoplasms (SPN), cystic pancreatic neuroendocrine neoplasias (cpNEN), serous cystadenocarcinomas). However, since up to 50–60% of the incidental pancreatic cysts detected by imaging show connections to pancreatic duct, they most likely represent intraductal papillary mucinous neoplasms (IPMNs), although there is no firm pathology to support this.

Several EUS findings have been evaluated as diagnostic criteria for pancreatic cystic lesions [43]. When surgical histology is used as a reference standard, the diagnostic accuracy of EUS imaging ranges from 40% to 96%. In a prospective study, the overall accuracy of EUS morphology for differentiating mucinous cysts (MCNs and IPMNs) from nonmucinous cysts was low (51%) [44]. In addition EUS imaging cannot reliably distinguish benign from malignant IPMNs; however, EUS may be useful in identifying predictors for malignancy. A meta-analysis including 1,373 patients found that a mural nodule, main pancreatic duct dilation, thickened septal walls, and cyst size >3 cm on radiologic or EUS imaging were independent predictors of malignant branch-duct IPMN [45]. Recently, an international consensus guideline developed in Fukuoka (Japan) identified a main pancreatic duct (MPD) size >10 mm or the presence of an enhancing solid component on radiologic imaging as high-risk stigmata (HR) [14]. Worrisome features (WF), thought to be associated with lower risk, included a cyst size of >3 cm, thickened enhancing cyst walls, nonenhancing mural nodules, MPD size of 5–9 mm, an abrupt change in the MPD caliber with upstream pancreatic atrophy, or the presence of peripancreatic lymphadenopathy (see Table 1). HR cysts are recommended to undergo surgery because of high cancer prevalence, for WFs cysts endoscopic ultrasonography (EUS) eventually with EUS-FNA for further risk stratification, and for non-HR/non-WF cysts cysts periodic surveillance at various intervals are recommended.

In the event that the combination of all available imaging modalities including contrast-enhanced MD-CT, MRI, and MRCP with diffusion weighting and EUS do not clarify the diagnosis EUS-guided aspiration of cyst fluid may help in establishing the nature of the cystic lesion. Cyst fluid sampled by EUS-FNA may be analyzed for cytologic, chemical, and/or molecular studies. Malignancy within a cystic neoplasm can be identified by cytology with 83–99% specificity, although reported sensitivities vary from 25% to 88% as summarized in [43]. Thus, a negative cytology does not help in the decision whether a pancreatic cyst is malignant or not. In addition to

Table 1 Risk stratification of branch-duct IPMN according to Fukooka guidelines

High-risk stigmata	Obstructive jaundice and cystic lesion in head of pancreas
	Enhancing solid component within cyst
	Main pancreatic duct ≥10 mm
Worrisome features	Clinical: presence of pancreatitis
	Imaging:
	Cyst ≥3 cm
	Thickened/enhancing cyst walls
	Main duct 5–9 mm
	Nonenhancing mural node
	Abrupt change in caliber of pancreatic duct with distal pancreatic atrophy

cytology, cyst fluid is analyzed routinely for amylase levels and the tumor marker CEA. These analyses do not allow to identify malignant cysts but they may help to differentiate mucinous cysts from serous cysts or pseudocysts. Studies indicate that amylase levels <250 U/L virtually exclude a pseudocyst (specificity 98%) [46] and a CEA cutoff of 192 ng/mL differentiates mucinous from nonmucinous cysts, providing a sensitivity of 75% and a specificity of 84% [44]. This is highly relevant for clinical management since nonmucinous cysts such as serous cystic adenomas have virtually no risk of malignancy and do need a less intense and no follow-up if stable after an initial follow-up period [47]. In contrast mucinous lesions such as MCN and IPMN have an inherent risk of malignancy and thus either need to be followed up more closely or resected when risk signs are present [14, 48].

In a recent a multicenter, retrospective study of 130 patients with resected pancreatic cystic neoplasms cyst fluid was analyzed to identify subtle mutations in genes known to be mutated in pancreatic cysts (BRAF, CDKN2A, CTNNB1, GNAS, KRAS, NRAS, PIK3CA, RNF43, SMAD4, TP53, and VHL) [49]. With this combined analyses, the authors identified molecular markers and clinical features that classified cyst type with 90–100% sensitivity and 92–98% specificity. The molecular marker panel correctly identified 67 of the 74 patients who did not require surgery and thereby reduced the number of unnecessary operations by 91%. In a recent study next-generation sequencing was most valuable in identifying mucinous cysts with nonmucinous CEA levels in cyst fluid FNA [50]. Molecular analysis of pancreatic cyst fluid sampled by EUS-FNA will most likely form part of the routine evaluation of pancreatic cysts, in particular, of those where size or risk features would lead physicians to recommend surgical resection.

An intriguing new approach is the development of a needle-based confocal laser endomicroscopy. A small probe can be advanced through a 19-gauge needle directly into the tissue or lesion of interest. A pilot study in pancreatic cystic neoplasms revealed a high specificity (100%) while sensitivity was low (59%) [51]. Another pilot study used this device to identify a vascular network pattern characteristic for serous cystic neoplasms [52]. Further validation of this technique will be necessary before it can be introduced in clinical practice (Figs. 3–5).

Fig. 3 Mainduct-IPMN in the tail of the pancreas in a 65-year-old female patient. Histology after distal pancreatic resection demonstrated an IPMN without signs of invasiveness

Fig. 4 Suspected serous cystadenoma in the head of the pancreas in a 77-year-old male patient

Fig. 5 Multiple branch-duct-IPMNs in a 68-year-old female patient. EUS showed several lesions with mucin but also mural nodules (worrisome features)

Screening of Individuals at Risk for Familial Pancreatic Cancer

Recent expert consensus conferences [53] considered it appropriate to perform pancreatic cancer (PC) screening in high-risk individuals for familial pancreatic cancer using a multidisciplinary approach under research protocol conditions. However, neither biomarkers nor reliable imaging modalities for the detection of high-grade precursor lesions are yet available. Most screening programs are currently based on EUS and magnetic resonance imaging, and first data demonstrated that PC precursor lesions such as IPMNs can be identified [53, 54]. There is yet no consensus regarding the age to initiate or stop screening and the optimal intervals for follow-up [53, 55–57]. A recent multicentric study could demonstrate that surveillance in high-risk individuals for pancreatic cancer carrying CDKN2A mutations was relatively successful, detecting the majority of PDACs in a resectable stage. In 13 of 178 screened high-risk individuals pancreatic adenocarcinoma was detected that could be resected in 75% [57]. In contrast, the value of surveillance for non-CDKN2 familial pancreatic cancer (FPC) family members is still not clear, and the main effect seems to be prevention of PDAC by removal of preneoplastic lesions such as IPMNs, which belong to the pancreatic phenotype of high-risk individuals for familial pancreatic cancer [54]. With further improvements in MRI technology and its wide availability, EUS may turn out to be an additional tool rather than the main test in surveillance programs. Envisaged applications for EUS are to supplement MRI combined with MRCP in longer time intervals and for specific tasks, such as the high resolution imaging of cystic pancreatic lesions. A recent multicentric study reached the conclusion that non-CDKN2A high-risk individuals for familial pancreatic cancer should receive annual MRI-based screening, starting at the age of 50, supplemented by EUS at the baseline examination. If unremarkable at baseline, the authors recommend to perform EUS only every 3 years in addition to MRI or when changes become evident in the annual MRI, eventually combined with EUS-FNA [56].

EUS-Guided Therapy: Overview and Perspectives

EUS has not only broadened its diagnostic spectrum by the use of EUS-FNA but has also entered the area of endoscopic therapy injected intra- or peripancreatically using EUS guidance.

EUS-CPN

EUS-guided celiac plexus neurolysis (CPN) in patients with refractory abdominal pain due to pancreatic cancer may be an option that has been described in detail elsewhere [58]. Advancing the needle via a transgastric approach, EUS-CPN aims to ablate the neurons of the celiac ganglia through the injection of cytolytic agents such as alcohol or phenol with prior injection of a local anesthetic (e.g., bupivacaine). Usually more than one session is necessary to achieve effective and persistent pain

relief. In an initial randomized study that compared EUS- and CT-guided CPN, the EUS approach was found to be superior [59].

A double-blind, controlled trial found that early EUS-CPN reduces pain and may moderate morphine consumption in patients with newly diagnosed, painful, inoperable pancreatic cancer [60].

The most common complications of EUS-guided CPB and CPN include transient diarrhea, pain, and hypotension, which are usually self-limiting. Gastroparesis, retroperitoneal hemorrhage, and peripancreatic abscess are rarely reported complications. However, serious adverse events include paralysis after infection of the anterior spinal cord [61], gastric perforation due to necrosis after multiple procedures [62], and infarction due to celiac artery thrombosis [63].

EUS-Guided Radiotherapy

EUS-guided fiducial placement has been used to aid in image-guided radiation therapy. Fiducials can be placed with either 19-gauge or 22-gauge needles using a technique comparable to EUS-guided FNA with or without fluoroscopy [64]. The rate of adverse events from fiducial placement is comparable to that of EUS-FNA of the pancreas. Adverse events include mild pancreatitis, minor bleeding, and fiducial migration, requiring a repeat procedure [65]. Alternatively, intratumoral radioactive seed implantation in combination with chemotherapy has been studied in 22 cases with three partial remissions and stable diseases reported. However, cancer progressed in 20 patients, all of whom died during 2 years of follow-up [66]. An additional study could not show any significant survival benefit by combining EUS-brachytherapy with gemcitabine-based chemotherapy, though a significant improvement in pain control was observed [67].

EUS-Guided Application of Immunotherapy

An allogeneic mixed lymphocyte culture (cytoimplant) delivered by endoscopic ultrasound-guided fine-needle injection in patients with advanced pancreatic carcinoma supposed to activate the host immune system was tested in a phase I trial in eight patients. Two partial and one minor response were observed with no major complications [68]. A pilot study evaluated the potential of EUS-guided injection of dendritic cells [69]. Only five patients were included yielding mixed results, though no adverse events were observed. EUS-guided transgastric/transduodenal or percutaneous intratumoral injection of tumor necrosis factor biological (TNFerade) in combination with chemoradition was tested in a large randomized trial with 304 patients with locally advanced tumors. Injection appeared safe but did not prolong survival as compared to chemoradiation alone [70]. Surprisingly, multivariate analysis showed that TNFerade injection by an endoscopic ultrasound-guided transgastric/transduodenal approach rather than a percutaneous transabdominal approach was a risk factor for inferior PFS (HR, 2.08; 95% CI, 1.06 to 4.06; $P = 0.032$).

EUS-Guided Biliary and Gastric Drainage

The use of EUS to guide biliary drainage has become an option when access to the bile duct via ERCP is not possible. Several techniques have evolved in recent years among others comprising EUS-guided guidewire placement into the common bile duct using EUSguidance and then passed through the papilla to guide further ERCP interventions as well as the direct EUS-guided transgastric or transduodenal puncture and stent placement into the common bile duct. Studies have reported high technical and clinical success rates in almost 90% of cases, but also adverse events in 10–20% [71, 72] including stent migration, bile leak, biliary peritonitis, and pneumoperitoneum.

There are limitations to enteral self-expandable metal stents and surgical gastrojejunostomy in the treatment of patients with gastric outlet obstruction (GOO). EUS-guided gastroenterostomy (EUS-GE) inserting a lumen-apposing metal stent in an adjacent jejunal loop under EUS guidance is a novel procedure that potentially offers long-lasting luminal patency without the risk of tumor ingrowth and/or overgrowth while avoiding the morbidity of a surgical procedure. In the small patient series published to date, technical success rates up to 90–100% with no or only mild procedure-related adverse events have been reported [73, 74].

Endoscopic Treatment of Cystic Lesions

Recently, endoscopic cyst ablation with ethanol alone or in combination with paclitaxel for suspected pancreatic cystic neoplasms has been proposed as an alternative to surgery [75, 76]. Since the procedure is associated with significant side effects, uncertainties remain regarding the durability of the approach, and it is unclear whether patients remain at risk to develop pancreatic cancer after cyst ablation; EUS-guided cyst ablation is not recommended as routine intervention. It should be reserved for individual centers performing this procedure using research protocols and for patients who have high-risk lesion and are not candidates for surgery [43].

Conclusion

In experienced hands EUS is the most sensitive imaging modality for pancreatic tumors <2 cm, the major limitation being its operator dependence. It has a role for preoperative pancreatic cancer staging and appears to be most useful as adjunct when staging is inconclusive in CT. Additional useful applications include the differential diagnosis of solid and cystic pancreatic lesions, rendering EUS an important baseline and adjunct screening tool in MRI-based research screening protocols for high-risk individuals for familial pancreatic cancer. EUS-guided tissue acquisition either as FNA or FNB has been established as an essential tool for differential diagnosis of pancreatic masses and cystic pancreatic lesions that is

associated with low overall complication rates. The use of EUS-FNA/FNB material for molecular analyses will expand the possible applications, e.g., for the molecular stratification of cystic pancreatic lesions or for the prognostic and predictive stratification of pancreatic cancer. EUS-guided therapeutic applications have been developed, and in particular the use of EUS to guide celiac plexus neurolysis (CPN) or biliary drainage is being used in everyday clinical practice. Overall, EUS has evolved as indispensable imaging modality for the diagnosis, staging, and screening of pancreatic cancer and its precursor lesions, with exiting novel diagnostic and therapeutic applications.

Laparoscopic Staging in Patients with Newly Diagnosed Pancreatic Cancer

Timothy Gilbert, Ryan Baron, Paula Ghaneh, and Christopher Halloran

Contents

Abstract

Prompt accurate staging is paramount in managing patients with newly diagnosed pancreatic cancer. Initially, diagnosis and staging are undertaken using contrast-enhanced multidetector computerized tomography (CE-MDCT) or magnetic resonance imaging (MRI), supplemented with endoscopic ultrasound in selected cases. Staging laparoscopy (SL) with or without laparoscopic ultrasound (L-LUS) has been

found to detect occult disease in 13–28% of patients with pancreatic cancer who are considered potentially resectable on imaging; however, between 1% and 30% of patients thought to be resectable on SL/L-LUS have subsequently been found to have unresectable disease. The clinical utility of SL/L-LUS can be enhanced by adopting a selective approach, only undertaking SL/L-LUS when one or more criteria are present, including (1) presumed pancreatic primary >3 cm diameter, (2) lesions in the body and tail of the pancreas, (3) CA 19–9>150 kU/L (>300 when total bilirubin >35 micromol/L), and (4) platelet/lymphocyte ratio >150. The judicious use of SL/L-LUS and cross-sectional imaging are complementary; however, the advent of PET-CT may lead to improvements in the detection of small previously radiologically occult metastases and may reduce the future role of SL/L-LUS.

Introduction

It is clear that over the last 15 years, a combination of better staging, surgical refinement, and standard use of adjuvant chemotherapy has achieved an unprecedented increase in survival of patients with pancreatic cancer, who have had surgery to around 30% at 5 years [1–4]. The importance of diagnosis and staging in the management of pancreas cancer becomes evident when surveying the outcome of patients with localized versus advanced disease.

Given the marked differences in survival between those who undergo potentially curative resection compared to those who cannot, accurate selection of patients for surgery is essential. Accurate selection for potentially curative resection will ensure this is undertaken in only patients who will benefit, and major abdominal surgery avoided in the vast majority of those who will not.

A variety of imaging strategies have been studied to determine the optimal approach to diagnosis and staging of suspected pancreatic cancer [5–15]. Contrast-enhanced multidetector computerized tomography (CE-MDCT) (see chapter ▶ "Pancreatic Adenocarcinoma: CT and PET/CT"), magnetic resonance imaging (MRI with or without magnetic resonance cholangiopancreatography, MRCP) (see chapter ▶ "MRI and MRCP for Diagnosis and Staging of Pancreatic Cancer"), endoscopic ultrasound (EUS), and staging laparoscopy with or without laparoscopic ultrasound (SL/L-LUS) have all been compared, and each has their protagonists. Current recommendations [4, 16, 17] agree on a standard approach making use of abdominal imaging with CE-MDCT performed according to a defined pancreas protocol with dual arterial and portal venous contrast phases, supplemented selectively with other adjuncts including MRI/MRCP and EUS [4]. Positron emission tomography–computed tomography (PET-CT) is considered an additional diagnostic adjunct to CE-MDCT and MRI, not a substitute for these modalities [4]. SL/L-LUS is only considered a selective adjunct to diagnosis and is not routinely included in any of the current major international guidelines.

Background to Staging and Assessment by Radiological Imaging

Contrast-enhanced multidetector computerized tomography (CE-MDCT) is the "gold standard" for clinical/radiological staging, since the reported accuracy of CE-MDCT using 2D and 3D algorithms in predicting resectability can exceed 95%, with a sensitivity of 94% and a specificity of 89% [5, 7, 11, 14, 18] (see chapter ▶ "Pancreatic Adenocarcinoma: CT and PET/CT"). Resectability rates may, however, appear artificially high if surgeons adopt a more conservative approach, operating only on easy cases and do not attempt resection in borderline resectable cases. Nevertheless, in the hands of experienced pancreatic radiologists using CE-MDCT, local tumor extension, vascular involvement, and lymph node and liver metastases correlate closely with surgical findings [14].

MRI using ultrahigh-field magnetic resonance has been reported to be superior to CT in the detection of non-contour-deforming masses (small pancreas cancers) due to its superior soft tissue contrast [6, 8] (see chapter ▶ "MRI and MRCP for Diagnosis and Staging of Pancreatic Cancer"). MRI may also be preferable for characterizing small liver and peritoneal/omental metastases [6]. MRI, MRI spectroscopy, and MRI functional imaging are under development to distinguish malignant from benign pancreas tumors, using protocols based on signal intensity [15], but these techniques are yet to gain a place in optimal standard staging approaches.

EUS with or without fine needle aspiration (FNA) biopsy has been found in one study to be highly accurate in diagnosing pancreas cancer (99%) with 88% sensitivity, 100% specificity, 100% PPV, and 99% NPV in patients with ambiguous CT findings [9]. These impressive results, however, were retrospective, and surgical confirmation of diagnoses was available in only a small proportion of these patients. EUS has the advantage of enabling biopsy, but a negative FNA does not exclude cancer, and the approach is highly operator dependent. Although EUS is the preferred biopsy route rather than percutaneous image-guided approaches, a decision to operate does not require histological confirmation, although this is required prior to administration of neoadjuvant or palliative chemotherapy [4, 19].

Positron emission tomography–computed tomography (PET-CT) (see chapter ▶ "Pancreatic Adenocarcinoma: CT and PET/CT") has recently emerged as a new imaging modality in pancreatic cancer. PET-CT is found to have a similar sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) in evaluating primary tumors as CE-MDCT [10, 20, 21], EUS [13, 22], and MRI [20], indicating that PET-CT does not add to the determination of resectability of local disease. However, the majority of this evidence is from small, single-center retrospective studies. The true value of PET-CT may lie in its ability to detect metastatic disease, with studies showing it to have a much greater sensitivity than MDCT or MRI, altering proposed surgical management in 10–45% of patients deemed resectable post MDCT/MRI [20, 23, 24]. In addition it has significant advantage in diagnosing invasive transformation within premalignant lesions [25], such as intraductal papillary mucinous neoplasms (see chapter ▶ "Management of Cystic Neoplasms of the Pancreas Including IPMNs"). The

full published results of the multicenter prospective PET-PANC trial are awaited; however, preliminary data demonstrates significantly improved sensitivity (92.7% vs. 88.5%, $p = 0.010$) and specificity (75.8% vs. 70.6%, $p = 0.023$) of FDG PET-CT over MDCT in diagnosing pancreatic cancer. FDG PET-CT correctly changed staging in 14% of patients and influenced the management of 45% of patients in the trial, importantly preventing futile attempted resection in 20% of patients due to undergo surgery [26].

Despite these significant advances in imaging techniques, even with state-of-the-art machines, metastatic lesions <5 mm may still not be detected, as is often the case in small hepatic and peritoneal deposits. Presence of these deposits would likely render the otherwise radiologically resectable or borderline resectable patient unresectable and thus preclude the need for an ultimately futile laparotomy. This has a cost benefit but more importantly a benefit to the patient allowing prompt initiation of alternative treatment pathways, i.e., neoadjuvant or palliative treatment. SL/L-LUS as an adjunct to radiological staging enables direct visualization of the peritoneal cavity thus providing an opportunity to identify these small lesions and simultaneously assess local resectability particularly with respect to vascular structures. The rationale for SL/L-LUS is that it enables (1) confirmation of diagnosis when in doubt; (2) the detection of radiological occult metastasis including biopsy of suspicious lesions; (3) assessment of local resectability and (4) peritoneal cytology; it aims to prevent unnecessary operations which (5) decrease patient morbidity; (6) it enables prompt initiation of more appropriate treatment pathway, i.e., chemotherapy; and (7) it provides more cost-effective/patient acceptable disease management.

SL/L-LUS in Potentially Resectable Patients

As is implicit in the discussion above, SL/L-LUS is an aid to diagnosis and staging, but not a sine qua non. It must be remembered that laparoscopy is an invasive procedure requiring general anesthetic and the relative absence of adhesions from prior disease or interventions to fully inspect the peritoneal cavity. Even then the view of the peritoneum is an extensive sampling rather than a complete inspection, and as regards the liver, small metastases (5 mm diameter or less) are only likely to be identified on the capsular surface. Larger liver metastases can be identified with a laparoscopic ultrasound (LUS) probe, an examination which requires gentle, systematic, and complete liver scanning; although, larger metastases should be identified preoperatively by an up-to-date CE-MDCT or MRI. In addition, LUS can be used as an adjunct when assessing local respectability by helping to delineate vessel encroachment. The guidelines published by the British Society of Gastroenterology and other UK specialist societies in 2005 recommend that when available, SL/L-LUS may be appropriate in selected patients with pancreas and periampullary cancer (recommendation grade B) [27], although the practice is not yet generally incorporated in other international guidelines [4, 16, 17]. SL/L-LUS has been found in studies, from specialist pancreatic centers, to identify occult advanced and metastatic

disease in 13–58% of patients considered resectable on radiological grounds; the majority of failures to detect occult disease are due to failure to appreciate fully the degree of vascular involvement in locally advanced cases rather than missed liver or peritoneal metastases (see Table 1). Most of these studies are highly selected and designed to answer specific questions: role of preoperative cancer antigen 19-9/sialylated Lewis (a) antigen (CA19-9) (see chapter ▶ "Development of Novel Diagnostic Pancreatic Tumor Biomarkers") in selection of patients for staging [28, 29], preoperative inflammatory markers [30], subsets of peripancreatic cancers [31], or cost-effectiveness [32]. To date there are no randomized clinical trials looking at the use of laparoscopy. There has been one meta-analysis and three systematic reviews reviewing the role of laparoscopy following imaging for "resectable" pancreatic cancer. Hariharan et al. in 2010 [33] looked at the benefit of SL/L-LUS in 2827 patients across 22 studies with radiologically resectable pancreatic/peri-pancreatic cancer. Results from this analysis showed the pooled sensitivity and specificity of SL/L-LUS for the detection of liver and peritoneal lesions to be 88% (95% CI 83–92) and 92% (95% CI 84–96), respectively. However, sensitivity for detection of locally advanced disease was poor: 58% (95% CI 51–65). The pooled yield of SL/L-LUS, i.e., proportion of patients in whom unnecessary laparotomy was avoided, was 25%. A Cochrane review, undertaken by Allen et al. in 2013, reported similar results [34]. This included 15 studies with a total of 1015 patients diagnosed with resectable pancreatic/periampullary cancer following initial staging CT scan. They reported a pooled sensitivity for SL/L-LUS of 68.7% (95% CI 54.3–80.2%). From the included studies, the authors calculated a median pretest probability for unresectable disease of 0.403. This would equate to 23% of patients avoiding an unnecessary laparotomy post SL/L-LUS [34]. The authors recognized the potential impact of advances in CT scan technology and adjusted for this by performing a post hoc meta-regression of studies published before and after the year 2000 and found no statistically significant difference. This was reviewed by the same group again in 2016 [48], with 16 studies, confirming a similar result (avoidance of 21 unnecessary laparotomies). Levy et al. in 2016 [49] performed a systematic review of prospectively conducted studies assessing the accuracy of SL/L-LUS in assessing the resectability of pancreatic tumors, comparing the predicted resection rates of SL/L-LUS with standard preoperative imaging and determining how the accuracy of these modalities has evolved over time. Nineteen prospective studies met the inclusion criteria including 1573 patients; 11 of these studies were performed after January 2000 in the MDCT era. Overall SL/L-LUS improved the resection rate of pancreatic malignancies from 55% to 79% over standard preoperative imaging, preventing non-curative laparotomy in 33% of study patients, with no increase in mortality and only a 0.8% complication rate. The added benefit of LUS to staging laparoscopy was directly addressed in three studies [50–52], which collectively showed a doubling of the yield of unresectable disease versus non-ultrasound laparoscopy alone.

Subgroup analysis of more recent studies (2009–2014), studies post January 2000, and studies comparing only MDCT imaging all demonstrated comparable findings with resection rates of 100% and 81% (two studies), 74% and 58% (four

Table 1 Identification of metastatic disease with SL/L-LUS in patients considered potentially resectable on radiological grounds

Study	Technique	Resectable patients (imaging)	Patients undergoing L-LUS	Patients unresectable on L-LUS (%)	Patients undergoing surgical exploration following L-LUS (%)	Non-resected (missed occult disease) following L-LUS (%)	Patients who underwent resection following L-LUS (%)

Does not include Connor et al. 2005 [46] or Smith et al. 2008 [47] as these reports include patients included in [28, 38]

studies), and 100% and 78% (one study) for SL/L-LUS versus MDCT, respectively.

All of these reviews acknowledge significant study heterogeneity, particularly with regard to resectability criteria, requirement to offer surgery for gastric outlet obstruction prior to routine use of duodenal stenting, multimodal imaging protocols, and the quality of CT technology.

Selective Criteria for SL/L-LUS

The advent of the MDCT era and more accurate preoperative imaging assessment of resectability results in a larger number of SL/L-LUS required to be performed to prevent one unnecessary laparotomy; Friess et al. demonstrate that only one laparotomy is avoided for every eight laparoscopies performed in patients with pancreatic cancer resulting in a reduction in the cost-benefit relationship associated with SL/L-LUS [53, 54]. These findings led to questioning of the clinical utility of SL/L-LUS on a routine basis and suggested a move toward selective SL/L-LUS. In addition to equivocal radiological staging, proposed criteria on which to select patients for SL/L-LUS include tumor size and tumor location, with clinical and laboratory findings associated with risk of locally advanced disease or metastasis such as hypoalbuminemia, weight loss, raised CA19-9, and back pain [55].

CA19-9

Early work by Doran et al. (2004) found SL/L-LUS to correctly identify unresectability in 28 (15%) of 190 patients considered potentially resectable on radiological (CE-MDCT) grounds [38]. Subsequent work by Connor et al. (2005) suggested that the utility of SL/L-LUS could be improved to detect unresectability in 20/78 (25%) of those considered potentially resectable, by selecting only those for SL/L-LUS with elevated CA19-9 levels above 150 kU/L or above 300 kU/L in the presence of an elevated serum bilirubin (>35 micromol/L, to account for the effect of cholestasis) [46]. This strategy was tested prospectively in a cohort of 164 [28] subsequent patients with potentially resectable disease on CE-MDCT. Ninety-four patients (including 14 who had gastric outlet obstruction and a high CA19-9, who would need surgery regardless) went straight to surgery. Sixty-three of the 80 (79%) patients with low CA19-9 were resected versus 2/14 (14%) with high CA19-9 and symptoms. Alternately, 70 patients went to L-LUS; this included 55 patients with high CA19-9 *and* 15 patients with low CA19-9 but with suspicious CT features. Nine patients (13%) were unresectable on L-LUS (one patient with low CA19-9). Thirty-seven patients were considered resectable of whom 30/37 (80%) were resected, 28 with a high CA19-9 and 4 with a low CA19-9. The other 24 patients were thought to have features of borderline respectability (notably vascular contact/distortion); 7/24 (29%) were resected, 5 with a high CA19-9 and 2 with a low CA19-9. The sensitivity of L-LUS for detecting unresectable disease in patients with a high CA19-9 level was 33%. This assumed that all borderline disease seen on L-LUS was resectable ($P < 0.001$). This remained the case even when borderline operable L-LUS disease

was assumed to be inoperable, in which case the sensitivity, specificity, positive predictive value, negative predictive value, and accuracy for L-LUS in detecting unresectable disease became 52%, 93%, 79%, 79%, and 79%, respectively ($P < 0.001$) [28]. These findings are supported by data from the Memorial Sloan-Kettering Cancer Center (MSKCC): in 262 patients with radiologically resectable pancreatic cancer, preoperative CA19-9 >130 U/ml was strongly associated with the identification of unresectable disease (HR 2.70; 95% CI 1.34–5.44; $P = 0.005$) [56].

Pancreatic Tumor Size and CA19-9

Satoi et al. selected patients for SL/L-LUS with both of the previously established risk factors for unresectable disease tumor size >3 cm [57, 58] and CA19-9 >150 U/ml [28, 46, 59]. Of 61 patients in this cohort, 16 patients underwent laparoscopy, 5 (31%) of which were unresectable. The remaining 11 patients were all resected. Only 4.4% of patients who did not meet the criteria for laparoscopy and went straight to laparotomy were found to have unresectable disease. The combination of tumor size >3 cm and CA19-9 > 150 U/ml was significantly associated with disease unresectability ($p = 0.0147$). The relatively high rate of vascular resection in this case series may account for the high resection rates observed with 29% of patients undergoing either portal vein or coeliac trunk resection [29].

Platelet/Lymphocyte Ratio

Smith et al. (2008) hypothetically evaluated the addition of the platelet/lymphocyte ratio to the currently used Ca19-9 selection criteria. Platelet/lymphocyte (P/L) ratio >150 was used as a marker for a pro-systemic inflammatory response associated with tumor invasiveness [47]. Based on the group of patients selected for SL/L-LUS on the basis of CA19-9 alone, they found that the addition of platelet/lymphocyte ratio >150 could improve both the sensitivity (96% vs. 51%) and positive predictive value (95% vs. 83%) of SL/L-LUS beyond that of Ca19-9 alone. This additional criterion would have reduced the number of SL/L-LUS by 21% at the expense of only a 5% false positive rate in those additional patients going straight to laparotomy, which is comparable to that seen in existing cohorts going straight to laparotomy. The combination of indices has still to be tested prospectively.

Pancreatic Tumor Location

The location of the tumor within the pancreas also affects the rate at which radiologically occult metastatic disease is identified relating to the fact that body and tail lesions usually present later due to a paucity of early symptoms compared with lesions in the pancreatic head [60, 61]. Two studies of SL/L-LUS have identified metastatic lesion twice as frequently when evaluating lesions in the body and tail of the pancreas compared with lesions in the head of the pancreas. Jimenez et al. identified metastasis in 39% of patients with body and tail lesions compared with only 17% of pancreatic head lesions [62], whereas Liu et al. found metastases in 53% of body and tail lesions and 28% of pancreatic head lesions [63]. The overall higher rate of metastasis detection by Liu et al. reflects that their population only included patients with locally advanced radiologically unresectable pancreatic cancer

patients. The utility of SL/L-LUS based on histological diagnosis has also been analyzed. Both found that the incidence of radiologically occult unresectable disease was higher for pancreatic head lesions compared with duodenal or ampullary lesions. Vollmer et al. discovered metastatic disease or local invasion of vessels precluding resection in 31% of patients with radiologically resectable pancreatic head cancers at SL/L-LUS; in contrast no patients with carcinomas of the ampulla or duodenum were discovered to have either metastatic disease or locally advanced unresectable disease as a result of SL/L-LUS [31]. White et al. confirm this observation finding unresectability in 17% of patients with potentially resectable pancreatic head adenocarcinoma imaged outside their institution and 8% of patients imaged within their institution; in contrast only 4% of patients with "non-pancreatic" tumors were found to have unresectable disease [42]. Both authors support only using SL/L-LUS in patients with pancreatic head cancers rather than peripancreatic disease; however, often a firm histological diagnosis is a retrospective finding only after the lesion has been resected and subjected to histological analysis, and therefore the clinical significance of these studies may be limited.

Shah et al. report their experience of selective use of SL/L-LUS in patients with MDCT-presumed resectable pancreatic cancer based on five criteria: primary tumor >4 cm in diameter, weight loss >20%, ascites, CA19-9 >1000 kU/L, or ambiguous findings on CE-MDCT. In their study SL/L-LUS avoided unnecessary laparotomy in 11 of 49 (22%) patients. This improved the positive predictive value of their staging protocol from 69% based on MDCT assessment alone to 89% based on MDCT and SL/L-LUS findings combined. Interestingly, 49% of patients meeting their criteria for SL/L-LUS had radiologically questionable liver lesions on MDCT, and in the current era, MRI may be a more appropriate and noninvasive modality by which to further characterize these lesions rather than SL/L-LUS.

Peritoneal Cytology at L/LUS

The value of peritoneal cytology obtained at SL/LUS for the staging of pancreatic cancer has been highlighted in work by Warshaw and colleagues at the Massachusetts General Hospital [60, 62, 64–66]. This work suggests that the presence of pancreatic adenocarcinoma cells in peritoneal ascites or irrigation fluid (undertaken with 500 ml saline) is a feature of advanced disease (M1 on the TNM system), whether or not there is other evidence of unresectability. Such a classification is consistent with the seventh edition of the American Joint Committee on Cancer (AJCC) staging system, which classifies positive peritoneal cytology as stage IV disease for pancreatic adenocarcinoma [67]. Supporting this Merchant et al. demonstrated that positive peritoneal cytology had a positive predictive value of 94%, specificity of 98%, and sensitivity of 25% for determining unresectability [68]. Although reduced overall survival associated with positive peritoneal cytology has been shown in a number of studies, median survivals are similar to that of patients with stage IV disease [69]. Yamada et al. demonstrated that resected patients with positive cytology had a significantly better survival (14.3 months) than patients with either cytology-negative or cytology-positive

unresectable disease (7.3 and 6.8 months, respectively; both <0.001). Among patients with positive cytology, median survival was longer in those who underwent adjuvant chemotherapy rather than those who underwent surgery alone (15.3 vs. 10.0 months) although this did not reach statistical significance. Positive cytology did not independently predict survival in their study [70]. The significance of positive peritoneal cytology on overall *and* disease-free survival has also been questioned in the setting of patients undergoing neoadjuvant chemotherapy prior to resection, although further research is required in this setting [71].

L/LUS in Radiologically Unresectable Patients

Many studies of the utility of SL/L-LUS have included patients with locally advanced unresectable disease [62, 63, 66, 72]. Two studies have included only patients with radiologically locally advanced unresectable disease due to vascular encasement [63, 73]. These studies found radiologically occult metastases on SL/L-LUS in 34% [63] and 37% [73] of patients. This distinction is clinically important in centers where patients with metastatic disease receive chemotherapy, whereas those with locally advanced unresectable disease in the absence of metastases receive chemoradiotherapy. By diagnosing radiologically occult metastatic disease, patients who will not benefit from chemoradiotherapy are spared the additional toxicity and time expenses associated with this therapy. On a population level, correctly staging patients to stage IV disease rather than stage III disease allows a better understanding of treatment protocols and stage-specific survival [73, 74].

Cost-Effectiveness of SL/LUS

An important issue in SL/L-LUS is its operational effectiveness, not least of which is cost. A cost study from the USA found that the use of SL/L-LUS in patients with pancreatic cancer does not add significantly to the overall expense of management: the cost for selective, routine use, or no use was found to be $91,805, $90,888, and $93,134, respectively [32]. By using pre- and posttest probabilities for unresectability [34], a UK study developed a model-based cost analysis for SL/L-LUS in pancreatic cancer [75]. Results of this analysis showed that laparoscopy prior to resection incurred similar cost per patient as proceeding straight to laparotomy, with the cost of the laparoscopy (£995) being offset by the savings of an unnecessary laparotomy (£7470; 95% CI £7215 - £7724 vs. £7480 95% CI £7219- £7741). Although, this was only the case if laparoscopy was performed at a separate sitting to the intended laparotomy as a positive SL/L-LUS conducted immediately prior to the intended laparotomy would result in a canceled operation and thus wasted theater resources. More importantly, however, this study showed that the quality adjusted life years (QALYs) were higher for SL/L-LUS compared to direct laparotomy (mean QALYs per patient 0.346 (95% CI 0.346–0.347) versus 0.337 (95% CI 0.337–0.338)) due to the morbidity associated with an unnecessary laparotomy [75]. A similar model-based cost analysis using published data on

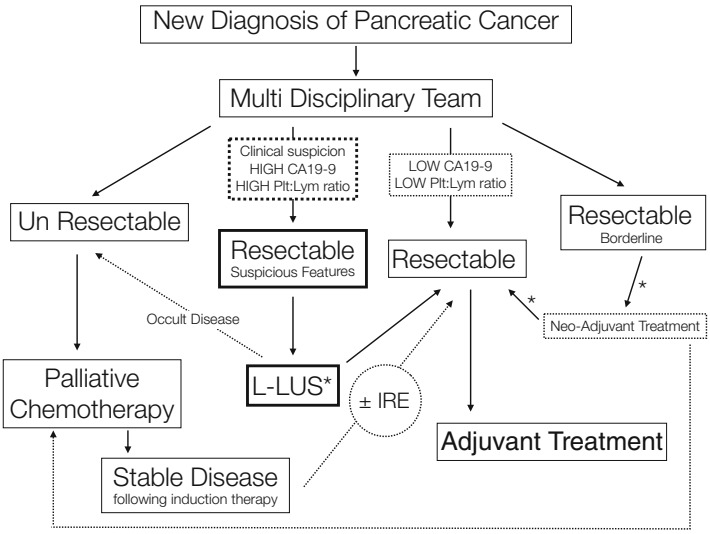

Fig. 1 Outlines a general algorithm to the management of pancreatic cancer, including selective application of L/LUS. *L-LUS* laparoscopy with laparoscopic ultrasound, *CA19-9* cancer antigen 19-9, *Plt: Lym ratio* platelet: lymphocyte ratio, *IRE* irreversible electroporation "Nanoknife™"

unresectability post-laparoscopy was conducted by a group in the USA [76]. In this study they also found an improvement in quality of life (QoL) when laparoscopy was performed prior to laparotomy and demonstrated a marginal cost saving (US$36,580 vs. US$46,830). As both these cost analyses rely on pooled estimates from the current literature, it's unclear whether the application of more selective criteria to patient selection of SL/L-LUS as discussed above would result in improved cost-effectiveness.

The current evidence would suggest that SL/L-LUS is at least cost neutral and appears to be associated with a slight improvement in QoL. It would therefore appear that the choice of whether to use SL/L-LUS in staging relates to other practical considerations, such as management priorities and practices, staff, and surgical and hospital resources, as well as additional uses to which laparoscopic approaches may be put to use, such as laparoscopic bypass surgery or evaluation of novel techniques or technologies (e.g., nano-device implantation). Figure 1 indicates where SL/L-LUS sits in current treatment algorithms.

Conclusion

Current imaging protocols and technology have resulted in significantly improved sensitivity and specificity for the diagnosis of locally advanced unresectable or metastatic disease. This has resulted in a reduction in the utility of SL/L-LUS, as it correctly identifies unresectable disease in only 15% of an *unselected* radiologically resectable population with pancreatic cancer. This has led to the *selective* use of SL/

L-LUS in patients considered at higher risk for metastatic or locally advanced cancers based on criteria such as tumor size and location, elevation of CA19-9, and questionable radiological findings. This selective use of SL/L-LUS has increased its positive predictive value back to 20–30%. Currently, SL/L-LUS is of greatest clinical utility in assessing for liver or peritoneal metastases (sensitivity 88% and 92%, respectively) and more limited in assessing locally advanced disease with vascular involvement (sensitivity 58%). The future use of SL/L-LUS will have to be continually reevaluated in light of advancing imaging technology, namely, FDG PET-CT, that is shown to improve staging of patients in a large multicenter prospective trial. This improvement in staging is of the same magnitude as that seen for SL/L-LUS, and it will be interesting to see if FDG PET-CT replaces the need for SL/L-LUS or finds a complimentary role alongside SL/L-LUS especially when combined with development in novel biomarkers. Development of future laparoscopic instruments, potentially incorporating confocal probes, may lead to prospective data on regional and or distant lymph node metastases, potentially even allowing sampling of crucial groups, allowing yet further staging potential.

Abstract

The results of anticancer therapy are suboptimal for pancreatic cancer and palliation of symptoms is an important goal. Pain, depression, cachexia, ascites, jaundice, thrombosis, and gastroparesis occur commonly in pancreatic cancer patients. Painless jaundice, often associated with cancer of the pancreatic head, can be surgically treated in resectable cases or managed with a biliary stent in patients with locally advanced or metastatic disease. Pain control is optimally achieved with the use of oral analgesics; however, a neurolytic celiac plexus block can be considered when oral opioids are ineffective. Depression is associated with poor symptom control, diminished social support, and advancing illness and should be treated. Symptoms of intractable nausea, early satiety, and weight loss, in the absence of mechanical gastric outlet obstruction, suggest gastroparesis. Prokinetic agents are beneficial for some patients, but in extreme cases, gastrostomy or jejunostomy is required. Cachexia is difficult to treat and requires nutritional support, orexigenic agents, diabetic control, and enzyme supplementation. Malignant ascites can be investigated with ascitic-serum albumin gradient; a high gradient in the absence of positive cytology suggests portal vein thrombosis. Constipation is common problem and can be treated with stool softeners, osmotic agents, and peripherally acting opioid receptor antagonists.

Introduction

Pancreatic cancer is one of the most feared diseases by patients and families because it is associated with symptoms that are often difficult to manage and poor prognosis. Indeed, there has been disappointingly little progress in the therapy for this disease over the past 30 years. Among patients with resectable disease, who undergo surgery alone, about 10% attain long-term survival, and roughly 20% survive only with some form of adjuvant therapy [1]. In advanced disease settings, the median survival duration is approximately 6 months and 18–23% of patients who receive palliative chemotherapy survive for 1 year [2]. Most patients who experience response to chemotherapy experience disease progression within 3–4 months and develop worsening of symptoms 1–2 months prior to documented treatment failure [3].

Cancer treatment yields a clinical benefit response in roughly 20–25% of patients overall [4], but only about 10% of moderate-to-severe symptoms at baseline improve [5]. The most prevalent and bothersome symptoms for patients with pancreatic cancer are fatigue, anorexia and weight loss, abdominal pain, constipation, and sleep disturbances [6]. Jaundice and pruritis are also common; more than two-thirds of patients with pancreatic head tumors experience jaundice. Biliary drainage is a critical first step in their palliation and should precede use of palliative chemotherapy.

Principles of Palliative Care

Palliative care is often misunderstood. Cancer patients, caregivers, and even healthcare providers believe palliative care is used only when no other options remain and results in a shortening of lifespan. The World Health Organization's definition of palliative care is:

> Palliative care is an approach that improves the quality of life of patients and their families facing problems associated with life-threatening illness through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual. [6]

Preliminary studies show earlier intervention by palliative care providers in patients with pancreatic cancer may improve QOL [7]. There are limitless methods of integrating optimal disease management and palliative care. The most appropriate plan for a given patient depends on many factors, including the trajectory of the patient's illness, the subjective experience of the symptoms, access to personal and professional care, and personal preferences.

Comprehensive Assessment

On the basis of our current understanding of symptom biology and symptom management, what does effective symptom-directed care involve? In interdisciplinary care, comprehensive assessments of the patient and family caregivers are collected and assimilated to help providers understand their sources of suffering. Appropriate interventions are implemented to reduce suffering, and most importantly, symptoms are reassessed. Assessment is not only the key to finding and solving various problems, but also a therapeutic tool in its own right. However, comprehensive assessment and treatment of a patient's symptom burden delivered in a longitudinal fashion is often challenging.

Multi-item screening tools, symptom surveys, and quality of life instruments are frequently used in research settings but are difficult to integrate into routine cancer-care practice in either academic or community settings. One commonly used pancreatic cancer-specific assessment module is the quality of life questionnaire-pancreatic

cancer module (QLQ-PAN 26), an instrument that comprises 26 questions on disease and treatment-related symptoms and emotional issues common in this disease including pain, altered bowel habits, dietary changes, jaundice, body image, sexual functioning, and emotional issues [8]. Another hepatobiliary cancer-specific module, the Functional Assessment of Cancer Therapy-Hepatobiliary (FACT-Hep), is also valid and useful, and an expert panel reduced the item pool from 26 to a final version involving 8 specific symptoms that were clinically relevant to address when treating hepatobiliary disease [9]. In nonresearch settings, pain assessment is the most useful starting point in pancreatic cancer care, and assessment of other symptoms often follows the same general model whereby the clinician ascertains the severity, location, timing, duration, precipitating factors, and relieving factors.

Establishing Goals of Care

Ms. N was a 60-year-old Caucasian woman with type II diabetes and hypertension. She experienced worsening glycemic control and weight loss for several months. Abdominal imaging revealed a large mass that infiltrated the body of the pancreas and celiac axis. Pulmonary, peritoneal, and right ovarian masses were visible and suggestive of metastatic disease. An ultrasound-guided fine needle aspirate confirmed ductal adenocarcinoma. She experienced moderate-to-severe right flank pain, chronic constipation, and early satiety.

The treatment goals in advanced pancreatic cancer care may include: cure, prolongation of life, control of symptoms, promotion of quality of life, and prevention of suffering. Some goals may be pursued simultaneously, and sometimes some of the goals may be considered conflicting. It is usually helpful to explore three fundamental questions with the patient and the family: (1) "What is happening to me?" (2) "What is going to happen?" and (3) "What can be done to help me?" The patient can be asked what his or her understanding of the diagnosis is and what it means. One might explore this by asking "Where do you see things going with your illness?" It is also worth asking about the patient's preference for information both in terms of how it is communicated and what level of detail is suitable.

Some unintentional clinician behaviors during goals of care discussions at the end of life can result in mistrust, entrenchment in pursuing futile therapies, or even requests for hastened death [10]. Examples of such unintended behaviors include:

1. Inadvertently linking relief of suffering to acceptance by patients and family of impending mortality
2. Debating with the patient and family about the reality of impending death or failing to assess their readiness to discuss the topic
3. Misunderstanding normal grief and expressions of the "wishful ideal" as denial

A metaphor that can be useful in helping clinicians communicate about the goals of care and avoid unintended behaviors is the quality of life tank model. As shown in Fig. 1, this model involves conceptualizing quality of life as a tank that can be filled

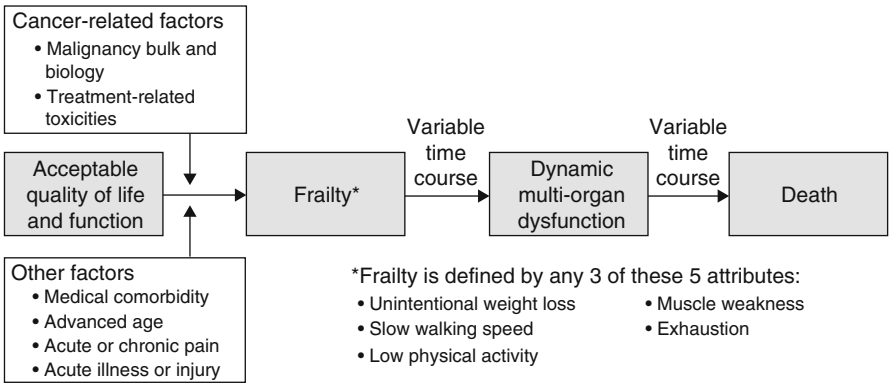

Fig. 1 The tank model

to certain levels. The very highest levels of the tank might best be considered in the realm of the "wishful ideal." For example, if Mrs. N were to talk about her deep need to help raise her 5- and 7-year-old grandchildren and see them go to college, this would be a truthful expression of her role and the perceived time horizon she once had, both of which are losses to now grieve. The clinician need not feel compelled to re-emphasize the terminal nature of the disease or assume that the patient is experiencing denial that will complicate her ongoing care. Instead, the clinician should acknowledge the patient's statements of the wishful ideal saying something like: "This is all just unspeakable. I wish things were different for you" [11]. The conversation can then transition to identifying the "realistic ideal," which is a specific level in the quality of life tank. This ideal is developed using the clinician's knowledge and experience and is often far more ambitious than what the patient actually expected. The clinician might say "Realistically, I expect that the new pain medications that I've prescribed along with the laxatives have a good chance at helping you feel much more energetic. I'd like to see you feeling well enough to be able to shop for your groceries on your own as soon as possible."

Mrs. N was anxious for detailed information and highly educated. She evaluated the risks and benefits of chemotherapy and decided to forego what she considered the small magnitude of potential benefit of systemic therapy. She focused on best supportive care alone, and sought relief of pain and constipation. When asked "What questions or concerns do you have," she indicated that it was puzzling to her how exactly pancreatic cancer causes death. Some deaths can seem rather sudden due to bleeding or infection or pulmonary embolism. On other hand, in most cases death is a slow process that occurs over a period of few months. Fig. 2 illustrates the "undertow" of advanced pancreatic cancer and the common transitions that patients make from acceptable quality of life and function to frailty, followed by multi-organ dysfunction and death. It was acknowledged that there remains uncertainty about the timing and nature of death, even when facing advanced pancreatic cancer. For this patient, who wanted information and was able to think abstractly, this model of the undertow model due to pancreatic cancer helped her feel more at ease. She strived to

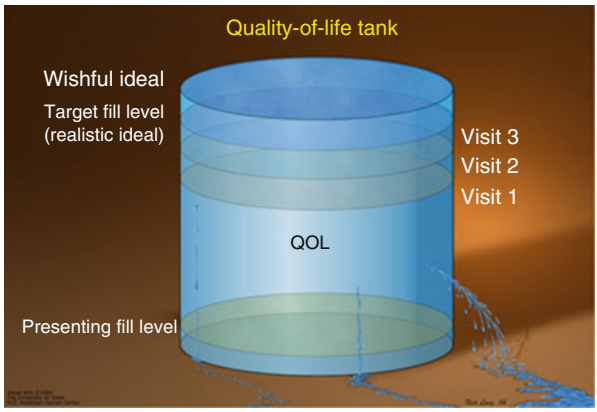

Fig. 2 The end-of-life trajectory in advanced pancreatic cancer

retain her health in the "acceptable quality of life and function" category by "paddling" against the undertow by using pain medication and laxatives, and by drawing upon her family and spiritual resources. Overall, every patient has their own way of assigning meaning and value to the potential goals of care, and no specific goal is inherently more important than another.

Systems and Teamwork

Mr. K was a 45-year-old single man with metastatic pancreatic cancer who was admitted to the hospital with abdominal discomfort, anorexia, recent weight loss, mild diarrhea with 3–4 loose stools per day, intermittent visual hallucinations, and shaking chills without fever. Three years earlier he had been treated for borderline resectable pancreatic cancer with chemoradiation followed by pancreaticoduodenectomy. He now has biopsy-proven mesenteric and retroperitoneal disease recurrence along with bilateral pleural effusions.

Pancreatic cancer care involves multidisciplinary collaboration. The multidisciplinary model is most emphasized in the initial care planning when gastroenterology, gastrointestinal medical oncology, surgical oncology, radiation oncology, pathology, and radiology are all represented in tumor board or treatment planning conferences for patients with localized pancreatic cancer. During the trajectory of illness, some of the disciplines remain closely involved, some fade back to an appropriate degree, and other services may join the team. Mr. K′s team included experts in pain management, palliative care, nutrition, and social work. During his hospital admission, many potential providers were available for problem-oriented assessment and care delivery. For most of these disciplines, the usual inpatient providers were not necessarily the same clinicians involved on an outpatient basis. Likewise, the medical disciplines also involved mid-level providers and sometimes clinicians in training. In these situations, the complexity of care can become nearly overwhelming, prone to errors, and miscommunication.

High-performing teams involved in pancreatic cancer care develop and discuss on an ongoing basis processes for specifying how work will proceed; who will do what for whom, with what purpose, when, where, and how. Multidisciplinary case conferences are not always restricted to treatment planning for new patients, but may also include some discussion of complex care for symptomatic patients who are at a different point in the trajectory of illness.

Pain Assessment and Management

Mr. D was a 52-year-old African-American man with metastatic pancreatic adenocarcinoma. His cancer was diagnosed after he had presented with persistent abdominal pain after an umbilical hernia repair. He had a 3.9 cm mass in the body of the pancreas and peritoneal carcinomatosis. On his symptom evaluation, he rated the severity of his pain in the past 24 h as an 8 on a numerical scale of 0 (the symptom not present) to 10 (the symptom is as bad as one can imagine it). He described the pain as a steady, constant feeling, similar to a heavy weight. He also experienced dysesthesias from the surgical incisions which he described as "the nerves are waking up" and a burning sensation in the periumbilical area (he was not sure whether that was acid indigestion or pain from his pancreas). Prior to his medical oncology visit, he had been prescribed 20 mg of long-acting oxycodone twice daily, but he found that to be difficult to tolerate because of a feeling of dizziness and sedation. On the remainder of his symptom inventory, he rates his fatigue at 2, nausea at 3, disturbed sleep at 3, and feelings of distress at 4. He did not experience shortness of breath, difficulty remembering things, lack of appetite, drowsiness, or dry mouth. He had no diarrhea, although he rated constipation at a 3 on a scale of 10. In terms of the way symptoms interfering with his life in the past 24 h, he rated the severity of interference in his general activity as a 7, mood as 5, work as 7, relations with other people as 5, walking as 4, and enjoyment of life as 5.

More than two-thirds of patients with pancreatic cancer experience pain at the time of their diagnosis. Pain is a particularly common presentation in patients with disease in the body or tail of the pancreas, whereas pancreatic head involvement presents as painless jaundice. Pancreatic cancer pain is often epigastric or in the central abdomen, chronic in nature. In some patients, pain may radiate to upper back or shoulder.

Successful symptom management is a multistep process, and attributions of success can be difficult. Managing symptoms, particularly pain in cancer patients, usually involves uncertainty as to the nature of the problem, and the reason for improvement. This uncertainty is partly due to the natural history of some symptoms. As in Mr. D's case, postoperative pain may have been involved, which improves over time. Interventions can reduce the severity and duration of the problems, but it is difficult to be sure how much to credit a specific intervention. In addition, there are almost always multiple simultaneous interventions. It is worth emphasizing that there is no need to delay analgesic therapy for the purpose of

investigating the cause of a complex abdominal pain syndrome in patients with pancreatic cancer.

Principles of Medical Pain Management

Mr. D's case vignette highlights several fundamental points in managing cancer pain in general, and pancreatic cancer pain in particular. First, based on the severity of the pain expression, an opioid analgesic was appropriate. If the oral route is available, as in this case, it should be used because it is effective, convenient, and cost-effective to do so. The patient's difficult initial experience with long-acting oxycodone was explicitly addressed with open-ended questions to discover his fears and misconceptions about opioids. Patients should be taught the potential benefits of opioids and the expected side effects and their management; distinctions between addiction, dependence, and tolerance should be explained.

For Mr. D, the starting opioid dose at 40 mg oxycodone per day (a morphine equivalent dose of 60 mg day^{-1}) was probably too high [15]. Dizziness and sedation, most likely due to the new opioid treatment, tend to improve spontaneously after 1–3 days with continued opioid exposure. However, patients do not accommodate to opioid side effects such as dry mouth and constipation. For that reason, it is critical to coprescribe laxative therapy along with strong opioids.

The choice of type of the initial opioid is not critical. One option would be to prescribe a short-acting, strong opioid (such as oxycodone, morphine, or hydromorphone) every 4–6 h around the clock. In this case, a low-dose sustained release opioid would also be reasonable. Examples include 20 mg day^{-1} of oxycodone, 30 mg day^{-1} of morphine sulfate, or 7.5–10 mg day^{-1} of methadone. In patients with renal insufficiency, fentanyl or methadone would be preferable long-acting opioid to minimize risk of delirium or myoclonus.

Mr. D's pain had a neuropathic component that may have been due to his recent surgery. Because he was starting an effective, tolerable opioid regimen, no specific adjuvant analgesic for neuropathic pain was needed. Opioids are effective for neuropathic pain (response rates roughly 40–50%), but that response rate is somewhat lower than for other pain syndromes such as somatic or visceral pain. There is little evidence to support the use of specific adjuvant drugs for pancreatic cancer pain management, but short-term corticosteroids and nonsteroidal anti-inflammatory agents are also particularly useful adjuvant analgesics in this disease.

The Role of Procedures Such as Neurolytic Celiac Plexus Block

The divisions of the vagus and splanchnic nerves from the celiac and mesenteric plexuses, and nerve fibers travel along the celiac and mesenteric arteries and their branches, reaching the pancreas and other viscera [12]. The celiac plexus is at least partly involved in the innervation of the pancreas, liver, gallbladder, adrenal, kidney, and gastrointestinal tract from the level of the gastro-esophageal junction to the

splenic flexure. As such, interventional pain specialists (usually trained in anesthesiology) have advocated for the use of neurolytic celiac plexus block (NCPB) on the basis of multiple uncontrolled trials and a few controlled trials [12].

The largest and most carefully conducted trial comparing NCPB with optimized systemic analgesic therapy involved the random assignment of 100 patients at a single institution with unresectable disease who received NCPB versus optimized systemic analgesic therapy plus sham injection. NCPB did not improve quality of life or overall survival in the cohort, nor did it significantly reduce opioid side effects or opioid consumption. However, NCPB did reduce the proportion of patients who experienced moderate to severe levels of pain in the first 6 weeks as compared with medical therapy (14% vs. 40%) [13]. The ideal time to consider a neurolytic celiac plexus block is unclear in patients with pancreatic cancer. In some instances, NCPB should be considered when opioid therapy is unsatisfactory or poorly tolerated, for instance, resulting in severe constipation. When palliative care expertise is available, use of opioid rotation (switching) and other assessment and treatments of not only physical but also emotional and existential pain is indicated for difficult cases. NCPB is generally a safe procedure, but the sympathetic denervation causes hypotension and hyperperistalsis (with diarrhea) in about one-third of patients, along with some local pain associated with the procedure. Major neurological complications such as paraplegia have been reported but are very rare.

Novel modalities for denervation have been used for pain resulting from pancreatitis and in some instances, from pancreatic cancer. Thoracoscopic splanchnicectomy (TS) can alleviate pain in >90% of patients with chronic pancreatitis [14]. However, the morbidity associated with this procedure is significant (16% as reported in a literature-based review) [14], as is the risk of conversion to open thoracotomy. While this procedure can be safely performed in a high-volume center, its benefit in the frail pancreatic cancer population may be outweighed by its associated risks. Small case series have also reported successful neurolysis using endoscopic ultrasound (EUS)-guided blocks [15]. EUS is now standard in the diagnostic work-up of these patients, and EUS-guided block may have potential value in patients whose pain is refractory to oral opiates [16]. However, larger randomized studies are needed to validate the use of this technique.

Depression

Mrs. L was a 57-year-old Caucasian lady old with metastatic pancreatic carcinoma with progressive disease for which she has recently started second-line combination chemotherapy. She was grieving for the loss of her mother, who had died recently of dementia. She had chronic, cancer-related abdominal, and pleuritic pain which was well-controlled with oral opioids. She appeared quite cheerful, but when asked about her mood, she admitted to feeling sad and blue. She admitted to a prior suicide attempt in early adulthood in the setting of severe depression, but she had discontinued antidepressant therapy 3 years before she being diagnosed with pancreatic cancer.

Depression is estimated to affect over 120 million persons worldwide [17]. Large, prospective studies have shown that the prevalence of major depression in the outpatient primary care setting is 6–14%, and the lifetime incidence of major depression is approximately 15% [18]. Depression is at least 2–3 times more common in hospitalized patients or patients with chronic illness [19]. Major depressive disorder is an illness that can lead to substantial morbidity due to severe functional impairment and risk of mortality because of suicide [20].

The association between pancreatic cancer and depression has been observed and explored for over 70 years. On one hand, it seems reasonable that patients with such a difficult, polysymptomatic disease would be susceptible to depressive disorders. However, Holland and colleagues found, after controlling for demographic and medical attributes, that self-ratings of depression were higher for pancreatic cancer patients than those for gastric cancer, a similarly difficult abdominal neoplasm [21]. More recently, Carney and colleagues conducted a large retrospective cohort study using longitudinal population-based insurance claims data and found that depression more commonly preceded pancreatic cancer than it did other gastrointestinal malignancies with an odds ratio of 4.6 (confidence interval 1.07–19.4) [22]. The biological basis of the relationship between pancreatic cancer and depression is not clear. The most common theories involve serotonin: this hormone may be secreted by pancreatic tumors or secreted antibodies could block the central serotonin receptors [23].

The paradigm for the diagnosis and treatment of depression is no different in pancreatic cancer than in the primary care setting. Most commonly, the diagnosis of depression is based on patient history and by the exclusion of competing diagnoses, using the criteria from the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-V) [24]. Major depression is defined as depressed mood or anhedonia for at least 2 weeks plus the presence of three or four other specific psychological symptoms including feelings of guilt or worthlessness and suicidality as well as vegetative signs (sleep disorder, poor concentration, and psychomotor retardation) not explained by the underlying medical condition. A recent review of case-finding instruments used in primary care showed that at least 11 questionnaires, ranging in length from 1 to 30 questions and ranging duration of administration from 1 to 5 min, have reasonable performance characteristics compared with a semi-structured interview that applies standard diagnostic criteria [25]. In busy oncology settings, clinicians commonly ask simple verbal questions about depressed mood or lack of interest in normal activities (anhedonia) to screen for depressed patients. A recent meta-analysis of this strategy showed that its positive predictive value was 57%, and its negative predictive value was 98%, thus making it more useful for excluding depression than for including it [21]. Patients, like Mrs. L, who screen positive for depressed mood should be more thoroughly evaluated. Risk factors for depression that should be evaluated in patients with pancreatic cancer include poor pain control, poor functional status, advanced disease, history of substance abuse, and poor social support. Recent losses and a personal or family history of depression are also risk factors. Major depression should be treated aggressively, even in patients with advanced pancreatic cancer, with supportive psychotherapy and judicious use of antidepressant medications.

Gastroparesis

Mr. C was a 62-year-old Hispanic man with the recent diagnosis of pancreatic cancer that involved the body of the pancreas, celiac, periportal lymph nodes and he also had a 2 cm metastatic lesion in the right lobe of the liver. His presenting symptoms were back pain, nausea, 20 pounds weight loss, and early satiety. His back pain was managed with sustained-release oral morphine and oral hydromorphone for "break-through" pain episodes. The patient and his oncologist decided in favor of systemic chemotherapy with weekly gemcitabine. Nausea became even more pronounced despite the use of prochlorperazine or ondansetron and was accompanied by vomiting and further weight loss. Chemotherapy was discontinued; however, there was no improvement in nausea or emesis. Patient presented to the emergency room with dehydration. An abdominal radiograph revealed a distended stomach, filled with fluid and food debris. An upper gastrointestinal contrast study was performed, which revealed no evidence of gastric or duodenal obstruction.

Gastroparesis is believed to affect over 60% of pancreatic cancer patients and is a "functional" form of gastric obstruction rather than a mechanical type of gastric outlet obstruction, which results from compression of the gastric pylorus and duodenum by a mass in the head of the pancreas. Cancer-associated gastroparesis may be accompanied by a generalized gastrointestinal dysmotility that results in ileus. Its consequences can be serious and include cachexia, dehydration, electrolyte imbalances, and impairment of quality of life. As in the case of Mr. C, this symptom complex can be exacerbated by chemotherapy-toxicity. The etiology of gastroparesis in most cases is thought to be antibody-mediated or secondary to neurological involvement by the malignant process. Comorbid conditions such as diabetes, hypothyroidism, and opioids contribute to worsening of symptoms of gastroparesis.

Diagnosis of Gastroparesis

The standard test for establishing diagnosis is gastric scintigraphy after a standardized solid meal of bread, jam, and egg substitute with 99 m Tc-sulfur colloid. Delayed gastric emptying is confirmed if more than 60% retention is present at 2 h or more than 10% is present at 4 h [26]. This investigation can be utilized both for diagnosis and monitoring of the effectiveness of prokinetic therapy [27]. A new, ambulatory method involves ingesting a radiotelemetry wireless capsule that measures luminal pH and pressure after being swallowed and transmits the data to a receiver worn by the patient (Smart Pill™, Buffalo, NY) [28]. Gastric emptying is detected by the sharp increase in pH as the capsule moves from the stomach to the duodenum.

Patients without weight loss, hypoalbuminemia, or other nutritional impairment can undergo dietary and behavioral modification, and be prescribed prokinetic and anti-emetic medications. However, for those with long-standing gastroparesis, correction of the fluid, and electrolyte disturbances, intravenous administration of

prokinetic and anti-emetic medications and nasogastric tube placement to decompress the stomach may be needed.

Dietary and Behavioral Modification

Dietary recommendations are based on measures that promote gastric emptying. Patient should be encouraged to sit erect, stand, or walk after a meal as gravity and body movement help in gastric emptying. Frequent small meals are encouraged, as is increasing the liquid nutrient component of meals, as liquids transit more rapidly than solids [29]. Lipids and indigestible fiber delay gastric emptying; thus a low-fat, low-residue, high carbohydrate meal is appropriate for patients with gastroparesis to avoid gastric distension and symptoms of bloating, satiety, and nausea.

Pharmacotherapy

Prokinetic agents and anti-emetic agents are the mainstay of therapy and the goals are to accelerate gastric emptying and prevent nausea or emesis. The commonly used prokinetic agents in the United States are metoclopramide and erythromycin. Tegaserod is no longer approved by the Food and Drug Administration (FDA). Cisapride and domperidone are not available in the United States but can be obtained under an investigational (IND) protocol.

Metoclopramide

Metoclopramide (Reglan®) is a 5-HT_4 receptor agonist and dopamine D_2 receptor antagonist. It promotes gastric emptying by facilitating gastrointestinal cholinergic and nitrergic (nitric oxide mediated) activity and improves gastric emptying and intestinal transit. Its anti-emetic properties are related to central and peripheral inhibition of dopamine receptors. At doses of 10–20 mg orally four times daily, metoclopramide results in subjective improvement in symptoms of nausea, vomiting, abdominal pain, postprandial fullness, nausea, and early satiety [30]. Metoclopramide readily crosses the blood-brain barrier, where D_2 receptor antagonism can cause akathisia or other extrapyramidal symptoms. Long-standing metoclopramide therapy, of over 3 months in duration, can result in irreversible tardive dyskinesia, in 1–10% of cases. Hence, this complication should be discussed before this medication is prescribed.

Erythromycin

Erythromycin is a bacteriostatic macrolide antibiotic with prokinetic properties that is widely used to treat diabetic gastroparesis. Erythromycin is a potent motilin

agonist that induces gastric peristalsis thus improving gastric emptying. Sturm et al. reviewed 36 clinical studies involving 514 patients who were treated with prokinetics for gastroparesis [31]. They concluded that erythromycin had the strongest effect on gastric emptying than did domperidone, cisapride, or metoclopramide. The side effects of high doses of erythromycin include abdominal pain, nausea, and vomiting secondary to increased gastrointestinal motility. Erythromycin also increased the risk of sudden cardiac death by as twice that of the control population [32].

Anti-Emetic Agents

Anti-emetic agents can be combined with prokinetic agents for a synergistic effect. Commonly used anti-emetics include phenothiazines such as promethazine, prochlorperazine or 5-HT_3 receptor antagonists such as odansetron and granisetron. In patients who do not experience response to one anti-emetic agent, another agent may be useful.

Botulinum Treatment

Small case series have reported improved symptoms and gastric emptying after the injection of botulinum toxin into the pylorus. This agent reduces the tone and phasic contractions of the pylorus by preventing cholinergic contractile activity [33]. The use of botulinum toxin for gastroparesis is considered off-label and prospective studies in patients with cancer-associated gastroparesis are lacking.

Surgical Management

Surgical intervention is increasingly used to treat refractory gastroparesis. The most common operation, gastric electrical stimulator implantation, has been performed in more than 1500 patients since 2001, mostly for diabetic gastroparesis. The gastric stimulator has been effective in the treatment of diabetic, idiopathic, and postsurgical gastroparesis. However, prospective studies of electrical stimulation in cancer-associated gastroparesis are needed.

Gastrostomy

Gastrostomy should be considered in refractory gastroparetic patients with severe nausea and vomiting. A gastrostomy tube can relieve symptoms, especially of interdigestive fullness, nausea, and bloating secondary to retained intragastric gas and liquids. Venting gastrostomy decreased symptoms, improved functional status

and weight in patients with idiopathic gastroparesis in a study with 3-year follow-up [34].

Jejunostomy

Cancer-associated gastroparesis patients with debilitating symptoms and nutritional compromise should be considered for jejunostomy tube placement. Before the placement of a permanent jejunal tube, a 48- to 72-h trial of nasojejunal feeding should be performed to confirm that the patient can tolerate the infusion of nutrients at a rate that delivers an adequate caloric and protein level [35]. Endoscopically placed jejunal tubes often migrate backwards into stomach, particularly in patients with recurrent vomiting. Thus, in patients requiring long-term enteral nutrition, surgically placed jejunostomy tubes are preferable to the endoscopically placed tubes. Enteral feeding with an iso-osmolar, nonelemental liquid supplement has been shown to be effective in the long-term care of patients with gastroparesis. Complications of the jejunal tube placement include infection, tube dysfunction, and tube dislodgment.

Parenteral Nutrition

Patients with cancer-associated gastroparesis may require parenteral nutrition if previous attempts of enteral nutrition have failed due to intolerance or enteral feeding complications. The morbidity of parenteral nutrition is considerable and includes vein thrombosis, sepsis, and hepatic cholestasis. Depending on a patient's prognosis and goals of care, parenteral nutrition should be considered after deliberation with patients and caregivers about risks and benefits. Periodic reassessment of the benefits of parenteral nutrition during the disease trajectory should be conducted, and if the risks are outweighed by benefits, it should be discontinued.

Jaundice

Ms. C was a 45-year-old Hispanic woman who presented with painless jaundice and 20 pounds of weight loss to her family practitioner. An ultrasound examination of the liver was recommended. This study revealed a mass in the head and uncinate process of the pancreas, dilatation of the common bile duct and pancreatic duct, and a solitary metastatic liver lesion. Laboratories revealed a serum bilirubin level of 7.8 mg dl − 1 and alkaline phosphatase level of 660 IU l − 1. She underwent an Endoscopic Retrograde Cholangio-Pancreatography (ERCP), which confirmed a stricture in the common bile duct. A plastic stent is placed across the common bile duct. After 2 weeks, the jaundice resolved. However, a month after stent placement, she developed recurrence of jaundice and fever.

The above case illustrates the typical presentation of a patient with cancer in the pancreatic head, with biliary obstruction resulting in jaundice. Palliation of jaundice in this instance can be achieved by surgical bypass (choledochojejunostomy) or nonsurgically by biliary stenting. Surgical therapy is considered for patients with resectable pancreatic cancer, or for patients with nonresectable, locally advanced but nonmetastatic cancer. In Ms. C′s case, the presence of liver metastasis was a clear indication for nonsurgical therapy. The potential advantages of surgical palliative therapy include the ability to add other procedures including celiac plexus block and gastrojejunal bypass for concurrent duodenal obstruction. The morbidity and mortality of these procedures is not minor, however, particularly in patients with inoperable pancreatic cancer. A recent retrospective review reported an overall mortality of 6% and mortality of 16% for unresectable pancreatic cancer patients who underwent palliative surgery [36]. The median survival for patients undergoing these procedures was 6 months only. Therefore, majority of these patients can be spared surgery and be palliated with nonsurgical stenting procedures.

Before endoscopic placement of biliary stents, ERCP evaluation is performed to evaluate the biliary tree and pancreatic duct. Preceding the procedure, antibiotics are administered prophylactically and coagulopathy corrected. The risk of stent occlusion increases after approximately 3 months. Elective stent exchange is reasonable if the physical condition of the patient is good. Endoscopic stent placement is safe and effective in this patient group; however, stents are prone to infection and occlusion from tumor ingrowth or debris [37]. Prophylactic administration of antibiotics and bile salts has not been shown to prevent stent occlusion. However, stent placement has lower morbidity and mortality as compared with biliary surgical bypass procedures.

Metallic stents are preferred to plastic, as these are wide-bored and less prone to occlusion and infection than plastic stents [38]. Metallic stents can be covered with a sheath (to prevent tumor ingrowth) or bare. The former type has a lower risk of occlusion but carry a significant risk of cholecystitis [39]. These are also easier to remove, in the case surgical resection is feasible. In all cases, if the patient has resectable disease, the surgeon should be consulted before the selection of the stent. As in Ms. C′s case, cholangitis is a common complication from biliary stents. Acute cholangitis is characterized by fever, jaundice, and abdominal pain that develops from biliary stasis and infection. Cholangitis can be a serious complication, and requires prompt intervention with antibiotics, intravenous fluids, and hospitalizations. In the majority of these cases, endoscopic stent replacement is required to reestablish biliary flow.

Cachexia

Ms. T was a 65-year-old Caucasian woman with a 6-month history of abdominal pain, backache, and asthenia. She experienced anorexia, abdominal bloating, flatulence, diarrhea, and 20-pound weight loss over the previous 6 months. Imaging studies revealed a pancreatic body mass with celiac adenopathy and encasement of

the superior mesenteric vein. Laboratory studies revealed an albumin of 2.8 g dl − 1 and fasting blood glucose level of 240 mg dl − 1. The patient received chemoradiotherapy and experienced a further 10-pound weight loss over the subsequent 2 months.

Ms. T's case vignette illustrates a commonly occurring problem in pancreatic cancer, "cancer cachexia." This condition is characterized by malnutrition, muscle wasting, weakness, and debility. When cachexia is associated with a failure of appetite responses, this condition is referred to as "anorexia-cachexia syndrome." Cancer cachexia occurs in >80% of patients with advanced pancreatic cancer. It can hasten death, reduce response to treatment, and exacerbate treatment toxicities [40]. The clinical stage of the malignancy (tumor burden) is not directly related to the extent of the cachexia. Indeed, small tumors in the pancreas can lead to significant weight loss, even in the absence of anorexia. Falconer et al. measured resting energy expenditure (REE) and found that patients had a higher REE than did control subjects [41]. Cancer patients have several metabolic abnormalities involving carbohydrates, amino acids, and lipids. Pancreatic cancer is associated with secondary diabetes in 50% of cases, and hyperglycemia alone is a negative prognostic factor in this disease [42]. The anorexia-cachexia process in advanced cancer appears to be mediated by circulating catabolic factors, either secreted by the tumor alone or in concert with host-derived factors, such as tumor necrosis factor-α (TNF-α), interleukins (IL) 1 and 6, gamma interferon (IFN-γ), and leukemia inhibitory factor [43].

Management of Cachexia

Medications such as glucocorticoids, megestrol acetate, and cannabinoids have the potential to stimulate appetite and increase weight but, unfortunately, have modest benefits for cancer cachexia.

Corticosteroids, such as dexamethasone, prednisolone, and methylprednisolone, result in short-term improvement in appetite, nausea, and energy. The usual dose of dexamethasone is 3–6 mg by mouth daily. Its exact mechanism of action is unknown; however, it is believed to interfere with inflammatory cytokines such as IL-1 and TNF-α [44]. Loprinzi et al. compared megestrol acetate, dexamethasone, and fluoxymesterone in a randomized control study of 475 patients with advanced cancer [45]. Fluoxymesterone resulted in the least improvement in appetite. Dexamethasone and megestrol showed a similar degree of benefit.

Megestrol acetate is a synthetic hormone that mimics progesterone in the body and interferes with hormone signaling. Megestrol improves appetite and quality of life in many patients but does not affect lean body mass or result in a change in performance status. It can cause weight gain, but body composition studies have indicated that megestrol increases body fluid and fat rather than lean body mass. Loprinzi et al. [46] randomly assigned 342 patients with cancer cachexia to receive megestrol acetate dose of 160, 480, 800, or 1280 mg day^{-1}. Patients who received 800 mg day^{-1} reported the greatest improvement in appetite and food intake. Fifteen

percent of patients treated with 800 mg of megestrol experienced weight gain; lower weight gains were noted in the other dose groups. There was also a trend toward higher serum albumin levels in the 800 mg day^{-1} group. Deep-vein thrombosis, hyperglycemia, adrenal insufficiency, and androgen deficiency in male patients are important adverse effects of megestrol therapy. Deep-vein thrombosis occurs in 2–18% of patients and hyperglycemia in 2–13% of patients receiving megestrol and is an important consideration in pancreatic cancer patients, who are predisposed to coagulopathic events and may have underlying diabetes.

Cannabinoids are marijuana derivatives; they act by interacting with cytokines or with endocannabinoid receptors in the brain limbic system and hypothalamus or in the peripheral organ systems. They work in palliating cachexia in cancer patients by stimulating appetite. Cannabinoids have anti-emetic properties and elevate mood. Their adverse effects include dysphoria, confusion, dizziness, loss of coordination, fluid retention, vomiting, and impotence [47]. The superiority of cannabinoids to steroids remains to be proven. Jatoi et al. [48] compared 2.5 mg dronabinol twice daily, 800 mg megestrol daily, and the combination in 469 advanced cancer patients. Patients reported greater appetite improvement and weight gain with megestrol. The combination of both drugs did not result in additional benefit.

Ten percent of patients with pancreatic cancer have a new onset of diabetes [49]. Cachectic cancer patients have glucose intolerance, which can contribute to weight loss as illustrated in the above vignette. Control of hyperglycemia in this case can improve cachexia symptoms. Lundholm et al. [50] randomized 138 patients with mainly advanced gastrointestinal malignancies to receive insulin plus best palliative support or best palliative support alone. They found that although overall daily caloric intake did not change between the groups, carbohydrate intake was significantly increased by insulin. Adequate control of hyperglycemia has been associated with improved survival in cancer patients.

Currently, treatments under investigation for cancer cachexia include omega-3 fatty acids (eicosapentaenoic acid and docosahexaenoic acid), amino acids including L-carnitine, nonsteroidal anti-inflammatory drugs, thalidomide, and ghrelin mimetics.

Nutritional Management

The goals of nutritional care are to improve caloric and nutrient intake, body composition, functional or performance status, immune function, and quality of life. Oral or enteral nutritional supplements are beneficial for patients whose quality of life and survival may be enhanced by anticancer therapy. Enteral nutrition is preferred over parenteral methods for patients with a functioning gastrointestinal tract [51]. Gastric enteral feedings are sufficient for most patients. However, patients at a high risk for aspiration, gastroparesis, gastric outlet obstruction, or who have a history of previous gastric surgery typically require jejunostomy feedings. Ideally, a registered dietitian (RD) should intervene at the initial diagnosis of cancer. Regular, consistent contact via telephone or face to face is encouraged. The role of the RD

should include the following: calculating nutrient and fluid consumption, evaluating nutritional status using patient recall data, anthropometrics, and laboratory indices, anticipating the nutritional risks of both the cancer and its treatment and managing nutrition-related adverse effects of cancer therapy. Encouraging patients to take a nutritional supplement at fixed times throughout the day (as when taking medication) can help optimize nutritional intake. Patients should aim to ingest a supplemental 300–600 Kcal daily in addition to regular meals [52]. Bauer et al. [53] evaluated compliance with nutritional prescriptions and their effect on outcomes in patients with unresectable pancreatic cancer. They found that compliance with a prescription of 1.5 cans of a protein- and energy-dense, oral nutrition supplement (with or without eicosapentanoic acid) improved total dietary intake and body weight. They also found that this level of supplement intake did not inhibit meal intake.

Pancreatic enzymes: Approximately 65% of patients will have some degree of fat malabsorption, and 50% have protein malabsorption [54]. Ms. T experienced the symptoms of fat malabsorption, including diarrhea, steatorrhea, flatulence, abdominal pain, and bloating. Pancreatic enzyme replacement can be used to treat nutrient malabsorption caused by pancreatic insufficiency. Enzyme replacement has been shown to improve the above symptoms and prevent further weight loss [55]. The goal of enzyme replacement therapy is to achieve normal enzyme activity in the duodenum. Current clinical practice involves the administration of 25,000–40,000 units of lipase/meal using pH-sensitive pancrelipase microspheres, along with dosage increases, compliance checks, and differential diagnosis in cases of treatment failure [56]. Ideally, patients should ingest enzymes with the first bite of every meal and snack and midway through the meal, to maximize enzymatic activity in the duodenal lumen simultaneously with the meal. Patients should maintain a detailed food and bowel diary to determine which foods and enzyme dosage are best tolerated.

Constipation

Mr. K was a 72-year-old African American man with pancreatic adenocarcinoma, involving the body of the pancreas with celiac adenopathy. He had considerable abdominal and back pain and was prescribed oral short-acting opioid analgesic and sustained-release oral morphine formulation. He was advised prophylactic use of a stool-softener to prevent constipation. Patient presented to the clinic 1 week later, complaining of bloating, constipation, nausea, and abdominal distention. He was advised a combination of a stimulant laxative and stool softener along with liberal oral hydration. No improvement results after 48 h of therapy. An osmotic laxative was added; laxation resulted and symptomatic relief occurred.

Constipation is a frequently occurring problem in pancreatic cancer patients and affects over 50% with an advanced disease stage. The distress resulting from this symptom equals that with cancer pain. The etiology of constipation in pancreatic cancer patients is multifactorial. Constipation may result from direct tumor invasion

into the transverse colon or into the enteric nerves and muscles, as a part of a larger paraneoplastic phenomenon, which may be hormonal or cytokine-mediated and accompanied by generalized gastrointestinal dysmotility including gastroparesis, or from the effects of treatment such as opioid analgesics and 5-HT_3 antagonists [57]. Over 60% of cancer patients require laxatives even without opioid usage while this figure approaches 90% with the use of concurrent opioids. The functional effect on the opioid receptors is to reduce peristalsis and increase intestinal circular muscle resting tone. In addition, opioids also alter intestinal fluid handling as a result of decreased transit time in the small bowel and decreased secretory gut function. The advanced age, poor appetite resulting in suboptimal intake of dietary fiber and fluids as well as poor performance status of pancreatic cancer patients contribute to the problem of constipation [58].

The current strategies for management include early intervention with patient education, dietary counseling, and agents to induce laxation. Mumford estimated that an increase of dietary fiber intake by 450% would be required so as to increase laxation by 50% in cancer patients receiving radiotherapy and suffering from constipation [59]. This degree of increased dietary fiber intake is not feasible in this patient group. The fluid requirement is also considerable: 1.5–2 l of oral fluid intake daily is needed to have a positive effect. Only a weak correlation exists between the dose of the narcotic used and the degree of constipation. Transdermal fentanyl may be less constipating than morphine or hydromorphone [60]. Methadone is also associated with a lower laxative requirement than morphine [61]. In the case of Mr. K, both the narcotic agents that were prescribed have constipation as a side-effect.

Commonly used pharmacological interventions can be grouped into the following categories: stool softeners, which act as detergents that enhance dispersion of fluid into the stool content; osmotic agents such as polyethylene glycol, lactulose, and sorbitol that withdraw fluid into the intestinal contents; and bulk fiber, such as psyllium which requires adequate oral hydration to be effective. Most patients receiving narcotics should be prophylactically started on a regimen of stool softener + stimulant laxative. This combination was also prescribed for Mr. K, but the results were suboptimal. In resistant cases, an osmotic agent is added. This was also the case with Mr. K, where the addition of lactulose to the combination of stimulant laxative and stool softener was needed. This regimen needs close monitoring so that changes can be instituted in dosage as needed and fecal impaction avoided.

The FDA has recently approved methylnaltrexone, a peripherally acting mu-opioid receptor antagonist, which selectively reverse opioid actions mediated by receptors outside the central nervous system, while preserving centrally mediated analgesia. Methylnatrexone is subcutaneously administered and was investigated in two randomized, double-blind placebo-controlled studies involving a total of 287 patients who were suffering from opioid-induced constipation that was not relieved with laxatives usage [62, 63]. In both studies, all patients had advanced late-stage illnesses with a life expectancy of less than 6 months. Prior to treatment with methylnaltrexone, patients had either less than three bowel movements in the week prior to treatment or no bowel movement for more than 2 days. Patients

receiving methylnaltrexone achieved a significantly higher rate of laxation within 4 h of dosing versus placebo (62% and 58% vs. placebo, 14%; $P < 0.0001$ for both). This agent has to be administered subcutaneously and its side-effects include gastrointestinal perforation, abdominal cramps, flatulence, diarrhea, nausea, and dizziness and is contraindicated in patients with advanced illness with impaired gastrointestinal wall integrity. Naldemedine, an oral, mu-opioid receptor antagonist, also has been approved for opioid-induced constipation in noncancer pain and may be considered for off-label use in cancer patients. Oral naloxone and naloxegol, a pegylated form of naloxone, appears to be effective for opioid-induced constipation in the noncancer patient population but concern for reversal of analgesic effect exists.

Malignant Ascites

Ms. D was a 45-year-old African American woman with metastatic pancreatic cancer that involved the liver, retroperitoneal nodes and omentum. Patient was treated with systemic gemcitabine followed by capecitabine chemotherapy; disease progression resulted and further chemotherapy was discontinued. She experienced abdominal distention and lower extremity edema, and the patient was treated with diuretics. No improvement in distention resulted. She then experienced exertional dyspnea and abdominal pain from progressive ascites. A large-volume (3 l) ascitic paracentesis was performed; a cytologic examination revealed adenocarcinoma. The fluid albumin level was 1.5 g dl − 1 (serum albumin was 2.2 g dl − 1). She experienced relief for 2 weeks, which was followed by reaccumulation of peritoneal fluid.

Malignant ascites results either from direct peritoneal invasion by the cancer or secondary effects of the underlying malignancy, such as venacaval or portal obstruction, lymphatic blockade, hypoalbuminemia, or enhanced vascular permeability secondary to cytokine release (including TNF, vascular endothelial growth factor, IL-6, and vascular permeability factor) [64]. The treatment of malignant ascites differs from that of ascites associated with hepatic cirrhosis, which is the most common cause of ascites in adults and therefore the management options differ. Ms. D experienced direct peritoneal invasion and therefore she had positive cytology. However, malignant cytologic characteristics occur in 50–60% of the cases and the overall sensitivity of cytological analysis in this condition is <75% [65]. An examination of ascitic fluid can provide clues as to the underlying etiology. Even in the absence of positive cytologic findings, low levels of ascitic glucose and a low serum-ascites albumin gradient (serum albumin-ascitic albumin <1.1 g dl^{-1}) are suggestive of carcinomatosis as in the case of Ms. D. An elevated serum-ascites albumin gradient, on the other hand, suggests portal hypertension or lymphatic blockade from the tumor [66].

Malignant ascites may resolve after the underlying cancer is treated with antineoplastic therapy. The goal of therapy is palliative so as to relieve ascites-induced discomfort and improve quality of life. Ms. D experienced no symptom

improvement from diuretic therapy, but the use of diuretics for malignant ascites is controversial. Lee et al. reported that diuretics were used by 61% of physicians to treat malignant ascites but by only 45% noted a benefit [67]. No randomized controlled trials have assessed the effectiveness of diuretic therapy in the treatment of malignant ascites. In the prospective study by Pockros and colleagues, a response to diuretics occurred in patients with liver metastases and a serum-ascites albumin gradient >1.1 g dl^{-1}, whereas patients with ascites caused by peritoneal carcinomatosis or chylous malignant ascites who had no portal hypertension and a serum-ascites albumin gradient <1.1 g dl^{-1} did not experience any benefit from the diuretics [68]. These data suggest that serum-ascites albumin gradient may serve as a useful guide for predicting response to diuretics.

Therapeutic paracentesis is the only available option for providing rapid symptom relief from malignant ascites. The ideal rate of fluid withdrawal has not yet been determined, but large-volume paracentesis, of up to 5 l, is usually safe. McNamara et al. performed a prospective study to determine how much fluid needs to be drained for symptom relief [69]. A significant improvement in abdominal pressure was found with the removal of a median of 4.9 l (range = 0.8–15 l). The complications of paracentesis include hypotension, renal failure, peritonitis, hypoalbuminemia, and pulmonary embolism. In ascites secondary to cirrhosis, concurrent albumin or plasma expanders have been shown to prevent circulatory collapse. However, there are no data to support their use in patients with malignant ascites. Rosenberg et al. performed a retrospective analysis of patients undergoing therapeutic paracentesis for malignant ascites; a median of 6 paracentesis was performed per patient [70]. The median interval between procedures was 10 days. Indwelling tunneled or nontunneled catheters can be considered for patients requiring frequent paracenteses. Tunneled catheters have a low risk of infection (2.5% in one retrospective series). Nontunneled (pigtail catheters) have a higher infection risk (as high as 30%) and are not recommended other than for patients with terminal disease.

Peritoneo-venous shunts are a one-way valve containing systems that direct peritoneal fluid to the vena cava while preventing reflux. These shunts (Leveen or Denver) are widely used in cirrhotic patients with ascites and can provide palliation for malignant ascites in refractory cases. Their complications include occlusion, disseminated coagulation, and a theoretical risk of tumor dissemination. Breast and ovarian cancer patients can be benefited from this surgical procedure. However, gastrointestinal cancer patients, particularly those with pancreatic cancer, are not appropriate candidates for this surgery, due to the poor prognosis [71].

Vascular Thrombosis

Mr. P was a 72-year-old Caucasian male with the diagnosis of locally advanced, unresectable cancer of the pancreatic body and with periportal adenopathy. He underwent systemic chemotherapy with gemcitabine. After 3 months of chemotherapy, he underwent a computed tomography scan, for tumor restaging. A minimal increase in the tumor mass was noted along with a new portal vein thrombus. Serum

CA 19–9 level increased from 340 IU ml − 1 before treatment to 1068 IU ml − 1 after treatment. Computed tomography scan of the chest reveals a pulmonary embolus in a distal branch of the right pulmonary artery. Doppler sonography of his lower extremities reveals right popliteal venous thrombus.

Pancreatic cancer is associated with a high risk of thromboembolic disease and which is related to an intrinsic hypercoagulable state. Tissue factor, an important procoagulant, is expressed by tumor cells and activates the extrinsic coagulation pathway [72]. Tissue factor also upregulates the vascular endothelial growth factor (VEGF) and downregulates thrombospondin leading to an angiogenic phenotype. Expression of tissue factor has been associated with an adverse outcome in pancreatic cancer. Other factors inducing thrombosis are thrombin and circulating carcinoma mucins, including CA 19–9, which activate thrombosis via platelet aggregation. Mutated k-ras on the other hand activates thrombosis by decreasing thrombospondin concentration; k-ras is also associated with increased angiogenesis. Other factors that contribute to hypercoagulability in pancreatic cancer include the use of cytoxic chemotherapy, surgical procedures, hospitalization, venous stasis from restricted mobility, and vascular obstruction from lymphadenopathy (as in the case of Mr. P) and metastatic liver disease.

The incidence of thromboembolic disease in pancreatic cancer is higher than in other metastatic cancers and ranges from 12% in clinical and 47% in autopsy series [73]. In a prospective trial of gemcitabine + erlotinib versus gemcitabine + placebo, Moore et al. reported a 14% incidence of vascular events. In this and other studies, thromboembolic disease correlated with an adverse clinical outcome [74]. Lower extremity venous thrombosis, thrombophlebitis migrans, portal vein thrombosis, and pulmonary thromboembolism are the common manifestations of thromboembolic disease in pancreatic cancer. Other manifestations include disseminated intravascular coagulation, splenic vein thrombosis, mesenteric vascular thrombosis, and venous gangrene or extremity ischemia.

At the current time, patients with thromboembolic disease due to pancreatic cancer should be considered for anticoagulation with low-molecular weight heparin or unfractionated heparin followed by long-term oral coumarin anticoagulant therapy. Mr. P had portal vein thrombosis, which has unique clinical features. In his case, there were no associated complications, such as portal hypertension, ascites, varices, and pain. In patients with these complications, portal vein stenting can be considered. However, the stent reocclusion rate is high, and the survival benefit of this approach is unknown. Thrombolytic therapies have been used particularly for acute thrombotic events, but the complication rate is high, and therefore, it cannot be recommended at this time. Portal vein thrombosis, particularly of recent onset, can be safely treated with anticoagulation therapy. All patients with pancreatic cancer, who undergo surgery, should be considered for prophylactic anticoagulation.

Low-molecular weight heparin has been proven to be superior to coumarin in prospective studies. Administration of the latter is complicated in patients with metastatic pancreatic cancer because of gastrointestinal symptoms such as emesis, concurrent chemotherapy, antibiotics, liver dysfunction, and malnutrition that results in vitamin K deficiency. The randomized comparison of low-molecular weight

heparin and oral anticoagulant (CLOT) study reported a 17% thromboembolic risk with coumarin as compared with a 9% risk with dalteparin [75]. Only 46% of the patients randomized to the coumarin arm had therapeutic anticoagulation in this study despite intensive monitoring. Therefore, low molecular weight heparin is preferred to coumarin anticoagulation for the treatment of thromboembolic disease in cancer patients. In the CLOT study, the investigators also reported a significantly higher mortality with coumarin, as compared with the low-molecular weight heparin arm (20% vs. 35% at 12 months, $p = 0.03$). These data have raised the discussion regarding prophylactic anticoagulation for pancreatic cancer patients, to favorably impact both thrombosis and early mortality.

As per National Comprehensive Cancer Network (NCCN) guidelines for the treatment of venous thromboembolism in cancer patients [76]: (1) all hospitalized cancer patients should be considered for thromboembolic prophylaxis with anticoagulants in the absence of bleeding or other contraindications; (2) routine prophylactic anticoagulation is not recommended, with the exception of patients receiving thalidomide or lenalidomide; (3) patients undergoing major surgery for malignant disease should be considered for pharmacologic thromboprophylaxis; (4) low molecular weight heparin is the preferred agent for both the initial and continuing treatment of cancer patients with established VTE; and (5) the effect of anticoagulants on cancer patient survival requires additional study and cannot be recommended at present.

Three low-molecular weight heparins have been approved for clinical usage in the United States: enoxaparin, dalteparin, and tinzaparin. Fondaparinux has also been approved, but is a pentasaccharide and not a heparin. There are no known differences between these, in terms of effectiveness, and there are few comparative studies. Wells et al. compared initial therapy of either tinzaparin or dalteparin followed by coumarin in thromboembolic disease and reported no significant differences between the treatment arms in either recurrent thrombotic or bleeding events [77]. They concluded that tinzaparin and dalteparin were safe and effective in outpatient treatment.

The direct oral anticoagulants, including the direct factor IIa inhibitor dabigatran and the factor Xa inhibitors apixaban, rivaroxaban, and edoxaban are under investigation in cancer patients. These agents offer practical benefits over traditional anticoagulants including ease of administration without frequent laboratory testing for monitoring coagulation parameters and reduced food interactions. However, data regarding long-term safety and efficacy in cancer patients is lacking. Subgroup analysis of the recent EINSTEIN-DVT study did investigate the safety and efficacy of rivaroxaban in patients with active malignancy and demonstrated no significant difference in venous thromboembolic recurrence or bleeding complications between the rivaroxaban and low molecular weight heparin followed by warfarin [78]. However, increasingly low molecular weight heparin is being used long-term instead of warfarin and this trial did not use the latter in the control arm. Given the limited prospective clinical trial data demonstrating the safety and efficacy of direct anticoagulants in cancer patients and lack of appropriate control arms, current published guidelines do not recommend their routine use in patients with cancer.

The use of inferior vena cava (IVC) filters in patients should be only in patients with contraindications to anticoagulation or in case of anticoagulation failure [79]. IVC filters offer short-term protection from pulmonary embolism but are associated with higher rates of deep vein and filter-site thrombosis compared with no filters and have not shown to offer any survival benefit.

Conclusion

- Treatment goals should be reviewed with the patient from the outset. Patients who are educated regarding their prognosis, treatment alternatives, and likelihood of success or failure can make informed treatment choices.
- Depressive symptoms are common in pancreatic cancer and often associated with uncontrolled pain, poor functional status, advanced disease, and inadequate social support. The diagnosis follows standard definitions and treatment is not substantially different from the primary-care setting.
- Gastroparesis is an under-recognized and therefore undertreated problem, despite its common occurrence. Early satiety, nausea, and cachexia in the absence of mechanical gastric outlet obstruction should raise suspicion. Nuclear gastric emptying study is useful to establish the diagnosis. Dietary and behavioral modification, prokinetics, and anti-emetics form the cornerstone of therapy. In refractory cases, enteral tubes and nutritional supplementation are required.
- Cachexia in pancreatic cancer is multifactorial in etiology and unrelated to the stage of the disease. Steroids and anti-inflammatory agents are used in its pharmacotherapy. Control of hyperglycemia, nutritional support, and pancreatic enzyme supplementation improves symptoms and prevents further weight loss.
- Ascites resulting from pancreatic cancer can be secondary to the tumor or its effects such as vascular or lymphatic blockade. Low serum to ascites albumin gradient is suggestive of carcinomatosis. Large-volume paracentesis is safe, and in case of recurrent ascites tunneled indwelling catheters are preferred. Non-tunneled pigtail catheters are associated with a higher infection risk.
- Constipation results not only from the use of opioid analgesics, but as a result of paraneoplastic and tumoral infiltration. Stimulant laxatives and stool softeners are the preferred initial approach, along with oral hydration. In resistant cases, osmotic laxatives are needed. The advent of peripheral opioid receptor antagonists, such as methylnaltrexone, has introduced a new paradigm in the management of this condition.

Therapeutic Endoscopy in the Management of Pancreatic Cancer

Alyson McGhan and Rebecca Burbridge

Contents

Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) is a safe and reliable method for the diagnosis, treatment, and palliation of pancreaticobiliary malignancy. In 2015, the estimated new cases of pancreatic cancer were about 48,960. The 5-year survival of pancreatic cancer is dismal at approximately 5% Siegel et al. (CA: Cancer J Clin 65(1):5–29, 2015). ERCP provides less invasive approaches to diagnosis with examination of the biliary and pancreatic ducts. The procedure also allows for therapeutic relief of biliary obstruction. Advanced endoscopic techniques offer palliation of symptoms related to advanced

Overview of ERCP

Since its inception in 1968, endoscopic retrograde cholangiopancreatography (ERCP) has become widely used in a variety of pancreaticobiliary disorders. Over the decades, the therapeutic and diagnostic applications of ERCP have changed to match the improvement in its technology for direct and nondirect visualization in conjunction with improvement in therapeutic devices and techniques.

ERCP combines endoscopy with fluoroscopy. Usually sedated by monitored anesthesia care or general anesthesia, a side-viewing endoscope, or duodenoscope, is passed through the patient's mouth and into the duodenum in order to visualize the ampulla of Vater. Cannulation of the desired duct is required for successful diagnostic and therapeutic ERCP. Cannulation is done with the use of sphincterotomes and guidewires in order to gain access. Once access is achieved, ductal anatomy is defined by injection of contrast into the biliary or pancreatic ducts, while fluoroscopy is employed for visualization. When the desired duct is accessed, several devices can be deployed such as biopsy forceps, stents, or balloon dilators for the goal of diagnosis or management of multiple pancreaticobiliary disorders.

Though ERCP is relatively safe, even in a skilled endoscopist's hands, the overall rate of adverse events approaches approximately 5–10%. Consensus definitions of adverse events related to endoscopic sphincterotomy and its severity grading were first introduced in 1991 and still widely used today. The most common adverse complication is pancreatitis which occurs in about 5% of cases. Post-ERCP pancreatitis can often require hospitalization for treatment and can be severe, requiring prolonged hospitalization and need for intensive care. Other common adverse events include bleeding, infection, and perforation. Death is rare and occurs in $<0.5\%$ of cases and is typically related to cardiopulmonary events related to sedation.

Diagnosis

Most patients with pancreatic adenocarcinoma present with obstructive jaundice, which unfortunately is a sign of advanced disease. Suspected pancreatic malignancy is often evaluated with multiple imaging modalities including CT or MRI; however, the diagnosis of pancreatic cancer relies heavily on the identification of a pancreatic

mass. Unfortunately, there are many instances in which there is no identifiable mass and ERCP is then necessary. The role of ERCP in the evaluation of pancreatic malignancy includes visualization of the ductal anatomy as well as histologic or cytologic tissue sampling. Endoscopic ultrasound has largely overtaken ERCP for the diagnosis of pancreatic head adenocarcinomas. However, ERCP with brush cytology and biopsy may be required for the evaluation of pancreatic duct strictures or in cases with nondiagnostic EUS sampling [1].

Endoscopic Features

Ductal adenocarcinoma is the most frequent type of pancreatic adenocarcinoma. It has nonspecific early symptoms, and there are no general tests for screening. ERCP findings suggestive of pancreatic cancer include stricture of both the bile and pancreatic ducts with upstream dilation, also known as the double duct sign. In a single center retrospective study, 355 patients with pancreatic duct strictures on ERCP were reviewed. The study revealed that 65% of patients with a double duct sign were diagnosed with pancreatic cancer resulting in a sensitivity of 76.7% and positive predictive value of 65%. Another endoscopic feature that was strongly associated with malignancy was stricture location within the pancreatic head or neck (odds ratio of 42, $p < 0.0001$) [2]. Overall, ERCP reaches a sensitivity of 80–90% for the diagnosis of ductal pancreatic adenocarcinoma.

Stricture features may assist in predicting prognosis of pancreatic cancer. Length of the stricture has been predictive of tumor size and stage. In a small retrospective study of 18 patients who underwent ERCP prior to surgery between 1991 and 1996, stricture length of biliary and pancreatic strictures was measured and compared to surgical specimens [3]. Pancreatic duct stricture length measured on ERCP correlated with both size (<0.001) and stage (<0.002) in resectable pancreatic cancer [4, 5].

Tissue Sampling

A key role in diagnostic ERCP is for tissue sampling via brushing, biopsy, or aspiration in order to achieve a definitive diagnosis. While tissue sampling should have a high sensitivity and specificity, simple to perform, and reliable, this is not always the case for pancreaticobiliary malignancy requiring diagnostic ERCP. Thus, diagnosis remains dependent on the technical skill of the endoscopist and the resources available within that center.

Malignant strictures of the bile duct are commonly caused by pancreatic cancer, cholangiocarcinoma, or periampullary carcinomas. Malignant strictures are difficult to differentiate from benign strictures caused by bile duct stones or inflammatory strictures due to chronic pancreatitis. The incidence of benign disease on pathology after pancreaticoduodenectomy for a presumed malignancy is estimated at 5–13% [6]. Confirming malignancy through tissue diagnosis is important before considering more aggressive surgical or medical management. The techniques utilized for tissue

sampling during ERCP remains important for adequate diagnosis of pancreatic cancer.

Brush Cytology

Brush cytology was first introduced in the 1970s for the diagnosis of malignant biliary or pancreatic strictures. Even now, brush cytology performed at ERCP has become the preferred initial method for tissue sampling of pancreaticobiliary ductal strictures. Several endoscopic factors can influence the yield of cytology including length of stricture, tightness of stricture, and location of the stricture. The quality of cytological specimen also affects the diagnostic yield including processing technique, cellularity, cellular preservation, and quantity of diagnostic cells. Though brush cytology is commonly utilized, the sensitivity has been reported to be as low as 30% [7]. Not only is the collection of biliary duct cytology important in diagnosis but the interpretation by an expert cytopathologist is paramount. In a study by Wight and colleagues, 129 biliary brushings from 120 patients were reviewed. The sensitivity of diagnosis of malignancy was increased from 49.4% to 89% when two expert cytopathologists reviewed the specimens instead of one cytopathologist. The authors deduced that this difference was due to the increased accuracy in diagnosis when more time was taken to review the specimen and the second reviewer reclassified "atypical" or "suspicious" results to malignancy [8]. Despite the ease of obtaining brush cytology, low complication rate, and low cost, the sensitivity of routine cytologic analysis remains suboptimal. Multiple studies have reported a specificity of nearly 100%; however, there is a wide range of sensitivity from 30% to 80%. There have been various attempts at increasing the yield of brush cytology such as dilating the stricture prior to brushing, new brushing devices, and use of supplemental testing and biomarkers.

Increased knowledge of cancer biology and genetics has paved the way for improved detection of malignancy. The use of fluorescence in situ hybridization (FISH) has advanced the yield of brush cytological sampling. Malignant cells typically have chromosomal abnormalities such as aneuploidy and gene deletions. These chromosomal alterations are visible with the use of FISH whereby fluorescently labeled DNA probes are used to identify specific chromosomal loci. In a study of 131 patients who were being evaluated for malignant biliary strictures, the sensitivity of cytology and FISH for the detection of bile duct brushing specimens were 15% and 34% ($p < 0.01$), respectively. The specificity of cytology brushings and FISH were 98% and 91% (p-0.06), respectively [9]. This study suggests that FISH can be used as an adjunct to routine brush cytology for the evaluation in patients suspected of having a malignant bile duct stricture. Gonda et al. [10] assessed 76 patients with indeterminate biliary strictures and revealed polysomy FISH had increased the sensitivity of brush cytology from 21% to 58% with a specificity of 98%. With the additional evaluation of institutional cost per patient of FISH, Gonda et al. concluded that the use of FISH should be limited to the evaluation of strictures with previously nondiagnostic cytology examination.

Brush cytology alone is not sufficient for the diagnosis of malignant biliary strictures, therefore alternative and supplemental methods for tissue sampling and cytohistopathologic examination is necessary.

Stricture Biopsy

Due to the low sensitivity of brush cytology, other methods for tissue collection have been developed. Biopsy of bile duct strictures with forceps was introduced in the early 1990s.

Stricture biopsy provides information about tissue structure as well as details on tissue invasion depending on the depth of the biopsy, unlike brush cytology. The data has been mixed about whether stricture biopsy has significantly improved clinical utility compared to brush cytology. In a recent review of 241 patients with biliary strictures at a single institution who underwent transpapillary brush cytology or forceps biopsy, the investigators looked to evaluate the diagnostic yield of brush cytology and biopsy forceps. The study revealed that the sensitivity of forceps biopsy for malignant biliary strictures was higher than that of brush cytology (60.6% vs. 36.1%, $p < 0.01$) [11]. In a meta-analysis of nine studies, the pooled sensitivity of intraductal biopsy and brush cytology in diagnosing malignant biliary strictures were 48.1% and 45%, respectively. A combination of both only modestly increased sensitivity to 59.4% [12]. Based on this meta-analysis, the use of both brush cytology and intraductal stricture biopsy during ERCP increases the yield in the diagnosis of malignant biliary strictures; however, the combined approach still has a relatively low diagnostic yield for malignancy.

Ductal biopsies may be more difficult to obtain as forceps are not passed over a wire and may pose a greater risk of perforation when the forceps are advanced through a fresh sphincterotomy. Unlike biliary brushings, biopsies are not obtained as often, may be difficult to obtain because of fibrosis, require greater technical skill, involve more time, and pose a slightly increased risk. There are differences of opinion on the value of biopsies, however. The use of a combined (i.e., brushing plus biopsy) approach may be employed in indeterminate strictures in whom there is a high suspicion for pancreatic cancer.

Fluid Aspiration and Molecular Analysis

Prior to the widespread use of EUS-FNA, cytologic examination of pancreatic juice aspirated during ERCP was utilized; however, the sensitivity of pancreatic juice aspiration ranges from 33% to 76%. Several tumor markers are tested to aid in the diagnosis of pancreatic cancer, including K-ras, CA 19-9, p53, and Span-1. Of the tumor markers, K-ras has been the most studied. Mutation of K-ras oncogene is one of the most common gene alterations in human malignancies and frequently found in pancreatic adenocarcinoma, occurring in up to 76% of cases. Multiple analyses have demonstrated that K-ras is a valuable molecular marker and independent diagnostic

tool for pancreatic cancer. K-ras in pancreatic juice has a higher sensitivity and specificity than that of serum K-ras; however, the biggest drawbacks of pancreatic juice K-ras include the high false-positive rate [7, 13, 14]. K-ras can be found in up to 25% of cases of chronic pancreatitis without evidence of malignancy. These results have been supported by other studies which have noted detectable K-ras in chronic pancreatitis or even in normal pancreas without evidence of malignancy on follow-up [15]. Serum carbohydrate antigen, CA 19-9, and Span-1 have also been associated with the presence of malignant pancreatic cells collected in bile duct aspiration, and CA 19-9 levels may indicate response to chemotherapy for pancreatic cancer; however, there is no consensus on the routine use of these tests on aspirates [16].

Cholangiopancreatoscopy

Over the recent years, much more focus has been placed on direct visualization of the biliary and pancreatic ducts. High-definition visualization with cholangiopancreatoscopy enhances the diagnostic yield of ERCP, particularly in patients with indeterminate biliary strictures. The advent of single operator cholangioscopy has improved the sensitivity and specificity in the diagnosis of malignant biliary strictures. Miniature endoscopes and optical catheters are passed through the working channel of a therapeutic duodenoscope during ERCP. Fiberoptic cholangioscopes range in 3.1–3.4 mm in diameter with a working channel of 1.2 mm that allow for biopsy forceps to be passed. Cholangioscopic findings suggestive of malignancy include the presence of easy oozing, irregular surface, as well as the presence of irregular, dilated, tortuous vessels called tumor vessels [17]. Though the tumor vessel may predict malignancy, it still does not help differentiate between biliary or pancreatic malignancy. In a prospective multicenter trial of cholangioscopy, a subgroup analysis of 95 patients demonstrated a sensitivity of the diagnosis of malignancy of 51% with ERCP impression, 78% with cholangioscopy impression, and 49% with cholangioscopy-directed biopsy. Specificity of each modality was 54%, 82%, and 98%, respectively [18]. Cholangioscopy has been used as an adjunct to ERCP in patients with previously diagnosed indeterminate strictures. Among 18 patients with indeterminate strictures who underwent cholangioscopy, 11 (61%) had a final diagnosis of malignancy [19]. In another recent large prospective multicenter study out of Japan, a total of 148 patients were enrolled for the diagnosis of indeterminate biliary or pancreatic strictures and for treatment of pancreaticobiliary disease. The procedure success rates for identifying the target lesions were 91.2%. Adequate tissue for histologic exam was secured in 81.4% of all patients who underwent directed biopsy by cholangiopancreatoscopy. Specifically, in those with pancreatic duct lesions, adequate tissue by direct biopsy was secured in 90.9% of patients. The incidence of adverse events was 5.4% [20]. Complications specific to cholangiopancreatoscopy include higher rates of cholangitis and pancreatitis related to intraductal irrigation compared to standard ERCP. As biliary endoscopists have become more familiar with cholangioscopy, there have been advances in the

modalities of visualization. Several techniques have included narrow band imaging (NBI), confocal endomicroscopy, as well as intraductal ultrasonography.

Cholangioscopy in combination with standard ERCP and brushings has increased the sensitivity for the diagnosis of malignant biliary strictures. Though the use of cholangioscopy has increased, it is still limited to centers with advanced biliary endoscopists and remains a technically challenging procedure.

Therapy

Surgery is the curative treatment of choice for pancreatic adenocarcinoma; however, only 20% of patients with pancreatic adenocarcinoma are found to have localized, operable disease at time of diagnosis. Unresectable pancreatic adenocarcinoma, primarily within the head of the pancreas, commonly presents as obstruction of the common bile duct as well as the duodenum, and therefore the goal of treatment is that of palliation. Advanced endoscopic procedures, such as ERCP, have now moved to the forefront in the management of stabilizing localized disease or palliation of advanced disease, given the higher morbidity and mortality with surgical approaches to palliation (i.e., biliary bypass, gastrojejunostomy) [21].

Palliation of Biliary Obstruction

Endoscopic biliary stenting was first introduced in the early 1980s with the use of plastic stents for decompression of biliary strictures. Until then, surgery was the mainstay of therapy. Placement of biliary stents is performed under fluoroscopic guidance once biliary cannulation is successful. Biliary sphincterotomy is typically performed prior to stent placement. The choice of stent will be determined by the length of the biliary stricture, relationship of cystic duct to the common bile duct, and the tumor characteristics and patient prognosis. The questions about durability and patency of plastic stents later fueled the development of metal stents in the late 1980s.

The goals of palliation using biliary stent placement are for symptomatic relief of obstructive jaundice, prevention of cholangitis, and prolongation of survival. Stenting has also been found to improve quality of life. Hyperbilirubinemia has been associated with poor quality of life in patients with malignant biliary obstruction and contributes to jaundice, pruritus, anorexia, and weight loss. Biliary decompression effectively improves QOL due to its improvement in the symptoms related to hyperbilirubinemia [22, 23].

Plastic stents were first designed for biliary decompression of malignant biliary strictures. Plastic stents are composed of polyethylene, polyurethane, or Teflon. Stent diameter ranges from 5 F to 12 F, though 10 F is the standard size used for bile duct obstruction. All plastic stents are radiopaque. Plastic stents are commonly used because of their efficacy and low cost. The primary indication for self-expandable metal stent (SEMS) placement in unresectable pancreatic cancer is for alleviation of

obstruction and improvement in the quality of life in patients with a survival greater than 4–6 months. SEMS are composed of metal alloys (most frequently nitinol) which allow for adequate expansible radial force without sacrificing flexibility and conformability to the duct. When fully expanded, SEMS diameter ranges from 6 to 10 mm. All self-expandable metal stents are radiopaque. Self-expandable metal stents can be covered, partially covered, or uncovered. They are also much more expensive than plastic stents [24].

Complications of biliary stent placement include the complications related to the ERCP itself along with stent-specific complications, including occlusion and migration. Plastic stents have been observed to have increased rates of occlusion compared to SEMS. Bacterial adhesion to the plastic stent with formation of glycoprotein-rich biofilms has been implicated in stent occlusion as well as the relatively small diameter. Occlusion typically occurs at 3–6 months with plastic stents. Stent occlusion is typically accompanied by cholangitis, and therefore exchange of the plastic stent is necessary [25].

Stent occlusion is also seen in metal stents, though seen at a lower rate. With uncovered metal stents, tumor in growth through the metal lattice has been the primary hypothesis for occlusion. Uncovered metal stents are typically unable to be removed or repositioned due to tumor ingrowth, whereas partially covered or fully covered metal stents can be removed with the use of a snare or repositioned if needed. While plastic stent occlusion is managed by stent removal and exchange, in SEMS typically another stent is placed in a stent-in-stent fashion, as SEMS are unable to be removed. Stent migration also poses concern when determining type of stent. Covered metal stents tend to have increased rates of migration compared to partially covered or uncovered metal stents. In a randomized, multicenter trial of 400 patients with unresectable distal malignant strictures, there was no statistical difference in survival, stent patency, or complication rates in covered versus uncovered metal stents; however, stent migration occurred in 3% of patients in the covered metal group compared to no patients in the uncovered metal group ($p = 0.03$) [26]. Lastly, another concern with the placement of plastic stents and fully covered SEMS is the risk of cholecystitis due to stent position in relation to the cystic duct take-off. The rate of cholecystitis after SEMS has ranged from 5% to 11% in many reports. Several risk factors for cholecystitis after SEMS include stent position as well as tumor involvement to the level of the orifice of the cystic duct [27]. Hence, care must be taken to identify the cystic duct take-off prior to stent deployment.

With the background knowledge of the types of stents available and complications related to each type of stent, multiple studies have been done in order to compare stent types to assist the providers in determining the appropriate stent for the right patient. Long-term outcomes of endoscopic palliative stenting have been detailed in the literature. In a retrospective study of 100 patients with unresectable pancreatic adenocarcinoma, common bile duct obstruction occurred in 81 patients. Of those patients, 74 (88%) had successful endoscopic placement of biliary stents. Of the patients who underwent endoscopic stent placement, 59 patients had SEMS placed at first intention with stent occlusion occurring in 31%. The median duration of metallic stent patency was 7 months. In the 15 patients with plastic stents placed,

13 (87%) developed occlusion with a median stent patency of 2.5 months [28]. One of the first major randomized studies done in Sweden was a single-center randomized prospective trial which compared plastic stents to covered SEMS in patients with malignant biliary strictures. One hundred patients were randomized to the plastic stent group or the covered SEMS group with the primary outcome being time to stent failure, as defined by signs and symptoms of cholangitis and rising bilirubin then confirmed by ERCP. The covered self-expandable metal stents were superior to plastic stents in patency times with a median patency of 3.6 months and 1.8 months, respectively. The investigators noted an overall shorter duration of stent patency compared to previous studies and attributed this to the low overall median survival in this study of 4.5 months [29].

When determining which stent is appropriate for which patient, the most suggested approach is to determine the life expectancy of the patient with unresectable pancreatic adenocarcinoma. In patients with shorter life expectancy, about 4 months or less, the mainstay for decompression is with the use of plastic stents. This is the most cost-effective method for quality of life improvement. With a life expectancy of greater than 4 months, no distant metastasis, or even as a bridge to more definitive therapy, SEMS placement is the most effective choice for biliary decompression. Successful placement of biliary stents to relieve malignant biliary obstruction occurs in greater than 90%. In general, patients with a life expectancy of greater than 4 months, SEMS are preferable to plastic stents due to lower stent failure, lower risk of cholangitis, decreased total number of hospitalizations secondary to stent-related complications, and therefore decreased overall cost.

Stenting in Resectable Disease

For localized pancreatic cancer, the goal is for curative therapy with surgery. However, there has been conflicting evidence about what to do with patients with resectable disease who develop symptoms of biliary obstruction. Stenting can relieve symptoms of biliary obstruction (pruritus, cholangitis), but controversy still remains about whether decompression can decrease the morbidity and mortality related to a Whipple procedure. Concerns of preoperative biliary stenting arise impart from the idea that inflammation from SEMS may lead to complications associated with surgical resection [30, 31]. Several studies have demonstrated that preoperative biliary decompression leads to increased complications, particularly infectious complications. In a Cochrane review which included 6 trials of 520 patients that compared preoperative biliary drainage versus no drainage, there was no significant difference in mortality; however, the overall serious morbidity was significantly higher in the preoperative biliary drainage group compared to the no-drainage group (RR 1.66; 95% CI 1.28–2.16; $P = 0.0002$) [32]. This review included all patients with biliary obstruction whether benign or malignant and noted that the results were at high risk of bias. The authors concluded that there was not enough evidence to support or refute the routine practice of preoperative biliary drainage for obstructive jaundice [25]. A retrospective analysis of 593

patients treated with pancreaticoduodenectomy (PD) at Memorial Sloan Kettering analyzed patients who did receive preoperative biliary drainage for pancreatic cancer to determine whether stent type (SEMS versus plastic) made a difference in surgical outcomes. The study revealed that self-expandable metal stents did not affect postoperative complications, 30-day mortality, length of stay, anastomotic leak, margin status, or determination of unresectability at time of resection; however, there were more wound infections and longer operative times observed compared to plastic stents and those who were not stented (wound infection rates, 31% SEMS vs. 12.8% plastic stent vs. 6.2% no stent groups, $p < 0.001$) [30]. In conclusions drawn from a surgical group in Italy studying post pancreaticoduodenectomy wound infections after preoperative biliary stenting, they note the need to reduce the wait time for PD as well as provide antibiotic prophylaxis to prevent incisional and abdominal wound infections [33].

In patients with locally advanced disease who are candidates for neoadjuvant chemotherapy and with symptoms of biliary obstruction, biliary decompression is necessary in order to proceed with chemotherapeutic agents, usually gemcitabine, while awaiting surgical resection. Placement of self-expandable biliary stents during the neoadjuvant period has been shown to be efficacious with lower complication rates compared to plastic stent placement [33–35]. In practice, routine preoperative biliary stenting is not indicated, except in patients who have a delay in pancreaticoduodenectomy for neoadjuvant chemotherapy or with symptomatic hyperbilirubinemia (i.e., cholangitis). Once the decision is made for biliary drainage, SEMS are superior to plastic stents in patency and appear to have no significant impact on resectability or overall serious impact on surgical complications.

Fiducial Placement

Radiation therapy has a role in the management of pancreatic adenocarcinoma, particularly for locally advanced disease and palliation of pain. Stereotactic radiation therapy allows delivery of high-dose beam radiation with pinpoint accuracy to a localized target. The difficulty with radiation therapy in pancreatic adenocarcinoma is the variation with respiratory motion. Fiducial markers are used for localization of the radiation site and to track respiratory motion. Fiducial markers are radiopaque coils or spheres that are implanted into the target lesion and serve as reference for real-time tumor tracking during radiation therapy. Given the excellent visualization of pancreatic adenocarcinoma within proximity to the luminal gastrointestinal tract, endoscopic ultrasound has become a growing method for the placement of fiducial markers. The technique for injection of fiducials is similar to fine needle aspiration and can be delivered with 19- or 22-gauge needles. Several studies have reported an 88–90% success rate of EUS-guided fiducial placement. The complication rate is approximately 2% with reported complications including pancreatitis, minor bleeding, abdominal pain, and elevated liver enzymes. The rate of fiducial migration has been reported to be about 7% [36, 37].

Palliation of Duodenal Obstruction

Advanced pancreatic adenocarcinoma of the head of pancreas can cause invasion into the adjacent duodenum thereby leading to gastric and duodenal obstruction. Symptoms are characterized by intractable nausea, vomiting, abdominal fullness, and early satiety. Duodenal stenosis can occur in 10–25% of unresectable head of pancreas adenocarcinoma and unfortunately is the presenting symptom in 6% of cases [38]. Historically, management of malignant gastric and duodenal obstruction secondary to pancreatic cancer was open surgical bypass which was a procedure with relatively high morbidity and mortality. The advances in endoscopic therapy have provided effective and less morbid means for palliation of gastric outlet obstruction.

Palliation of gastric or duodenal outlet obstruction is done with an enteral self-expandable metal stent (SEMS) with a large diameter of up to 22 mm and 60–90 mm in length. The stent can be flared at the proximal end or at both ends to help reduce the risk of migration. Due to the size of the delivery catheter, a therapeutic endoscope, which has a large working channel, is required. The stent is positioned across the stricture typically with the use of fluoroscopic guidance. Contraindications to enteral stenting include perforation and multiple discrete areas of distal obstruction, which can be due to peritoneal carcinomatosis. Importantly, peritoneal carcinomatosis alone, without obstruction, is not a contraindication to enteral stenting. Most common complications include stent obstruction, migration, and more rarely perforation. Duodenal stenting has been shown to be technically feasible with a technical success rate of 96% and provides clinical relief of symptoms with an 88% efficacy rate [28, 39]. The difference between technical success and clinical success may be, in part, due to alterations in gastrointestinal motility in patients with pancreatic cancer. In a recent prospective, multicenter observational study out of Japan, 39 patients (41% with pancreatic adenocarcinoma) underwent uncovered self-expandable metal duodenal stent placement for gastric outlet obstruction. The clinical success rate was found to be 92% [40]. Researchers in the UK also report a positive experience with SEMS in relieving gastric outlet obstruction in the setting of advanced pancreatic adenocarcinoma. In a small case series of eight patients, stenting was successful in seven patients with a success rate of 88%. All patients were able to tolerate a solid diet upon hospital discharge. There were no complications in this cohort; however, the median survival after stent placement was 10 weeks. This low median survival unfortunately reflects the advanced and aggressive nature of pancreatic cancer once duodenal invasion occurs. Several investigators have also assessed quality of life scores after palliative enteral stenting for gastric outlet obstruction. In a randomized control trial from Mehta et al. 27 patients were randomized to laparoscopic gastrojejunostomy versus duodenal stenting. Length of hospitalization was longer ($p = 0.02$) and postprocedure pain scores were worse ($p = 0.05$) after laparoscopic gastrojejunostomy. After 1 month, patients who received duodenal stents reported significant improvement in quality of life based on physical health questionnaire assessments [41].

Duodenal obstruction can coincide with biliary obstruction in patients with advanced disease. In this case, biliary stent placement should be done during the same procedure as enteric stent placement. Self-expandable biliary stents should be placed prior to duodenal stent because biliary access becomes significantly difficult as the duodenal stent crosses the papilla [39]. Palliation of duodenal obstruction with enteral stenting improves quality of life with less associated morbidity and mortality and has become the method of choice.

Palliation of Pain

Medical management of pain secondary to pancreatic cancer relies on nonsteroidal anti-inflammatory medications, with opioids as the next line. Abdominal pain is a common symptom for pancreatic adenocarcinoma. It is usually chronic, continuous, and dull, often requiring opioids for relief. Opioids can often provide adequate relief but are associated with constipation, sedation, drowsiness, nausea, and vomiting. There are many cases in which pain symptoms become severe and resistant to opioids. It is postulated that refractory abdominal pain is due to tumor invasion into the celiac plexus or neural alterations within the pancreas itself. With EUS guidance, advanced endoscopists have begun to relieve abdominal pain symptoms with celiac plexus neurolysis and blocks. The procedure is technically straightforward since the celiac axis is typically located within a few centimeters of the gastric wall. After identification of the celiac artery take-off from the aorta by endoultrasonography, a solution of absolute alcohol is injected adjacent to the ganglion and is used to permanently ablate neural tissue of the celiac ganglion (neurolysis). Alternatively, a solution of triamcinolone can be used for more temporary analgesia (celiac plexus block) though this is a less suitable option for patients with refractory abdominal pain from pancreatic cancer. In a meta-analysis by Puli et al., the pooled proportion of patients with relief of pancreatic cancer pain after EUS-guided celiac plexus neurolysis was 80.2% [42]. The treatment effect is approximately 4–5 weeks, but reports indicate effects can last up to 3 months. Side effects of celiac plexus neurolysis include bleeding, infection, diarrhea, and hypotension. These complications are commonly associated with direct blockade of the sympathetic efferent activity and are typically minor and self-limited [43]. Rare are reports of paresis or paresthesias. Given its reasonable efficacy and favorable safety profile, early consideration of EUS-guided neurolysis is recommended for patients with unresectable pancreatic adenocarcinoma who have abdominal pain requiring regular use of opiates.

Another component of pancreatic cancer pain is “obstructive pain” which is secondary to upstream dilation of the pancreatic duct (PD) due to a distal pancreatic stricture. This pain typically worsens after meals, similar to chronic pancreatitis. One of the initial case series by Costamagna of 12 patients with obstructive pain who received pancreatic duct stents revealed a technical success rate of 66% and pain resolution occurring in 87% [44]. A subsequent small prospective study enrolled 20 patients with unresectable pancreatic cancer with PD obstruction and postprandial

abdominal pain. Plastic pancreatic duct stents were placed. Pain scores decreased by three points at 4 weeks ($p < 0.001$) and quality of life scores also improved at 4 weeks ($p < 0.01$) [45, 46]. Thus, in a selected group of patients with obstructive pain symptoms, pancreatic duct stenting may be an alternative and safe measure for palliation.

Conclusion

Advanced endoscopy, including the use of ERCP and EUS, has become a key tool in the diagnosis, treatment, and palliation of pancreatic cancer. Diagnosis and management of pancreatic cancer require a multidisciplinary approach. The difficulty with diagnosis has driven the field of therapeutic endoscopy to find alternative methods from routine brush cytology, to the use of cytogenetics and molecular analysis to direct visualization imaging modalities and biopsy. With advances in endoscopy and ERCP in particular, there has been an evolution from surgical or percutaneous biliary decompression to endobiliary stent placement, leading to relief of obstructive jaundice, reduction of pain, and improved quality of life. Advanced endoscopists should be an active member in the care of patients with pancreaticobiliary malignancy in all stages of disease.

Abstract

Pancreatic adenocarcinoma is the 12th most common malignancy globally, holding joint position with renal cancer, and is the seventh leading cause of cancer-related mortality and second most common cause of cancer deaths for all gastrointestinal-related carcinomas. Most patients present late in their course and have either locally extensive or metastatic disease with a median survival of only 4–6 months. At the time of diagnosis, unfortunately only 10–20% of patients are candidates for curative resection. The late presentation, aggressive nature, and lack of effective therapies all contribute to the poor prognosis. It is typical that these patients with more advanced disease will undergo either interventional radiology (IR)- or endoscopic ultrasound (EUS)-guided interventions to deliver either preoperative or palliative care. The objective of this chapter is to highlight currently available and emerging IR- and EUS-guided interventions as they apply to the care of patients with pancreatic carcinoma.

Keywords

Endoscopic ultrasound · Endoscopic retrograde cholangiography-guided drainage · Endoscopic ultrasound-guided bile duct drainage · Duodenal stenting · Celiac plexus and ganglia neurolysis · Ablative antitumor therapies

Introduction

During the first 75 years of the American Roentgen Ray Society (ARRS), which was the first established radiology society in the United States, the field of interventional radiology (IR) was viewed largely as a rogue practice that dealt with theoretical concepts and practices. Angiographers were the pioneers of the field, but were often viewed as heretics by surgeons, and their practice was seen as time-consuming and of minimal utility and productivity by radiology colleagues. Early interventions were limited and restricted to the care of bleeding lesions and hypervascular tumors [1]. The advent of modern IR suites containing mobile multi-angle fluoroscopy C-arms, the capability of digital image acquisition, and the development of an array of dedicated accessories fostered the development of new techniques that are applied to a growing number and broader spectrum of diseases.

Similarly, endoscopic ultrasound (EUS) has experienced an evolution in its role since its introduction in 1980. From that time until the mid-1990s, EUS was utilized solely as a diagnostic imaging modality, providing greater diagnostic sensitivity than transabdominal ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomography for most benign and malignant pancreatic disorders [2–6]. With the development of linear array imaging, it became possible to obtain tissue samples under real-time ultrasound guidance permitting fine needle aspiration (FNA) with cytological evaluation and core biopsy histological architecture assessment, which further enhanced diagnostic accuracy [7, 8]. More recently, EUS has been utilized to guide therapeutic interventions for an array of pancreatic disorders.

Interventional radiology- and EUS-guided interventions may be applied with diagnostic and/or therapeutic intent for a spectrum of benign and malignant pancreatic diseases. The objective of this chapter is to review these interventions and to focus more fully on EUS-guided therapies and to discuss the various techniques, their role, and available data as applied specifically to the management of patients with pancreatic carcinoma.

Bile Duct Drainage

Malignant biliary obstruction is most commonly associated with pancreatic carcinoma and develops in 70–90% of patients often resulting in jaundice, pruritus, hepatocellular dysfunction, cholangitis, malabsorption, and coagulopathy [9–11]. Biliary decompression may be achieved by endoscopic retrograde cholangiography (ERC), interventional radiologic or surgical means. These techniques are equally effective at relieving jaundice with no difference in overall survival [10–19]. Endoscopic stent insertion safely and effectively reestablishes bile flow, alleviates jaundice and pruritus, and may improve quality of life (QOL) [10–22]. In addition, ERC and stent placement may offer lower morbidity and mortality, shorter hospitalization, and diminished overall cost compared to radiologic or surgical approaches [10, 13–15, 19]. Therefore, in most centers, ERC is favored for palliation of malignant biliary obstruction in patients who require neoadjuvant therapy as a bridge to surgery or for patients with unresectable disease resulting from extensive locoregional spread or distant metastases as a palliative intervention.

Endoscopic Retrograde Cholangiography (ERC)-Guided Drainage

Endoscopic insertion of plastic or metal stents is technically successful in about 90–95% of patients with malignant biliary obstruction [23–27]. Plastic stents are commonly used due to their efficacy and low cost (Fig. 1). These stents are easily exchanged as long as duodenal narrowing does not prohibit passage of the endoscope. The major drawback of plastic stents is the formation of a bacterial biofilm leading to stent obstruction, recurrent jaundice, and occasional cholangitis. As a result, repeat ERC and stent exchange are necessary in about 30–60% of patients [10, 18, 23, 25, 27, 28]. Efforts to prolong plastic stent patency have included alterations in stent design and administration of ursodeoxycholic acid, antibiotics, aspirin, or other agents [29–32]. Unfortunately, these therapies have had minimal impact on stent patency and clinical outcomes. More recently, self-expanding metal stents (SEMS), which achieve a larger luminal diameter, have been used with the goal of prolonging stent patency (Fig. 2). Comparative trials demonstrate greater patency and overall cost-effectiveness for SEMS relative to plastic stents, due to the need for fewer repeat interventions [23–27]. However, they offer no survival advantage compared to plastic stents and have an uncertain influence on quality of life [23–27]. Therefore, the selection of plastic versus SEMS for the relief of malignant

Fig. 1 A fluoroscopic image demonstrates the deployment of two plastic stents that provide drainage for malignant biliary obstruction

Fig. 2 A fluoroscopic image demonstrates the deployment of two metal stents that provide drainage for malignant biliary obstruction

extrahepatic biliary obstruction is currently debated. However, most agree that for patients with biopsy-proven unresectable malignant obstruction as a bridge to surgery while receiving neoadjuvant therapy or poor operative candidates, with >6 months of expected survival, the weight of evidence favors initial insertion of a SEMS (Fig. 3). In this setting, the prolonged patency provided by SEMS compared

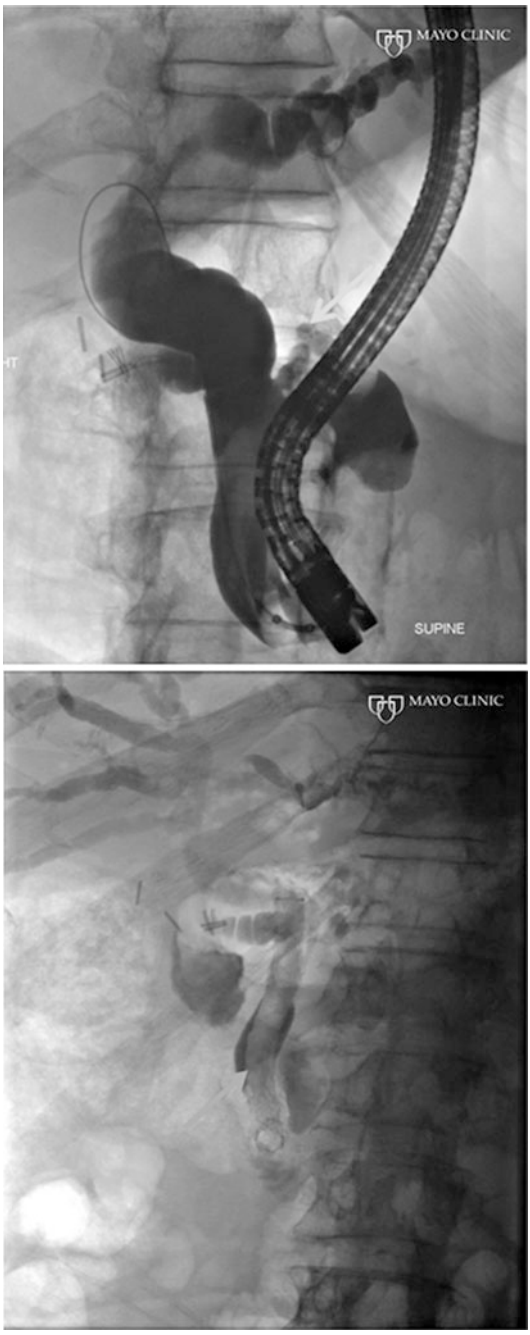

Fig. 3 A patient with malignant transformation of IPMN presented with jaundice secondary to passage of mucous via a fistula tract that developed from the pancreatic duct and tumor into the biliary tree (*top image*). A covered metal stent was placed to inhibit the flow of mucous resulting in marked improvement in the biliary obstruction (*bottom* image)

to plastic stents favors their use for patients with relatively prolonged expected survival because of the potential to obviate the need for repeat ERC and stent exchange. For patients with expected survival of 6 months or less, the literature supports placement of a plastic stent [33]. The principles of stent patency and selection appear to apply regardless of the means of access or deployment.

Interventional Radiology (IR)-Guided Drainage

ERC may not provide drainage secondary to failed cannulation, presence of severe tumor-induced stricturing of the bile duct and/or duodenum, or an inaccessible papilla secondary to congenital or surgically altered anatomy. In the case of failed ERC, depending on the center, interventional radiology may be employed to perform a percutaneous transhepatic biliary drainage (PTBD). PTBD was initially described more than three decades ago and is usually performed using transabdominal ultrasound guidance [34]. An intrahepatic bile duct branch is accessed usually with an 18–22-gauge needle and a guidewire is inserted over which a 7–10-Fr catheter is placed under fluoroscopic guidance. Puncture with a smaller caliber (22-gauge) needle has been shown to be safer in patients without intrahepatic bile duct dilatation. Drainage is successful in approximately 95% of patients with dilated intrahepatic bile ducts, but only 70% of patients with non-dilated ducts [35]. Complications develop in as many as 32% of patients undergoing PTBD including cholangitis, fistula formation, peritonitis, empyema, and liver abscess [36, 37]. Percutaneous metal stent placement provides comparable palliation regardless of tumor site (proximal vs. distal) and irrespective of tumor type. Studies demonstrate that for extrahepatic malignant obstruction, the duration of stent patency is comparable whether the stent traverses the malignant stricture and papilla as compared to a position proximal to, and upstream from, the site of obstruction [38].

Endoscopic Ultrasound (EUS)-Guided Drainage

EUS is a more recently introduced method for providing bile duct drainage following failed ERC and provides an alternative to IR and surgical approaches. Depending on the procedure indication, patient anatomy, and scope access, one may use EUS to perform either transpapillary or transanastomotic drainage versus transluminal drainage in the form of either a hepaticogastrostomy or choledochoduodenostomy. EUS is ideally performed with a “therapeutic” linear array echoendoscope that contains a larger caliber channel thereby allowing the use of a greater array of accessories and insertion of larger (up to 10-Fr) diameter stents. Smaller caliber “diagnostic” echoendoscopes may be used to perform a rendezvous wire passage or for placement of 7-Fr or smaller stents.

The most common indication for EUS-guided biliary tree access and therapy is following failed efforts at standard endoscopic (ERC) techniques, for access and drainage may occur as a result of:

1. Underlying pathology, including inflammation, tumor, stricture, stone, etc., that prohibits biliary and/or gastrointestinal luminal access or traversal
2. Anatomical variants such as a duodenal diverticulum, pancreas divisum, or a disrupted duct
3. Surgically altered anatomy resulting from pancreaticoduodenectomy or anastomotic stricture

These techniques are also performed following failed, or instead of, percutaneous efforts for biliary and standard endoscopic (ERC) techniques, for access and drainage may occur as a result of caliber channel thereby allowing ultrasound for poor operative candidates.

Transpapillary/Transanastomotic Drainage

Transpapillary drainage is possible only when a guidewire can be advanced through the site for biliary and standard endoscopic (ERC) techniques, for access and drainage may occur as a result of completion of the rendezvous portion of the procedure. Similar techniques and principles apply to transanastomotic drainage, which may be necessary to evaluate for tumor recurrence or complications following pancreaticoduodenectomy.

The procedure involves positioning the echoendoscope within the stomach or duodenum in a manner that allows traversal of the least amount of tissue to access the desired duct. The echoendoscope is typically placed within the duodenal bulb when accessing the extrahepatic bile duct or within the stomach (cardia, fundus, or proximal body) when accessing an intrahepatic bile duct. Concurrent EUS imaging allows one to exclude the presence of intervening structures such as blood vessels and any undesired ducts. A needle is advanced under EUS guidance preferentially into a dilated duct and one that lies in a longitudinal (or parallel) orientation in order to facilitate access, passage of accessories, and device deployment. Typically either a 19- or 22-gauge needle is employed. Larger caliber needles allow the use of a larger gauge and stiffer wire that facilitates traversal of stenotic strictures and passage of accessories. However, initial duct access can be more difficult when using a larger gauge and stiffer needle. A clear understanding of the procedure goals can help guide equipment selection. For example, it may be reasonable to use a 25-gauge needle if the intended goal is to only obtain a cholangiogram. Some also prefer the smaller gauge needle to determine if contrast freely flows into the anastomosed bowel lumen suggesting the absence of critical stenosis, thereby potentially obviating the need for therapeutic intervention (e.g., anastomotic dilation and stenting). However, this practice is controversial and some instead advocate noninvasive imaging modalities such as magnetic resonance imaging (MRI) and cholangiopathy (MRCP).

Duct access is confirmed by aspirating bile and performing cholangiography, which also allows delineation of the anatomy. Next a guidewire is advanced in an antegrade fashion across the site of obstruction and papilla under fluoroscopic guidance and then coiled within the small bowel to reduce the risk of dislodgement that may occur with removal of the echoendoscope or during insertion of the duodenoscope. Care must be taken to minimize the risk of wire shearing that may

result from manipulation of the wire and abrasion against the sharp needle tip. The selection of guidewire caliber is based on the needle caliber. The use of a 19-gauge needle allows the use of 0.035 in guidewires or smaller, whereas 22-gauge needles can only accommodate 0.018 in guidewires. One cannot automatically assume that a needle of a particular gauge, or wire of a particular caliber, can replace a similarly sized needle or wire, because of the minor variation that exists in equipment among companies [39].

Depending on the echoendoscope orientation, access from the duodenal bulb often results in passage of the guidewire into the proximal (intrahepatic) ducts rather than distally through the papilla. This problem can usually be overcome by altering the scope position and/or by elevator deflection. Alternatively, the guidewire may be intentionally advanced into the intrahepatic biliary tree to induce looping and eventual passage in the alternate direction toward the papilla. Likewise, access to the left intrahepatic bile duct often leads to inadvertent passage to the right intrahepatic ductal system instead of the intended extrahepatic bile duct, sometimes overcome by altering the angle of entry or by intentionally looping within the right system and eventually distal migration.

Once the guidewire is adequately positioned, the echoendoscope is back-loaded leaving the guidewire in place and the rendezvous portion of the procedure is performed. To do so, a standard forward-viewing or side-viewing duodenoscope is advanced alongside to the guidewire and down to the papilla or site of anastomosis. A snare or biopsy forceps is used to grasp the guidewire, which is then withdrawn through the accessory channel. Care must be taken when grasping and retracting the guidewire due to the resulting tension that may be placed on the wire and resulting risk of severing tissues traversed by the wire. Thereafter, the ERC (retrograde) portion of the procedure, including dilation (catheter or balloon) and stent placement, is performed in standard fashion. In patients requiring transanastomotic drainage, for instance, within an afferent jejunal limb or Roux-en-Y reconstruction after pancreaticoduodenectomy, the ERC is typically performed with either a pediatric colonoscope or a prototype long, oblique-viewing enteroscope [39].

Transluminal Drainage

Transluminal stenting indicates the creation of a trans-enteric fistula with placement of a stent across the gastric wall into an intrahepatic bile duct (hepaticogastrostomy) or across the duodenal bulb wall and into the extrahepatic bile duct (choledochoduodenostomy) via a suprapancreatic or intrapancreatic route. These techniques are required when the guidewire cannot be advanced through the site of obstruction or papilla or when an endoscope cannot be advanced into the small bowel to allow guidewire retrieval.

While many of the aforementioned techniques and principles for EUS-guided transpapillary drainage also apply to transluminal drainage, there are some notable differences. The goal of EUS-assisted portion of transpapillary drainage was simply to provide guidewire insertion to allow the subsequent rendezvous portion of the exam (Fig. 4). Therefore, transpapillary drainage does not require dilation of the tract from the gut wall to the bile duct and intervening tissues. In this circumstance, a

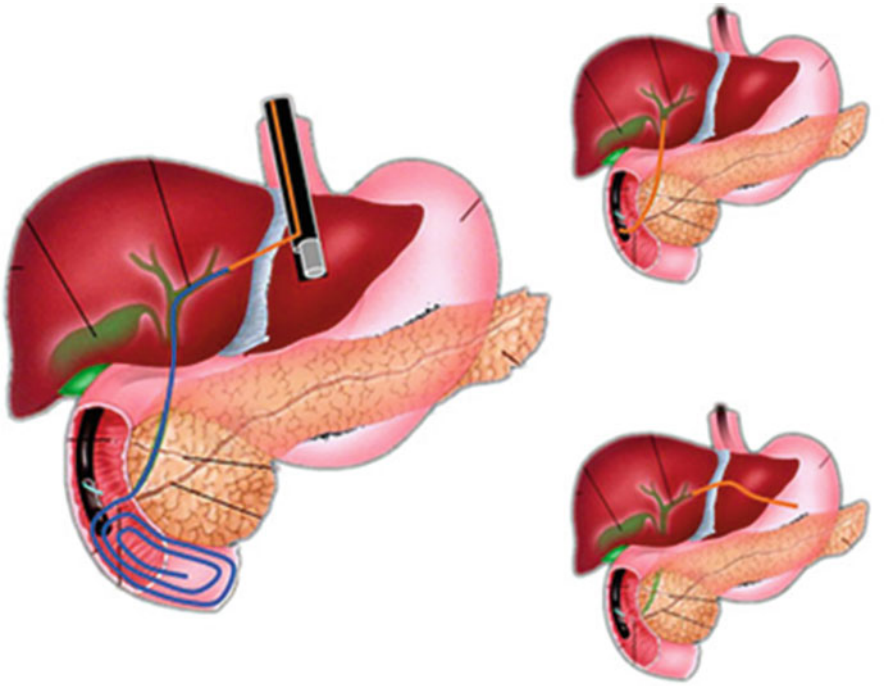

Fig. 4 Aspects of EUS-guided rendezvous procedures. The image to the *left* demonstrates EUS-guided access to a left intrahepatic bile duct with guidewire passage through the papilla and coiled within the duodenum as may be necessary following failed endoscopic retrograde cholangiography. Doing so allows subsequent transpapillary drainage (*right*, *top*). When transpapillary drainage cannot be achieved, then hepaticogastrostomy with stent placement through the stomach to an intrahepatic bile duct provides an alternative means of drainage (*right*, *bottom*)

smaller channel diagnostic echoendoscope is sufficient. Transluminal drainage, on the other hand, does necessitate tract dilation and benefits from the use of a larger caliber echoendoscope thereby allowing the use of a broader range of accessories and deployment of larger caliber stents. A variety of standard biliary and pancreatic catheter dilators and balloon dilators may be used with selection based on the patients' anatomy. Equipment use varies among endoscopist and may require trial and error and often necessitates use of multiple devices. Following tract dilation, a stent is advanced through the gut lumen and into the biliary tree. There are also reports of EUS-guided antegrade stent insertion directly into a dilated bile duct via the gastric wall [40].

Technical Success, Outcomes, and Complications (For EUS-Guided Bile Duct Drainage)

There is a relative paucity of data regarding EUS-guided bile duct drainage, and they arise from studies that employed varying techniques and sometimes limited methodology (Figs. 5 and 6). Therefore, it is not possible to firmly establish the technical success

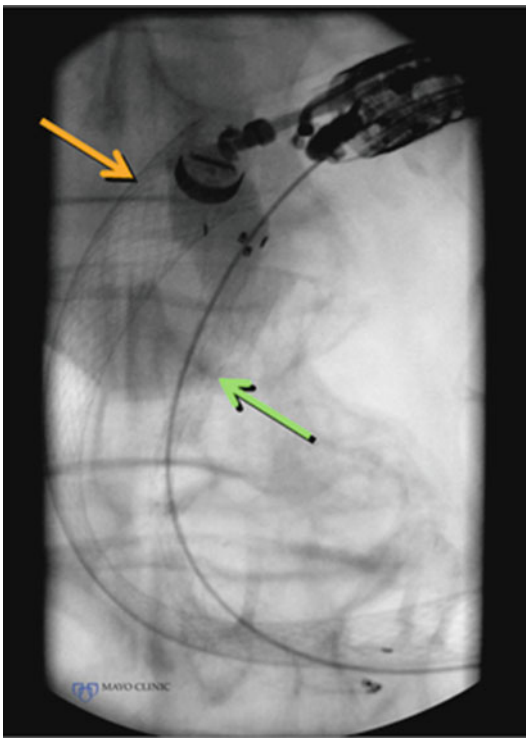

Fig. 5 A patient presented with an indwelling duodenal stent (*orange arrow*) to help alleviate duodenal obstruction secondary to pancreas cancer. Given that the papilla was no longer accessible and following two failed efforts at ERC, the patient was referred for EUS-guided bile duct access with a stent placed (*green arrow*) via an EUS scope in an antegrade fashion

and complication rates. It is even more difficult to verify the clinical success and role of these techniques based on current data when evaluating the collective literature [1996–2008, $n = 92$ patients]; it appeared that EUS-guided biliary access, either transhepatic or extrahepatic, had a 79% technical success rate (Table 1) [39–52]. Available data suggest that pain relief was experienced in approximately 65% of patients in whom this served as the primary indication for the procedure. The impact on other clinical features such as recurrent pancreatitis or steatorrhea cannot be discerned.

However, with the advent of the development of a lumen-apposing metal stent, there are now some preliminary case reports and series highlighting the possible role in gallbladder drainage for patients ineligible for operative intervention [53–55].

These reports also indicate a complication rate of 14% for patients undergoing EUS-guided biliary intervention. Complications included a bile leak ($n = 3$, one patient with a biloma), cholangitis ($n = 2$), pneumoperitoneum ($n = 3$), and one patient each developing pancreatitis, peritonitis, hemorrhage, ileus, and phlegmonous cholecystitis. The duration of follow-up among these studies is too brief to clearly establish the need and timing of re-intervention and long-term outcomes, and many of the studies did not address this issue. The data, however, suggest that stent migration and/or occlusion developed in approximately 20–55% of patients during an often short duration of follow-up. Yamao noted that stents occluded at a time between 4 weeks and 4 months post-procedure [48].

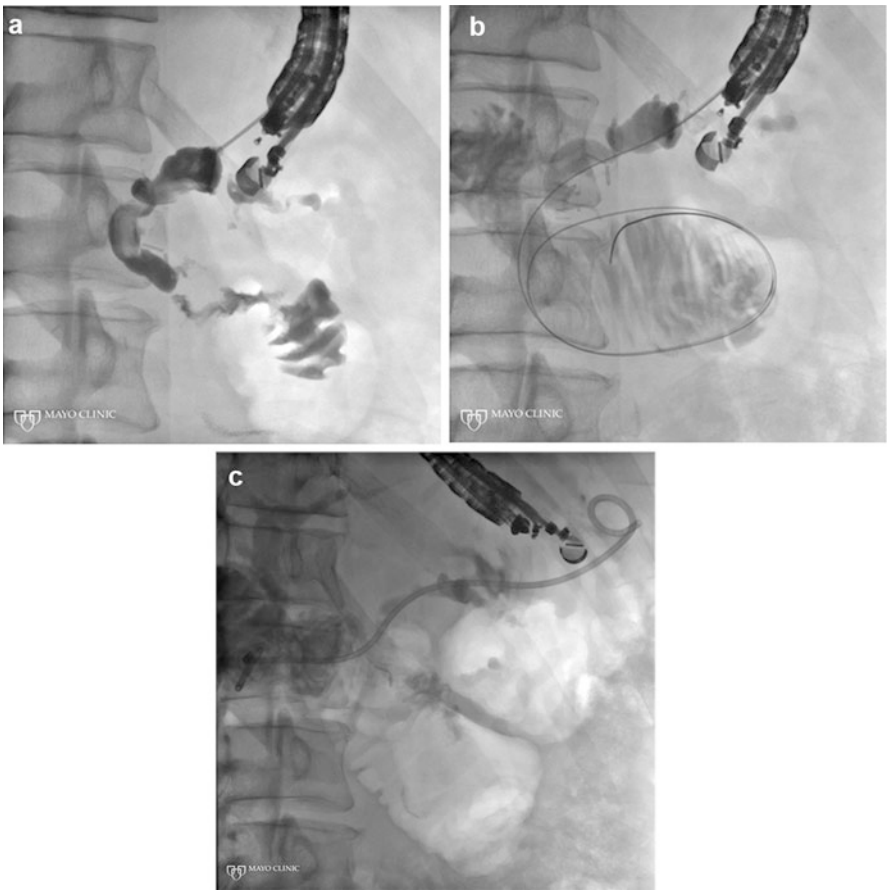

Fig. 6 (**a**–**c**) EUS pancreatitis rendezvous procedure: a patient who had undergone prior pancreaticoduodenectomy for pancreatic cancer presented with recurrent acute pancreatitis felt secondary to a pancreaticojejunal anastomotic stricture. After two failed efforts to identify the anastomosis with a forward-viewing instrument, the patient was referred for EUS-guided therapy. EUS-guided injection revealed a dilated pancreatic duct and anastomotic stricture (**a**). A guidewire was advanced from the stomach, into the pancreatic duct, and coiled within the small bowel (**b**). After balloon dilation, a stent was inserted along the same path (**c**)

Duodenal Lumen Stenting

Patients with pancreatic carcinoma often suffer from gastric retention manifested by bloating, early satiety, and weight loss. This may result from tumor-induced luminal obstruction and/or dysmotility. Palliative surgical intervention for malignant duodenal obstruction is often associated with a significant morbidity. Duodenal stenting has become a popular treatment in cases of malignant stenosis and may be performed by interventional radiologists or endoscopists. These techniques are typically

performed under fluoroscopic guidance and have proven a safe, effective, and less invasive alternative to surgical bypass for managing patients with malignant gastroduodenal outlet obstruction. However, because of the risk, modest impact on clinical endpoints, and cost, there is some debate as to the role and patient selection for these less invasive techniques relative to surgical bypass.

Interventional Radiology (IR)-Guided Duodenal Stenting

Duodenal stenting when performed via interventional radiology involves fluoroscopically assisted catheter and guidewire placement through the esophagus and stomach and eventually traverses the site of malignant duodenal obstruction. Water-soluble contrast is injected to demonstrate the upper and lower aspects of the stricture followed by insertion of a self-expanding metal stent (SEMS). No standard exists regarding catheter, guidewire, or stent selection in terms of length and caliber. Following deployment, contrast is injected to ensure luminal patency and free flow beyond the stent.

Endoscopic Ultrasound-Guided Duodenal Stenting

Endoscopically guided stenting adopts many of the same techniques except for the delivery of devices via a standard forward-viewing endoscope or side-viewing duodenoscope [57]. Initially an endoscopy is performed to delineate the site, degree, and length of obstruction. The length and number of stents used are based on the length of stricture, with the intent that at least 2 cm of additional stent length is on each side of the stricture (Fig. 7). In some cases, multiple overlapping stents may be deployed in a "stent-within-stent" fashion to achieve complete coverage of the stricture. When the nature of the stricture is difficult to interpret by endoscopic visualization, water-soluble radiographic contrast may be injected under fluoroscopic guidance through a catheter passed through the endoscope to define the stricture characteristics. The majority of patients are able to tolerate some oral intake within 24 h of the procedure, and patients should be able to fully resume eating within 7 days. A systematic review of endoscopic SEMS placement for malignant duodenal obstruction analyzed data from 32 case series that included 606 patients [58]. They found that stent placement and deployment was successful in 97% of patients. Clinical success, although variably defined among studies, was achieved in 87% of patients. Disease-related factors accounted for the majority of clinical failures. Subsequent resumption of oral intake was possible for all patients in whom stent deployment was successful, with 87% of patients tolerating soft solids or a full diet, with final resolution of symptoms occurring at a mean of 4 days. There was no procedure-related mortality and the mean survival was 12 weeks. Severe complications (bleeding and perforation) were observed in 1.2% of patients and stent migration was reported in 5%. Stent obstruction developed in 18%, mainly due to tumor infiltration. A more recent prospective evaluation of 51 patients undergoing duodenal stent placement reached

Fig. 7 A fluoroscopic image of a self-expanding metal duodenal stent placed for duodenal obstruction

similar conclusions and demonstrated the feasibility even for those patients requiring concurrent biliary stenting [59]. Priority is often given to first performing biliary stenting prior to duodenal stenting due to the risk and outcome of an uncompressed biliary tree relative to that of gastric retention. However, experience demonstrates that biliary access and drainage may often be achieved either endoscopically or via IR by working through the mesh of a previously placed duodenal SEMS [60]. Similarly, initial placement of a metal duodenal stent proximal to the papilla can allow subsequent biliary access and drainage if necessary (Fig. 8).

Celiac Plexus and Ganglia Neurolysis

Pancreatic cancer commonly produces pain that is difficult to control [61, 62]. Initial therapy with nonsteroidal anti-inflammatory agents is often inadequate and necessitates opioid administration. Although opioids effectively relieve pain, they are associated with a dry mouth, constipation, nausea, vomiting, drowsiness, delirium, and impaired immune function [63, 64]. Therefore, non-pharmacologic therapies, such as celiac plexus neurolysis (CPN), are often given with the goal of improving pain control and quality of life while reducing the risk of drug-related side effects.

Although the terms "celiac plexus" and "splanchnic nerves" are often used interchangeably, they are anatomically distinct structures [65–67]. The splanchnic nerves are located cephalic to the diaphragm (retrocrural), anterior most often to the 12th thoracic vertebra. The celiac plexus is located caudal to the diaphragm (antecrural), surrounds the origin of the celiac trunk, and is comprised of a dense network of ganglia and interconnecting fibers. Ganglia vary in number [1–5], size (diameter

Fig. 8 A fluoroscopic image displaying an example of combined duodenal and biliary metal stent placement in a patient presenting with both duodenal and biliary obstruction

0.5–4.5 cm), and location (T12-L2) [65]. The celiac plexus transmits the sensation of pain for the pancreas and most of the abdominal viscera [68]. The nerves that supply the pancreas can receive nociceptive stimulation and then transmit this pain information to the celiac plexus [69, 70]. Stimuli reach the thalamus and cortex of the brain and this information is perceived as pain. Descending inhibitory mechanisms may also modulate the ascending pain information.

Percutaneous-Guided Celiac Plexus Neurolysis

Kappis described the classic technique in 1914 [71]. Modifications have been created in an attempt to improve the accuracy of needle placement and pain relief, while reducing procedure-related complications. These techniques differ with respect to the route of needle insertion, use of radiologic guidance versus a blind procedure, and chemical composition of the injectate.

For CPN in cancer patients, the injectate usually includes a local anesthetic (bupivacaine or lidocaine) and neurolytic agent (phenol or alcohol). The local anesthetic reduces the discomfort caused by the neurolytic agent. Phenol produces minimal pain because of its local anesthetic effect. Although direct comparisons between alcohol and phenol have not been performed, alcohol is favored because it induces greater neurolysis and presumably greater pain relief [72].

Three meta-analyses have reached conflicting conclusions regarding PQ CPN for intra-abdominal malignancy [73–75]. Lebovits et al. concluded that CPN leads to very successful relief of pancreatic cancer pain [73]. Sharfman et al., on the other hand, found the data insufficient to judge the efficacy, long-term morbidity, or

cost-effectiveness [74]. Most recently, Eisenberg et al. reviewed the literature from 1966 to 1993 including 24 studies, of which 2 were randomized controlled trials, 1 was prospective, and 21 were retrospective uncontrolled trials [75]. The cancer type was specified in 1,117 patients (63% pancreatic, 37% non-pancreatic). Good to excellent pain relief was reported in 89% of patients during the first 2 weeks following CPN. Partial to complete pain relief was reported in about 90% of patients at 3 months and 70–90% at the time of death. Interestingly, pain relief was not influenced by the technical approach or the use of radiologic guidance. The most common side effects, local pain (96%), diarrhea (44%), and hypotension (38%), were generally mild and transient. The authors concluded that (1) CPN has long-lasting benefit for 70–90% of patients with pancreatic and other intra-abdominal cancers, regardless of the technique used, and (2) adverse effects are common but generally transient and mild.

More recently, a prospective, randomized, double-blind study of 24 patients with pancreatic cancer who underwent PQ CPN was reported [76]. The CPN group had a significant reduction in analgesic consumption and drug-induced side effects versus patients treated with drugs alone. Kawamata et al. showed that CPN results in less deterioration in quality of life for pancreatic cancer patients when added to morphine therapy compared to morphine therapy alone or NSAIDs alone, due to the increased duration of the analgesic effect and reduced opioid side effects [77]. A further double-blind, randomized clinical trial assigned 100 patients to receive either CPN or systemic analgesic therapy alone with a sham injection [78]. The CPN and optimized systemic analgesic therapy alone can provide effective analgesia, though CPN can provide significantly better analgesia than optimized systemic analgesic therapy alone. The report also highlighted that CPN had no effect on opioid consumption, quality of life, or survival.

Major complications develop in about 1–2% of patients and include lower extremity weakness and paresthesia, paraplegia, puncture of adjacent organs, and chronic gastroparesis and diarrhea [67, 75, 79]. Neurologic complications result from spinal cord ischemia or direct injury to the spinal cord or somatic nerves. Spinal cord ischemia may result from thrombosis or spasm of the artery of Adamkiewicz located on the left of the spine between T8 and L4, which perfuses the lower two-thirds of the spinal cord [80, 81]. Despite theoretical advantages of given methods, it is believed that the risk of neural dysfunction is not influenced by the technical approach. Paraplegia has been reported with each PQ method regardless of the use of radiologic guidance. There are even several reports of paraplegia following the most direct approach (surgical neurolysis) [82].

Endoscopic Ultrasound-Guided Celiac Plexus Neurolysis

More recently, EUS CPN has been developed for the purpose of enhancing needle localization and spread of the injectate [83]. By doing so, one hopes to minimize complications and improve pain relief. Patients are questioned regarding allergies and the use of anticoagulants. Informed consent is obtained with specific attention to

the unique complications associated with CPN/CPB. Patients are initially hydrated with 500–1,000 ml normal saline to minimize the risk of hypotension. Patients are placed in the left lateral decubitus position and sedated using medications such as midazolam, meperidine, and in some cases droperidol. Throughout the procedure, patients are continuously monitored by an automated noninvasive blood pressure device and pulse oximeter.

Linear array endosonographic imaging from the posterior lesser curve of the gastric fundus allows identification of the aorta, which appears in a longitudinal plane. The aorta is traced distally to the celiac trunk, which is the first major branch below the diaphragm. Color Doppler is used to confirm the vascular nature of the structures. A 22-gauge needle is primed with saline to remove air and then placed through the biopsy channel and affixed to the hub. The needle is inserted under EUS guidance immediately adjacent and anterior to the lateral aspect of the aorta at the level of the celiac trunk, which is the general vicinity of the celiac plexus (Fig. 9). The needle is flushed with 3 ml of normal saline to remove any tissue acquired during insertion. An aspiration test may be performed to rule out vessel penetration prior to injection. Typically, 10 ml (0.25%) of bupivacaine is injected followed by 10 ml (98%) dehydrated alcohol. The alcohol, which produces an echogenic cloud, may lead to discomfort despite sedation. Before withdrawing the needle, it may be flushed with 3 ml normal saline to minimize seeding of the needle track with alcohol, which may produce transient severe post-procedure pain. The entire process is then repeated on the opposite side of the aorta. Occasionally, altered anatomy resulting from significant lymphadenopathy and/or bulky tumors may necessitate injection of the entire solution into one "unilateral" site. The efficacy of "unilateral" versus "bilateral" injection has never been well studied, but data suggest equivalency. After the procedure, which takes about 15 min, the vital signs are monitored for 2 h prior to discharge; patients' blood pressure is checked in both a supine and erect position to assess for orthostasis. CPN is routinely performed as an outpatient procedure, rarely necessitating hospitalization.

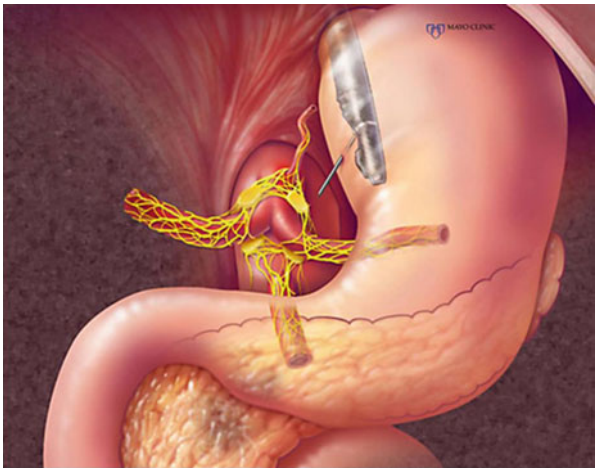

Fig. 9 Illustration demonstrates needle placement adjacent and anterior to the lateral aspect of the aorta at the level of the celiac trunk when performing standard celiac plexus neurolysis

Wiersema et al. published the initial study evaluating EUS CPN [83]. The same group published a follow-up study that included all 25 patients with pancreatic cancer from their initial report [84]. This later prospective study involved 58 patients who underwent EUS CPN for pain secondary to inoperable pancreatic cancer. They injected 3–6 ml (0.25%) bupivacaine and 10 ml (98%) alcohol into both sides of the celiac region. Pain scores were assessed using a standardized 11-point visual analog scale. Forty-five patients (78%) experienced a drop in pain score after EUS CPN. The overall pain scores were significantly lower 2 weeks after the procedure ($p < 0.0001$). Multivariate analysis revealed that sustained pain relief for 24 weeks was independent of morphine use or adjuvant therapy. However, patients who received chemotherapy alone or chemotherapy plus radiation experienced pain relief in addition to that offered by EUS CPN. Pain relief resulting from adjuvant therapy increased over time and at 24 weeks was statistically significant ($p = 0.002$). Although opioid administration increased throughout the study, the increase was not statistically significant. There were no major complications. Minor complications were mild and transient and included hypotension (20%), diarrhea (17%), and pain exacerbation (9%).

Despite 45 patients (78%) experiencing a reduction in pain score, only 31 (54%) experienced a decline of greater than two points, which is a measure of improvement that some consider necessary to signify efficacy. The efficacy of EUS CPN diminished at 8–12 weeks, after which pain scores in patients not receiving adjuvant therapy trended upward. While this study offers preliminary data suggesting the efficacy and safety of EUS CPN, the small sample size, absence of a placebo control group, and no physician or patient blinding limit the strength of the conclusions. These data considered in isolation do not allow us to make definitive conclusions regarding the safety and efficacy of EUS CPN in pancreatic cancer (Fig. 10).

Despite shortcomings in the literature, a review of existing data reached the following conclusions:

Fig. 10 Magnetic resonance imaging reveals decreased perfusion and an anterior spinal cord infarct following EUS-guided celiac neurolysis for pain management in a patient with unresectable pancreatic adenocarcinoma

1. The efficacy of CPN is similar regardless of the technique (PQ vs. EUS). This view is supported by the finding of a meta-analysis, which concluded that the efficacy of CPN was independent of the PQ approach or the use of radiologic guidance [75]. The reported efficacy rates of EUS CPN have been similar to those reported for PQ methods. Although comparative studies have not been performed, the efficacy is similar.
2. The risk of EUS CPN is similar or slightly lower than PQ methods. Many complications (such as paraplegia) have never been reported with EUS. This is likely because PQ methods are used far more often than EUS, as much as because of any difference in the inherent risk for a particular procedure. However, EUS is an "anterior" approach and thereby avoids the retrocrural space and may reduce this risk of neurologic dysfunction and pulmonary complications. Furthermore, as opposed to the PQ anterior approach, with EUS the needle only traverses the gastric wall, presumably eliminating complications resulting from inadvertent penetration of surrounding organs. The authors theorized that the risk of local pain, hypotension, diarrhea, and abscess formation would be similar for EUS and PQ approaches.

If EUS guidance offers no advantage in terms of pain relief, and no to minimal risk advantage, then one may wonder the role of EUS versus PQ techniques. The major disadvantage with EUS CPN is the inherent cost associated with the endoscopy and conscious sedation. However, the ability to perform EUS CPN at the time of tumor biopsy and staging combines diagnostic and therapeutic modalities which simplify patient care and may reduce cost. Most reserve EUS CPN for patients undergoing EUS for another reason, such as diagnosis or staging, for poor operative candidates, or those in whom disease spreads, precludes a satisfactory PQ approach.

The timing of the block relative to the onset of pain may predict response. In one study, CPN was more effective when performed early after pain onset rather than late in its course [66]. This may be explained by the fact that early pancreatic cancer pain appears to derive mainly from the celiac plexus. While most studies have found that CPN reduces cancer pain, it rarely eliminates pain and nearly all patients require continued opioid use, albeit often at a lower dose. When counseling patients, it is important to emphasize a realistic goal, which is not to eliminate pain, but to optimize oral pharmacologic therapy and to allow a dose reduction in order to minimize the side effects.

Based on an established classification system (Table 2) and definitions for level of evidence, the authors considered pancreatic cancer pain a Class IIa indication, as the weight of evidence favors the efficacy of EUS CPN [85].

Endoscopic Ultrasound-Guided Celiac Ganglia Neurolysis

Unfortunately, while CPN and CPB are considered safe, they provide limited benefit in terms of degree and duration of pain relief. The limited efficacy may partially be explained by the fact that until recently it was believed that the celiac ganglia could

Table 2 Classification system pertaining to the usefulness or efficacy of a certain procedure or treatment and associated level of evidence

Classification system
Class I: Conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective
Class II: Conditions for which there is conflicting evidence or a divergence of opinion about the usefulness/efficacy of a procedure or treatment
Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy
Class IIb: Usefulness/efficacy is less well established by evidence/opinion
Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful
Level of evidence
Level of evidence A: Data derived from multiple randomized clinical trials
Level of evidence B: Data derived from a single randomized trial or nonrandomized studies
Level of evidence C: Consensus opinions of experts

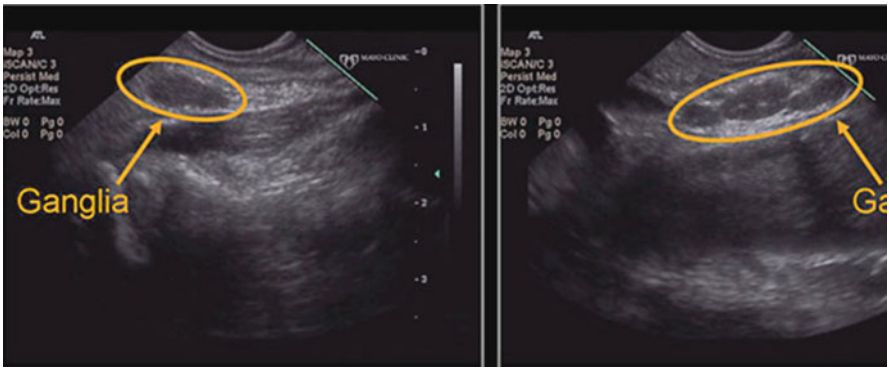

Fig. 11 Linear EUS images of celiac ganglia revealing hypoechoic oval or almond-shaped structures with irregular margins. Central echo-rich strands or foci may be present, and echo-poor threads are usually seen arising from ganglia

not be imaged. Therefore, with standard EUS, intraoperative, and anterior transcutaneous approaches, a needle was inserted adjacent and anterior to the lateral aspect of the aorta at the level of the celiac trunk in an attempt to deliver the injectate into the general region of the celiac plexus. The recent recognition that celiac ganglia can be visualized and accessed by EUS allows for direct injection into individual celiac ganglia to perform celiac ganglia neurolysis (CGN) and celiac ganglia block (CGB) (Figs. 11, 12, and 13). This more precise delivery of therapy offers the potential for enhanced efficacy and safety. To evaluate this hypothesis, a pilot study was conducted in patients with moderate to severe pain undergoing direct CGN for unresectable pancreatic carcinoma [86].

Eighteen patients underwent direct ganglia injection with bupivacaine (0.25%) and alcohol (99%) (Fig. 14). Clinical, technical, safety, and efficacy data are presented in Table 3. The mean age was 66 years (standard deviation [SD], 13.4 years; range,

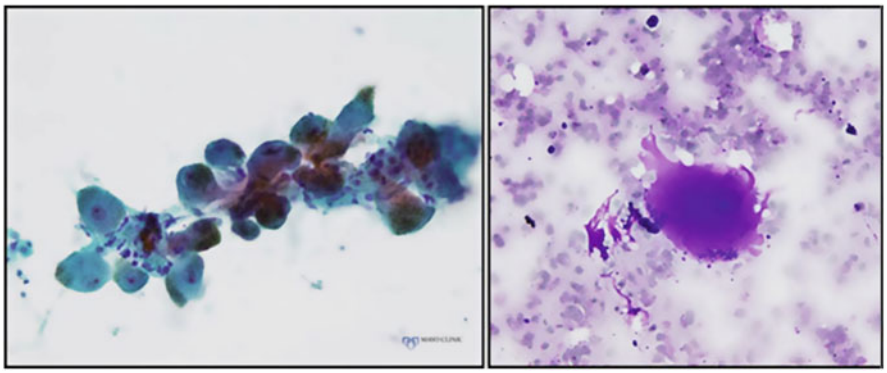

Fig. 12 Cytology specimens demonstrated nerve cell bodies without lymphocytes or malignant cells. The ganglion cells are large epithelioid cells with prominent nucleoli, with round-to-oval borders and abundant granular cytoplasm (*blue*/*purple*)

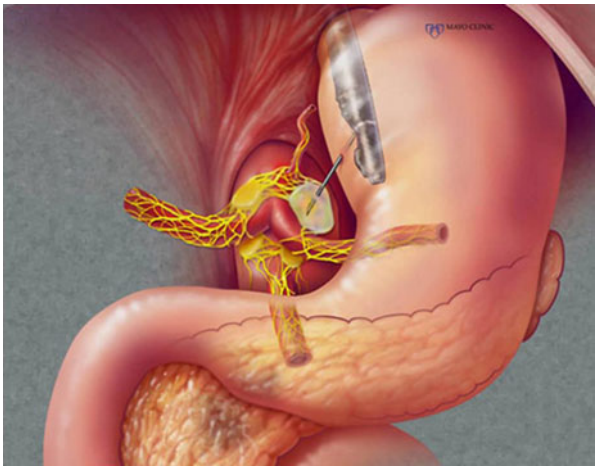

Fig. 13 Illustration demonstrates needle placement when performing direct celiac intra-ganglia neurolysis

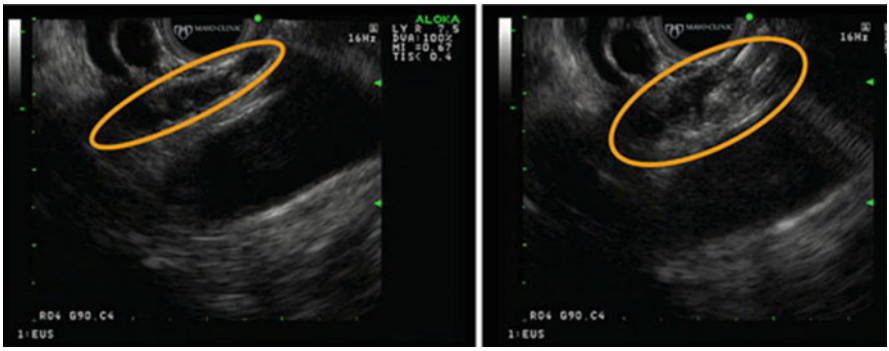

Fig. 14 Linear EUS images of celiac ganglia (*left* panel) and a corresponding direct celiac intra-ganglia injection (*right* panel)

Table 3 Clinical, technical, safety, and efficacy data following EUS CGN

Disease	Age (years)	Ganglia identified	Ganglia injected	Bupivacaine volume (ml)	Alcohol volume (ml)	Depo-medrol (mg)	Pain relief (complete or partial)
	Mean (range)						
Pancreatic cancer	66	3.0	2.7	8.3	12.7	80.0	Alcohol 16/17 (94%)
	(39–80)	(1–6)	(1–6)	(1–17)	(2–20)	(80, $n = 1$)	Steroid 0/117 (9)
($n = 18$)				($n = 18$)	($n = 17$)		$P = 0.004$

EUS endoscopic ultrasound, *CGN* celiac ganglia neurolysis, *CGB* celiac ganglia block

39–80 years), including eight males and ten females. Ganglia could be seen and accessed in 33 of 35 (95%) of patients. A mean of 3.0 (range 1–6) ganglia was identified, and a mean of 2.7 (range 1–6) ganglia was injected. Patients reported pain relief in 16/17 (94%) when alcohol was injected and 0/1 (00%; $p = 0.004$) when steroid was injected. For those who reported pain relief, 16 patients reported partial relief and none experienced complete pain relief. Narcotic use increased in 2 patients, remained equivalent in 13 patients, and decreased in 3 patients.

Patients were described as having "immediate" pain when discomfort was observed, while the needle was within the ganglia despite sedation. This pain was distinguished from "initial" pain exacerbation, which began in the recovery room or soon thereafter. Seven patients experienced an "initial" pain exacerbation lasting a mean duration of 2.2 days and requiring hospitalization in one patient. Notably, patients who developed an initial pain exacerbation tended to eventually experience greater pain relief at follow-up. All seven patients (100%) who had an initial pain exacerbation reported eventual efficacy of CGN versus 9 of 11 (81%; $p = 0.23$).

Transient hypotension defined by a decrease in blood pressure exceeding 20 mmHg systolic or 10 mm Hg diastolic occurring within 3 min of upright tilt developed in six (33%) patients, one of whom required additional fluid administration. Four (22%) patients subjectively noted marked ($n = 2$) and mild ($n = 2$) improvement of their narcotic-induced constipation. There was no evidence of other complications and specifically no patients described any neurologic deficits. The retrospective, noncontrolled nature of the study, which included a limited enrollment, provided inadequate power to permit firm conclusions and raises as many questions as it answers.

Methodological limitations include the varied and noncontrolled technique for injection, composition of the injectate, use of general descriptors of pain response instead of a visual analog scale, lack of a precise measure of the impact on opioid analgesic consumption, brief duration of follow-up, and lack of correlation with quality of life and with survival. Recognizing these limitations, the objective was simply to provide pilot data regarding the safety and initial efficacy of direct CGN and CGB in patients with moderate to severe pain resulting from unresectable

pancreatic carcinoma or chronic pancreatitis. The varied study limitations prohibit one from making firm conclusions regarding the safety or efficacy of this modified approach to pain management. However, initial data suggest that in patients with moderate to severe pain secondary to pancreatic cancer, the direct CGN with alcohol injection is safe and effective in initial pain management. Interestingly, a subsequent review of patients with unresectable PC who underwent neurolysis, either celiac plexus or celiac ganglia over a 12-year period, noted that neurolysis was an independent predictor of shortened survival [87]. Prospective, controlled, and comparative trials are needed to confirm the safety and assess the long-term efficacy of the ganglia neurolysis approach to pain management relative to conventional techniques.

Locally Injected Antitumor Therapies

Almost 40 years ago, it was shown that combined 5-fluorouracil (5-FU) and radiation therapy prolonged median survival to 9 or 10 months for patients with locally advanced pancreatic cancer (LAPC) [88]. Gemcitabine and FOLFIRINOX are now the standard chemotherapeutic agents for LAPC following evidence to suggest superior results to 5-FU [89–91]. Such agents act as a radiosensitizer through nucleotide pool alterations, cell cycle redistribution, induction of apoptosis, inhibition of DNA synthesis, and altered DNA repair [92–94]. Despite evaluation of more than 30 new agents designed to enhance the effect of chemoradiotherapy, there has been little advance with each drug, failing to produce meaningful improvement in the resectability rate or survival. FOLFIRINOX is associated with a survival advantage but with an increased toxicity profile. Indeed, currently the median survival of patients with LAPC is only 3–6 months with a 5-year survival of a dismal 7% [95].

Conventional multimodality therapy is minimally effective in patients with LAPC and even less so when attempting to downstage tumors to allow R0 resection. The poor efficacy results not only from the tumor biology but likely also because of dose limitations necessary to limited damage to normal tissues. Efficacy is further limited by current problems with drug delivery that may be overcome by direct IR or EUS-guided intratumoral injection. Their use may allow increased intratumoral drug concentrations and augment the efficacy of chemoradiation while minimizing the risk. Although speculative, locally directed therapies are likely to target the primary tumor with minimal impact on likely sites of local infiltration and distant metastasis. There is need to develop these techniques and chemotherapeutic agents to allow spread of the injected agents along the same patterns of metastasis as assumed by the cancer itself. Patients may also benefit and require use of other locally delivered ablative therapies (discussed later in this chapter) as well as concomitant systemic therapies. Experience and data are limited at this time and generally regarded as investigational, but will be briefly reviewed herein.

Interventional Radiology (IR)-Guided Injection

Intra-arterial Injection

The pancreaticoduodenal arcade is the targeted arterial system of interest for pancreatic head pathology. Branches of the superior mesenteric artery (SMA) and the transverse pancreatic artery are important landmarks to gain access to targeted areas of the pancreatic body and tail. The pancreatic arteries are selectively cannulated and a catheter is placed into the vessel of choice to allow chemotherapeutic embolization.

In a pilot study, 20 patients with unresectable pancreatic cancer underwent continuous 5-FU infusion for 5 days a week for 5 weeks, with concurrent radiation therapy [96]. A partial response was seen in 70% of patients. The 1- and 3-year survival rates were 40 and 17%, respectively, with median survival duration of 11 months. A similar study, which also included systemic gemcitabine therapy, demonstrated a partial response rate of 21% [97]. A phase I trial involving arterial infusion of gemcitabine and 5-FU resulted in an overall response rate of 33% with 1- and 2-year overall survival occurring in 83 and 25% of patients, respectively [98]. Other agents have been used to include cisplatin [99].

Others have targeted therapy into larger caliber vessels including the celiac trunk via the femoral artery, as was true in one study of 211 patients injecting the FLEC regime (5-fluorouracil, leucovorin, epirubicin, and carboplatin) once every 3 weeks for a combined total of 764 cycles, approximating 3 cycles per patient [100]. Prognostic factors of overall survival in patients receiving this particular regimen included pain reduction, disease stage, and the number of administered intra-arterial chemotherapy cycles.

A separate catheter may be inserted to allow hepatic infusion to potentially prevent or treat liver metastasis. This method is primarily reported for management of hepatic metastases secondary to colorectal cancer. Hepatic arterial infusion of 5-FU in patients with liver metastasis specifically from pancreatic carcinoma has also been reported but was considered to be minimally effective using a 5-day regime by continuous hepatic arterial infusion every 4 weeks [101]. Alternatively, established hepatic metastasis may be treated by a weekly hepatic arterial infusion of 5-FU in addition to external beam radiation therapy (total dose, 50 Gy; 2 Gy day^{-1}). Following a median of 13 cycles of chemotherapy, a partial response of 41% with a 1-year overall survival of 11.8% was observed [102].

Computed Tomography Injection

Oncolytic viruses for the treatment of pancreatic cancer studied in recent experimental and clinical work include adenoviruses, herpesviruses, and reoviruses. These replication-selective viral agents hold promise as a novel cancer treatment platform (virotherapy). ONYX-015, an E1B-55 kDa gene-deleted adenovirus, was the first such genetically engineered agent to be tested in humans. In combination with chemotherapy, some antitumoral activity has been demonstrated. CT-guided injection of ONYX-015 which is thought to preferentially replicate within and kills malignant

cells has been evaluated [103]. Although well tolerated, the results showed no objective tumor response and no viral replication. Unfortunately, as tumor seeding is a well-recognized complication of any CT-guided percutaneous intervention in cancer patients, this may not be the most suitable method of direct intratumoral administration [104]. Therefore, alternative and improved delivery methods are required for the local injection therapy to manage patients with pancreatic cancer.

Endoscopic Ultrasound (EUS)-Guided Injection

EUS-guided FNI is a relatively new method system for the delivery of antitumor agents. The initial fine needle aspiration (FNA) of a pancreatic malignancy was reported in 1992 and is now a routine part of EUS examination [105]. The initial indications for FNA were proposed by Erickson and have been modified over time to include (1) sampling of pancreatic masses when other techniques have failed, (2) sampling CT-detected mediastinal adenopathy when other techniques have failed, (3) distinguishing benign from malignant disease, and (4) staging of cancer to provide evidence of malignancy prior to neoadjuvant therapy or to guide palliative care [106]. The pancreas and biliary tree are generally observed from three regions: the stomach, the duodenal bulb, and the second portion of the duodenum. The identified areas are accessible for fine needle aspiration and, by default, amenable to fine needle injection. The echoendoscope and current needle devices are the same as that used for standard FNA. This is an emerging indication for EUS, but merits some mention to highlight the potential role, while awaiting further studies accompanied by technical success, clinical success, and adverse event data.

As with EUS FNA, FNI is optimal when the target lesion is visualized but merits some mention to highlight the potential role, while awaiting further study of fine needle aspiration and, by default, amenable to fine needle injection, but injections per session, volume and composition of the injectate, and total number of sessions vary among reports. The only direct injection of standard gemcitabine chemotherapy for patients with locally advanced or metastatic pancreatic cancer has been reported by Levy et al. highlighting the safety and feasibility in 36 patients [107] (Fig. 15).

Allogenic Mixed Lymphocyte Culture (Cytoimplant)

EUS FNI was introduced as a new means for local delivery of antitumor agents for patients with locally advanced pancreatic carcinoma (LAPC) in a study published in 2000. In a phase I clinical trial, eight patients underwent EUS-guided administration of an allogenic mixed lymphocyte culture (cytoimplant) to treat patients with LAPC (four patients in Stage II, three in Stage III, and one in Stage IV) [108]. Cytoimplants were delivered locally into the tumor using a novel EUS-guided FNI technique. Escalating doses of three, six, or nine billion cells were implanted into the pancreatic tumor by a single EUS-guided FNI. Toxicity (modified National Cancer Institute criteria) was assessed at day 1, week 1, and months 1 and 3, whereby there were no bone marrow, hemorrhagic, infectious, renal, cardiac, or pulmonary toxicities.

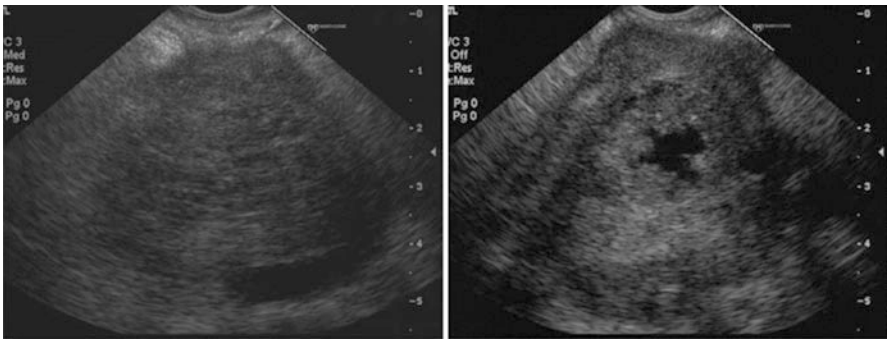

Fig. 15 EUS imaging demonstrates a pancreatic cancer prior to therapy (*left*) and following fine needle injection of gemcitabine with the resulting effects demonstrating and altering echodensity and echo pattern (*right*)

However, a low-grade fever was experienced by 86% and responded to acetaminophen, resolving within 28 days. There were no reported procedure-related complications suggesting that a single injection of cytoimplant immunotherapy by EUS-guided FNI may be safe.

ONYX-015

Oncolytic virus therapy was developed early in the last century upon observing occasional tumor regression in cancer patients suffering from viral infections or those receiving vaccinations. EUS FNI has also been applied to the delivery of the antitumor agent ONYX-015 (Onyx Pharmaceuticals, USA), which is a gene-deleted replication-selective adenovirus that preferentially kills malignant cells. In a phase I/II clinical trial designed to demonstrate feasibility, tolerability, and efficacy, 21 patients underwent eight injections over an 8-week period [109]. The FNI protocol consisted of 1 ml of virus per injection, with up to ten injections per session depending on tumor size. The latter four treatments were given in combination with gemcitabine on the same day. Four complications were encountered including sepsis ($n = 2$) and duodenal perforation ($n = 2$). Eleven patients had progressive disease or evidence of treatment toxicity. No clinical pancreatitis occurred despite mild, transient elevations in serum lipase levels in a few patients. Two patients had partial regression, 2 patients had a minor response, and 11 patients had disease progression or toxicity prohibiting study completion. Phase I clinical trials are underway using alternative oncolytic viral therapies including herpes virus hrR3 and HSV-1 strain HF clone, which are specifically designed to express other genes to increase the susceptibility of tumor cells to chemotherapy. The results are awaited and may provide future potential EUS FNI antitumoral agents.

TNFerade™

More recently EUS has been used to deliver TNFerade™ antitumor therapy in a dose-escalating study and to obtain initial data regarding safety [110, 111]. TNFerade™ is a second-generation adenovector, which expresses the cDNA encoding human tumor necrosis factor (TNF). In addition, a radiation-inducible immediate response *Egr-1*

(early growth response) promoter was placed upstream of the transcriptional start site of the human TNF. In a pilot study involving 50 patients, TNFerade was administered either percutaneously via ultrasound or CT, or via EUS guidance. Local therapy was given in conjunction with continuous systemic intravenous 5-FU [112]. TNFerade was injected by a single percutaneous needle pass or up to four EUS injections. Dose-limiting toxicities developed in 4 of 50 patients including pancreatitis in two patients and hypotension and biliary obstruction in one patient each. No severe complications were noted. At the maximum tolerated dose (MTD), four out of five patients reassessed as surgically resectable achieved pathologically negative margins, and three survived 24 months. Intratumoral therapy did not interfere with subsequent surgical resection.

OncoGel (ReGel/Paclitaxel)

OncoGel (ReGel/paclitaxel) is a new formulation for intralesional injection of the chemotherapeutic drug paclitaxel, developed by MacroMed Inc. (Sandy, Utah), for local tumor management. OncoGel uses MacroMed's ReGel drug delivery system, a thermosensitive, biodegradable triblock copolymer composed of poly(lactide-co-glycolide)-polyethylene glycol-poly(lactide-co-glycolide). Upon injection and in response to body temperature, ReGel is transformed from a water-soluble polymer to a water-insoluble biodegradable hydrogel that releases paclitaxel continuously into the adjacent tissue for up to 6 weeks [113]. In a porcine pancreas study, EUS FNI with OncoGel demonstrated high and sustained localized concentrations of paclitaxel highlighting a further potential minimally invasive local treatment option for unresectable pancreatic tumors [114, 115]. In a canine model, another polymer implantation alternative for interstitial chemotherapy has demonstrated successful implantation and localized tissue necrosis in the absence of significant complications [116]. Clinical data are unavailable.

Immature Dendritic Cells

Dendritic cells are potent antigen-presenting cells utilized to induce primary T-cell dependent immune responses. When the cells are injected intratumorally, they acquire and process tumor antigens in situ and migrate to regional lymph nodes whereby they initiate a strong tumor-specific immune response. A pilot study investigated the feasibility, safety, and clinical response following EUS FNI of immature dendritic cells into pancreatic cancer deemed refractory to systemic gemcitabine therapy [117]. The study included seven patients who received EUS FNI intratumoral injection of immature dendritic cells at two to three sites. Five of seven patients received radiation therapy before initial EUS FNI of dendritic cells to induce apoptosis and necrosis. There were no reported complications and the median survival period was 10 months.

Ablative Antitumor Therapies

A variety of imaging techniques have been used to guide pancreatic tumor ablation including ultrasound (percutaneous, intraoperative, and endoscopic), CT, CT fluoroscopy, MRI, and fluoroscopy. Available ablative therapies include brachytherapy,

cryoablation, radiofrequency ablation (RFA), microwave coagulation therapy (MCT), laser interstitial thermal therapy, and high-intensity focused ultrasound (HIFU). However, only few are utilized in the management of pancreatic cancer. The following discussion will focus predominantly on EUS-guided methods for delivering ablative therapy. Experience and data are limited at this time and generally regarded as investigational or preliminary human experience, but will be briefly reviewed herein.

Brachytherapy

Traditional Brachytherapy

Prostate brachytherapy, with transrectal ultrasound-guided placement of radioactive seeds, is an effective treatment option for early-stage prostate cancer [118, 119]. Its potential advantage over traditional external beam radiation therapy is the ability to limit radiation toxicity to the surrounding normal tissues. Following radioactive seed placement, the target tissue is exposed to gamma rays, which in turn produce localized tissue injury and tumor ablation.

Brachytherapy (iodine, gold, iridium) delivered by percutaneous approaches to pancreatic tumors has not been particularly effective. Percutaneous intratumoral injection with radioactive 32P has also been reported, but with disappointing results [120–122]. Memorial Sloan Kettering Cancer Center evaluated their initial experience in 98 patients with biopsy-proven unresectable pancreatic adenocarcinoma from 1974 to 1987 [123]. Patients were treated with I-125 implants during laparotomy performed for biopsy alone, gastric bypass, biliary bypass, and partial or total pancreatectomy with incomplete resection. In addition, 27 patients received postoperative external irradiation and 27 patients received chemotherapy. Postoperative complications included postoperative death, biliary fistulae, intra-abdominal abscess, GI bleeding, gastric or small bowel obstruction, sepsis, and deep vein thrombophlebitis. A multivariate analysis highlighted that four factors significantly affected survival: (1) T stage, (2) N stage, (3) administration of chemotherapy, and (4) >30% reduction in the size of the implant on follow-up films. A subgroup of patients with T1N0 stage disease who received chemotherapy survived 18.5 months. A percutaneous ultrasound study of 19 patients reported no difference in survival or palliation between patients treated with I-125 seed implantation compared with those treated with seeds and external radiation despite satisfactory seed placement and delivery of the planned radiation dose in most cases [124].

Computed tomography was used to guide therapy in 26 patients who had a mean tumor size of 6.1 cm by inserting I-125 seeds at a distance of 1.0–1.5 cm [125]. Over the 3–12 months of follow-up, complete symptom relief was seen in nine patients, partial relief in two, and no change in four with an effective rate of 73%. A CT performed 2 months following implantation demonstrated complete response, partial response, no change, and progression in 2, 13, 5, and 5 cases, respectively, with an

overall effective rate of 57.7%. Migration of the seeds into the liver was seen in three patients. No severe complications were reported.

In another pilot study, intraoperative or percutaneous cryosurgery was performed under ultrasound and/or CT guidance, and the less invasive form of therapy was found to result in a lower rate of adverse events [126]. I-125 seed implantation can destroy residual surviving cancer cells following cryosurgery. Hence, a combination of modalities may augment the effects, both beneficial and potential detrimental. Others believe that brachytherapy, when combined with external radiation therapy and systemic chemotherapy, probably provides the best local control of pancreatic cancer, but these contentions cannot be validated based on current data [127].

Placement of fiducials within pancreatic cancer tumor enables easy identification of the target lesion during radiation therapy. Therapy can be delivered in a precise and targeted manner despite respiration excursion. Although percutaneous placement of fiducials is possible using CT guidance, the procedure is technically cumbersome and there is concern regarding tumor seeding [128, 129]. To date, reports regarding CT-guided placement of fiducials pertain almost entirely to the therapy of lung cancer.

EUS-Guided Delivery of Fiducial Markers and Brachytherapy

EUS-guided fiducial marker placement has been reported in patients with mediastinal or intra-abdominal tumors including pancreatic carcinoma in patients scheduled to undergo stereotactic radiosurgery [130–133]. A total of three to six fiducials were placed in each patient. The impact of EUS-guided fiducial placement and stereotactic therapy on patient survival or quality of life is unknown.

EUS-guided implantation of radioactive seeds into pancreatic parenchyma of a porcine model ($n = 6$) was reported to be a safe, simple, and minimally invasive technique for interstitial brachytherapy [134]. The radioactive iodine seeds were inserted into the lumen of the tip of a modified EUS needle, which had a normal 22-gauge needle body with a 2.5-cm-long, 18-gauge needle tip attached to the distal end. In a pilot trial of 15 patients with advanced pancreatic cancer, EUS-guided interstitial brachytherapy was evaluated with respect to tumor response, clinical response, safety, and complications [135]. A mean number of 22 radioactive seeds per patient were implanted into the tumors. It had a moderate local tumor effect and a clinical benefit was demonstrated in 30%. Complications were experienced by six patients to include pancreatitis, pseudocyst formation, and hematologic toxicity. Another study involving 22 patients, which successfully implanted a median of ten radioactive iodine seeds per patient, suggested an improvement in pain scores the first week post procedure, which however was not sustained, and no long-term survival benefit was demonstrated [136].

The future of this particular ablative method has yet to be established primarily because of the uncertain impact on patient outcomes and due to issues regarding how best to handle radioactive material in the endoscopy suite and proper disposal of radioactive accessories.

Photodynamic Therapy

Traditional Photodynamic Therapy

Photodynamic therapy works through the induction of apoptosis and tissue necrosis caused by a direct cellular action and/or by altering tumor blood supply. In the mid-1970s, the feasibility of tumor eradication with photodynamic therapy (PDT) was demonstrated in animal models, and the first patient studies were reported shortly thereafter [137]. Studies have subsequently revealed that PDT produces local tissue necrosis, and in experimental studies, it has been shown to deliver relatively tumor-specific injury with minimal injurious effect to the normal surrounding pancreatic and peripancreatic tissues [138–140]. A randomized controlled trial of PDT with 5-aminolevulinic acid for implanted pancreatic cancers in hamsters highlighted that survival time in the group treated with PDT was significantly greater than that of control animals [141].

EUS-Guided Photodynamic Therapy

EUS-guided PDT of the pancreas was initially studied in a porcine model [142]. Following injection of porfimer sodium, a 19-gauge needle was inserted into the pancreas, in addition to other organs under EUS guidance. Subsequently, a small-diameter quartz optical fiber was passed through the EUS needle and used to illuminate the tissue with laser light. Localized tissue necrosis was achieved without significant complication. To date, no comparative study has been performed between PDT and external beam radiation. An alternative photosensitizer (verteporfin) has also been evaluated and was associated with less photosensitivity than porfimer sodium, while achieving localized pancreatic tissue ablation of porcine pancreas in a dose-related fashion [143]. Preliminary data from four patients with advanced pancreaticobiliary disease suggests that EUS-guided PDT with a second-generation photosensitizer (chlorin e6 derivative) and a flexible laser probe is feasible and safe [144].

Radiofrequency Ablation

Traditional Radiofrequency Ablation

Image-guided percutaneous radiofrequency ablation (RFA) has been increasingly performed in recent years to treat solid tumors. Radiofrequency ablation renders a zone of coagulation necrosis by an intense thermal burn. It has been used as an ablative modality in the setting of primary and secondary liver lesions either surgically (laparoscopically or open) or percutaneously by ultrasound-, MRI-, or CT-guided methods. Cryotherapy and radiofrequency treatment can ablate metastases in 50–90% of cases and are relatively safe compared to hepatic resection. The goal of RF thermal ablation is to destroy the tumor as well as a 5 ± 10-mm circumferential cuff of adjacent normal hepatic parenchyma. There has been no randomized comparison using RFA in the setting of primary pancreatic cancer or associated hepatic metastases. A recent study of 18 patients with unresectable

disease, treated by RFA with a "cool-tip needle," highlighted that the most notable effect was in relieving back pain and was safer if used in the pancreatic body/tail region [145]. Smaller studies have demonstrated similar results highlighting that to date RFA of unresectable pancreatic carcinoma is feasible, efficacious, and safe and is also feasible for metastatic lesions to the pancreas to include renal cell carcinoma [146–148]. Initial clinical experience has shown that approximately one-third of patients develop low-grade fever and flu-like symptoms, which include malaise, myalgia, and nausea and/or vomiting, after RFA [149].

An ex vivo model of RFA of the porcine pancreas was evaluated to determine the thermal kinetic profile of the ablation effect as there have been some concerns regarding injury to the duodenum, bile duct, or portal vein [150–152]. In practice, small tumors (less than 3 cm) are more likely to be resected, and thus ablation will potentially see clinical use in larger unresectable pancreatic tumors, where a more prolonged ablation time may be required. A minimal duration of 5 min is probably required to produce a 2 cm area of ablation [150].

EUS-Guided Radiofrequency Ablation

The feasibility and effectiveness of RFA under EUS guidance in the porcine pancreatic tail has been confirmed by necroscopy [153]. Radiofrequency was applied for 6 min with a goal tip temperature of 90 °F and the subsequent area of necrosis measured 1 cm. Biochemical parameters were normal in all except in one pig that developed pancreatitis and an associated pancreatic fluid collection. Other complications included gastric and intestinal burns secondary to misplacement of electrodes. The simultaneous combination of RF and cryoablation with the use of a novel applicator design yields significantly larger coagulation zones than either modality alone [154]. Since the initial porcine studies, its role, although preliminary in nature, has been reported for the management of cystic neoplasia, insulinomas, and unresectable pancreatic cancer [155–157]. Reported adverse events related to EUS RFA have included acute pancreatitis, gastric wall burns, and gut adhesions [158].

EUS-Guided Alcohol Ablation Therapy

Until a few years ago, tumor ablation therapy consisted of the injection of sclerosing agents (i.e., absolute alcohol) into primary or metastatic tumors of the liver. Percutaneous ethanol injection (PEI) of large and multiple hepatocellular carcinomas showed survival similar to conventional PEI for patients with smaller tumors [159]. Although alcohol ablation therapy has been a successful mode of therapy, its use has generally been confined to patients with cirrhosis whose tumors are anatomically amenable to a percutaneous approach.

EUS-guided alcohol injection of solitary hepatic metastasis and adrenal metastases and ablation of gastric stromal cell submucosal and pancreatic neuroendocrine tumors have been reported [160–163]. This alternative ablative therapy with an ethanol injection was performed in a pilot study to determine if pancreatic tissue

ablation (98% ethanol preparation) could be safely performed and to attempt to define the dose response of pancreatic tissue to ethanol [164]. All animals demonstrated some degree of fibrosis and necrosis, with no significant difference between 98% and 50% ethanol. A subsequent study used 2 ml of ethanol, in an increasing concentration of 0–100%, and determined that the cross-sectional area of necrosis was proportional to the concentration of ethanol [165]. The use of contrast-enhanced EUS with microspheres improves visualization of altered pancreatic vascular perfusion and can be used to facilitate detection of small pancreatic lesions and respective follow-up after ablative therapy [166]. Ethanol has also been used to ablate a functioning insulinoma in a nonsurgical candidate [167, 168].

Conclusion

Interventional radiology and EUS are performed in patients with pancreatic cancer to allow diagnosis, staging, and increasingly now with therapeutic intent. In the setting of malignant biliary and gastric outlet obstruction, there are established standards of care derived from evidence-based guidelines. There are a variety of modalities to ameliorate the pain associated with pancreatic cancer, and direct intraganglionic therapy via EUS is a realistic potential route for therapy. However, further research is necessary to evaluate injection and ablative therapies, which are currently in the early stages of development and human study. These latter techniques cannot be widely advocated as a part of routine clinical care until their efficacy, technical success, and respective safety profiles have been established.

Key Research Points

- Interventional radiology and EUS-guided procedures are increasingly utilized in the care of patients with pancreatic carcinoma. As new devices and techniques are introduced and validated, they tend to replace an equivalent surgical procedure.
- Endoscopic palliative treatment of malignant biliary and duodenal stenosis using metal prostheses is highly feasible, safe, and effective including in patients with combined obstructions even with associated biliary stenting.
- With the advent of EUS-guided celiac plexus neurolysis, an alternative route to percutaneous access has been developed. As ganglia are now readily visualized by EUS, they may be a future target for fine needle injection therapies.
- EUS ablation of solid tumors and lymph nodes is primarily investigational although reports are beginning to emerge particularly in the field of RFA describing their clinical application.
- A variety of agents are available but seldom used at this time for tumor ablation including ethanol, gel-based and polymer-based chemotherapies, brachytherapy seeds, radiofrequency ablation, and attenuated viral vectors.

Published Guidelines None

- No specific published guidelines.

Future Research/Directions

In patients with malignant biliary and/or duodenal obstruction to:

- Develop larger, long-term, prospective randomized controlled trials that evaluate cost, clinical outcomes, and quality of life following biliary and/or duodenal bypass.
- Identify factors that reliably predict survival and stent patency. This information is crucial in identifying patients who will most benefit from initial placement of an expandable SEMS as opposed to those who may be well palliated with a less expensive plastic stent.
- Develop new, or improve existing, technologies to prolong stent patency.
- Develop the techniques and accessories (catheters and guidewires) to improve upon the novel endoscopic approaches for bypassing malignant biliary obstruction.

In patients with pancreatic carcinoma related pain to:

- Develop larger, long-term, prospective randomized controlled trials that evaluate cost, clinical outcomes, and quality of life following celiac plexus neurolysis (CPN) and/or celiac ganglia neurolysis (CGN). Only then can the verification of the efficacy and safety of EUS CPN and identify advantages and disadvantages of the various techniques.
- Determine the (1) optimal timing and route for CPN/CGN, (2) ideal composition of the injectate, (3) cost, (4) patient preference, (5) influence on quality of life, (6) effect of neurolysis (duration in those with chronic pancreatitis), and (7) potential survival advantage.
- With regard to local tumor therapies to:
  - Develop larger, long-term, prospective randomized controlled trials that evaluate cost, clinical outcomes, and quality of life following these therapies.
  - Develop 3-D mapping systems or devices to more precisely control and deliver the dosing of ablative energy.
  - Determine if a combination of local with or without systemic ablative therapies may provide a synergistic affect.

Palliative Surgery in Advanced Pancreatic Cancer

Florian Scheufele and Helmut Friess

Contents

Abstract

In patients with pancreatic cancer, a high percentage is not eligible for curative treatment, and therefore palliative care is indicated. Malignant obstructive jaundice, severe pain, and gastric outlet obstruction (GOO) contribute a major compromise to patients' quality of life. To manage these symptoms, different strategies of treatment, either surgical or interventional, are available.

Obstructive jaundice can either be treated by hepatico-/choledochojejunostomy or by interventional placement of a biliary stent. Patency of surgical bypasses by hepaticojejunostomy is longer, when compared to interventionally placed biliary stents. However, self-expandable metal stents (SEMS) display better patency rates, expanding the spectrum of biliary stenting also on patients with longer life expectancy.

GOO significantly contributes to decreased quality of life (QOL). Patients with an unresectable pancreatic cancer at exploration should receive a gastrojejunostomy. Surgical palliation for GOO should be considered due to superiority to interventional duodenal stenting if life expectancy is longer than 2 months.

Pain can sufficiently be treated with neurolytic interventions. Splanchnicectomy provides more sufficient pain relief than neurolysis of the celiac plexus. Prior to neurolytic interventions, a sufficient pharmacological analgesic treatment should be undertaken, and neurolysis should be performed early during workup if irresectability is evident.

In light of potent neoadjuvant treatment regimens, today's resection polices are getting more aggressive, and exploration should be performed whenever possible. If irresectability is evident during operation, R2 resections should be avoided due to increased postoperative complications and no survival benefit. In these situations, a double bypass surgery is always a better option.

Introduction

Pancreatic cancer is a major cause of cancer-related death, currently lying behind lung cancer, prostate cancer, breast cancer, and colorectal cancer and conferring 7% of cancer-related deaths in the USA. For the year 2016, there are 53,070 new cases of pancreatic cancer estimated for the USA with a total number of 41,780 estimated new deaths during the course of this year. Although 5-year survival is still poor lying around 8% (2005–2011), advantages in treatment of pancreatic cancer are visible, as there has been a significant improvement of the 5-year survival rate having been 3% 30 years ago ($p < 0.05$) [1]. To date, consensus exists that resection of pancreatic cancer is the only chance for cure, although even after radical resection survival remains limited, and resection often ends in a palliative situation [2]. Median survival after curative resection with adjuvant chemotherapy has been reported with 23 months (using fluorouracil plus folinic acid) and 23.6 months (using gemcitabine), respectively, in the ESPAC-3 trial [3]. On the other hand, patients receiving palliative treatment have worse prognosis, although even in unresectable disease progress has been made using the FOLFIRINOX treatment regime reaching a median survival of approximately 11.1 months [4]. Further emphasizing the importance of palliative treatment for patients with pancreatic cancer is the low number of resectable tumors at the time of diagnosis with only approx. 1/3, when compared to 1/3 of the patients with locally advanced tumors at primary diagnosis

and 1/3 with metastatic disease leading to a 1-year survival of 74% (resection), 30% (chemotherapy/chemoradiation), and 16% (chemotherapy/chemoradiation) in the respective groups [5]. Thus, palliative treatment of patients suffering from pancreatic cancer is a major field facing common symptoms of advanced pancreatic cancer as obstructive jaundice, malignant gastric outlet obstruction, and severe pain. These symptoms are significantly compromising patient's quality of life, and amelioration can either be achieved by surgical or interventional treatment. The advantages and disadvantages of the different techniques are analyzed and outlined in the following.

Surgical and Interventional Treatment of Obstructive Jaundice

Malignant obstructive jaundice is a common symptom of advanced pancreatic cancer and tumors of the pancreatic head. If jaundice is untreated, it can give rise to consecutive diseases as cholangitis, progressive liver dysfunction, secondary liver cirrhosis, renal dysfunction, organ failure, and finally death. While obstructive jaundice due to benign diseases should be treated surgically to reach a definitive solution, in malignant disease, the picture is less clear related to the life expectancy of the patient. On the background of limited expected survival, morbidity and mortality associated with surgical treatment have to be critically evaluated, and interventional methods of drainage thereby have a significant value. On the other hand, the latter are associated with procedure-related complications such as stent migration, occlusion, and cholangitis, making readmission, replacement of the stent, and antibiotic therapy necessary. Thus, no final consensus exists on the ideal treatment strategy of those patients. Especially on the background of improved perioperative care, these different strategies for palliation of obstructive jaundice have to be reevaluated [6].

In the early 1990s, three controlled randomized clinical trials have been published comparing stenting of obstructive jaundice with surgical bypass [7–9]. These studies revealed that both procedures had high technical (93% vs. 95%) and clinical success rates (91% vs. 92%). Procedure-related mortality (3% vs. 14%, $p = 0.01$), major complications (11% vs. 29%, $p = 0.02$), and hospital stay (20 vs. 26 days, $p = 0.001$) were lower in the stented group. On the other hand, the incidence of recurrent jaundice (2.0% vs. 36%) and gastric outlet obstruction (7% vs. 17%) was reduced in the surgical group, when compared to stented patients. However, these studies are nowadays more than 20 years old, and in regard of improvements in stenting and in surgical techniques, e.g., minimal invasive surgery, new RCT should be initiated on this topic.

Besides endoscopic stenting, percutaneous transhepatic stenting offers an alternative method of decompression of the biliary tree. Transhepatic biliary stenting due to increased invasiveness and associated complications does not depict the first-line approach to decompress obstructive jaundice. Although after repeated unsuccessful endoscopic stenting or in case of impossibility of endoscopic stenting (e.g., after Billroth procedure), it has its benefits. Bornman and coworkers compared palliation of malignant obstructive jaundice by percutaneous transhepatic placement of a

biliary stent ($n = 25$) with surgical bypass ($n = 25$) in a randomized controlled trial with patients suffering from unresectable pancreatic cancer. Technical success was 84% in the stent and 76% in the surgical group, and postoperative complications (stenting 7 (28%) vs. surgery 8 (32%)) and 30-day mortality (stenting 2 (8%) vs. surgery 5 (20%)) were equal in both groups. Recurrent jaundice however was increased after percutaneous biliary decompression (38%), when compared to surgery (16%). Initial length of hospital stay (LOS) was increased after surgery, but this difference vanished over time due to stent occlusion and gastric outlet obstruction (GOO) in the interventional group resulting in repeated consultations and readmissions [10].

A major limitation of interventional biliary drainage is stent occlusion compromising long-lasting efficacy of palliation when compared to surgical procedures. A significantly higher rate of readmissions, 76.9% of which is due to recurrent jaundice and sepsis, was reported in patients treated with biliary stents ($n = 33$) when compared to patients receiving a hepaticojejunostomy and a gastrojejunostomy ($n = 23$) in a retrospective analysis in 2009 (39.4% vs. 13.0%, respectively, $p < 0.05$) [11].

The long-lasting effects of surgical palliation with low rates of recurrent jaundice and acceptable incidence of postoperative complications were further demonstrated in 118 consecutive patients with unresectable pancreatic cancer diagnosed upon surgical exploration. The most commonly performed surgical procedure was a double bypass (biliary bypass with gastrojejunostomy in 75%) with a total of 107 patients receiving a gastrojejunostomy. Overall postoperative complication rate was 37%, while wound infections were most common with 10%, cholangitis developed in 8%, and delayed gastric emptying in 8%. Hospital death occurred in 2.5%. During the follow-up, only 4% developed gastric outlet obstruction (GOO), and 2% suffered from recurrent jaundice during a mean survival after palliative surgery of 7.7 months [12]. Additionally, the beneficial long-term effects of surgical treatment of obstructive jaundice (recurrent jaundice: 8%) with acceptable perioperative morbidity (21% of early complications) have also been confirmed in other studies, and surgical palliation for unresectable pancreatic cancer by a surgical double bypass was advocated to be the first-line treatment with high success rates (>95%) in patients eligible for surgery [6, 13–15].

Furthermore, a recent meta-analysis on five randomized controlled trials comprising 379 patients comparing biliary stent placement with surgical bypass confirmed these single study data. There was no significant difference in the success rate between the different strategies ($p = 0.67$). Importantly, major complications and mortality were not increased after surgical palliation ($p = 0.14$), but surgical treatment was associated with decreased recurrence of jaundice when compared to biliary stent placement (RR 0.14, $p < 0.01$). Thus, if operative risk is moderate or low, surgical palliation should always be considered as the first choice [16].

A critical point for surgical palliation is the selection of patients being eligible for surgery. In this context, the association between the Portsmouth Physiological and Operative Severity Score for the enUmeration of Mortality and Morbidity (P-POSSUM) and cardiopulmonary exercise testing (CPET) and the incidence of

postoperative complications was recently analyzed. 50 patients were included undergoing double bypass surgery for unresectable pancreatic cancer and collected demographic data, preoperative anesthetic performance and postoperative outcome were evaluated. The P-POSSUM score was significantly increased in patients experiencing postoperative complications (median P-POSSUM physiology score: 18.7 vs. 16.5, $p = 0.005$), while the aerobic threshold was significantly lower in patients with postoperative complications (11.3 ml/kg/min vs. 14.1 ml/kg/min, $p = 0.016$). Additionally, multivariate analysis showed postoperative complications being an independent risk factor for decreased survival (OR 3.261, 0.95 CI 1.492–7.129, $p = 0.003$). Therefore, a critical patient selection is always mandatory in patients planned for surgical palliation [17].

Interestingly, if patients undergo preoperative endoscopic intervention, they have higher postoperative morbidity and mortality following palliative bypass surgery. In 204 patients receiving double bypass (77.45%), biliary bypass (18.13%) or gastric bypass (4.32%), wound infection rate (40% vs. 8.37%, $p < 0.001$), bile leak rate (28% vs. 1.76%, $p < 0.001$), and hospital mortality (8% vs. 0%, $p < 0.001$) were significantly increased after a previous biliary endoscopic intervention. Therefore, surgery should always be considered as a first step to palliate jaundice in fit pancreatic cancer patients [18].

Significant improvements in biliary decompression were achieved by the development and usage of metal stents delivering higher patency rates than plastic stents. The effect of metal stent placement ($n = 29$) for palliation in patients with unresectable pancreatic cancer in comparison with surgical palliation by either biliodigestive bypass operation ($n = 11$) or palliative Whipple's procedure ($n = 12$, defined as R1 resection with initially curative intent) was recently investigated. Indications for stenting were metastatic disease, progression during neoadjuvant treatment, age over 80 years, or if patients were unfit for resection or they refused surgery. Primary endpoints were mortality within 30 days and survival, while second endpoints were complications and biliary and intestinal patency rates. There was no mortality within 30 days reported. Median survival was 280 days (95% CI, 103–456 days), 157 days (95% CI, 0–411 days), and 647 days (95% CI, 300–993 days) in patients with stenting, bypass surgery, and Whipple's procedure, respectively ($p = 0.111$). Patency of the biliary and intestinal track was not significantly different within the groups ($p = 0.112$) [19]. These data delineated the role of interventional palliation in selected patients, especially in light of newly developed metal stents, which have also been shown to lead to improved outcomes in quality of life ($p = 0.042$) with reduced costs ($p = 0.0013$) [20].

The most common surgical approach in jaundiced patients is the use of a hepaticojejunostomy for efficient biliary drainage. However, alternatives such as a hepaticocholecystoduodenostomy are possible. In a controlled randomized trial comparing surgical drainage via hepaticocholecystoduodenostomy ($n = 10$) with drainage by Roux-en-Y choledochojejunostomy ($n = 10$), technical success was similar in both groups, but patients receiving a hepaticocholecystoduodenostomy had a shorter operative time ($p < 0.0001$), less blood loss ($p = 0.0001$), and shorter

hospital stay ($p < 0.0001$). With similar rates of recurrent jaundice, gastroduodenal obstruction, and hemorrhage, hepaticocholecystoduodenostomy might be an alternative technique for palliative biliary drainage [21].

Indications for surgical palliation also seem to change. In a large single institutional survey on 1913 patients of whom 583 underwent palliative treatment, indication for palliative bypass surgery changed from locally advanced disease vs. liver or peritoneal metastasis between 2002 and 2007 with 49.2% vs. 50.8%, respectively, to 17.2% vs. 82.7% between 2008 and 2010 ($p = 0.005$). These numbers might reflect more aggressive resection polices also in locally advanced disease and the use of potent neoadjuvant therapy regimes which convert many patients with locally unresectable disease into resectable cases [22].

Different Techniques of Interventional Drainage: Which Stent to Choose?

Endoscopic treatment of malignant biliary obstruction, especially with increasing use of self-expandable metal stents (SEMS), displays a promising approach for patients suffering from unresectable metastatic pancreatic cancer, particularly when expected survival is short, or patients are not eligible for surgery.

A randomized trial showed median patency being higher in SEMS (covered) than in plastic stents (3.6 months vs. 1.8 months, $p = 0.002$) [23]. Additionally, partially covered metal stents (pcSEMS) also have longer patency rates when compared to plastic stents (385.3 $\pm$ 52.5 days vs. 153.3 $\pm$ 19.8 days, $p = 0.006$). Interestingly, cholangitis occurred significantly more often in the plastic stent group when compared to the metal stent group (24.5% vs. 4.9%, $p = 0.029$) [24].

When comparing partially covered SEMS ($n = 51$) and uncovered SEMS ($n = 52$), patency, survival, stent dysfunction, and adverse events were not significantly different [25]. Although, stent material seems to be of relevance, since in 200 randomized patients with malignant biliary obstruction increased patency rates after 300 days were observed in covered nitinol SEMS (89%) vs. steel SEMS (77%, $p = 0.01$) [26]. Thus, SEMS seems to be superior to plastic stents, but covered stents seem to have no benefit over uncovered stents.

Readmission due to stent occlusion and associated complications (e.g., cholangitis) plays an important role for interventional drainage and thereby contributes a significant cost factor for the public health system. In a cost-efficacy analysis within a randomized trial of 219 patients receiving plastic stents ($n = 73$), partially covered ($n = 71$) and uncovered SEMS ($n = 75$) due to malignant biliary obstruction, functional patency time was significantly longer in SEMS (uncovered, 288 days, vs. partially covered, 299 days, vs. plastic, 172 days, $p < 0.005$). After 1 year of follow-up, 83% of the patients were dead (182/219), while 14% were still alive and 3% were lost during follow-up. The overall median survival in this patient cohort was 109 days, and the type of stent did not significantly change survival ($p = 0.241$). Concerning treatment cost, although initial costs were higher after the placement of a metal stent ($p = 0.001$), costs did not differ after 1 year of follow-up

($p = 0.61$). Even in patients with short survival (less than 3 months), costs were not significantly different in respect of the placed stent type [27]. Therefore, in a definitive palliative situation, a metal stent should be used and plastic stents avoided.

If stents cannot be placed endoscopically via the papilla of Vater route, alternative routes of nonanatomical biliary drainage are endoscopic ultrasound (EUS)-guided biliary drainage by either hepaticogastrostomy (HPG) or choledochoduodenostomy (CD), both using a partially covered SEMS. In a group of 49 patients with unresectable malignant biliary obstruction, 25 patients were randomized to receive HPG after failed endoscopic retrograde cholangiopancreatography (ERCP), while 24 received CD. Both HPG and CD were associated with a high technical (96% vs. 91%, $p = 0.609$) and clinical (resolution of jaundice) (91% vs. 77%, $p = 0.234$) success rate, respectively. Quality of life improved significantly in both groups, without differences in survival ($p = 0.603$). Therefore, after failed ERCP drainage, nonanatomical biliary drainage might be an option in selected patients if experience with this procedure is present [28].

Prophylactic Gastrojejunostomy for Unresectable Periampullary Cancer

Besides obstruction of the biliary track, patients with unresectable malignancy of the pancreas and especially of the pancreatic head are prone to develop gastric outlet obstruction (GOO) within the course of their disease. Even among those patients considered to have a low risk of developing GOO, the incidence lies between 10 and 15% [29, 30]. To overcome this, performance of a prophylactic gastrojejunostomy at exploration is possible and even recommended, even in asymptomatic patients, if expected survival is not very limited [31]. Whether this procedure is feasible and accompanied with acceptable morbidity and mortality was investigated in two randomized trails.

In a prospective randomized trial ($n = 87$ patients) on the efficacy of a prophylactic retrocolic gastrojejunostomy in patients who were initially planned for curative pancreaticoduodenectomy (PD) and were found to have unresectable disease at exploration, 44 patients were randomized for prophylactic gastric bypass surgery, while 43 did not receive a bypass. No difference was reported on postoperative morbidity and mortality (32% vs. 33%) nor on hospital stay (8.5 days $\pm$ 0.5 day vs. 8.0 days $\pm$ 0.5 day) or long-term survival (8.3 months for both groups) in both groups. Most importantly, 19% of the patients without gastrojejunostomy developed gastric outlet obstruction and needed further interventions, after a mean period of 2 months postoperatively. On the other hand, none of the patients with bypass surgery developed a gastric outlet obstruction ($p < 0.01$). These data strongly support the recommendation that patients with unresectable pancreatic malignancy at exploration should receive a gastrojejunostomy on a routine basis [32]. These data were reconfirmed by a randomized study comparing 65 patients with unresectable periampullary tumors in whom a double bypass (hepaticojejunostomy and retrocolic gastrojejunostomy, $n = 36$) was compared with a single bypass alone

(hepaticojejunostomy, $n = 29$). The incidence of gastric outlet obstruction during follow-up was significantly higher in patients with a single bypass when compared with patients receiving a double bypass (41.4% vs. 5.5%, $p = 0.001$). Of the 12 patients experiencing GOO after single bypass, 50% underwent a relaparotomy with a secondary gastrojejunostomy after a median time of 3.5 months after initial exploration. On the other hand, postoperative morbidity (31% vs. 28%, $p = 0.12$), length of hospital stay (11 days vs. 9 days, $p = 0.06$), and median survival (7.2 months vs. 8.4 months, $p = 0.15$) were not significantly different between the double bypass group and the single bypass group, respectively. Quality of life was also not different between the procedures [33].

The importance of a prophylactic gastrojejunostomy in palliative pancreatic cancer was further underlined by Gurusamy et al. who pooled the abovementioned studies in a meta-analysis and confirmed a significant reduction of gastric outlet obstruction (2.5% vs. 27.8%, RR 0.10, 95% CI 0.03–0.37) in patients undergoing a prophylactic gastrojejunostomy compared to patients without gastric bypass. On the other hand, survival (HR 1.02, 95% CI 0.84–1.25), as wells as morbidity, and quality of life were unchanged. Naturally, interventions involving a gastrojejunostomy had an increased operating time (MD 45 min, 95% CI 21.39–68.61) [34].

Furthermore, underlining the efficacy of surgical palliation and delineating the timing of surgical palliation, van Wagensveld and coworkers investigated the effects of palliative surgical procedures in 126 patients suffering from unresectable pancreatic cancer receiving a Roux-en-Y hepaticojejunostomy and a gastrojejunostomy. Indication for palliative approach was irresectability at exploration in 44 patients, failure of endoscopic treatment in 43, GOO in 28 patients, and other reasons in 11 patients. One hundred-eighteen patients received a double bypass, six a single biliary bypass, and two only a gastrojejunostomy. Most patients in this study received a prophylactic gastrojejunostomy (77%), while only a minority of patients (23%) was symptomatic at the time of surgery. Complications developed in 10% of the patients, and the 30-day mortality was 1%. Delayed gastric emptying (DGE) developed in 14% of the patients. Patients that were symptomatic for GOO at the time of surgery had an increased risk of developing DGE when compared to the asymptomatic patients prior to surgery (25% vs. 12%, $p < 0.05$). Late obstruction occurred in 11% at a median time of 141 days (21 – 356 days) after treatment. This study further underlines surgical palliation being an effective method associated with low morbidity and mortality. Most notably, gastric bypass surgery should also be performed in asymptomatic patients if irresectability is found during exploration [35].

The surgical principle to perform a gastric bypass in palliation of GOO is of pivotal importance. A Roux-en-Y gastrojejunostomy (GE) by antecolic latero-lateral gastrojejunostomy after dissection of the jejunum 20 cm after the ligament of Treitz without transection of the stomach ($n = 21$) is superior compared with a conventional GE (hand-sewn side-to-side antecolic gastroenterostomy, 20 cm after the ligament of Treitz) ($n = 20$) in non-jaundiced patients with unresectable pancreatic cancer. The time to nasogastric tube removal ($p < 0.001$), time to liquid ($p < 0.001$), soft ($p < 0.001$), and regular diet ($p < 0.002$), as well as need for prokinetics ($p = 0.025$) were significantly reduced. Additionally, hospital stay was

significantly reduced (7.7 days vs. 9.6 days, $p = 0.006$) after Roux-en-Y gastroenterostomy [36].

Most of these gastric bypass procedures can nowadays be performed laparoscopically. Laparoscopic gastrojejunostomy for palliation of malignant gastric outlet obstruction gives no advantage in regard to operation time ($p = 0.75$), but intraoperative blood loss ($p = 0.0001$), time to oral food intake ($p = 0.04$), and incidence of delayed gastric emptying ($p = 0.04$) were significantly reduced when compared to open surgery [37].

Interventional Approaches for Gastric Outlet Obstruction

Gastric outlet obstruction can also be treated by endoscopic stent placement. Comparing gastrojejunostomy ($n = 18$) with endoscopic duodenal stent placement ($n = 21$) in a randomized controlled trial (SUSTENT study), food intake, according to a standardized GOO scoring system (GOOSS), was improved more rapidly after stenting than after surgery (GOOSS $\geq$ 2: 5 days vs. 8 days, $p < 0.01$), while long-term effects were significantly better after gastrojejunostomy compared with stenting (GOOSS $\geq$ 2 for 72 days vs. 50 days, $p = 0.05$). Additionally, major complications ($p = 0.02$), recurrent obstruction ($p = 0.02$), and re-interventions ($p < 0.01$) occurred more frequently after stenting compared to surgery. Interestingly, post-interventional complications were similar when eliminating stent occlusion ($p = 0.4$). Furthermore, median survival ($p = 0.19$) and QOL were equal between the groups [38].

Cost analysis in this study revealed that initial costs were significantly higher in the group receiving a gastrojejunostomy ($p < 0.001$), an effect mainly due to longer hospital stay after surgery (15 days vs. 7 days, $p = 0.04$). However, the follow-up costs were equal between the two groups ($p = 0.7$). Overall, total costs per patient were higher in the surgical group, when compared to the interventional group ($p = 0.049$). However, cost-effectiveness ratio showed only increased cost of 164€ per extra day without GOO (GOOSS $\geq$ 2). Based on these studies, gastrojejunostomy is the treatment of choice if expected survival is not very compromised (>2 months), although costs might be higher. Therefore, a gastrojejunostomy should be preferred in light of improved long-term outcome in patients with gastric outlet obstruction [39].

Pain Management in Advanced Pancreatic Cancer

Many patients with advanced pancreatic cancer suffer from pain located in the upper abdomen and the back resulting from neural invasion and neurogenic inflammation, which drastically compromises quality of life [40]. Thus, adequate pain treatment is mandatory in most pancreatic cancer patients. In general, first-line treatment is performed by oral analgesics, ideally in accordance to the WHO guidelines. Further steps in severe pain treatment are neurolytic interventions leading to pain reduction

by denervation. This can be performed at different levels (e.g., at the thoracic level with splanchnicectomy or at the abdominal level by neurolysis of the celiac plexus) leading to a reliable pain control. On the other hand, those interventions are capable of giving rise to associated complications due to denervation like diarrhea, orthostatic hypotension, or most seriously paraplegia. The advantages, disadvantages, and optimal timing of interventions are discussed in the following sections [41, 42].

One method of pain relief is neurolysis of the celiac plexus, which can be performed in a uni- or bilateral manner. In a randomized controlled trial, no differences between unilateral and bilateral celiac plexus neurolysis (50% ethanol + 0.25% bupivacaine) with percutaneous anterior abdominal ultrasound guidance in unresectable GI cancer were observed. The onset of pain relief was not dependent of uni- or bilateral injection technique ($p = 0.17$) as was not patients' satisfaction after treatment (64.67 ± 26.06 vs. 67.00 ± 26.51, scale: 0–100, $p = 0.73$). Additionally, post-interventional complications such as diarrhea (40% vs. 33.3%, $p = 0.59$) or hypotension (13.3% vs. 10%, $p = 1.00$) were similarly frequent comparing uni- and bilateral injection technique. Furthermore, long-term results revealed comparable outcomes with pain scores (numerical rating scale of 0–100) of 18.7 ± 12.8 for the unilateral and 20.0 ± 11.17 for the bilateral technique ($p = 0.53$) [43].

Besides transcutaneous sonography guidance, neurolysis of the celiac plexus can be achieved using computed tomography (CT) or EUS guidance. In a randomized trial, celiac plexus blockade by EUS guidance ($n = 10$), performed by injection of 10 ml of bupivacaine (0.75%) and 3 ml of triamcinolone (40 mg), achieved pain reduction in 50% of the patients, while by CT guidance ($n = 8$) only 25% of the patients experienced sufficient pain relief. Additionally, cost analysis revealed that the EUS technique was less costly when compared to the CT technique [44].

Beside the route of injection, also the target of injection plays an important role. Celiac neurolysis can either be directed selectively against the celiac plexus or the celiac ganglia. When in a randomized controlled trial, EUS-guided celiac plexus neurolysis ($n = 34$) was compared with celiac ganglia neurolysis ($n = 34$); patients receiving blockade of the celiac ganglia had a significantly higher response rate 7 days after the intervention when compared to patients receiving block of the celiac plexus (73.5% vs. 45.5%, $p = 0.026$). Furthermore, the complete response rate (pain level of 1 or lower on a scale of 0–10) was significantly higher after blockade of the celiac ganglia, compared to neurolysis of the celiac plexus (50.0% vs. 18.2%, $p = 0.01$). Adverse events or duration of pain relief was similar in both groups indicating that celiac ganglia blockade is superior to celiac plexus blockade for palliation of pain in advanced pancreatic cancer [45].

In addition to celiac plexus blockade, palliation of pain can also be achieved by splanchnicectomy, either performed bilaterally or unilaterally by thoracoscopy. When prospecting the effect of bilateral thoracoscopic splanchnicectomy by transection of the nerve in patients suffering from pancreatic cancer ($n = 23$) or chronic pancreatitis ($n = 21$) in the follow-up (3 months for cancer, 43 months for chronic pancreatitis), a long-lasting pain relief of $\geq$50% (visual analog scale (VAS) scale, 0–10) was demonstrated, already beginning in the first postoperative week. This

was associated with decreased analgesic medication consumption, while exocrine (secretin test) and endocrine pancreatic functions (basal serum glucose, plasma insulin, C-peptide) were unaffected. There was no procedure-related death, but nine patients required a thoracotomy because of bleeding [46]. A significant pain relief can also be achieved by left-sided thoracoscopic splanchnicectomy via nerve transection. The sufficient effect of pain relief by thoracoscopic splanchnicectomy was verified in 26 patients with advanced pancreatic cancer, where a significant reduction of pain was achieved in all patients. After 1 week, pain scores were significantly reduced (8.54 vs. 1.77, scale: 0–10, $p < 0.001$) when compared to scores prior to the operation. Additionally, interference with general activity decreased significantly after the intervention (8.42 vs. 2.38, $p < 0.0001$). Simultaneously, the analgesic treatment regime improved, and patients did not depend on opioid consumption [47].

Thus, thoracoscopic splanchnicectomy is a beneficial intervention for amelioration of pain without compromising exocrine and endocrine pancreatic function.

When the effect of intraoperative splanchnicectomy using 50% alcohol ($n = 65$) vs. saline 0.9% ($n = 72$) was studied (double-blinded study) in unresectable pancreatic cancer patients, the postoperative complication rate (35% vs. 34%) and length of hospital stay (13.8 days vs. 13.9 days) were not significantly different. Importantly, a significant reduction of pain was observed in the alcohol group at 2, 4, and 6 months of follow-up ($p < 0.05$). Interestingly, alcohol injection significantly reduced the pain pattern in both patients that had pain before the intervention and patients without pain before the intervention ($p < 0.05$). Furthermore, patients with pre-interventional pain experienced a prolonged survival after alcohol injection when compared to saline injection ($p < 0.0001$). During long-term follow-up, 10% of the patients in the alcohol group needed further intervention by percutaneous celiac axis block compared to 12% in the saline group. Most notably, the time to re-intervention was significantly longer after alcohol treatment when compared to saline (11.8 ± 3.2 months vs. 4.0 ± 1.1 months, $p < 0.05$) [48].

An additional analysis of those patients in a follow-up study verified the positive impact on survival (9.15 months vs. 6.75 months, $p < 0.05$) after alcohol treatment. Additionally, the patients are divided into two groups according to their mood state (scale 0–10), those with highly negative mood suffered more pain (VAS 0–10: 4.33 vs. 2.52, $p < 0.0001$) and experienced more interference of daily activities (scale 0–10: 4.94 vs. 3.07, $p < 0.0001$) when compared to patients with lower negative mood, further underlining the beneficial effects of pain relief [49].

When both available neurolytic approaches, celiac plexus ($n = 19$) and splanchnic nerve blockade ($n = 20$) were compared in a randomized trial in patients suffering from carcinoma of the body or the tail of the pancreas a significantly higher reduction of pain after splanchnic nerve blockade was observed 14 weeks after the intervention ($p < 0.001$). Additionally, in the 4-week follow-up, patients' satisfaction was significantly higher after splanchnic nerve blockade ($p = 0.003$). Alongside with this, patients with splanchnic nerve blockade had a significantly increased reduction in opioid consumption and a longer survival than patients receiving celiac plexus blockade (68.85 ± 7.3 days vs. 45.37 ± 5.82 days, $p = 0.0072$) [50].

Another important aspect in interventional pain treatment is the correct timing and interplay with pharmacological analgesic treatment. In this context, the effect of timing of celiac plexus blockade on pain relief in patients with pancreatic carcinoma receiving pharmacological pain treatment before blockade of the celiac plexus compared to patients receiving pharmacological treatment after blockade of the plexus was investigated. At all time points, pain scores (VAS) were significantly lower after treatment by neurolytic celiac plexus blockade ($p < 0.0001$), supporting the efficacy of this approach. However, pain scores were significantly lower in patients who received pharmacological pain treatment before plexus blockade ($p < 0.0001$) alongside with increased quality of life (QLQ-C30) ($p < 0.0001$). Therefore, a pharmacological treatment of pain prior to plexus blockade seems to be more effective than vice versa [51]. In addition, early celiac plexus blockade by EUS is associated with an increased pain relief ($p = 0.01$) and a tendency toward a reduction of morphine consumption ($p = 0.10$). Therefore, early plexus neurolysis should be considered in patients with unresectable pancreatic cancer during diagnostic or staging EUS [52].

However, limitation of interventional splanchnicectomy or celiac plexus blockade is also reported [53]. Comparison of opioid analgesics, celiac plexus blockade, and thoracoscopic splanchnicectomy for pain relief in unresectable malignancies of the pancreas revealed no difference in pain relief after 2 months of follow-up, raising the question of the value of invasive pain interventions, in light of potential complications [53]. Additionally, comparison of patients receiving celiac plexus blockade (0.5% bupivacaine/100% alcohol) with patients treated with systemic analgesics and sham injection revealed no effect on opioid consumption ($p = 0.93$) and QOL ($p = 0.46$) besides, however, a significant ($p = 0.005$) and long-lasting ($p = 0.01$) amelioration of pain [54].

Palliative Pancreaticoduodenectomy

As imaging modalities proceed and reporting of preoperative CT imaging is more standardized, preoperative staging of pancreatic cancer is becoming more accurate, and resectability can in most cases be determined very clearly [55]. On the other hand, resection policies in locally advanced pancreatic cancer are getting more aggressive, especially in light of higher resection rates and survival after potent neoadjuvant treatment protocols like FOLFIRINOX [56]. Nevertheless, in some cases, a surgeon can end in a situation where complete resection of the malignancy is not feasible, and surgery ends in an R2 resection. This is an unfavorable situation because R2 resections are associated with a longer operative time (397.5 min vs. 240 min, $p < 0.0001$), higher blood loss (750 ml vs. 200 ml, $p < 0.0001$), higher morbidity (47.4% vs. 21.7%, $p = 0.0197$), more relaparotomies (13.2% vs. 0%, $p = 0.0163$), and longer hospital stay (12.5 days vs. 10.5 days, $p = 0.011$) compared to patients undergoing palliative bypass surgery. Postoperative mortality (7.9% vs. 2.2%, $p = 0.3239$) is not significantly different. However, there is also no improvement in median survival after R2 resection compared with bypass surgery

(10.7 months, $p = 0.656$) [57]. The missing impact on survival after R2 resection with increased morbidity (RR of 1.75 ($p < 0.0001$)) and mortality (RR 2.98 ($p = 0.009$)) was further validated in a meta-analysis comprising 399 patients, of which 138 received an R2 resection and 261 bypass surgery [58]. Thus, tumor mass reduction (R2 resection) is not an intended treatment option for pancreatic cancer.

On the other hand, patients receiving an unintended R2 resection have no major disadvantage, and therefore aggressive exploration of pancreatic cancer should be performed whenever possible.

In contrast to R2 resections, nonradical resections (R1 with tumor 1 mm from the resection margin) offer a survival benefit compared to palliative bypass surgery. Bypass surgery was associated with lower morbidity and hospital stay. However, median survival was significantly longer after R1 resection (17.4 months), when compared to R2 (8.5 months) and bypass surgery (9 months, $p < 0.001$), and survival rates within 1 year were significantly improved after R1 resection (71% for R1, 46% for R2, and 32% for bypass surgery; $p < 0.001$). These findings were also confirmed in a systematic review including eight studies with 1,535 patients. After R1 or R2 resection, morbidity was increased (both 48%) when compared to bypass procedures (30–34%). However, median survival was significantly longer in R1-resected patients, and therefore exploration with R0/R1 resection should always be aspired to, when compared to bypass surgery [59].

Conclusion

In conclusion, surgical palliation for obstructive jaundice in unresectable pancreatic cancer is a potential, feasible, and safe treatment option. Recurrent jaundice is significantly reduced after surgery when compared to interventional approaches (endoscopic stents, percutaneous transhepatic stents). In patients with poor expected survival of self-expandable metal stents display a promising alternative for palliation of obstructive jaundice.

When interventional biliary drainage is inevitable, self-expandable metal stents show higher patency compared to plastic stents and are cost effective even in patients with short survival. Additionally, self-expandable metal stents were also associated with reduced rates of cholangitis when compared to plastic prosthesis.

If irresectability is evident during exploration, performance of a prophylactic gastrojejunostomy is recommended to overcome the potential risk of GOO even in asymptomatic patients. There is evidence that a Roux-en-Y gastrojejunostomy is superior to a conventional gastroenterostomy in light of faster postoperative recovery. A recent RCT showed surgical palliation being superior to interventional palliation by duodenal stenting and being the treatment of choice if survival is longer than 2 months. If patients are eligible, laparoscopic palliation might be considered because of faster postoperative recovery.

Neurolytic procedures, either by splanchnicectomy or by neurolysis of the celiac plexus or ganglia, provide a potential treatment option for pain associated with advanced malignancy of the pancreas. Splanchnicectomy seems to be superior to

interventions affecting the celiac plexus. However, sufficient pharmacological pain relief should be achieved prior to neurolytic interventions. Blockade of the celiac plexus by EUS can be considered also in the early time points of irresectability. Additionally, celiac ganglia blockade is superior to celiac plexus blockade.

In light of potent neoadjuvant treatment, patients with likelihood of non-curative resection should undergo pretreatment. Following neoadjuvant therapy, exploration and evaluation of resectability should be intended whenever possible. Planned R2 resections should be avoided due to increased postoperative complications without survival benefit, unless a point of no return (e.g., dissection of the pancreatic neck) has been passed.

Abstract

Gemcitabine has been key to the management of advanced pancreatic cancer since its superiority over 5-fluorouracil (5-FU) for clinical benefit, and overall survival (OS) was established in a clinical trial published in 1997. The addition of the tyrosine kinase inhibitor (TKI), erlotinib, to gemcitabine has shown a modest but statistically significant improvement in OS compared to gemcitabine alone, making it a new standard for advanced pancreatic cancer. However, limited access to targeted agents due to high costs has meant that erlotinib is not available to all patients. A meta-analysis has demonstrated that the combination of the oral fluoropyrimidine, capecitabine, and gemcitabine (GemCap) has an OS benefit of a similar magnitude to combination with erlotinib; therefore, it is a very good alternative for patients without access to funding for the higher-cost drug and is an accepted standard at many centers. Pooled analyses of trials combining gemcitabine with platinum agents have similarly demonstrated an advantage over single-agent gemcitabine offering a further therapeutic option. Recently, the therapeutic armamentarium for advanced pancreatic cancer has been enriched by two additional chemotherapy regimens including a combination of 5-FU, folinic acid, irinotecan, and oxaliplatin (FOLFIRINOX) and a combination of gemcitabine plus nab-paclitaxel. Both regimens have been demonstrated to be superior to gemcitabine alone in terms of response rate, progression-free survival, and OS and have become standard first-line treatments for patients with good performance status. Also, evidence has increasingly emerged suggesting that chemorefractory patients may benefit from the use of second-line chemotherapy. Clinical trials have shown that combining 5-FU and folinic acid with either oxaliplatin or nanoliposomal irinotecan can improve OS following progression to first-line gemcitabine-based therapies. Nevertheless, despite recent advances in medical oncology, survival from advanced pancreatic cancer remains poor and significant breakthroughs are urgently needed.

Introduction

Although only the tenth most commonly diagnosed cancer, pancreatic cancer was the fourth most common cause of cancer death in Europe in 2012 [1], suggesting that its treatment is lagging far behind that of more common cancers. Presentation is typically late with either inoperable locally advanced or metastatic disease.

This, combined with the aggressive and relatively chemotherapy- and radiotherapy-resistant underlying tumor biology, makes pancreatic cancer a particular oncological challenge. Survival for patients with advanced disease is poor at a median of 2.5–3.5 months with supportive care alone. Of the patients who undergo curative surgery, the majority will eventually relapse, with 5-year survival ranging from 10.4% to 28.8% in resected patients, with or without adjuvant chemotherapy, respectively [2, 3]. Palliative chemotherapy improves survival compared to supportive care alone [4], with newer combination regimens showing more activity than gemcitabine monotherapy, although the benefits in duration of survival are modest. In contrast, the role of chemoradiation either as upfront or consolidation treatment after systemic chemotherapy in locally advanced disease is not clear. This chapter will discuss the current therapeutic options for patients with advanced pancreatic cancer and review data from clinical trials of chemotherapeutic agents and targeted therapies in this setting.

First-Line Chemotherapy

5-FU Monotherapy

Continuous 5-FU infusion demonstrated activity with moderate toxicity in a small phase II study of 16 patients with advanced pancreatic cancer in 1988. The response rate was reported as 19%, with a further 50% of patients achieving stable disease [5]. A 1991 phase II trial demonstrated that bolus 5-FU with leucovorin was also active in advanced pancreatic cancer, reporting three partial responses in the 42-patient study (7%) and a 6.2-month median OS in patients treated on a weekly schedule for 6 weeks out of an 8-week cycle [6]. In contrast, a concurrently reported phase II trial of high-dose infused leucovorin and bolus 5-FU demonstrated significant toxicity, mainly stomatitis and diarrhea, coupled with no partial or complete responses and a median survival of only 10 weeks [7], showing the fine balance between therapeutic dosing and toxicity that is required to achieve survival benefits. Protracted venous infusion (PVI) 5-FU was compared to a combination of PVI 5-FU and mitomycin C in a randomized phase III trial of 209 patients, but despite an improvement in response rate in the combination arm (17.6% vs. 8.4%, $p = 0.04$), the improvements in median failure-free survival (3.8 vs. 2.8 months) and overall survival (6.5 vs. 5.1 months) failed to reach statistical significance [8]. Although 5-FU is clearly an active agent in this setting, neither 5-FU monotherapy nor combination with mitomycin C would be considered a standard treatment regimen in advanced pancreatic cancer.

Gemcitabine Monotherapy

There was no internationally accepted standard regimen for advanced pancreatic cancer until a randomized trial demonstrated improved clinical benefit and survival

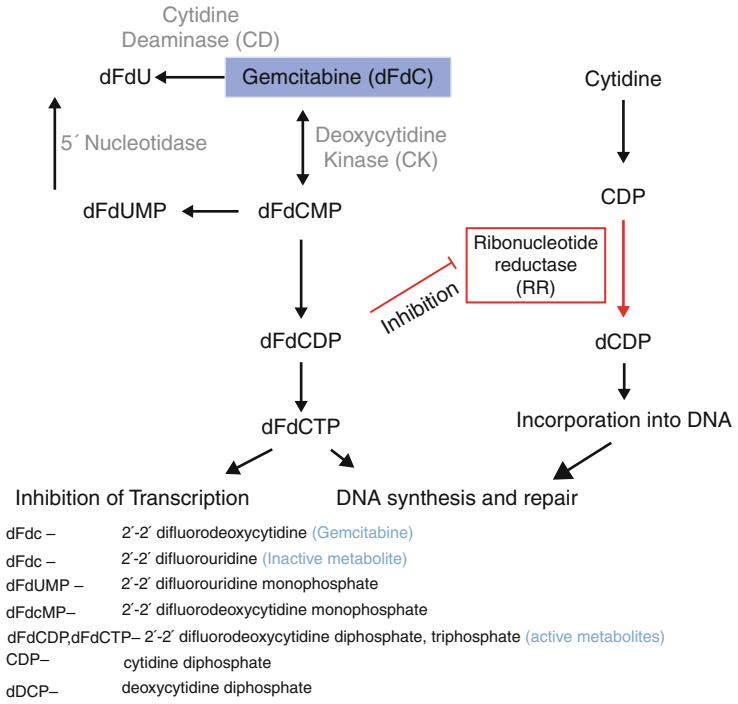

Fig. 1 Gemcitabine metabolism and action

from gemcitabine monotherapy compared to 5-FU in the first-line setting [9]. Gemcitabine hydrochloride is metabolized intracellularly to nucleoside analogues (Fig. 1) which inhibit DNA synthesis and induce apoptosis (programmed cell death). One hundred twenty-six patients with symptomatic advanced pancreatic cancer were randomized to receive a weekly 30-min infusion of 5-FU, or gemcitabine for 7 weeks followed by 1 week off, then weekly for 3 weeks out of a 4-week cycle. A clinical benefit was defined as an improvement in at least one of the following: pain and analgesic requirements, Karnofsky performance status (PS), or weight, sustained for at least 4 weeks without deterioration in any of the other factors. Twenty-three point eight percent of patients treated with gemcitabine achieved a clinical benefit compared to only 4.8% of those treated with 5-FU ($p = 0.0022$). OS was also statistically significantly better in the gemcitabine arm, although the actual benefit was relatively small (median 5.65 months vs. 4.41 months, $p = 0.0025$).

Common gemcitabine toxicities include myelosuppression, nausea and vomiting, peripheral edema, fatigue, fever, and flu-like symptoms. Gemcitabine is usually administered as a weekly infusion over 30 min for 3 weeks out of a 28-day cycle at a dose of 1,000 mg/m^2, often after 7 weekly doses in an initial 8-week cycle.

Gemcitabine monotherapy remains the standard of care for frail patients (i.e., ECOG PS 2) in many centers, with response rates of 5.6–17.3%, disease stabilization rates around 40% and median OS of 4.6–7.2 months in phase III trials using gemcitabine monotherapy as the control arm [10–15]. Of note, these response and survival rates have been achieved in selected clinical trial populations and therefore cannot be extrapolated to patients of poor performance status, or those with severe renal or hepatic dysfunction.

Fixed Dose Rate Gemcitabine

Deoxycytidine kinase, the enzyme which initiates phosphorylation of gemcitabine, and therefore eventual conversion of gemcitabine to the active gemcitabine triphosphate, has saturable kinetics. Attempts have been made to maximize conversion of gemcitabine using a fixed dose rate (FDR) delivery of 10 mg/m^2/min, rather than the standard 30-min infusion. This has been investigated in the phase I setting, where a total dose of 1,500 mg/m^2 was recommended, and in the randomized phase II setting, with no significant improvement in time to treatment failure (the primary endpoint) demonstrated when compared to a higher dose of gemcitabine given over 30 min (median 2.1 vs. 1.8 months, $p = 0.09$) with increased hematological toxicity seen in the FDR arm. However, a median OS difference was demonstrated (8.0 vs. 5.0 months, $p = 0.013$); therefore, the use of FDR gemcitabine was investigated within combination chemotherapy regimens. A single-arm phase II trial of FDR gemcitabine in combination with 5-FU demonstrated a median OS of 5.7 months; therefore, the combination was not further evaluated. In contrast, a very promising median OS of 9.2 months was seen for FDR gemcitabine (1,000 mg/m^2/100 min) in combination with oxaliplatin 100 mg/m^2 (GEMOX) in a randomized phase II study. This led to the three-arm phase III trial of 832 patients randomized to receive gemcitabine (1,000 mg/m^2/30 min), FDR gemcitabine (1,500 mg/m^2/150 min), or GEMOX (as per the phase II schedule), in which a nonsignificant trend toward superiority of FDR gemcitabine compared to gemcitabine standard administration was demonstrated (median OS 6.2 vs. 4.9 months, HR 0.83, 95% CI 0.69–1.00, $p = 0.04$) [16]. The trend toward superiority of the combination regimen GEMOX also failed to reach statistical significance compared to standard gemcitabine monotherapy (median 5.7 vs. 4.9 months, HR 0.88, 95% CI 0.73–1.05, $p = 0.22$). The median OS from the combination regimen was no better than that achieved with FDR gemcitabine alone (median survival 5.7 months vs. 6.2 months and 1-year survival 21% vs. 22%, respectively, confirming that FDR gemcitabine may be a useful treatment strategy).

Gemcitabine Combination Chemotherapy

The modest benefits provided by a single-agent approach led investigators to focus on potential combination chemotherapy, investigating whether doublet or triplet regimens could further improve survival. A similar approach had been successfully

employed in other gastrointestinal malignancies resulting in significant improvements in outcomes in the advanced disease setting.

Gemcitabine with 5-FU

The logical initial combination of chemotherapy agents to be investigated was gemcitabine with 5-FU, since both drugs had shown activity in pancreatic cancer and had individually demonstrated improvements in OS and clinical benefit. Additionally, both in vitro and in vivo studies in pancreatic cell lines have demonstrated a synergistic effect between gemcitabine and 5-FU, suggesting that the two drugs interfere with pyrimidine synthesis and catabolism at different levels (Figs. 1 and 2).

Several phase II studies have combined either bolus or infused 5-FU with gemcitabine, using a variety of regimens. Response rates vary from 5% to 31%, while OS from this combination ranges from 4 to 13 months. The combination proved to be well tolerated in these studies, with the common toxicities being neutropenia, thrombocytopenia, stomatitis, diarrhea, and hand-foot syndrome. However, neither the bolus 5-FU nor the continuously infused 5-FU combination regimens have been shown to be superior to gemcitabine alone.

The first randomized study of gemcitabine in combination with bolus 5-FU was attempted by the Eastern Cooperative Oncology Group (ECOG), where 327 patients

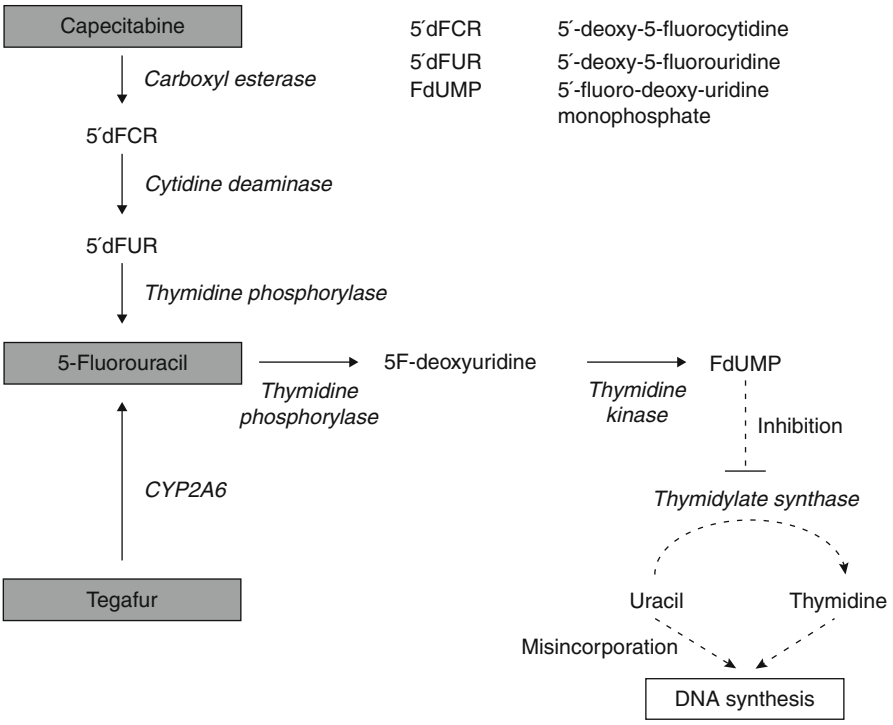

Fig. 2 5-Fluorouracil and its prodrugs

were randomly assigned to weekly gemcitabine or gemcitabine plus bolus 5-FU [11]. The median survival in the gemcitabine alone arm was 5.4 months, compared to 6.7 months for the combination group. However, statistical significance was not reached ($p = 0.09$), with the 1-year survival being identical in the two groups. A more detailed analysis of the two cohorts revealed an imbalance in the performance status of the patients and the distribution of disease. The combination arm cohort had more patients of ECOG PS 1, and patients with tumors in the pancreatic body, but fewer patients with distant metastases. When the survival analysis was adjusted to take account of these variations, statistical significance was reached, but despite a statistically significant improvement in progression-free survival (PFS) in the combination arm compared to the single-agent arm (3.4 months compared to 2.2 months, respectively, $p = 0.022$), the authors concluded that there is no clinically meaningful advantage to combining gemcitabine with 5-FU. Grade 3 and 4 toxicities were predominantly hematological or gastrointestinal in both arms, with a slightly increased rate in the combination cohort, which did not reach statistical significance (Table 1).

A second phase III study by Riess et al., which randomized 466 patients to gemcitabine with or without continuously infused 5-FU, and a randomized phase II study by the Italian Oncology Group for Clinical Research (GOIRC), using an alternative gemcitabine regimen with or without continuously infused 5-FU in 91 patients, both showed no advantage of combination chemotherapy over single-agent gemcitabine [17, 18]. In fact, both trials reported reduced median survival rates for the combination arms compared to the gemcitabine monotherapy arm (5.85 vs. 6.2 months [$p = 0.68$] and 6.9 vs. 7.2 months for the German and Italian studies, respectively). The German phase III study also failed to show any improvement in median time to progression (TTP), which was 3.5 months in both arms.

A meta-analysis of the data from these three randomized trials has confirmed that no significant advantage is afforded by the combination of gemcitabine and 5-FU over single-agent gemcitabine (HR 0.98, 95% CI 0.86–1.11). Although suggestions have been made that altering the dosing regimens may provide an improvement of outcomes, the general acceptance is that any improvement would be modest.

Gemcitabine and Capecitabine

Capecitabine (Xeloda™) is an oral fluoropyrimidine, which is selectively metabolized in tumor cells to 5-FU via a three-step enzymatic conversion process (Figs. 2 and 3). Single-agent capecitabine in chemotherapy-naïve, advanced pancreatic cancer patients has been evaluated in a phase II study, demonstrating a partial response rate of 7.3% and a clinical benefit rate of 24%, similar to single-agent 5-FU in the same setting. An initial phase I/II dose escalation study combining gemcitabine with capecitabine recruited 36 patients. The reported response rate was 18.5%, median OS 6.3 months, and 1-year survival 33%. Several randomized phase II and phase III studies have since been conducted using gemcitabine with or without capecitabine. Two phase II studies reported encouraging OS rates of 9.5 months and 9.0 months, although these were not achieved in larger phase III trials (Table 2).

Table 1 Randomized trials of gemcitabine and 5-fluorouracil (FU) in advanced pancreatic cancer

Study	Phase	Treatment	No. of patients	Median OS (months)	Median TTP (months)	Response rate (%)
Di Costanzo et al. (2005) [18]	II	Gem 1,000 mg/m^2 weekly for 7 weeks, then 1-week rest, followed by weekly for 3 weeks every 4 weeks + FU 200 mg/m^2/day CI weeks 1–6, then daily for 3 weeks every 4 weeks	43	6.9	4.2[a]	11

[a]Progression-free survival

The two phase III studies evaluating the gemcitabine plus capecitabine combination (GemCap) used different dosing regimens for the capecitabine, which might explain the difference in their reported results [14, 19]. The Swiss group demonstrated a trend toward superiority of the combination, but no significant difference in the median survival between the two arms (8.4 months for the combination arm compared to 7.2 months in the gemcitabine alone arm, $p = 0.234$) [14]. Similarly, there was no statistically significant improvement in PFS with the addition of capecitabine (4.3 months for the combination arm vs. 3.9 months, $p = 0.103$). A post hoc subgroup analysis of the patients with Karnofsky PS of 90–100% ($n = 84$) showed a statistically significant improvement in OS with capecitabine in that subgroup (median OS 10.1 months for the combination arm, 7.4 months for the gemcitabine arm, $p = 0.014$). PFS was also significantly better in the subgroup with good Karnofsky PS who received combination chemotherapy compared to those treated with single-agent gemcitabine (HR 0.69, 95% CI 0.50–0.95, $p = 0.022$). There were similar toxicity rates seen in the two arms, with neutropenia being the most common grade 3/4 adverse event. The authors therefore recommended that this combination could be used in advanced pancreatic cancer patients with good performance status. This was, however, a post hoc analysis and the study was not sufficiently powered to show a small benefit from combination chemotherapy over gemcitabine alone.

The second phase III trial, undertaken by the UK National Cancer Research Institute (NCRI), used higher total doses of gemcitabine and capecitabine with good effect [19]. A total of 533 patients were randomized to receive gemcitabine monotherapy or GemCap. A higher rate of grade 3/4 neutropenia was observed in the combination arm, but otherwise toxicity rates and quality of life data were similar between the two arms. This study showed that GemCap was superior over single-agent gemcitabine in terms of objective response rate (19.1% vs. 12.4%, $p = 0.034$) and PFS (5.3 vs. 3.8 months, HR 0.78, 95% CI 0.66–0.93, $p = 0.004$), but the OS difference did not reach statistical significance (median 7.1 vs. 6.2 months, HR 0.86, 95% CI 0.72–1.02, $p = 0.080$). However, the investigators undertook a meta-analysis of the NCRI trial combined with the Swiss trial and the randomized phase II data published by Scheithauer and colleagues and found an overall survival benefit in favor of GemCap in the 468 patients included in the analysis (HR 0.86, 95% CI 0.75–0.98, $p = 0.02$), suggesting that most of the studies to date have been individually underpowered to detect the small benefit in OS from the addition of capecitabine [19]. The GemCap regimen remains a standard first-line regimen in the United Kingdom based on these data.

Gemcitabine and S-1

S-1 is a new oral fluorinated pyrimidine which has been used increasingly in the Far East, especially in gastric cancer. The compound consists of tegafur (a prodrug of 5-FU, converted through a multistage process in vivo) (Fig. 2), 5-chloro-2,4-dihydroxypyridine (CDHP or gimeracil), and potassium oxonate (Oxo), an inhibitor of pyrimidine phosphoribosyl transferase enzyme preferentially taken up by gastrointestinal cells, which decreases activation of 5-FU, thus theoretically reducing the

gastrointestinal side effects normally associated with 5-FU (Fig. 3). S-1 has also been developed to increase the efficacy of 5-FU by incorporating CDHP, an inhibitor of dihydropyrimidine dehydrogenase (DPD) which degrades 5-FU. Studies with S-1 in gastric and colorectal cancers suggest that there may be greater activity in genotypes from the Far East than in Western populations. Given the preclinical

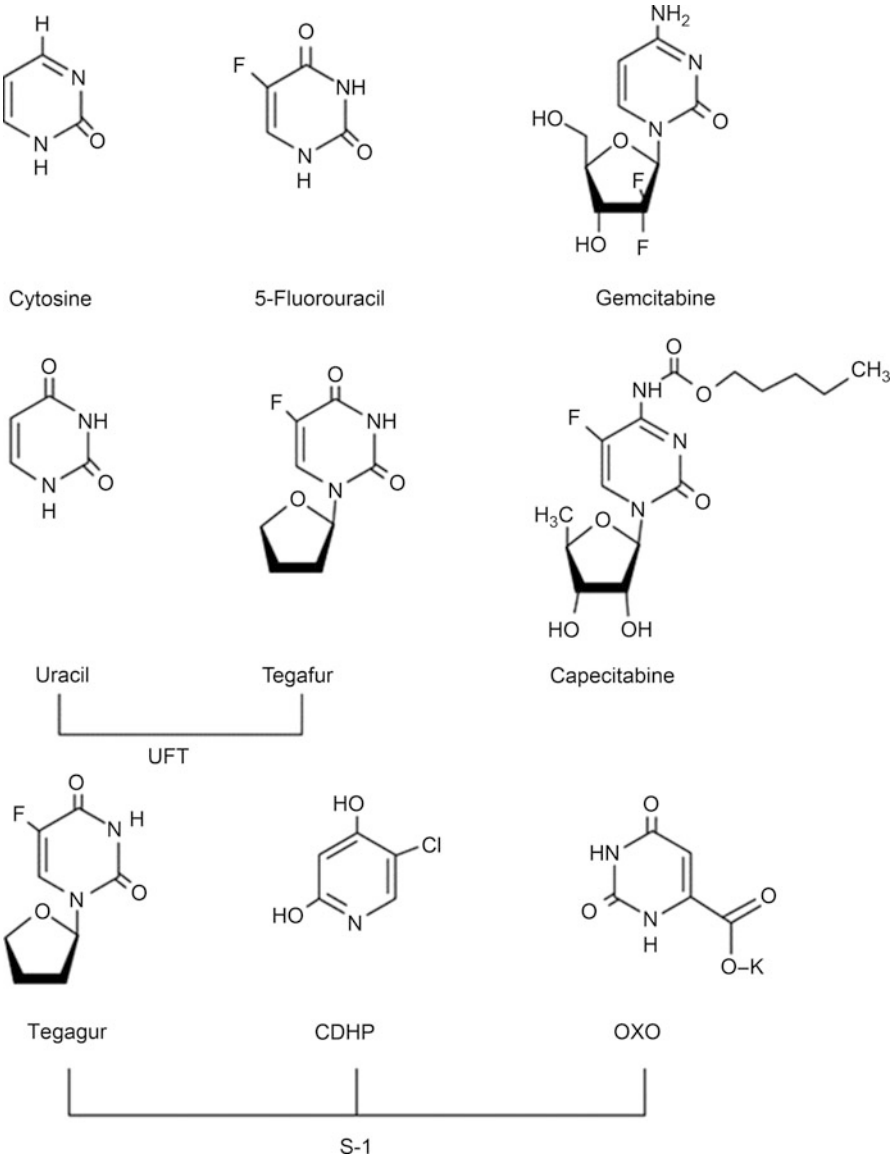

Fig. 3 Chemical structures of natural pyrimidines and synthetic analogues

data suggesting synergism between gemcitabine and 5-FU, S-1 has been investigated as an alternative in this doublet regimen.

Initial studies with single-agent S-1 in advanced pancreatic cancer have shown promising activity. A small phase II Japanese trial using the gemcitabine plus S-1 combination in 33 chemotherapy-naïve patients used a regime of S-1 orally (30 mg/m^2) twice daily for 14 consecutive days and gemcitabine (1,000 mg/m^2) on days 8 and 15, every 21 days. The reported response rate and median survival were 48% and 12.5 months, respectively, which was particularly impressive since all patients had distant metastatic disease. Neutropenia was the most prevalent grade 3/4 toxicity seen with this combination and, at 55%, appeared significantly higher than in the other gemcitabine/fluoropyrimidine combination trials.

Two multicenter phase II studies ($n = 38$ and $n = 55$), using a higher dose S-1 regimen (S-1 orally 40 mg/m^2 twice daily for 14 consecutive days and gemcitabine 1,000 mg/m^2 on days 1 and 8, every 21 days), have reported objective response rates of 32% and 44%, median PFS of 5.4 and 5.9 months, and median OS of 8.4 and 10.1 months, respectively. In both studies, neutropenia was again the most prevalent grade 3/4 toxicity. While in the study by Oh et al., the incidence of grade 3/4 neutropenia was 39.5%, in the study by Ueno et al., this was unacceptably high at 80%.

More recently, a large randomized three-arm phase III trial from Japan and Taiwan compared single-agent S-1 (80, 100, or 120 mg/day according to body surface area on days 1–28 of a 42-day cycle) and S-1 plus gemcitabine (60, 80, or 100 mg/day of S-1 according to body surface area on days 1–14 and gemcitabine 1,000 mg/m^2 on days 1 and 8 of a 21-day cycle) with gemcitabine alone (gemcitabine 1,000 mg/m2 on days 1, 8, and 15 of a 28-day cycle) [20]. The objective of this study was to demonstrate non-inferiority of S-1 as well as superiority of S-1 plus gemcitabine compared with standard single-agent gemcitabine. The primary endpoint was OS. A total of 832 chemotherapy-naïve patients with ECOG PS 0–1 were enrolled. While non-inferiority of S-1 to gemcitabine was shown (median OS 9.7 vs. 8.8 months HR 0.96, 97.5% CI 0.78–1.18, $p < 0.001$), the study failed to demonstrate the superiority of S-1 plus gemcitabine to gemcitabine alone (median OS 10.1 vs. 8.8 months, HR 0.88, 97.5% CI 0.7–1.08, $p = 0.15$). However, it is interesting to note that the combination of S-1 plus gemcitabine was associated with a statistically significant improvement in both objective response rate (29.3% vs.13.3%, $p < 0.001$) and median PFS (5.7 vs. 4.1 months, HR 0.66, 97.5% CI 0.54–0.81, $p < 0.001$) compared with single-agent gemcitabine. In contrast to previous phase II trials, lower doses of S-1 were used in the combination arm to minimize the risk of neutropenia. However, the rate of grade 3/4 neutropenia was 62.2% in the S-1 plus gemcitabine arm compared to 41.0% ($p < 0.001$) and 8.8% ($p < 0.001$) in the gemcitabine arm and S-1 arm, respectively. Increased rates of grade 3/4 thrombocytopenia, diarrhea, vomiting, and stomatitis were also reported in the combination treatment group.

Extrapolation of these results to the general treatment population is not recommended, considering the differences seen in results between Japanese and

Western population sub-analyses in earlier studies with S-1. It would be certainly interesting to determine the activity of S-1 in a Western pancreatic cancer population, to see if the discrepancies between East and West seen in gastric and colorectal cancer patients are also true in this disease setting (Table 3).

Gemcitabine and UFT

UFT, or uracil-tegafur, is another oral fluoropyrimidine (Figs. 2 and 3) which is a combination of 1-(2-tetrahydrofuryl)-5-fluorouracil (tegafur, a prodrug of 5-FU) and uracil (which inhibits catabolism of 5-FU, thus increasing the plasma concentration). Single-agent UFT showed no statistically significant activity in advanced pancreatic cancer. However, several phase II studies have been conducted combining gemcitabine with UFT, which have shown moderate activity. Currently, no phase III data have been published, but data from the phase II studies using FDR gemcitabine dosing or use of leucovorin modulation suggest modest activity. The toxicity profile appears similar to other oral fluoropyrimidine-containing gemcitabine combinations and again is more convenient for patients than infused 5-FU. However, until further supporting data are available, the gemcitabine-UFT combination cannot be recommended as a standard first-line treatment.

Gemcitabine and Platinum Agents

Preclinical data suggest that the combination of gemcitabine with platinum analogues not only increases platinum-induced DNA cross-links but also effectively inhibits their repair. Cisplatin also appears to enhance the incorporation of gemcitabine triphosphates into DNA and induces apoptosis of tumor cells. Synergistic cytotoxicity has been observed in vitro and relates to multiple mechanisms of drug interaction between the two agents. Based on these observations, clinical studies were initiated to investigate the efficacy of this combination in advanced pancreatic cancer.

Single-agent cisplatin (also known as cis-diamminedicholoroplatinum or CDDP) had been previously shown to have useful activity in advanced pancreatic cancer in a small phase II study of 33 patients. A response rate of 21% was reported by the authors, using a dose of 100 mg/m^2 on a 4-weekly cycle, but required intensive hydration to prevent nephrotoxicity, which usually necessitated an overnight inpatient admission. Other toxicities seen with cisplatin include neurotoxicity, ototoxicity, alopecia, myelosuppression, and nausea and vomiting. The addition of cisplatin to gemcitabine is logical, as there are no overlapping, dose-limiting toxicities. Several phase II studies have combined gemcitabine with cisplatin in different regimens, providing median OS rates of 5.6–9.6 months and response rates of 9–31%. The major reported grade 3/4 toxicity was myelosuppression (as high as 93% in one study), with the least toxic regimen also reporting the lowest efficacy.

The first randomized phase III study of gemcitabine with or without cisplatin recruited 107 patients with both locally advanced (approximately 50%) and metastatic disease [10]. The median OS showed a non-statistically significant improvement with the addition of cisplatin (6.9 months for the combination arm compared to 4.6 months for the gemcitabine alone arm, $p = 0.48$). However, the median TTP was

Table 3 Phase II and III trials of gemcitabine and S-1 or UFT in advanced pancreatic cancer

Study	Treatment	No. of patients	Median OS (months)	Median TTP (months)	Response rate (%)

[a]Progression-free survival

statistically significantly increased in favor of the combination arm at 4.6 months versus 1.8 months for the monotherapy arm ($p = 0.048$). A similar benefit was seen in the response rate, which was 26.4% versus 9.2%, in the combination and monotherapy arm, respectively ($p = 0.02$). An alternative gemcitabine dosing schedule was employed in a second randomized phase III study, which recruited 195 chemotherapy-naïve patients with both metastatic and locally advanced disease not amenable to surgery at diagnosis [13]. In contrast to the previous study, approximately 80% of patients in each arm had metastatic disease. The study again demonstrated no statistically significant advantage in median OS in the combination arm compared to gemcitabine alone (7.5 months vs. 6.0 months, $p = 0.15$), and response rates were comparable between the two groups (10.2% vs. 8.2%). However, the proportion of patients with stable disease was statistically significant higher in the doublet regimen arm (60.2% versus 40.2%, $p < 0.001$). The gemcitabine/cisplatin combination also conferred an increased but statistically nonsignificant PFS benefit of 5.3 months compared to 3.1 months ($p = 0.053$). In a post hoc analysis of patients with Karnofsky PS (KPS) of 90–100%, the gemcitabine/cisplatin regimen resulted in an increase in median OS from 6.9 to 10.7 months ($p = 0.051$), while no significant difference was seen in patients with KPS of 70–80% (4.9 months vs. 4.8 months, respectively). PFS was also superior in patients with KPS 90–100% receiving the combination (7.7 months vs. 2.8 months, $p = 0.013$), whereas no advantage from the addition of cisplatin to gemcitabine was seen in the remaining patients. A subgroup analysis also demonstrated that in the patients with metastatic disease, median OS was 7.2 months versus 4.7 months for the combination and monotherapy arms, respectively. The grade 3/4 toxicity rates were similar between the two arms, with only nausea and vomiting being more frequent in the combination arm (22.2% vs. 5.9%, $p = 0.0002$). When patient quality of life (QOL) was assessed using the Spitzer QOL index, no difference was observed between the two groups.

More recently, the results of a larger ($n = 400$) randomized phase III trial (GIP-1) have been reported where a weekly schedule of cisplatin plus gemcitabine was compared with standard single-agent gemcitabine in patients with locally advanced or metastatic disease [21]. Similar to previous studies, no difference was observed in OS (primary endpoint). Patients who received combination treatment had a median OS of 7.2 months compared with 8.3 months for those who were treated with gemcitabine alone (HR 1.10, 95% CI 0.89–1.35, $p = 0.38$). Median PFS (3.8 vs. 3.9 months, HR 0.97; 95% CI 0.80–1.19, $p = 0.80$) and objective response rate (12.9% vs. 10.1%, $p = 0.37$) were also similar between arms. On the other hand, an increased risk of grade 3/4 hematologic toxicities (including neutropenia, anemia, and thrombocytopenia) was observed in the investigational treatment group.

Oxaliplatin (Eloxatin™) has been shown to be non-inferior to cisplatin in the treatment of advanced gastric cancer. Oxaliplatin is more convenient than cisplatin as it does not require prehydration, meaning that treatment can be administered on an

outpatient basis. The main toxicity is peripheral sensory neuropathy, which tends to occur with cumulative exposure. The other notable side effect experienced by patients is laryngeal dysesthesia. Oxaliplatin monotherapy has shown disappointing activity in advanced pancreatic cancer, but one phase II study of 47 patients found that in combination with gemcitabine, it provided an OS of 6.2 months and response rate of 10.9%. As previously discussed, promising OS results were reported in a phase II study using FDR gemcitabine with oxaliplatin (GEMOX) in 64 patients with advanced pancreatic cancer (OS 9.2 months, response rate 30.6%), but the subsequent phase III evaluation failed to confirm a statistically significant difference compared to gemcitabine monotherapy [16]. The French Multidisciplinary Clinical Research Group (GERCOR)/Italian Group for the Study of Gastrointestinal Tract Cancer (GISCAD) intergroup phase III study also compared gemcitabine to the GEMOX regimen [12]. Median OS was increased with the doublet regimen, but again, the difference was not statistically significant (9.0 months vs. 7.1 months, $p = 0.13$), therefore failing to meet the trial primary endpoint. A subgroup analysis of patients with metastatic cancer also demonstrated a non-statistically significant OS advantage with the doublet regimen (8.5 months vs. 6.7 months, $p = 0.17$), whereas response rate, PFS, and clinical benefit response were all statistically significantly superior in the combination arm (26.8% vs. 17.3%, $p = 0.04$; 5.8 months vs. 3.7 months, $p = 0.04$; 38.2% vs. 26.9%, $p = 0.03$, respectively). Both regimens were well tolerated, although an increased rate of grade 3/4 thrombocytopenia (14.0% vs. 3.2%), vomiting (8.9% vs. 3.2%), and peripheral neuropathy (19.1% vs. 0%) was observed in the combination arm.

Of interest, a pooled analysis of the German multicenter study of gemcitabine versus gemcitabine/cisplatin [19] and the GERCOR/GISCAD study of gemcitabine versus gemcitabine/oxaliplatin [18] demonstrated that gemcitabine in combination with a platinum analogue was significantly more efficacious compared to single-agent gemcitabine [22]. A total of 503 patients were evaluated in the analysis, 251 patients in the gemcitabine alone analysis and 252 in the combination group. The combination provided significant improvements in overall response rate (22% vs. 14%; HR 1.69, 95% CI 1.06–2.70, $p = 0.028$), OS (36 weeks vs. 29 weeks; HR 0.81, 95% CI 0.67–0.98, $p = 0.031$), and PFS (24 weeks vs. 14 weeks; HR 0.75, 95% CI 0.61–0.90, $p = 0.0030$) compared to gemcitabine monotherapy. These improvements were most marked in patients with metastatic disease and in patients with better initial performance status.

Two other, larger meta-analyses incorporating outcome data from 4,465 to 6,296 patients, respectively, have demonstrated statistically significant improvement in PFS and response rate with a gemcitabine and platinum combination over single-agent gemcitabine [23, 24]. Similar conclusions were also reached in a third meta-analysis, which reported that gemcitabine plus platinum provided an OS advantage over gemcitabine alone, based on analysis of three randomized phase III trials with a total of 1,077 patients (HR 0.85, 95% CI 0.74–0.96) [25]. These meta-analyses again indicate that the studies reported have been underpowered to discern any small advantage over gemcitabine alone but that gemcitabine-platinum combination,

especially gemcitabine with oxaliplatin, may provide an alternative regimen in the first-line setting.

Gemcitabine and Topoisomerase Inhibitors

Irinotecan (CPT-11, Camptosar™) is the most widely used topoisomerase inhibitor in gastrointestinal oncology. Initial studies with single-agent treatment in advanced pancreatic cancer have shown a response rate of 9%. Addition of gemcitabine in the phase II setting has increased this to 20%, and the investigators reported a 1-year survival of 27%, but only modest median TTP (2.8 months) and median OS (5.7 months) [26]. A randomized phase III study of gemcitabine with or without irinotecan ($n = 360$) reported a slightly lower OS in the combination chemotherapy arm (6.3 months vs. 6.6 months) despite a significantly better response rate (16.1% vs. 4.4%, $p = 0.001$) [27]. The most commonly reported grade 3/4 toxicity was neutropenia, which was similar between the two arms (37.6% and 32%), with only grade 3/4 diarrhea being notably higher in the combination arm (18.5% vs. 1.8%) and no reduction in patient QOL despite this. As the primary endpoint of the trial was a 40% increase in median OS, the trial was negative and this combination, although apparently active, cannot be recommended in this setting.

Exatecan (DX-8951f) is another topoisomerase inhibitor which has been investigated as a treatment for advanced pancreatic cancer. Single-agent activity in this setting is modest, and subsequent combination with gemcitabine has been reported as non-superior to gemcitabine alone in a randomized phase III study [28]. The median OS was 6.7 months in the combination arm versus 6.2 months in the monotherapy arm ($p = 0.52$), while the median TTP was 3.7 months and 3.8 months, respectively ($p = 0.22$). Also, significantly more patients in the combination arm developed grade 3/4 toxicities, especially neutropenia, thrombocytopenia, and vomiting; therefore, again, this combination cannot be recommended.

An oral topoisomerase inhibitor, rubitecan (9-nitrocamptothecin or RFS-2000), has also been evaluated in the setting of chemorefractory pancreatic cancer. While preliminary studies suggested single-agent activity, subsequent phase III trials failed to show significant survival improvement in OS compared with standard therapy [29].

Gemcitabine and Taxanes

Taxanes are diterpenes which promote the intracellular assembly of microtubules and inhibit the depolymerization of tubulin, causing cell cycle arrest in the G2/M phase. Paclitaxel (Taxol™) was derived from the Pacific yew tree (*Taxus brevifolia*) and has been in clinical use in ovarian, breast, and lung cancer. Docetaxel (Taxotere™) is a semisynthetic taxane derived from an inactive precursor extracted from the European yew tree (*Taxus baccata*) and has been used in a wide variety of cancers. Preclinical data of docetaxel shows activity in pancreatic cancer cell lines, and phase II trials with single-agent docetaxel (dose ranging from 60 to 100 mg/m^2 given 3/4 weekly) in pancreatic cancer have shown modest activity (5–15% response rate and 5.9–8.3 months median OS). The most common toxicity reported in these studies was myelosuppression (grade 3/4 neutropenia ranging from 12% to 95%),

but another significant toxicity was gastrointestinal disturbance. Of note, the study which reported the lowest neutropenia rate used granulocyte colony-stimulating factor (G-CSF) support during chemotherapy.

In order to improve outcome and reduce the high rates of grade 3/4 toxicities seen with high dose single agent docetaxel, investigators have introduced docetaxel-based doublet regimens. Phase I/II studies combining docetaxel with gemcitabine have reported response rates from 12.5% to 18%, but median OS of 4.7–8.9 months, no better than docetaxel single-agent regimens. Grade 3/4 neutropenia was still the most commonly reported toxicity, with rates ranging from 14% to 85%, again with the lowest rates in the studies that utilized G-CSF supportive therapy. Overall, docetaxel is an effective addition to the armory of drugs for advanced pancreatic cancer, but is hindered by the high rates of grade 3/4 toxicities which may limit its clinical use and therefore cannot be currently recommended as a standard therapy.

Single-agent paclitaxel has shown some modest activity in advanced pancreatic cancer; the Southwest Oncology Group (SWOG) published data from a phase II trial reporting an overall response rate of 8%, similar to results from single-agent gemcitabine and 5-FU. Notably, the dose-intense paclitaxel regimen (250 mg/m^2 3 weekly) used in the study was with G-CSF support and resulted in 85% of patients reporting fatigue and 74% reporting nausea, vomiting, or anorexia, suggesting toxicity outweighs any clinical benefit.

Data from a phase II study using a novel micellar formulation of paclitaxel in a low molecular weight biodegradable synthetic polymer suggest similar outcome to single-agent gemcitabine (overall response rate 6.7%, median PFS 2.8 months, and median OS 6.2 months), but a more favorable safety profile [30]. More recently, a novel formulation of paclitaxel embedded in cationic liposomes (EndoTAG®-1) has been tested in a four-arm, randomized phase II trial where three different dosages of this agent were given in combination with gemcitabine versus single-agent gemcitabine [31]. A total of 212 chemotherapy-naïve patients were included. While no difference in objective response rate was observed between treatment groups, patients who were allocated to the combination arm appeared to have better median PFS (4.1–4.6 vs. 2.7 months) and median OS (8.1–9.3 vs. 6.8 months) compared with patient receiving gemcitabine alone. Furthermore, safety of the combination treatment appeared manageable with no report of treatment-related neuropathy. Overall, these data support the contention that, due to a higher therapeutic index compared with docetaxel and paclitaxel, novel formulations of taxanes can be safely combined with other cytotoxic agents for advanced pancreatic cancer.

Gemcitabine and Nab-Paclitaxel

Nab-paclitaxel (ABI-007) is a novel formulation of paclitaxel consisting of a colloidal suspension of 130-nm albumin-bound paclitaxel particles. The albumin-bound technology allows intravenous administration of paclitaxel without oil-based solvents (i.e., polyethylated castor oil and ethanol) which are normally required to solubilize this hydrophobic agent and may also cause infusion-related reactions. As a result, *nab*-paclitaxel does not need premedication and can be delivered at higher

doses and with shorter infusion schedules compared to the standard formulation of paclitaxel.

Historically, most of the available data on *nab*-paclitaxel are from studies in advanced breast cancer where this agent was proven to be more effective (in terms of response rate and TTP) compared to Cremophor-based paclitaxel. The difference in antitumor activity is thought to be secondary to a more favorable biodistribution and increased drug penetration into the tumor area of the albumin-bound formulation [32]. It has been proposed that the mechanism leading to accumulation of *nab*-paclitaxel into the tumor tissue includes transport of albumin into the interstitial space through glycoprotein-60-mediated endothelial cell transcytosis and subsequent binding of albumin to secreted protein acidic and rich in cysteine (SPARC), a glycoprotein expressed in the tumor microenvironment of most pancreatic tumors [32]. As far as safety is concerned, the toxicity profile of *nab*-paclitaxel appears to differ to that of standard paclitaxel due to a reduced risk of grade $\geq$3 neutropenia and increased risk of grade $\geq$3 peripheral neuropathy.

Using the natural vehicle properties of albumin to ensure increased drug penetration into the tumor area is an attractive strategy for tumors like pancreatic cancer which are characterized by a thick desmoplastic stroma. Further rationale for investigating *nab*-paclitaxel in this disease is provided by the results of preclinical studies where a synergistic activity with gemcitabine was observed, this possibly explained by reduced activity of the enzyme cytidine deaminase and increased intratumoral concentration of gemcitabine [33].

Following the promising results of a pivotal phase I/II trial (i.e., objective response rate 48%, median PFS 7.9 months, median OS 12.2 months among patients treated at the maximum tolerated dose) [34], the combination of *nab*-paclitaxel and gemcitabine was tested in the MPACT study, an international, multicenter, randomized phase III trial [35]. In this study 861 patients who had a Karnofsky score $\geq$70 and were chemotherapy-naïve (including adjuvant chemotherapy) were randomly allocated in a 1:1 ratio to single-agent gemcitabine (1,000 mg/mg^2 on days 1, 8, and 15, every 28 days) or gemcitabine plus *nab*-paclitaxel (gemcitabine 1,000 mg/mg^2 followed by nab-paclitaxel 125 mg/m^2 on days 1, 8, and 15, every 28 days). The primary endpoint of the study was OS. Adding *nab*-paclitaxel to gemcitabine led to a statistically significant improvement in median OS (8.5 versus 6.7 months, HR 0.72, $p < 0.0001$), median PFS (5.5 versus 3.7 months, HR 0.69, $p < 0.0001$), and objective response rate (23% versus 7%, $p < 0.001$). The proportion of patients alive at 1, 2, and 3 years in the combination treatment group and standard treatment group was 35% versus 22%, 10% versus 5%, and 4% versus 0%, respectively [36]. Neutropenia (38% vs. 27%), leukopenia (31% vs. 16%), fatigue (17% vs. 7%), and peripheral neuropathy (17% vs. 1%) were the treatment-related grade $\geq$3 toxicities which were reported significantly more frequently in the investigational arm than in the comparator arm. It is worth noting that, although *nab*-paclitaxel-related peripheral neuropathy (any grade) occurred in 54% of study patients and led to dose reduction and treatment discontinuation in 10% and 8% of patients, respectively, this appeared to be rapidly reversible (i.e., in less than 1 month) in most cases [37].

Activity and safety of this combination regimen have also been confirmed by studies conducted in Asian populations. In two small phase I/II trials which included only Chinese ($n = 21$) and Japanese ($n = 34$) chemotherapy-naïve patients, the administration of gemcitabine and *nab*-paclitaxel according to the same dose and schedule used in the MPACT trial was associated with objective response rates of 42–58%, median PFS of 5.2–6.5 months, and a median OS of 12.2–13.5 months.

Recently, alternative administration schedules of gemcitabine plus *nab*-paclitaxel have been investigated in the attempt to reduce toxicities and maintain efficacy. Administering gemcitabine and *nab*-paclitaxel once every 2 weeks (instead of weekly for 3 out of 4 weeks) has been reported to be effective and associated with a reduced risk of grade $\geq$3 neutropenia, fatigue, and neuropathy as well as reduced costs [38].

There are currently no established biomarkers to identify patients who are more likely to benefit from the use of *nab*-paclitaxel. Based on the putative role of SPARC in the mechanisms of penetration of nab-paclitaxel into the tumor area, it was originally hypothesized that expression of this glycoprotein could serve as a valuable tool for patient selection. However, retrospective analyses of the MPACT trial showed lack of association between clinical benefit from *nab*-paclitaxel and expression of SPARC either in the tumor tissue (stroma or epithelia) or in the plasma.

Gemcitabine with Other Agents

Gemcitabine has been combined with several additional chemotherapy agents. Pemetrexed (Alimta™, MTA, LY231514) is a pyrrolopyrimidine-based antifolate compound routinely used in non small cell lung cancer. Single-agent use in advanced pancreatic cancer shows minimal activity. However, preclinical studies have shown a synergistic effect with gemcitabine, suggesting improved clinical activity. The potential for this combination was seen with a reported response rate of 32% in the phase II setting. Unfortunately, this combination did not improve OS, PFS, time to treatment failure, or 1-year survival in a randomized phase III study (OS 6.2 months for the combination vs. 6.3 months, $p = 0.848$) [39]. QOL assessed by the EORTC QLQ C30 questionnaire was not statistically different between the two groups, despite a statistically greater rate of grade 3/4 myelotoxicity.

Gemcitabine has also been combined with agents previously shown to enhance the effect of cytotoxic therapy. One such agent is celecoxib, a selective cycloxygenase-2 (COX-2) inhibitor. Previous molecular studies had demonstrated an overexpression of COX-2 in pancreatic cancer cell lines, involved in inflammation, carcinogenesis, and modulation of angiogenesis. Limited phase II data are available, reporting mixed results, although any gains were modest.

Other Doublet Regimens

Doublet regimens not based on gemcitabine have also been examined. Preclinical data suggest synergistic benefit with taxanes and irinotecan. Docetaxel combined

with irinotecan in a phase II study has shown a median OS of 8.5 months, but grade 3/4 neutropenia rates of 78%, using a regimen of 60 mg/m^2 for docetaxel and 250 mg/m^2 for irinotecan on a 3-weekly cycle [40]. A weekly dosing schedule for the first 4 consecutive weeks out of every 5 weeks (35 mg/m^2 of docetaxel and 50 mg/m^2 of irinotecan) was also investigated in a phase II study [41]. The authors reported a median OS of 9.4 months in the 37 patients enrolled and a response rate of 27%. The level of grade 3/4 neutropenia reported was 30%, with a 21% rate of grade 3/4 diarrhea. This split-dosing regimen of docetaxel appears more promising, reducing the incidence of grade 3/4 toxicities, as has been demonstrated in other tumor types.

The combination of 5-FU with oxaliplatin is a standard treatment for colorectal cancer, both in the adjuvant and metastatic settings. Preclinical data suggest a synergistic effect, and the safety profile of this combination is acceptable, with myelosuppression and cumulative neurotoxicity being the predominant toxicities. A phase II study randomized 65 patients from ten French centers to receive either single-agent oxaliplatin (130 mg/m^2 3 weekly), single-agent infused 5-FU (1,000 mg/m^2 over days 1–4, every 3 weeks), or the two drugs combined [42]. The authors reported a response rate of 10% and a median OS of 9 months in the combination arm, compared to 3.4 months and 2.4 months in the oxaliplatin and 5-FU arms, respectively. Grade 3/4 neutropenia was reported in 18% and grade 3 neuropathy in 6.5% of patients in the combination arm.

More recently, a phase II study investigating 5-FU, folinic acid, and oxaliplatin (FOLFOX-6) in previously untreated advanced pancreatic cancer reported a response rate and OS of 27.6% and 7.5 months, respectively, in the 30 patients recruited [43]. Again, the regimen was well tolerated with acceptable levels of grade 3/4 toxicities. However, this regimen has not been evaluated in a phase III randomized controlled trial, and as the outcomes do not appear to be superior to those reported in other trials of gemcitabine monotherapy or gemcitabine-based combinations, this too, cannot be considered a standard regimen.

Three or More Drug Regimens

Triplet chemotherapy regimens are standard practice in the treatment of gastric and esophageal carcinomas and more recently emerged as a treatment option for colorectal cancer. The data from the doublet regimen clinical trials in advanced pancreatic cancer have only shown a modest benefit over single-agent gemcitabine at best, and therefore focus has shifted to improving combinations with triplet regimens to attempt to maximize benefit from chemotherapy.

Gemcitabine in combination with docetaxel and capecitabine (GTX) has been investigated in the United States. In a retrospective study of 35 patients (including chemotherapy-naïve and refractory patients), an overall response rate of 29% was reported, with 20% being alive at 2 years. One cycle of GTX was given over 14 days consisting of capecitabine, 750 mg/m^2 twice daily on days 1–14 (total 1,500 mg/m^2/day), with gemcitabine (750 mg/m^2) followed by docetaxel (30 mg/m^2 over) on days

4 and 11. More recently, similar results were reported in a multicenter retrospective analysis of 154 patients with locally advanced or metastatic tumors. The overall response rate was 11% and median OS was 11.6 months (25.0 months for locally advanced cancer patients and 11.3 months for patients with metastatic disease). In this study, grade $\geq$3 hematologic and non-hematologic adverse events were reported in 41% and 9% of cases, respectively.

The combination of gemcitabine, 5-FU, leucovorin, and a platinum agent has also stimulated interest, with several small studies having interval results presented at meetings, but with no study demonstrating a significant improvement in OS compared to gemcitabine alone or standard gemcitabine doublet regimens.

Gemcitabine was combined with cisplatin, epirubicin, and 5-FU in a regimen termed PEF-G. Promising results were obtained in the phase II setting, with a response rate of 58% and a median OS of 10 months. It was then compared to gemcitabine alone in a randomized phase III study which recruited 99 patients [44]. The treatment regimens used were 40 mg/m^2 cisplatin and 40 mg/m^2 epirubicin both given on day 1, 600 mg/m^2 gemcitabine administered on days 1 and 8, and fluorouracil 200 mg/m^2/day given by continuous infusion on days 1–28 of a 4-week cycle (PEF-G regimen), compared to 1,000 mg/m^2 gemcitabine given once a week for 7 of 8 consecutive weeks in cycle 1 and for 3 of 4 weeks thereafter in the gemcitabine only arm. The response rates were 38.5% for the combination arm compared to 8.5% for single-agent gemcitabine ($p = 0.0008$). Interestingly, the authors chose PFS at 4 months as the primary endpoint to reflect that the majority of patients who failed on first-line treatment usually went on to have salvage regimens within the first 4 months, thus affecting the 6-monthly median OS rates. The combination arm resulted in a PFS rate at 4 months of 60% (95% CI 46–72) versus 28% (95% CI 17–42) for the gemcitabine arm (HR 0.46, 95% CI 0.26–0.79) although toxicity was also increased; the rate of grade 3/4 neutropenia was 43% versus 14%, respectively ($p < 0.0001$). The authors conclude that PEF-G is an attractive regimen with significant activity compared to single-agent gemcitabine. However, a larger randomized trial is needed to confirm the exact impact of PEF-G on clinical outcome. More recently, in a randomized phase II trial including both locally advanced and metastatic cancer patients, the same investigators showed that replacing epirubicin (30 mg/m^2 day 1 and 15) with docetaxel (25–30 mg/m^2 day 1 and 15) in a 4-weekly regimen including cisplatin (30 mg/m^2 day 1 and 15), gemcitabine (800 mg/m^2 day 1 and 15), and capecitabine (1,250 mg/m^2/day days 1–28) was associated with a higher response rate (60% vs. 37%) and a lower incidence of grade $\geq$3 neutropenia (4% vs. 13%).

FOLFIRINOX

The combination of 5-FU with leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX regime) has now become a standard first-line treatment for patients with advanced pancreatic cancer. This combination chemotherapy was originally tested in a small phase II study where 46 chemotherapy-naïve patients were treated with 2-weekly cycles of oxaliplatin 85 mg/m^2 and irinotecan 180 mg/m^2 plus leucovorin 400 mg/m^2 followed by bolus FU 400 mg/m^2 on day 1, then FU

2,400 mg/m^2 as a 46-h continuous infusion. The objective response rate was reported as 26%, while median TTP and OS were 8.2 months and 10.2 months, respectively. Grade 3/4 neutropenia rates were high at 52%, and grade 3 neuropathy was seen in 15% of patients.

More recently, a large randomized phase III trial (ACCORD-11) compared FOLFIRINOX against standard treatment with single-agent gemcitabine [45]. In this study, 342 patients with age $\leq$75 years and ECOG PS $\leq$1 were randomized in a 1:1 ratio to receive 6 months of FOLFIRINOX or gemcitabine as frontline treatment for metastatic disease. OS was the primary endpoint. The study was successful in that patients who were randomly assigned to the investigational arm were found to have better median OS (11.1 versus 6.8 months, HR 0.57, $p < 0.001$), PFS (6.4 versus 3.3 months, HR 0.47, $p < 0.001$), and objective response rates (31.6% versus 9.4%, $p < 0.001$) compared to those who received standard treatment. Safety data from this study were in line with those reported in the pivotal phase II trial. In particular, FOLFIRINOX treatment was associated with an increased risk of grade $\geq$3 neutropenia (45.7% versus 21.0%), febrile neutropenia (5.4% versus 1.2%), sensory neuropathy (9.0% versus 0%), diarrhea (12.7% versus 1.8%), and thrombocytopenia (9.1% versus 3.6%) compared to gemcitabine. However, it is also worth noting that, despite the increased toxicity, patients who were treated with FOLFIRINOX were less likely to experience a significant deterioration of quality of life at 6 months (31% versus 66%, HR 0.47, $p < 0.001$). More recently, Singhal et al. reported the results of another randomized phase III study which was conducted in India and had the same design and primary endpoint as the ACCORD-11 trial [46]. This study included 310 metastatic pancreatic cancer patients with ECOG performance status $\leq$1. Similar to the study by Conroy et al., an improvement in median OS (10.8 versus 7.4 months, HR 0.48, $p < 0.001$), median PFS (5.6 versus 3.1 months, HR 0.44, $p < 0.001$), and objective response rates (29.6% versus 8.3%, $p < 0.001$) was observed for patients treated with FOLFIRINOX compared with those treated with gemcitabine. Notably, safety and quality of life data were also very similar between the two trials, with 29% of patients in the FOLFIRINOX arm experiencing a definitive deterioration of quality of life at 6 months compared with 59% in the gemcitabine group (HR 0.45, $p < 0.001$).

While concerns were initially raised regarding the safety and feasibility of administering triplet combination chemotherapy with 5-FU, irinotecan, and oxaliplatin in real-world metastatic pancreatic cancer patients, efficacy and safety data from the abovementioned phase III trials have been largely reproduced in a number of retrospective/observational studies. This provides further support to the contention that FOLFIRINOX should be regarded as the optimal first-line treatment choice for fit patients (i.e., age $\leq$75 years and ECOG PS $\leq$1) with no significant comorbidities. Nevertheless, frequency and severity of treatment-related toxicities has prompted the investigation of modified versions of this regimen in the attempt to improve its safety profile while maintaining efficacy. In particular, data from retrospective studies suggest that omitting the bolus 5-FU and/or reducing the dose of irinotecan may minimize the risk of grade 3/4 toxicities without significantly

affecting overall treatment outcomes. Using alternative, more tolerable, schedules of FOLFIRINOX is also important considering that this regimen has been increasingly used as chemotherapy backbone for the investigation of combination strategies with novel therapeutics in clinical trials.

Second-Line Chemotherapy

The relatively high occurrence of early disease progression in advanced pancreatic cancer, despite best available current first-line therapy, has resulted in a need to define optimal second-line therapy. However, due to the generally poor performance status and unfavorable prognosis of refractory patients, conducting meaningful phase III studies has been difficult, reflected by the sparse literature reports in this setting.

Studies investigating single-agent chemotherapy (capecitabine, oxaliplatin, irinotecan, raltitrexed, and taxanes) in patients with good performance status have reported some benefit as second-line agents, with reported median PFS ranging from 1 to 4 months and median OS from 4 to 7.5 months. In order to improve on these promising but modest results, combination chemotherapy regimens or new drug formulations have been developed for second-line treatment. Over the last few years, four phase III trials have addressed the optimal management of refractory patients who experience progression after first-line gemcitabine-based therapy. Overall, the results from these trials suggest that salvage chemotherapy improves survival compared with best supportive care, and combination chemotherapy may be superior over single-agent chemotherapy.

The use of second-line treatments in pancreatic cancer has certainly increased and contributed to the improved median OS reported in recent trials. Nevertheless, there is still no international consensus on a second-line regimen. Also, the recent availability and increased use of new combination treatments (especially non-gemcitabine regimens such as FOLFIRINOX) in the first-line setting of advanced pancreatic cancer inevitably limits the generalizability of the results of previous clinical trials which were conducted in the gemcitabine era. Finally, it is worth considering that best supportive should be still considered as an option for those patients whose performance status contraindicates the use of further treatment.

Oxaliplatin-Based Regimens (OFF and FOLFOX)

The evidence that second-line chemotherapy provides a survival advantage in refractory pancreatic cancer was provided by the CONKO-003 randomized phase III trial [47, 48]. The study initially randomized patients with Karnofsky score >60% to receive either oxaliplatin, folinic acid (FA) and 24 h infused 5-FU (OFF regimen), or best supportive care. Forty-six patients were recruited out of a planned 165, before the study was discontinued due to low recruitment. At that time, a clinically significant improvement in median OS with OFF was shown (4.82 months vs.

2.30 months, HR 0.45, $p = 0.008$) with no major issues in terms of treatment-related adverse events [47]. The best supportive care arm was closed to recruitment after this analysis, and patients were instead randomized to an alternative control arm of FA and 24 h infused 5-FU (FF regimen). The primary endpoint of this study was OS and a total of 168 patients were recruited. The median OS with OFF was 5.9 months compared to 3.3 months with FF (HR 0.66, $p = 0.01$). The median PFS also statistically significantly favored OFF (2.9 months vs. 2.0 months; HR 0.68, $p = 0.019$) suggesting that oxaliplatin in combination with 5-FU/FA is an attractive treatment choice for patients of good performance status who have failed gemcitabine therapy. Of note, treatment-related adverse events did not appear to differ between treatment arms with the only exception of an increased risk of grade 1–2 (38.2% vs. 7.1%) and grade 3 (4.0% vs. 0%) toxicities for patients randomized to the OFF group [48].

Interestingly, the results of the CONKO-003 study have been recently challenged by the findings of the PANCREOX trial. In this randomized phase III trial, 108 patients with ECOG PS $\leq$2 received 5-FU and folinic acid or modified FOLFOX6 (mFOLFOX6) for the treatment of gemcitabine-refractory advanced pancreatic cancer [49]. The primary endpoint of the study was PFS and this was not different between the study arms (median PFS 2.9 months versus 3.1 months; HR 1.0, $p = 0.99$). Interestingly, median OS was inferior in patients randomly allocated to mFOLFOX6 (6.1 months versus 9.9 months, HR 1.78, $p = 0.02$). The unexpected findings of the PANCREOX study are of difficult interpretation. However, they could be explained by the higher rate of grade $\geq$3 adverse events (63% vs. 11%) and treatment discontinuation (20.4% vs. 1.9%) and a lower use of subsequent lines of treatment (6.8% vs. 25%) in the mFOLFOX6 arm compared with the 5-FU and folinic acid arm. Therefore, an oxaliplatin-based doublet regimen still remains a reasonable treatment option for patients who have progressed to a gemcitabine-based treatment and are still fit to receive further chemotherapy.

Smaller studies have also investigated oxaliplatin in combination with capecitabine (i.e., CAPOX). In a phase II study that included 39 patients who had progressed to a gemcitabine-based first-line treatment, CAPOX was associated with a response rate of 2.6%, median PFS of 9.9 weeks, median OS of 23 weeks, and a 1-year OS rate of 21%. The safety profile was overall similar to that reported for the OFF and mFOLFOX6 regimens.

Irinotecan-Based Regimens and Nanoliposomal Irinotecan

A number of small studies have shown activity of Irinotecan as a monotherapy or in combination with other cytotoxic agents in refractory pancreatic cancer patients. A phase II study, which randomized 38 patients who had failed gemcitabine first-line therapy, to either raltitrexed alone or irinotecan plus raltitrexed was closed early due to the finding of a clear benefit from the combination arm. The primary endpoint of the trial was response rate, which was noted to be 16% in the combination arm versus 0% with raltitrexed monotherapy at the first interim analysis. Despite the

higher incidence of any grade toxicities with the combination, the rate of grade 3/4 toxicities was similar in both arms. The activity of irinotecan-based treatments in the refractory setting was confirmed in a phase II study where the use of FOLFIRI (i.e., irinotecan, 5-FU, and folinic acid) was associated with a response rate of 8%, median PFS of 3.2 months, and median OS of 5 months in 50 patients who had been previously treated with gemcitabine plus a platinum agent. In a randomized phase II trial, a modified FOLFIRI regimen (i.e., mFOLFIRI.3) was compared with mFOLFOX for the treatment of gemcitabine-refractory pancreatic cancer [50]. A total of 61 patients were enrolled in this study. No difference in 6-month survival rate (primary endpoint of the study) was observed, this being 27% for the mFOLFIRI.3 arm and 30% for the mFOLFOX arm (95% CI 15–49%). Treatment groups appeared also similar in terms of disease control rate (23% vs. 17%), median PFS (8.3 vs. 6.0 weeks), and median OS (16.6 vs. 14.9 weeks). Although the overall rate of grade 3/4 toxicities was the same in both arms (38%), patients who were treated with mFOLFIRI.3 experienced more grade 3/4 diarrhea (7% vs. 0%) but less grade 3/4 asthenia (3% vs. 14%) compared with those who received mFOLFOX.

Recently, a novel liposomal formulation of this cytotoxic agent has been developed to ensure increased drug stability in the circulation and higher concentration of the active metabolite SN-38 in the tumor area. In a phase II study of 40 patients who had been previously treated with gemcitabine-based therapy, second-line treatment with single-agent nanoliposomal irinotecan was associated with an objective response rate of 7.5%, disease control rate of 50.0%, a median PFS of 2.4 months, and a median OS of 5.2 months. In a subsequent open-label, three-arm, phase III trial (NAPOLI-1), 417 pancreatic cancer patients with Karnofsky score $\geq$70 and gemcitabine-refractory tumors were randomized to nanoliposomal irinotecan as single agent or in combination with 5-FU and folinic acid or 5-FU and folinic acid alone [51]. The primary endpoint of the study was OS. While no difference in outcome was observed between single-agent nanoliposomal irinotecan and 5-FU plus folinic acid for any of the outcome measures, patients who were treated with nanoliposomal irinotecan plus 5-FU and folinic acid had better median OS (6.1 months versus 4.2 months, HR 0.67, $p = 0.012$), median PFS (3.1 months versus 1.5 months, HR 0.56, $p = 0.0001$), and objective response rate (16% versus 1%, $p = 0.0001$) compared to those who received 5-FU and folinic acid alone. The safety profile of nanoliposomal irinotecan was manageable with most common grade $\geq$3 adverse events in the combination arm including neutropenia (27%), fatigue (14%), diarrhea (13%), and vomiting (11%). Based on these results, nanoliposomal irinotecan in combination with 5-FU and folinic acid has been recently approved as a treatment option in the second-line setting of metastatic pancreatic cancer.

Other Chemotherapy Combinations

A series of different phase II studies evaluating alternative options in gemcitabine-refractory advanced disease have only reported modest improvements in clinical outcome. The majority of these combinations have been doublet regimens.

A gemcitabine and oxaliplatin doublet regimen was used in a phase II study which recruited 33 patients who had progressed on or after receiving gemcitabine as first-line therapy. The median duration of response was 4.5 months, and median survival was 6 months, which, with a reported CBR rate of 54%, suggest that this combination may warrant further investigation in a randomized phase III trial. Oxaliplatin has also been combined with raltitrexed in gemcitabine resistant cases, giving similarly promising results, particularly in patients with a previous PFS of greater than 6 months. Retrospective studies also showed similar outcomes when oxaliplatin was combined with S-1.

Other platinum agents were investigated in the refractory setting. In a randomized phase III trial comparing two sequential strategies, a response rate of 7% and a clinical benefit rate of 45% were observed in patients who received cisplatin plus 5-FU and folinic acid after progression to single-agent gemcitabine [52]. This study also showed that first-line cisplatin plus 5-FU and folinic acid followed by second-line gemcitabine was not superior in terms of overall survival compared with the opposite sequence.

A combination of capecitabine and docetaxel was investigated in a phase II trial which included 43 gemcitabine-refractory patients. The investigators reported an objective response rate of 14%, median PFS of 3.7 months, and median OS of 5.3 months. It is worth noting, however, that 50% of patients experienced grade 3/4 toxicity.

Second-line studies with single-agent chemotherapy have been conducted especially in Japan and used S-1. In two phase II trials including 40 and 21 gemcitabine-refractory patients, respectively, S-1 administered at a dose of 40 mg/m^2 twice daily for 28 days, followed by 14 days' rest was associated with response rates of 10–15%, clinical benefit rate of 53–58%, median PFS of 2.0–4.1 months, and median OS of 4.5–6.3 months. Although it is not known whether these findings can be generalized to a Western population, they suggest that single-agent treatment with S-1 may be a reasonable option in the refractory setting.

The positive results of the ACCORD-11 and MPACT trial in chemotherapy-naïve patients have recently encouraged the use of FOLFIRINOX and gemcitabine plus nab-paclitaxel as chemotherapy regimens in patients who had progressed to gemcitabine-based and FOLFIRINOX chemotherapy, respectively. Although there are currently no data from prospective clinical trials, a number of small retrospective studies have reported promising efficacy and safety data suggesting that these combination treatments may also have a potential role in the refractory setting. For example, in a prospectively recorded series of 57 advanced pancreatic cancer patients who were treated with gemcitabine plus *nab*-paclitaxel following progression to frontline FOLFIRINOX, interesting outcome data were reported with an objective response rate of 17.5%, a clinical benefit rate of 58%, and a median PFS of 5.1 months. Median OS from start of second- and first-line treatment was 8.8 months and 18.0 months, respectively. Of note, the safety profile of gemcitabine plus *nab*-paclitaxel did not differ significantly from that reported in the MPACT study. In another retrospective series of 27 patients who had progressed to gemcitabine, second-line

FOLFIRINOX was associated with a response rate of 18.5%, CBR of 63%, median TTP of 5.4 months, and median OS of 8.5 months. Again, the rate of grade $\geq$3 neutropenia (55.6%) was in line with that reported in the ACCORD-11 trial.

Careful selection of appropriate patients from those who progress after first-line therapy is crucial to deciding who will benefit from second-line treatment. Single-agent second-line chemotherapy may be associated with a lower rate of toxicities, along with a lower rate of clinical response. Therefore, combination chemotherapy should be considered for those who have a good baseline PS. As best supportive care measures become more refined, the oncologist is faced with the paradox of maximizing outcome while maintaining or improving QOL. The greater the number of chemotherapy lines or number of drugs per combination, the higher the likelihood of treatment related toxicities. As a result, emphasis has shifted over the last decade toward determining the role of targeted agents alongside chemotherapy (Tables 4 and 5).

Targeted Agents

The Epidermal Growth Factor Receptor (EGFR)

Adding novel targeted agents to chemotherapy has been a successful therapeutic strategy in a number of solid tumors. The epidermal growth factor receptor (EGFR) has been the subject of targeted therapy, using both monoclonal antibodies to the receptor itself such as cetuximab and panitumumab and small molecule receptor tyrosine kinase inhibitors (TKIs) such as erlotinib, gefitinib, and afatinib.

The human EGFR, a transmembrane glycoprotein receptor with an extracellular ligand-binding domain and an intracellular tyrosine kinase domain, is part of the ErbB family, which also includes ErbB-2 (Her-2), ErbB-3, and ErbB-4. Ligand binding to the EGFR stimulates receptor homodimerization, or heterodimerization with another receptor from the family, and results in phosphorylation of the tyrosine kinase domains and a cascade of intracellular events which lead to cell cycle progression, proliferation, and differentiation. The EGFR and two of its ligands, epidermal growth factor (EGF) and transforming growth factor alpha (TGFα), are found in normal pancreatic acini and ducts and are overexpressed in pancreatic cancers [53].

Erlotinib

Preclinical studies of erlotinib (Tarceva™), a selective small molecule inhibitor of the EGFR tyrosine kinase domain demonstrated that it can completely prevent EGF-induced autophosphorylation of head and neck cancer xenografts, inhibit in vitro proliferation of colon cancer cells that overexpress EGFR and block progression through the cell cycle at G_1 phase in both. Blockade of EGFR phosphorylation was

[a]PFS

also observed in a study of pancreatic cancer xenografts and of clinical importance; enhancement of gemcitabine-induced apoptosis was noted. Phase I testing of erlotinib established that the drug displayed dose-dependent pharmacokinetics and did not accumulate on a continuous daily dosing schedule. The maximum tolerated dose (MTD) was 150 mg once daily orally for continuous dosing, with diarrhea and cutaneous toxicity as the dose-limiting toxicities (DLTs). A phase Ib study of dose-escalation erlotinib added to gemcitabine showed that this dose could also be achieved with chemotherapy without DLTs. Fifteen of the 26 patients included in the study had advanced pancreatic cancer and an impressive 51% 1-year survival rate was observed, prompting further investigation of this combination in pancreatic cancer. The activity of the combination was confirmed in a phase III randomized controlled trial of gemcitabine plus either erlotinib or placebo [15]. In this National Cancer Institute of Canada Clinical Trials Group (NCIC CTG) study, 569 patients with unresectable locally advanced ($n = 138$) or metastatic ($n = 431$) pancreatic cancer were randomized to receive standard dosing schedule gemcitabine with erlotinib 100–150 mg/day or placebo. The study met its primary endpoint by demonstrating a small improvement in OS in the combination therapy arm (median OS 6.24 vs. 5.91 months, HR 0.82, 95% CI 0.69–0.99) as well as a statistically significant prolongation of PFS (median 3.75 vs. 3.55 months, HR 0.77, 95%CI 0.64–0.92), despite no difference in the objective response rate (8.6% vs. 8.0%). As too few patients were treated with erlotinib at 150 mg/day, the authors recommended the lower dose (100 mg/day) for clinical practice in combination with gemcitabine. This is the first study that showed a statistically significant benefit from adding a biological agent to gemcitabine, although the incremental gain is relatively minor, and this combination has therefore not been universally accepted as the standard of care, especially where cost-effectiveness is taken into account.

Erlotinib has also been shown to be active in combination with capecitabine in gemcitabine-refractory pancreatic cancer in a small phase II trial [54]. Of the 30 patients treated with capecitabine 2,000 mg/m^2/day days 1–14 of a 21-day cycle with continuous dosing of erlotinib 150 mg/day, three patients (10%) had an objective partial response, meeting the study primary endpoint, and the median OS for all patients treated was 6.5 months. There were no grade 4 toxicities recorded but grade 3 diarrhea (17%), rash (13%), hand-foot syndrome (13%), and stomatitis (10%) were all relatively common, which could limit the regimen acceptability. As is characteristic of EGFR inhibitors, development of a papulo-pustular rash is an indication of response to erlotinib and is associated with improved survival.

More recently, a sequential strategy with first-line capecitabine plus erlotinib followed by second-line gemcitabine was compared with first-line gemcitabine plus erlotinib followed by second-line capecitabine in a randomized, non-inferiority, phase III trial that included 281 patients. The primary endpoint was time to treatment failure after second-line chemotherapy (TTF-2). Although no difference was observed in TTF-2 between arms, patients who were randomized to gemcitabine plus erlotinib had better ORR (16% vs. 5%), clinical benefit rate (51% vs. 38%), and time to treatment failure after first-line treatment (TTF-1, 3.2 vs. 2.2 months, HR 0.69, $p = 0.0034$) compared with those who were treated with

capecitabine plus erlotinib [55]. Small phase II trials have also investigated erlotinib in the first-line setting combination with combination chemotherapy (gemcitabine plus capecitabine) with or without a targeted therapy (i.e., bevacizumab) with promising results.

Erlotinib has also been investigated in addition to chemoradiation for locally advanced pancreatic cancer in phase I studies. In particular, it has been added to a number of combination chemoradiation regimens including single-agent gemcitabine, gemcitabine plus paclitaxel, single-agent capecitabine, and capecitabine plus bevacizumab. Generally, in these studies treatment was well tolerated with manageable toxicity. Also, preliminary data of efficacy were encouraging.

Gefitinib

Gefitinib (Iressa™) is also an EGFR TKI which has been similarly investigated in advanced pancreatic cancer. A phase I dose-finding trial of fixed dose gefitinib (250 mg/day) in combination with gemcitabine 1,000–1,500 mg/m^2 weekly for 3 out of every 4 weeks found hematological DLTs above 1,200 mg/m^2 gemcitabine and reported a median OS of 7.13 months for 13 patients with advanced pancreatic cancer. In a subsequent phase II study of gefitinib (250 mg daily) plus gemcitabine (1,000 mg/m2 weekly), an objective response rate was observed in six out of fifty-three patients (11.3%), while median PFS and OS were 4.1 and 7.3 months, respectively [56]. Gefitinib has also been evaluated in two small phase II studies in combination with docetaxel as second-line therapy after gemcitabine. The combination appeared ineffective as the median survival time was only 2.9 and 4.5 months. Furthermore, in one of these studies, an acceptable high rate of febrile neutropenia (27%) was reported.

Like erlotinib, gefitinib has been investigated in combination with chemoradiation in patients with locally advanced pancreatic cancer. Toxicity was acceptable but the median survival was only 7.5 months in combination with gemcitabine-based chemoradiation in a phase I study of 18 patients, which does not compare favorably to phase I data of erlotinib and chemoradiation. Combination with capecitabine-based chemoradiation was highly toxic, mainly due to diarrhea, and therefore this regimen has not been recommended for further study. Also, a combination of gefitinib plus paclitaxel-based chemoradiation was tested in a small phase I study with mainly gastrointestinal toxicity.

Cetuximab

Cetuximab (Erbitux™) is a chimeric IgG-1 monoclonal antibody to the EGFR. Early phase II results of cetuximab in combination with gemcitabine were promising, with 5/58 patients achieving a partial response and a further 26 achieving disease stabilization. However, a subsequent randomized phase II trial of 40 patients treated with gemcitabine and cisplatin, with or without cetuximab, showed no significant improvement in response rate, PFS, or OS with the addition of cetuximab. More encouraging were the results of a multicenter phase II trial combining cetuximab

with the GemOx regimen in the first-line setting; a 33% response rate was seen in the 61 evaluable patients, with a further 31% achieving stable disease.

The only randomized phase III study which investigated cetuximab in pancreatic cancer was the SWOG S0205 trial [57]. A total of 766 patients with locally advanced or metastatic disease were assigned to receive gemcitabine with or without cetuximab as first-line treatment. The primary endpoint was OS. The study failed to show any survival advantage in favor of cetuximab (median OS 5.9 months for gemcitabine alone and 6.3 months for gemcitabine plus cetuximab, HR 1.06, $p = 0.19$), and no difference was observed between arms in terms of objective response rate and median PFS. Interestingly, EGFR expression did not appear to be associated with cetuximab benefit. One explanation for the relatively poor results from adding cetuximab to chemotherapy in pancreatic cancer may be the high incidence of Kirsten ras mutations (estimated as up to 90%) [58] seen in these tumors; Kirsten ras mutations are known to confer resistance to anti-EGFR antibodies in metastatic colorectal cancer; therefore, it is possible that the same is true in this setting.

Cetuximab has been demonstrated to be beneficial in combination with radiotherapy versus radiotherapy alone in head and neck cancers. The radiosensitizing properties of this anti-EGFR monoclonal antibody have also been investigated in pancreatic cancer. In the phase II PARC trial, 68 patients with inoperable locally advanced tumors were treated with gemcitabine plus cetuximab in combination with intensity-modulated radiotherapy (IMRT). Partial response was observed in 23 cases (33.8%) and 14 patients (20.6%) became suitable for a surgical resection. Two-year OS was 20%. These results were confirmed in a subsequent phase II study where combining cetuximab with gemcitabine and radiotherapy was associated with encouraging response rate (30%) and led to surgical resection in 18/23 patients with borderline resectable tumor and 3/6 patients with unresectable tumors at baseline. In the same study, pathological complete response was observed in 8% of cases. Also, cetuximab was investigated in combination with induction GEMOX chemotherapy and sequential capecitabine-based chemoradiotherapy in a phase II study of 69 patients with locally advanced disease. In this study a median OS of 19.2 months was reported and 11.3% of patients were alive at 4 years.

Vascular Endothelial Growth Factor (VEGF)

Bevacizumab

Bevacizumab (Avastin™) is a monoclonal antibody against VEGF, a proangiogenic growth factor involved in the regulation of vascular permeability and proliferation. Bevacizumab can be safely added to gemcitabine chemotherapy. A 21% response rate (and 46% disease stabilization rate) was reported from a phase II trial of 52 patients. The median PFS was 5.4 months and OS an encouraging 8.8 months. Well-described bevacizumab-related grade 3/4 toxicities including hypertension (19%), thrombosis (13%), visceral perforation (8%), and bleeding (2%) appeared more

frequent than described in previous large studies in colorectal cancer, but this did not deter further investigation. Disappointingly, a large phase III trial of this combination failed to demonstrate a role for bevacizumab in advanced pancreatic cancer. In the CALGB 80303 study, 602 patients with untreated locally advanced or metastatic tumors were randomized to receive gemcitabine plus bevacizumab or placebo in a double-blinded trial [59]. No significant survival benefit was demonstrated from the addition of bevacizumab, with a median OS of 5.8 months in the combination arm and 5.9 months in the gemcitabine/placebo arm ($p = 0.95$). Objective response rates were also similar between arms (13% vs. 10%), and interestingly trends toward a worse median PFS were observed for patients treated with bevacizumab (2.9 vs. 3.8 months, $p = 0.07$). It is also worth noting that much lower incidences of bevacizumab-related toxicities were seen in this trial than in the phase II setting (grade 3/4 hypertension 10%, perforation 0.4%, bleeding 5%, venous thrombosis 14%).

Bevacizumab has also been investigated with combination chemotherapy regimens. In a phase II trial of 50 patients with mostly stage IV pancreatic cancer treated with GemCap plus bevacizumab, the investigators reported a 22% response rate, 5.8 months median PFS, and 9.8 months OS. In another phase II trial of GemOx plus bevacizumab which included 50 patients (34 with metastatic disease), response rate was 36%, median PFS 4.9 months, and median OS 11.9 months. However, the rate of grade 3/4 toxicity was unacceptably high at 94%.

Finally, the combination of gemcitabine plus erlotinib with or without bevacizumab was assessed in 301 metastatic pancreatic cancer patients in the randomized, placebo-controlled phase III AViTA trial [60]. Although the triplet combination significantly improved the median PFS (4.6 vs. 3.6 months, HR 0.73, 95% CI 0.61–0.86, $p = 0.0002$) and showed a trend toward a higher ORR (13.5% vs. 8.6% $p = 0.0574$), the trial failed to meet its primary endpoint of a benefit in median OS (7.1 vs. 6.0 months, HR 0.89, 95% CI 0.74–1.07, $p = 0.2087$). This, combined with the high cost associated with a regimen including two targeted agents, makes it unlikely that this will be used as a standard treatment option.

Bevacizumab has also been evaluated in combination with chemoradiation for locally advanced unresectable pancreatic cancer in phase I and II studies. While the safety profile was manageable, the efficacy data appeared overall similar to those obtained with standard chemoradiation.

Other Anti-Angiogenic Agents

Sorafenib (Nexavar™) is a VEGF receptor-2 TKI and Raf-1 kinase inhibitor with demonstrated PFS benefit in renal cell carcinomas and OS benefit in hepatocellular carcinoma. A randomized, double-blind, phase III trial of gemcitabine plus sorafenib or placebo in locally advanced or metastatic pancreatic cancer patients ($n = 102$) failed to show an improvement in median PFS (primary endpoint) (5.7 months with placebo vs. 3.8 months with sorafenib, $p = 0.902$) [61].

Similar results were reported with the combination of gemcitabine plus axitinib, an inhibitor of VEGF-R 1-3, c-KIT, and PDGFR. In a randomized phase III trial

($n = 632$), median OS (primary endpoint of the study) was similar between patients who received the investigational treatment and those who were randomized to standard gemcitabine alone (8.5 vs. 8.3 months, HR 1.014, $p = 0.5436$) [62]. More recently, a randomized, placebo-controlled, phase III study comparing gemcitabine plus or minus aflibercept (VEGF trap) was discontinued for futility when a preplanned interim analysis did not show any improvement in median OS (i.e., 7.8 months for the standard arm vs. 6.5 months for the investigational arm, HR 1.17, 95% CI 0.92–1.47, $p = 0.203$) [63] (Table 6).

Other Biological Agents

Other biological agents including (but not limited to) selumetinib and trametinib (MEK inhibitors), everolimus and temsirolimus (mTOR inhibitors), trastuzumab (HER-2 inhibitor), and bortezomib (proteasome inhibitor) have been evaluated in the phase II setting, and some, including tipifarnib (farnesyl transferase inhibitor) [64], gastrazole (CCK2/gastrin receptor antagonist) [65], marimastat (matrix metalloproteinase inhibitor) [66], ganitumab (anti-IGF-1R monoclonal antibody) [67], and masitinib (multi-tyrosine kinase inhibitor) [68], reached phase III testing. However, other than erlotinib, no biological agent has demonstrated any significant survival benefit over gemcitabine alone.

Chemoradiation

In approximately 40% of cases, pancreatic cancer presents as a locally advanced tumor that is not amenable to surgical resection. Patients with inoperable, locally advanced tumors have a better prognosis than those with disseminated metastatic disease (i.e., 5-year survival 9% vs. 2%), but the optimal management strategy remains controversial. Most trials of palliative systemic chemotherapy included patients with locally advanced and metastatic disease; therefore, single-agent gemcitabine or combination chemotherapy can be considered as standard treatment options in this setting.

Although chemoradiation is a potentially useful tool to optimize local control, much less information is available on this treatment strategy. A Cochrane meta-analysis demonstrated clearly that chemoradiation is superior to best supportive care for these patients (1-year survival 58% compared to 0%, $p = 0.001$), but concluded that there was insufficient evidence to recommend it as standard treatment for locally advanced disease [69].

Chemoradiotherapy has been investigated as either upfront treatment before systemic chemotherapy or consolidation treatment after induction systemic chemotherapy. The former strategy has been assessed by two trials with contradictory results. The FFCD-SFRO phase III trial randomized 119 patients with locally advanced unresectable pancreatic cancer to receive systemic chemotherapy with

Table 6 Phase III trials using targeted agents in advanced pancreatic cancer

Trial	Protocol treatment (number of patients)	Response rate	PFS/ months	HR (95% CI)	Significance	OS/ months	HR (95% CI)	Significance
NCI CTG phase III double-blind placebo-controlled RCT	Gemcitabine + placebo (284)	8.0%	3.55			5.91		
	Gemcitabine + erlotinib (285)	8.6%	3.75	0.77 (0.64–0.92)	$p = 0.004$	6.24	0.82 (0.69–0.99)	$p = 0.038$

single-agent gemcitabine or cisplatin/5-FU-based chemoradiation (60 Gy) followed by gemcitabine [70]. The study was closed early due to the unexpected finding of reduced survival in the chemoradiation arm. The median OS and 1-year survival rate were 8.6 months and 32% compared to 13 months and 53%, respectively, with systemic chemotherapy alone ($p = 0.03$). Although these findings may be explained by an increased risk of toxicity in the chemoradiation arm, a per-protocol analysis of patients who received at least 75% of the planned dose of radiotherapy showed similar results. The ECOG-4201 phase III trial compared single-agent gemcitabine versus chemoradiation (50.4 Gy) with weekly gemcitabine followed by systemic gemcitabine [71]. This study was closed early due to poor accrual. Despite increased toxicity in the chemoradiation arm, in the 74 patients who were randomized, a significant survival benefit was seen from the addition of radiation therapy, with a median survival time of 11.1 months, compared to 9.2 months in those receiving gemcitabine alone ($p = 0.017$). However, it must be noted that the survival curves for the two arms only separated after around 8 months, suggesting that only a subset of the patients with chemotherapy sensitive disease actually benefited from the addition of radiotherapy and that induction chemotherapy might be a useful strategy to select such patients for chemoradiation. In support of this, a retrospective analysis of the phase II and III GERCOR studies suggested that chemoradiation after chemotherapy may improve survival in locally advanced unresectable disease [72]. In particular, in patients who did not experience local or distant tumor progression after 3 months of chemotherapy (71% of the overall population), administration of sequential chemoradiation was associated with an improvement in median PFS (10.8 vs. 7.4 months, $p = 0.005$), median OS (15.0 vs. 11.7 months, $p = 0.0009$), and 1-year survival rate (65.3% vs. 47.5%).

Nevertheless, the contention that upfront systemic chemotherapy followed by chemoradiotherapy could be superior to systemic chemotherapy alone has been challenged by the results of the LAP07 trial [73]. In this randomized phase III trial, 442 patients with inoperable locally advanced tumors were first randomized to receive 4 months of chemotherapy with gemcitabine alone or gemcitabine plus erlotinib. If at least stable disease was achieved after induction chemotherapy, then a second randomization was performed, and patients were treated with capecitabine chemoradiation (54 Gy) or systemic chemotherapy for 2 more months (with or without maintenance erlotinib depending on the outcome of the first randomization). The primary endpoint was median OS from the first randomization. The trial was stopped prematurely when the results of a preplanned interim analysis showed no survival advantage from sequential chemoradiation. In the chemotherapy group, median OS was 16.5 months compared with 15.2 months in the chemoradiotherapy group (HR 1.03; $p = 0.83$). The only difference between treatment groups was in the pattern of tumor recurrence with patients in the chemoradiotherapy arm experiencing less locoregional failure (32% vs. 46%) but more distant metastases (60% vs. 44%) compared with those in the chemotherapy arm ($p = 0.04$).

Numerous phase II trials have investigating the addition of targeted agents to chemoradiation, but such treatments remain experimental.

Conclusions

While single-agent gemcitabine has been the only available treatment option for advanced pancreatic cancer until few years ago, the therapeutic armamentarium for this disease has been recently enriched by new, more effective combination chemotherapy regimens including FOLFIRINOX, gemcitabine plus *nab*-paclitaxel, and other gemcitabine-containing regimens. This has allowed clinicians to adopt a more selective treatment approach in routine clinical practice. A number of factors, including patient clinical condition, comorbidities, treatment goals, preference, etc., are now taken into account in the decision-making process in order to weigh pros and cons of each treatment strategy and offer patients the best treatment strategy. Evidence has also increasingly emerged to support the use of non-cross resistant second-line chemotherapy at least in patients who maintain a reasonably good performance status following progression to first-line treatment.

Nevertheless, the overall prognosis of advanced pancreatic cancer remains significantly poor (i.e., <12 months), and improved treatment strategies are urgently needed. Furthermore, there is no doubt that the treatment for this disease is still largely based on the use of cytotoxic agents, while there is no role for target therapies with the only exception of erlotinib, the survival advantage associated with this drug being however marginal. Overall, this highlights the challenges encountered in the identification and validation of valuable therapeutic targets in this setting and reflects the disappointing results of clinical trials testing novel therapeutics that show initial promise in preclinical models.

The biology of pancreatic cancer is complex especially due to the strong influence of the surrounding stroma that is now universally recognized as an important determinant of the mechanisms of tumor drug penetration, resistance to treatment, and suppression of the antitumor immune response. A number of immunotherapy strategies and drugs targeting the stroma or interfering with the interplay between tumor cells and stromal components are currently under investigation and may possibly become valid treatment options in the next future with or without standard chemotherapy.

Key Practice Points

- *First-line treatment for metastatic pancreatic cancer in patients of good performance status* (i.e., *ECOG 0-1*): Palliative chemotherapy with triplet (i.e., FOLFIRINOX) or doublet (i.e., gemcitabine plus nab-paclitaxel, gemcitabine plus erlotinib, gemcitabine plus capecitabine, or gemcitabine plus platinum) combination chemotherapy or treatment within a clinical trial, plus best supportive care.
- *First line treatment for metastatic pancreatic cancer in patients of intermediate performance status* (i.e., *ECOG 2):* Palliative chemotherapy with single-agent

chemotherapy (i.e., gemcitabine) or treatment within a clinical trial, plus best supportive care alone.

- *Treatment for metastatic pancreatic cancer in patients of poor performance status* (i.e., *ECOG >2*): Best supportive care alone.
- *First-line treatment for locally advanced unresectable pancreatic cancer*: Palliative chemotherapy with triplet (i.e., FOLFIRINOX), doublet (i.e., gemcitabine plus nab-paclitaxel, gemcitabine plus erlotinib, gemcitabine plus capecitabine, or gemcitabine plus platinum), or single agent (i.e., gemcitabine), plus best supportive care. Consideration could be given to consolidation capecitabine- or gemcitabine-based chemoradiation in patients who do not experience tumor progression after at least 3–4 months of systemic chemotherapy. Surgery should also be considered for those patients who become resectable after upfront medical treatment. Enrollment into a clinical trial is a reasonable option.
- *Second-line treatment for advanced disease*: Palliative chemotherapy with oxaliplatin (i.e., OFF or FOLFOX) or irinotecan based (i.e., nanoliposomal irinotecan plus 5-FU and folinic acid) in patients who have failed first-line gemcitabine-containing treatment, plus best supportive care. Gemcitabine-based chemotherapy in patients who have received FOLFIRINOX in the frontline setting. Treatment within a clinical trial or best supportive care remains reasonable alternative strategies.

The recommended treatment algorithm for advanced pancreatic cancer is shown in Fig. 4 (Table 7).

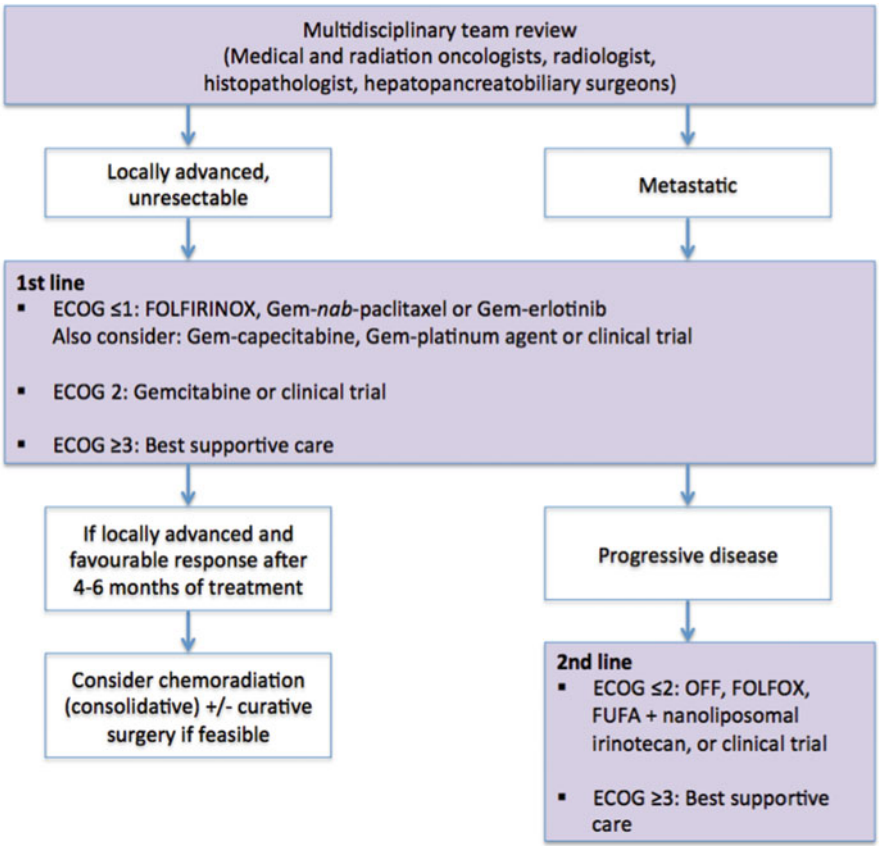

Fig. 4 Decision pathway for the management of advanced pancreatic cancer

Future Research Directions

- Treatment selection in pancreatic cancer is entirely based on clinical parameters. Better understanding of the mechanisms underlying resistance to treatment may lead to the identification of prognostic/predictive tumor biomarkers and selective use and improved efficacy of currently available treatment options.
- Less is known about the molecular aspects of carcinogenesis in pancreatic cancer compared with other tumor types. Further elucidation of the genetic basis of this disease and interaction network between tumor cells and surrounding stroma may reveal novel, potentially useful, therapeutic targets.
- Treatment of pancreatic cancer is largely based on chemotherapy and the impact of targeted therapies has been negligible. Investigation into novel treatment

Table 7 Selected current phase II and III trials in locally advanced and/or metastatic pancreatic cancer

Trial name/ sponsor	Setting	Treatment arms	Planned recruitment
NEOPAN (NCT02539537)	Locally advanced inoperable adenocarcinoma of the pancreas	FOLFIRINOX (5-FU/LV, oxaliplatin and irinotecan) or gemcitabine	170
CONKO-007 (NCT01827553)	Locally advanced inoperable adenocarcinoma of the pancreas	Induction FOLFIRINOX (5-FU/LV, oxaliplatin, and irinotecan) or gemcitabine (investigator's choice) for 12 weeks followed by either continuation of the same chemotherapy or gemcitabine-based chemoradiation	830
NCT01926197	Locally advanced inoperable adenocarcinoma of the pancreas	Modified FOLFIRINOX (5-FU/LV, oxaliplatin, and irinotecan) vs. modified FOLFIRINOX + stereotactic body radiotherapy	172
NCT02551991	Metastatic pancreatic cancer	Nanoliposomal irinotecan +5-FU/LV vs. nanoliposomal irinotecan +5-FU/LV + oxaliplatin vs. gemcitabine + *nab*-paclitaxel	168

strategies (including immunotherapy) remains key to the future management of this challenging tumor type.

Surgical Resection for Pancreatic Cancer Using the International Study Group of Pancreatic Surgery (ISGPS) Classifications

Thilo Hackert, Christoph W. Michalski, and Markus W. Büchler

Contents

Abstract

The International Study Group of Pancreatic Surgery (ISGPS) has published a number of definitions within the last decade to standardize terminology and reporting in the field of pancreatic surgery. Furthermore, the group has also extended their approach of summarizing expert opinions in terms of recommendations for the surgical treatment of pancreatic cancer. These definitions and consensus statements have been highly accepted in the worldwide surgical community, and the citations of the respective papers are steadily increasing, which underlines their importance not only in clinical practice but also in the setting of study conductance and scientific reporting. Besides the initial definitions of postoperative complications (postoperative pancreatic fistula, hemorrhage, and delayed gastric emptying), the recent ISGPS publications have addressed important issues of

pancreatic cancer (PDAC) surgery, especially with regard to preoperative evaluation of resectability, extended resections, and lymph node management during PDAC resection. Currently, more ISGPS publications are being prepared to cover the entire field of surgical and perioperative management in pancreatic surgery.

This chapter gives a general overview of the ISGPS definitions and consensus recommendations and, in addition, puts a special focus on the publications of the group dealing with PDAC surgery.

Introduction

The International Study Group of Pancreatic Surgery (ISGPS) has originally been introduced in 2005 as the "International Study Group of Pancreatic Fistula (ISGPF)" which was formed as an expert panel including 37 pancreatic surgeons from all over the world with the initial aim to address the topic of the definition of postoperative pancreatic fistula (POPF) [1]. The background of this approach was the fact that in 2004, a total number of 26 different definitions for POPF were used in the international literature [2]. This caused a significant bias in reporting outcomes after pancreatic resections with the consequence that POPF rates were neither comparable nor was a valid examination of outcomes between studies possible. In the light of this problem, the ISGPF introduced a standardized POPF definition with a grading system to reflect POPF severity [1]. Fulfilling the criteria of an easy clinical application, this initial definition was therefore quickly accepted by most centers and became the standard reporting tool for POPF in retrospective as well as prospective studies. With an average number of 150 citations per year, this publication has been cited more than 1,800 times (July 2016) which gives an impression of its relevance in the field of pancreatic surgery [3]. Currently, the ISGPS has decided to update the POPF definition as in the meantime, it has been shown that there are some points of debate, especially with regard to percutaneous drainage in the management of these patients [4]. A revised classification will be proposed in autumn 2016. Apart from POPF, the ISGPS has established definitions on postpancreatectomy hemorrhage (PPH) [5] and delayed gastric emptying (DGE) [6]. Both of these definitions are applied by most authors in the meantime and have also led to a more standardized reporting on morbidity of pancreatic resections. Furthermore, reporting systems and consensus statements on postoperative chyle leaks and pancreatic anastomoses are currently in preparation [7].

With specific regard to pancreatic cancer (PDAC) surgery, three definitions and consensus publications by the ISGPS were recently published in 2014,

aiming at standardized procedures and reporting. They cover the topics of lymphadenectomy [8], extended procedures [9], and borderline resectability [10] including the controversial field of neoadjuvant treatment versus upfront resection in the respective patients. During preparation of these three recommendations, the current evidence has been systematically collected, reviewed, and condensed under consideration of other already existing guidelines (i.e., the National Comprehensive Cancer Network (NCCN) guidelines). Finally, the expert panel of pancreatic surgeons has voted on the statements of every topic and has approved the recommendations which are consequently given with a comment on the strength of evidence and agreement.

Based on the ISGPS recommendation for staging of PDAC [10], a contrast-enhanced computed tomography (CE-CT) using a pancreas-specific protocol should be the gold standard to determine local tumor extension, exclude liver metastases, and evaluate a possible vascular infiltration. The CE-CT should offer a visualization and differentiation of normal and tumorous pancreatic tissue in an arterial and venous phase including an optimal contrast imaging of the vascular structure in both phases as well as a visualization of the liver parenchyma. For the definition of local resectability in PDAC, the extension of the tumor toward the superior mesenteric vein (SMV)/portal vein (PV) and the celiac axis (CA) as well as the superior mesenteric artery (SMA) is of utmost importance. CE-CT is available in nearly all institutions and offers sensitivity and specificity rates of 63–82% and 92–100%, respectively, with regard to PDAC diagnosis. The use of a pancreas-specific CE-CT examination protocol with a 30° right-sided position of the patient and oral water intake to enhance the contrast in the gastroduodenal region is the basis to maximize accuracy in the preoperative diagnostics [11]. In case of contraindications for a CE-CT, magnetic resonance imaging (MRI) can be used instead of CE-CT as the accuracy of MRI is comparable to CE-CT regarding diagnosis of PDAC and evaluation of the local tumor extension [12].

The ISGPS criteria for local resectability [10] are mainly based on the recommendations of the National Comprehensive Cancer Network [13]. Resectability is defined as primary resectable PDAC, borderline resectable PDAC (BR-PDAC), or unresectable PDAC. The terms "unresectable," "irresectable," and "locally advanced" PDAC are mostly used as synonyms indicating that no upfront resection is possible but that the tumor is still locally limited and no distant spread is present.

Resectable PDAC is characterized by the absence of any vascular attachment (no distortion of SMV or PV) and clearly preserved fat planes toward CA and AMS. BR-PDACincludes findings with a distortion/narrowing or occlusion of the respective veins but a technical possibility of reconstruction on the proximal and distal margin of the veins (Fig. 1). With regard to the arterial structures, a semi-circumferential abutment ($\leq$180°) of the SMA or an attachment at the hepatic artery (HA) without contact toward the CA is also regarded as BR-PDAC. Unresectable PDAC is defined as a more extended involvement of the SMA, CA, aorta, or inferior

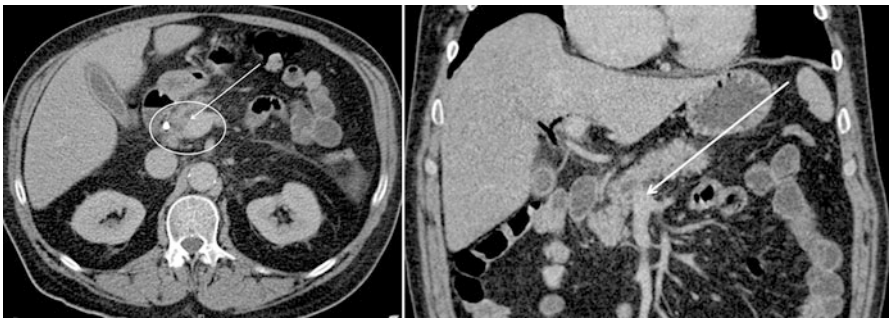

Fig. 1 BR-PDAC of the pancreatic neck. Contrast-enhanced CT scan (porto-venous phase, axial left, and coronary reformatting right side). Tumor (*white circle*) with contact to the porto-venous confluence (*white arrow*)

vena cava as well as a SMV/PV venous involvement without a possibility for surgical reconstruction of the venous tract due to the lack of a suitable luminal diameter of the feeding and/or draining vein. This situation is most likely to be found in tumor-associated portal cavernous transformation.

For the consecutive therapeutic decision, the recommendations for resectable and irresectable PDAC are clearly defined. While patients with resectable PDAC should undergo surgical exploration and radical resection, for unresectable PDAC patients, the option of neoadjuvant treatment should be considered as the therapy of choice with the chance of a reevaluation and eventually surgical exploration (see below). In BR-PDAC, therapeutic decisions have to differentiate between venous and arterial vessel involvement. Consequently, some authors differentiate between these two situations and define venous BR-PDAC (BR-PV) and arterial BR-PDAC (BR-A) as separate findings, although this subclassification is not included in the original ISGPS publication. In venous BR-PDAC, upfront surgery should be performed and – if the intraoperative finding matches the presumed borderline situation as defined above – completed as an en bloc tumor removal with venous replacement [14]. In contrast, when suspected arterial BR-PDAC is intraoperatively found to be a true arterial involvement, no general recommendation for resection is given; neoadjuvant treatment with a consecutive reexploration and the option for a secondary resection is possible as well as direct arterial resection in exceptional cases or under study conditions.

Exceeding the topic of vascular tumor involvement, the involvement of any adjacent organ, i.e., the mesocolon, colon, stomach, adrenal gland, or kidney, may be regarded as BR-PDAC as well. Although this is not covered by the ISGPS definition for BR-PDAC, surgery for respective findings is defined as an extended approach by the ISGPS [9]. There is international consensus that these extended approaches are feasible in terms of surgical and oncological outcome, and organ involvement should not be considered an obstacle for resection as long as a radical

tumor removal is possible. Consequently, these patients should undergo upfront surgery and should not be treated in a neoadjuvant setting [9].

ISGPS Definitions on Surgical Procedures and Resectability

Lymphadenectomy During PDAC Surgery

The extent of lymphadenectomy has been under debate since the late 1990s and numerous studies have been conducted on this question [15–21]. To define lymph node positions and classify intra- and postoperative findings, the lymph node classification of the Japanese Pancreatic Society [22] has been accepted worldwide and is used in most scientific publications. Consequently, this nomenclature has also been chosen as the basis of the ISGPS consensus statement [8]. According to this system, the peripancreatic lymph nodes can be divided into three groups (1st, 2nd, 3rd order) of regional lymph nodes that are further subdivided in some positions such as the hepatoduodenal ligament (group 12a, b, c, h, p). This classification is helpful not only clinically to describe lymph node spread in detail but also to make studies on lymph node dissection comparable (Fig. 3).

Another important topic in the ISGPS statement is the number of lymph nodes that should be retrieved as a minimum prerequisite for a valid pathological staging. As a low number of harvested lymph nodes bears the risk of understaging and a consequent N0 classification may not be an actual N0 stage as positive nodes may have been left in situ, the minimum number of examined lymph nodes during any type of PDAC surgery should be 15 nodes [8]. After neoadjuvant treatment, a lower number of lymph nodes were defined to be acceptable as in this situation; less lymph nodes may be identified even with a most accurate pathological examination of the specimen. Furthermore, in all cases, the lymph node ratio should be provided in the pathological report according to the ISGPS recommendation as a lymph node ratio of >0.2 has been shown to be a negative predictor of survival [23–25].

Partial duodenopancreatectomy includes a standardized lymphadenectomy, which contains the lymph nodes of the hepatoduodenal ligament (group 12b and c), along the common hepatic artery (group 8a), the cranial portion of superior mesenteric vein (group 5 and 6), as well as right-sided lymph nodes of the superior mesenteric artery (group 14a and b) and the peripancreatic nodes (group 13 and 17, Fig. 2) [8]. The impact of extended lymph node dissection (i.e., in the interaortocaval space, left side of the celiac trunk and superior mesenteric artery) has been investigated in several randomized controlled trials between 1998 and 2012 [15–20]. Although there were certain differences in the studies with regard to the number of resected lymph nodes (20 vs. up to 40), most of the authors could not show any survival difference in the study collectives, neither in N0 nor in N1 patients that underwent standard or extended resections. Only Pedrazzoli et al. [15] found a

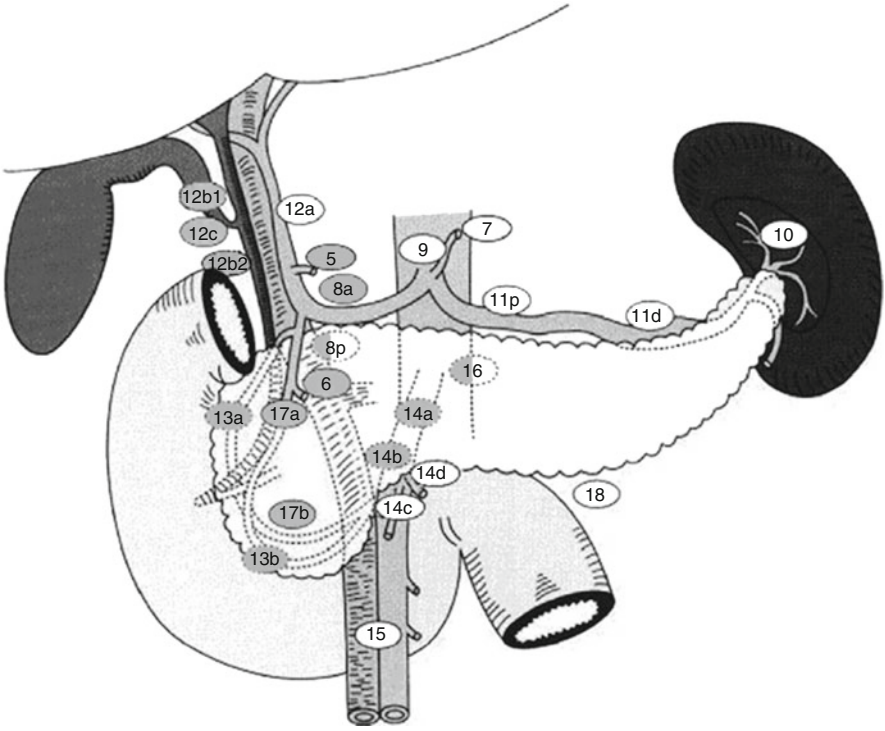

Fig. 2 Standardized lymphadenectomy during pancreatoduodenectomy according to the ISGPS consensus (Adopted from Ref. [8]). Dissected lymph node stations are marked in *gray*

survival benefit of 7 months in the subgroup analysis for N1 patients that underwent extended resection. Furthermore, all authors besides Pedrazzoli et al. observed a significantly increased surgical morbidity or decreased quality of life in the postoperative follow-up.

Two meta-analyses published in 2007 and 2009, respectively [21, 26], analyzed these studies – with regard to their individual scientific quality and results. No benefit for an extended approach of lymph node dissection could be concluded with respect to tumor control and survival. Furthermore, an increased rate of perioperative complications and a decreased quality of life were demonstrated. Therefore, with regard to these studies and consequently based on a level 1 evidence, the concept of extended lymphadenectomy is not recommended in PD as stated in the ISGPS consensus.

Considering distal pancreatectomy (DP), lymph node involvement is mainly observed in the peripancreatic lymph nodes along the body and the tail of the gland [27]. Further frequent metastases sites are the nodes along the splenic artery, the para-aortic area, and along the inferior margin of the pancreas as well as along the superior mesenteric artery. The regional lymph nodes attached to the pancreas, along the inferior margin (group 18) and at the splenic artery (group 11), are routinely

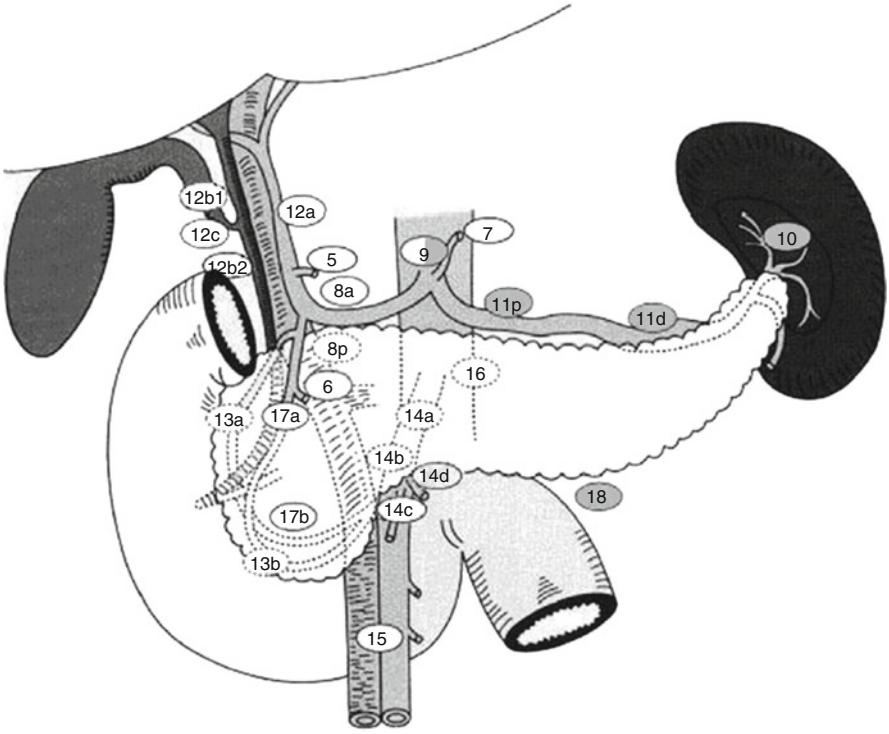

Fig. 3 Standardized lymphadenectomy during distal pancreatectomy according to the ISGPS consensus (Adopted from Ref. [8]). Dissected lymph node stations are marked in *gray*

removed during DP as well as group 10 in the splenic hilum as a standard splenectomy should always be performed in DP for PDAC [28]. The lymph nodes at the basis of the celiac axis (group 9) should be resected according to the ISGPS statement in case of tumors of the pancreatic body (Fig. 3). Para-aortic dissection (lymph node groups 7 and 16) is not recommended as a standard procedure [8].

Lymphadenectomy in total pancreatectomy, which is usually performed en bloc with splenectomy for PDAC, is not explicitly defined by the ISGPS. However, it seems reasonable to regard total pancreatectomy as a combination of PD and DP and combine standard lymph node dissection of both procedures. This procedure will usually result in approximately 30–50 lymph nodes included in the resected specimen. Interaortocaval lymph node resection during total pancreatectomy can be regarded as an extended approach and should not be performed as a routine procedure.

However, the ISGPS recommendation explicitly states that no definitive consensus is currently reached regarding the prognostic impact of para-aortic lymph nodes on one hand and that – in addition – there is no recommendation on how to proceed in cases where lymph nodes outside the standard resection area are found to be positive intraoperatively [8]. The issue of continuing or terminating resection in

this case remains unsolved and is handled differently in centers around the world to date.

Borderline Resectable PDAC Including Vascular and Extended Resections

Venous Resections

Vascular resections during pancreatoduodenectomy to achieve tumor clearance and improved survival in case of SMV/PV involvement have been advocated for the last three decades [29]. Today, these approaches have gained wide acceptance and been included in national and international guidelines around the world [10, 13], although most recent publications question this approach with regard to morbidity and oncological outcome [30]. However, they do not conclude that venous resections should generally not be performed but that a greater emphasis should be put on preoperative patient selection. According to the ISGPS, venous involvement is neither a criterion for unresectability nor for neoadjuvant therapy as long as the technical possibility to restore vessel continuity is given [10]. This must be intraoperatively confirmed by evaluation of the diameter of the proximal and distal vein before resection. There are mainly four types of PV/SMV resection defined by the ISGPS [10]. In case of minimal tumor adherence to PV/SMV, resection can be performed as a tangential resection of the vein with a direct suture (type 1 reconstruction). This is possible for pancreatoduodenectomy as well as for distal pancreatectomy if the direct suture closure does not lead to a hemodynamically relevant stenosis and a consecutive risk of acute postoperative thrombosis. The second possibility is the closure of a short tangential defect by a patch insertion (type 2, Fig. 4). This patch can either be harvested from a homologous venous graft (i.e., saphenous or internal jugular vein) or – as a suitable alternative – a peritoneal patch can be harvested and used with the peritoneal surface directed toward the lumen of the vein [31]. If this is not possible due to the length of the resected segment, the mesenteric root can be mobilized completely by resolving the

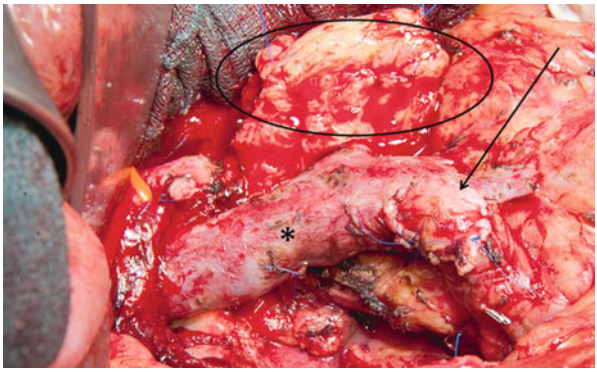

Fig. 4 Intraoperative view after ISGPS type 2 (peritoneal patch) reconstruction of the superior mesenteric vein. Patch (*black arrow*) on the right lateral superior mesenteric vein, portal vein (*black star*), and cut margin of the pancreas (*black circle*)

attachment of the right hemicolon to the retroperitoneal adhesions (Cattell-Braasch maneuver [32]) and a direct anastomosis in an end-to-end fashion. If this is impossible, the interposition of a vascular graft, using either autologous structures (saphenous vein, left renal vein, or internal jugular vein) or allogenous synthetic grafts (ringed polytetrafluoroethylene (PTFE) graft), can be performed (type 4 reconstruction) [33].

The feasibility of SMV/PV resection has been demonstrated in large series that showed surgical morbidity and mortality rates comparable to pancreatic head resections without vascular involvement [34, 35] as well as in a recent systematic review including data on the outcome of more than 1,600 patients from 52 publications [14]. With a median operation time of 8.5 h and a median blood loss of 1,750 ml, SMV/PV resections resulted in an average perioperative mortality of 5.9% and overall morbidity of 42%.

Even if preoperative diagnostics show a tumor-related complete obstruction of the portal vein, this must not be regarded as a contraindication for surgery. Although intraoperatively, the preparation may be more difficult due to the collateral vessels, the restoration of the portal venous flow after resection and anastomosis offers an adequate drainage of the bowel despite the removal of most of the collateral vessels that may be necessary during the preparation.

Oncological outcome in patients with venous resections is similar to patients undergoing standard resections for PDAC without increased rates of local or systemic failure [14]. The rate of histologically proven SMV/PV invasion is app. 65%, and in addition, a positive lymph node stage is found in two thirds of the patients, too. These findings result in a 1-, 3-, and 5- year overall survival of app. 50%, 18%, and 8% [14, 34] which is clearly superior to any type of palliative treatment. To address the high percentage of positive nodal findings in patients who undergo portal or superior mesenteric vein resection, the importance of adjuvant therapy has to be underlined. Since adjuvant treatment has strongly improved survival and been introduced as the standard of care for patients with pancreatic cancer, future survival rates of patients with venous resection should be even better than those reported so far. SMV/PV resections during PDAC surgery can therefore be regarded as a standard procedure to achieve a complete removal of the tumor and can also be performed during multivisceral resections with the same intent of complete tumor clearance [36].

Arterial Resections

In contrast to venous tumor adhesion, arterial encasement of CA or SMA can be regarded as a symptom of a very aggressive tumor biology, and the decision to perform a surgical resection in this situation is highly individual and still regarded as an extraordinary approach in PDAC surgery [37, 38]. According to the ISGPS, the extent of arterial encasement determines the classification of the finding as BR-PDAC or unresectable PDAC as described before.

Both major arterial structures – CA and SMA – have to be evaluated differently with regard to the performance of a pancreaticoduodenectomy or a distal pancreatectomy and the extent of tumor abutment. If the SMA is involved in the tumor

process exceeding 180° of the circumference or in case of CA abutment, this is rather a general exclusion criterion for resection, and tumor resection with arterial reconstruction has only been reported in few patients [37]. In contrast, situations with an arterial tumor abutment <180° along the SMA or short-segment abutment of the HA as the only vitally important structure of the CA must not be considered as irresectable but fulfil the criteria of BR-PDAC [10].

There is consensus that all patients with suspected BR-PDAC due to an arterial involvement should undergo surgical exploration to confirm this situation and decide on the consecutive therapy. To evaluate arterial infiltration along the SMA and/or CA, "artery-first" approaches can be useful [39, 40]. These techniques describe the preparation of the SMA or CA as an initial step before reaching any "point-of-no-return" situation during surgery. In the meantime, more than six different techniques have been described as "artery-first" techniques and are used according to the respective surgeons' or centers' preference [41].

In case of confirmed tumor infiltration of the CA or the SMA, palliative treatment is recommended as the standard of care. However, the possibility of arterial resections as an individual approach or within clinical trials and the consideration of a neoadjuvant treatment with a consecutive reexploration have to be mentioned. On one hand these approaches have been reported especially during distal pancreatectomy; on the other hand the topic of neoadjuvant therapy of BR-PDAC is currently one of the most important fields in PDAC treatment.

Regarding distal pancreatectomy, CA resection without revascularization (modified Appleby procedure) is an option for tumor removal as long as the proper hepatic artery is preserved and a sufficient arterial inflow via the gastroduodenal artery is present. Including approximately 200 patients, numerous case series have described this procedure with reasonable results in terms of surgical and oncological outcome which seems to be nearly equal to the standard approaches [42–44]. According to the larger series in the literature, that include more than ten patients, these procedures can be carried out with mortality rates of 0–7% and an average overall morbidity of app. 50%. Median survival in these reports ranges between 10 and 25 months; in the majority of publications, app. 20 months can be achieved. According to these retrospective studies, CA resection during distal pancreatectomy seems to be a considerable option in terms of postoperative and long-term outcome; however, no high-level evidence is available to support these findings.

In case of resection of the HA or SMA during pancreatoduodenectomy or total pancreatectomy, restoration of the arterial perfusion has to be performed either with a direct anastomosis or graft insertion to replace the resected vessel. This reconstruction can be done with an interposition of any arterial vessel of the celiac axis or a venous interposition graft. In a recent review, the role of arterial resection has been critically evaluated including all currently available studies [38]. Regarding resection of the SMA, five studies were identified, including a total number of less than 30 patients. All authors showed that the resection is technically possible; grafting with the saphenous vein was the most commonly used method for reconstruction. However, morbidity of this approach is high and the oncological outcome is not yet

convincing from the limited evidence. Overall, CA or HA resection is performed more often than SMA resection. Surgical morbidity is up to 40%, and mortality in pancreaticoduodenectomy with arterial resection ranges from 0 to 35%, showing the inconsistent data basis of this approach. The major risk following HA reconstruction is the occurrence of arterial hepatic perfusion failure that may cause acute problems postoperatively in terms of liver ischemia, necrosis, and infection with a high associated mortality [45, 46]. Besides the operative complications in procedures with arterial resections, even more importantly, the mentioned meta-analysis showed a poor oncological outcome with significantly impaired survival in comparison to standard PDAC resections [38]. Consequently, resection of arterial vessels during PDAC surgery does not represent a standard procedure. It may be a feasible option with regard to distal pancreatectomy and en bloc CA resection under preservation of the proper HA without reconstruction of a major arterial vessel. All other arterial resections are highly individual approaches for selected patients and need to be carried out by experienced pancreatic surgeons to minimize postoperative complications.

Multivisceral Resections

Beyond infiltration of vascular structures, also adjacent organs can be affected by locally advanced PDAC. Mainly, the colon, stomach, left adrenal gland, small bowel, and left kidney are affected. A complete tumor removal therefore requires partial or total resection of these organs during partial, distal, or total pancreatectomy. These multivisceral resections fulfil the criteria of "extended resections" defined by the ISGPS in 2014 [9]. A neoadjuvant treatment is not indicated, if a complete resection seems to be technically possible on the basis of the preoperative cross-sectional imaging. In larger series reporting on multivisceral resections, 20 up to more than 270 patients are included [36, 47]. The most commonly resected organs are the colon and stomach in case of partial or total pancreatectomy and the adrenal gland during distal pancreatectomy. Remarkably, also PV/SMV resections are often performed synchronously reflecting the local extension of the tumor and the close anatomic relationship of these venous structures.

The currently largest single-center series from Heidelberg included 101 patients and showed that multivisceral resections were associated with an increased postoperative morbidity but not mortality [36]. Postoperative morbidity was predicted by a long operation time and a resection of two or more additional organs as independent risk factors for intra-abdominal complications or need for relaparotomy. Regarding oncological outcome, survival was similar to standard resections. In a study on 55 patients with multivisceral resections for PDAC [48], median survival was 16 months versus 18 months for standard resections, which was significantly better than palliative bypass surgery. Multivariate risk factors for postoperative morbidity during multivisceral resections in this study included intraoperative blood transfusion and nephrectomy, whereas survival was determined by T status, kidney resection, resection of four or more organs, any postoperative transfusion, and intensive care unit stay of >2 days in the univariate analysis, and T status alone was confirmed as a predictor of survival in the multivariate analysis.

A present update of the first study analyzing 600 PDAC patients who underwent extended resections for BR-PDAC compared to 1,200 standard resections confirms the mentioned findings [49]. The performance of extended resections is associated with increased postoperative morbidity and mortality for patients with relevant comorbidities and operation times of more than 5 h. Apart from these two risk factors, multivisceral and vascular resections were not identified as parameters for poor postoperative outcomes. Extended PDAC resections resulted in 16 months median and 11% 5-year survival, which is clearly superior to any palliative treatment option. On one hand, these results underline that extended surgery is a feasible approach; on the other hand, they raise the unsolved question of an accurate patient selection as certain subgroups seem to have a much greater benefit from surgery than others, and valid preoperative markers for this stratification are not defined yet.

Neoadjuvant Treatment for BR-PDAC and Unresectable PDAC

Today, there is no sufficient evidence to support neoadjuvant treatment in resectable PDAC which is clearly stated in the ISGPS consensus [10]. Neither chemoradiation nor chemotherapy alone has shown a benefit in this situation [50]. Comparably, in case of BR-PDAC, no neoadjuvant treatment is recommended for venous tumor adherence or involvement of adjacent organs if a resection is technically possible and complete tumor removal can be achieved. According to the consensus recommendation of the ISGPS, these patients should undergo upfront resection as well [10]. In this context, it must be emphasized that there are a number of ongoing studies on this issue that evaluate the effect of neoadjuvant therapy in the abovementioned situations, and more evidence-based result are expected in the next 5–10 years [51–56]. The possible advantages of neoadjuvant therapy could include a stratification of patients with regard to tumor biology indicating those subgroups of patients with a very aggressive tumor that would not benefit from a resection despite the absence of systemic spread at the time of diagnosis. In addition, neoadjuvant treatment could improve R0 resection rates and decrease the incidence of local recurrence. Therefore, the results of these studies are highly warranted and may change clinical practice, comparable to studies investigating esophageal-gastric cancer outcome during the early 2000s and establishing the recommendation and international agreement on neoadjuvant treatment for the majority of these patients, today [57].

In case of BR-PDAC or clearly unresectable PDAC due to arterial involvement, neoadjuvant treatment should be considered instead of upfront surgery [10]. This consideration is based on the fact that arterial resections – although often technically possible – are associated with a significant increase in postoperative morbidity as well as mortality. Moreover, even patients after successfully undergone arterial resection often have a very limited oncological benefit and suffer from early recurrence or metastatic spread [38]. These limitations can be overcome by neoadjuvant therapy as on one hand a patient selection can be conducted, because patients showing a tumor progression will be excluded from surgery. On the other hand, an arterial resection can be avoided during surgery in a considerable number of patients. If only fibrosis is found along the arterial structures instead of former vital tumor

formations, dissection of the arteries instead of resection can be performed. This clinical observation raises the question of diagnostic accuracy of the restaging after completion of neoadjuvant treatment. Many patients do not show an explicit downstaging of the local findings in CT scans after chemotherapy or chemoradiation [58].

As perineural spread has been shown to be an important prognostic factor [59], this has been investigated in several studies with regard to preoperative imaging prediction [60, 61]. Although in primary diagnosis, high-resolution CT scan can predict perineural invasion along larger vessels with an accuracy of 95% [61], this does not seem to be reliable in a post-neoadjuvant setting and diagnostic sensitivity and specificity are highly limited [58].

An additional particular challenge of restaging is as the differentiation of vital tumor and fibrosis by conventional cross-sectional imaging is limited and even PET-CT scans do not offer 100% accuracy [62]. Patients with a clear tumor progression under neoadjuvant treatment should be excluded from secondary exploration. As to date, no valid diagnostic modality or marker is available that differentiates between vital tumor and residual fibrotic tissue with a sufficient sensitivity and specificity; all other patients should undergo surgical exploration to definitely evaluate this and perform a resection whenever possible. Intraoperatively, after confirming the absence of vital tumor by frozen section, a resection is often possible and eventually an ypT0 situation may be found. Due to the three scenarios described, neoadjuvant treatment is helpful to stratify patients and recognize those with BR-PDAC, who do not benefit from extended resections.

The debate on the most effective neoadjuvant treatment scheme is a currently unsolved issue. Traditionally, chemoradiation for locally advanced PDAC using gemcitabine- or 5FU-based protocols along with 50–54 Gy of radiation has been used [63] and shown secondary resection rates of app. 30% [64]. With the introduction of highly effective chemotherapy regimens such as Folfirinox (5-FU, leucovorin, irinotecan, oxaliplatin) or nab-paclitaxel, this approach has been challenged [65–67]. Based on the observations in metastatic disease, where this therapy has been shown to be significantly more effective than gemcitabine [68], several studies have reported on its efficacy in the neoadjuvant setting. For borderline resectable and locally advanced findings, a secondary resection rate of 85% was found in a 40-patient study; however, 24 of the included patients received an additional chemoradiation before surgery [58]. For locally advanced disease, a recent study on 575 patients receiving different chemotherapy regimens found that the highest secondary resection rate (61%) was observed for the subcollective of 125 Folfirinox patients [69]. As there are no randomized studies comparing these approaches, evidence-based recommendations on the best treatment option cannot be given, but a Folfirinox-based regimen seems to be the most promising approach.

To facilitate patient selection with BR-PDAC for the most promising therapy (upfront resection vs. neoadjuvant treatment), various prognostic scores and parameters have been examined. Imaging criteria (i.e., suspicion of lymph node metastases) and clinical performance status were used in a publication by Katz et al. [70] but did not reliably predict prognosis. Currently, the modified Glasgow Prognostic Score (mGPS) and CA 19–9 levels are the most reliable prognostic parameters [71,

72]. Especially a decrease or even normalization of elevated CA 19–9 during neoadjuvant treatment is associated with a good prognosis [72, 73]. The mGPS – although not as commonly used as CA 19–9 – seems to be an additional valid predictor as a score value of two can be regarded as a poor prognostic outcome parameter in the neoadjuvant setting [74]. Other biomarkers or genetic specifications cannot yet be recommended for prognostic stratification or therapy decisions [10].

Conclusion

The International Study Group of Pancreatic Surgery (ISGPS) has standardized preoperative classifications and postoperative outcome definitions in pancreatic surgery. These definitions are accepted as a standard in the pancreatic surgery community and are valued because they – for the first time – allow for outcome comparisons across different institution. These definitions are updated regularly by the study group members and include statements on postoperative complications, preoperative assessment of resectability, extended resections, and lymph node management.

Abstract

Because of their anatomical proximity to the pancreatic head, the portal vein (PV) and superior mesenteric vein (SMV) are frequently involved in pancreatic head cancers. PV/SMV resection and reconstruction should be arranged according to the degree of PV/SMV invasion. In case of minimal invasion, the PV/SMV wall can be partially resected and repaired with direct suture, or a patch repair using a vein graft can be performed. In case of wide invasion of the lateral aspect of the vein or circumferential involvement, segmental resection of the PV/SMV should be performed. Reconstruction in this case will be performed using either direct end-to-end anastomosis or the interposition of vein graft. When the confluence of the splenic vein (SV) is involved and ligation and division of the SV is performed, varices caused by left-sided portal hypertension may form in the late phase after surgery. In such cases, preservation of the omentum and the transverse and right colic marginal vein is important to maintain the collateral route and to avoid the formation of varices. Several reports have indicated that pancreatectomy with PV/SMV resection can be performed with acceptable morbidity and mortality. Moreover, survival is comparable for patients with and without PV/SMV resection, although some reports indicate that the prognosis in patients with PV/SMV resection is worse than that of patients who do not undergo PV/SMV resection. The clinical benefit of PV/SMV resection for pancreatic cancer is still controversial.

Introduction

Pancreatic head cancer spreads quickly to the adjacent tissues and distant organs. In addition to the regional lymph nodes, pancreatic cancer invades the retropancreatic neural tissue, duodenum, portal vein (PV), superior mesenteric vein (SMV), and superior mesenteric artery (SMA). For this reason, aggressive surgery that completely removes the cancerous lesion and surrounding tissues was recommended in the early 1970s. Fortner proposed an extensive surgical procedure called "regional pancreatectomy," which permits en bloc resection of the pancreatic segment of the PV/SMV, the celiac axis, and the proximal portion of the SMA together with the lymph nodes and lymphatic vessels. However, this aggressive procedure unexpectedly failed to improve patients' survival and resulted in unacceptable short-term surgical outcomes with high morbidity and mortality [1, 2]. Nevertheless, the "regional pancreatectomy" proposed by Fortner encouraged Japanese surgeons in high-volume centers, and they performed radical surgery for pancreatic cancer in the

1980s [3, 4]. Their reports showed a benefit of radical surgery for advanced pancreatic cancer in terms of overall survival. One of the major flaws of these reports, however, was that they were all retrospective case control analyses and did not include any randomized controlled trials (RCT). Therefore, the benefit of performing radical pancreatectomy in patients with pancreatic cancer was still controversial.

In the 1980s, an Italian group performed the first RCT that compared standard pancreatoduodenectomy (resection of only peripancreatic tissue) and extended pancreatoduodenectomy (thorough resection of neural and lymphatic tissues, including the lymph nodes in the hepatoduodenal ligament and the nerve plexus around the SMA) for pancreatic head cancer [5]. Subsequently, similar RCTs (although there were minor differences in the protocols) have been performed in the United States [6–8], Japan [9], and Korea [10] from the 1980s to the 2010s (Table 1). Interestingly, all of the RCTs failed to show any survival benefit for extended pancreatoduodenectomy despite its high postoperative morbidity rate and negative impact on short- and long-term quality of life. These results clearly indicated that the use of routine "prophylactic" extended lymphadenectomy for pancreatic head cancer may not be necessary to improve survival. However, they do not mean that radical surgery to achieve R0 resection is not worthwhile. Considerable evidence has shown a better prognosis in patients who underwent R0 resection compared with those who underwent R1 or R2 resection for pancreatic cancer [11, 12]. In fact, when the tumor is resected with R0 status irrespective of the extent of surgery, the median survival of patients may be better for those treated with best currently available combination chemotherapy such as FOLFIRINOX or gemcitabine and nab-paclitaxel [13, 14]. Moreover, recent reports have indicated that adjuvant chemotherapy substantially improved survival in patients who underwent resection for pancreatic cancer [15–17]. Therefore, surgeons must make every effort to achieve R0 resection for pancreatic cancer. Radical pancreatectomy that includes the extensive resection of peripancreatic tissues and organs should be permitted for this purpose.

The PV and SMV are the most commonly involved vessels when pancreatic cancer involves the pancreatic head. Even after five RCTs failed to find a survival benefit for "prophylactic extended surgery" for pancreatic head cancer, many surgeons continue to combine the resection of PV/SMV when the tumor has invaded this vessel and when they can achieve R0 resection by resecting this vessel. However, since there is no RCT focusing on the clinical value of PV/SMV resection, the benefit of resecting PV/SMV remains unclear. Nevertheless, it is important to elucidate the value of PV/SMV resection in pancreatic cancer through the accumulation and analysis of currently available best practice data. This chapter discusses the pattern of PV/SMV involvement in pancreatic cancer, the surgical techniques for PV/SMV resection and reconstruction, complications related to PV/SMV resection, and the clinical value of combined PV/SMV resection when performing pancreatectomy for pancreatic cancer.

Is Combined Vascular Resection Acceptable in Pancreatic Cancer Surgery?

Because of their anatomical proximity to the pancreatic head, the PV and SMV are frequently involved in pancreatic head cancers. To resect the tumor with negative surgical margins (R0 resection), wedge or segmental resection of the PV or SMV is necessary. The survival of patients who require PV/SMV resection can be worse than that of patients without PV/SMV invasion because of the high clinical stage and more active biological malignancy [18, 19]. However, previous reports, including two RCTs comparing pancreatic resection with PV/SMV resection and palliative treatment, showed that patients who underwent pancreatectomy with PV/SMV resection had better survival than those who underwent palliative surgery or radiochemotherapy [20–22]. Therefore, isolated PV/SMV involvement should not be a contraindication for pancreatic resection because postoperative morbidity and mortality rates following pancreatectomy with PV/SMV resection are acceptable [23–25]. When performing pancreatectomy with PV/SMV resection, it is important to completely remove the lesion that involves PV/SMV without violating the integrity of the tumor because a pathologically negative surgical margin is essential for improved survival [26].

Patterns of PV/SMV Invasion

There are several patterns of vascular invasion of pancreatic cancer to the PV and/or SMV. In 1992, Ishikawa et al. [27] proposed the angiographic typing of PV/SMV invasion using the portal phase of superior mesenteric artery (SMA) angiography. They classified angiographic findings into the following five types (Fig. 1): (1) normal, (2) smooth shift without narrowing, (3) unilateral narrowing, (4) bilateral narrowing, and (5) bilateral narrowing and the presence of collateral veins. According to these classifications, the postsurgical prognosis was very poor in patients with type IV or V, and their cumulative survival rates were almost identical to those of non-resectable patients. Conversely, a far better prognosis could be expected for type I and II patients. It should be noted that the portal phase of SMA angiography is likely to underestimate the true invasion of the PV/SMV. In the study by Ishikawa et al., angiography resulted in 40% underestimations, 54% correct diagnoses, and only 6% overestimations. The discrepancy may be explained by the fact that the internal diameter of the PV/SMV is unaffected when cancer invasion is limited to the tunica adventitia. Nakao et al. also presented a similar classification for PV/SMV invasion [28]. They classified PV invasion in pancreatic head cancer as type A (absent), B (unilateral narrowing), C (bilateral narrowing), or D (stenosis or obstruction with collaterals) (Fig. 1). Among a total of 358 patients with resected pancreatic head cancer, PV/SMV resection was performed in 21 out of 111 type A patients (19%), 77 out of 82 type B patients (94%), 96 out of 97 type C patients (99%), and all 68 of the type D patients (100%). No pathological PV/SMV wall invasion was observed in the 21 type A patients who underwent PV/SMV resection.

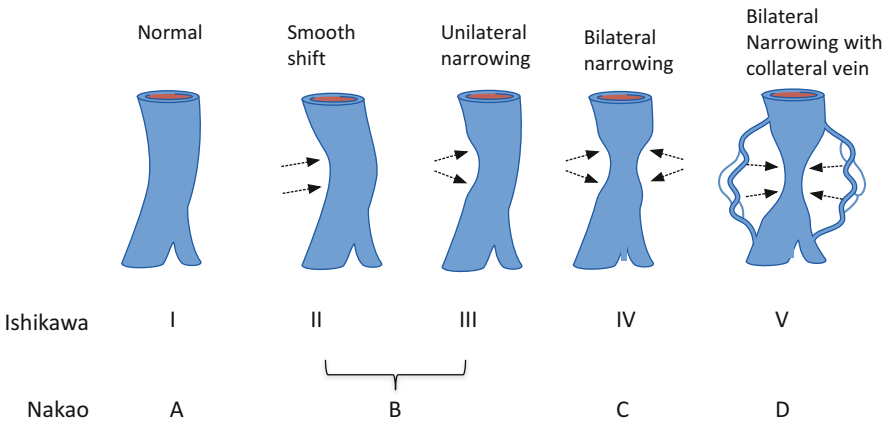

Fig. 1 Angiographic typing of PV/SMV invasion *Upper line*: Ref. [27]. *Lower line*: Ref. [28]

In contrast, the incidences of pathological PV/SMV wall invasion in types B, C, and D were 51%, 74%, and 93%, respectively. Moreover, the rate of tumor invasion into the tunica intima increased according to the radiographic type of PV/SMV invasion. In terms of prognosis after surgery, type A patients showed a significantly higher survival rates than other types. Type B patients had a significantly better prognosis than the type C and type D patients. No significant difference in survival rates was observed between patients with type C and D invasion, although those with type D had a higher survival rate than the unresectable group. Currently, the angiographic classification of PV/SMV invasion can be much less invasively determined using recent advances in multi-detector computed tomography (MD-CT) imaging [29–31].

Techniques for PV/SMV Resection and Reconstruction

Partial Resection and Reconstruction

In cases of minimal invasion of the lateral aspect of the vein, a vascular clamp is placed longitudinally, and the invaded part of the vein is resected and directly sutured. When PV/SMV stenosis is anticipated, the vascular clamps are placed proximally and distally, and transverse suturing after longitudinal resection should be applied to avoid stenosis of the reconstructed vein (Fig. 2a). The large defect can also be repaired with autologous vein grafts using the great saphenous vein, left renal vein, internal jugular vein, or synthetic material [23, 32–35] (Fig. 2b).

Segmental Resection and Reconstruction

In cases of wide invasion of the lateral aspect of the vein or circumferential involvement, vascular clamps are placed proximally and distally to the

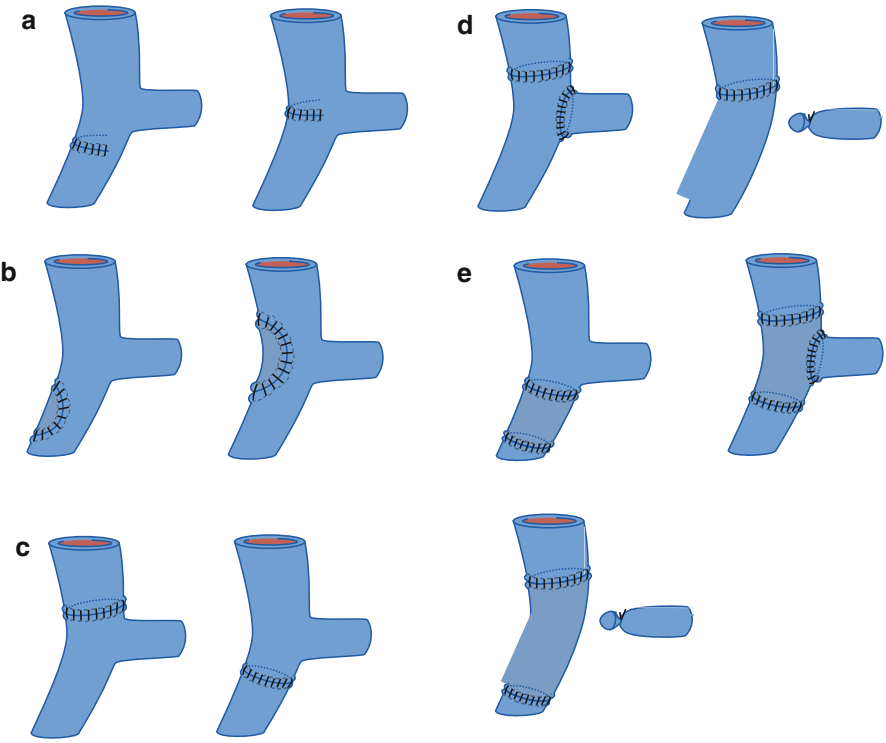

Fig. 2 Various patterns of PV/SMV resection and reconstruction

invaded portion, and segmental resection of PV/SMV should be performed (Fig. 2c). It is better to place the vascular clamps well apart from the invaded portion to retain sufficient flexibility for suturing the vessels (Fig. 3). When the PV/SMV defect is lengthy, full mobilization of the right hemicolon mesentery may help to approximate the proximal and distal resected ends of the PV/SMV.

There are two major procedures for the end-to-end anastomosis of PV/SMV or vein grafts. One is the "rotation method," and the other is the "intraluminal and over-and-over method." In case of the "rotation method" (Fig. 4), the vascular clamp is applied perpendicularly, and segmental resection of the involved vein is performed. First, the vascular clamps are turned 90° toward the right side, stay sutures are placed at the bilateral edges of the resected vein, and the left lateral wall is anastomosed using a continuous over-and-over suture technique. After the left lateral wall anastomosis is completed, the vascular clamps are turned back 180° toward the left side, and right-side wall anastomosis is performed using the continuous over-and-over suture technique. Next, the threads are tied after the proximal vascular clamp is removed, and the anastomosis is dilated. Finally, the distal vascular clamp is released. If the proximal cancer invasion has progressed near the jejunal veins or proximal or distal cancer invasion is found near the porto-mesenteric confluence, the previously described technique cannot be used before dissecting the SMA because

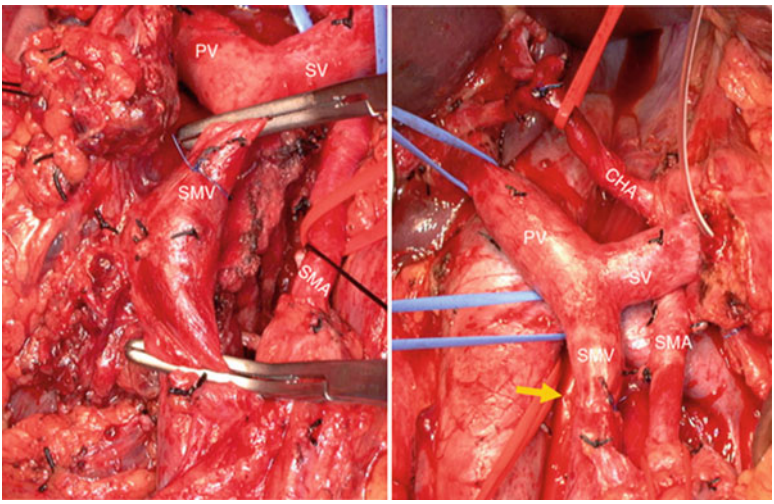

Fig. 3 Combined SMV resection and end-to-end anastomosis. *PV* portal vein, *SMV* superior mesenteric vein, *SV* splenic vein, *SMA* superior mesenteric artery, *CHA* common hepatic artery. An arrow indicates SMV anastomosis

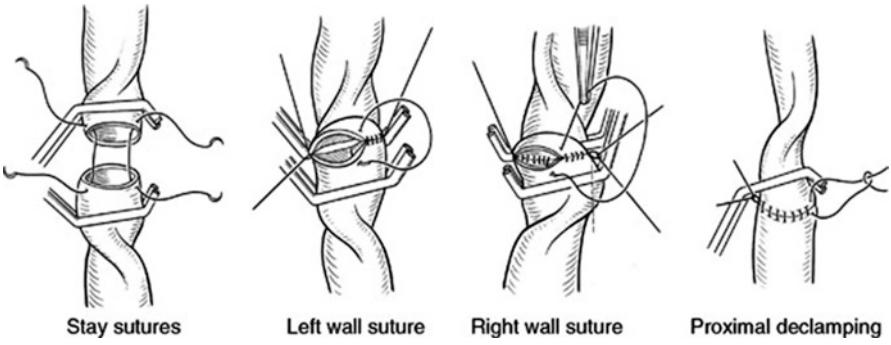

Fig. 4 Rotation technique for SMV/PV anastomosis

the PV/SMV cannot be turned 180°. In such instances, the "intraluminal and over-and-over method" is used (Fig. 5). In this method, the vascular clamps are placed horizontally near the jejunal vein and the splenic vein, and the involved vein is resected. For the reconstruction of the resected vein, stay sutures are placed at the bilateral edges of the resected vein, the intraluminal suture technique is applied for the posterior wall anastomosis, and the over-and-over suture technique is used for the anterior wall anastomosis.

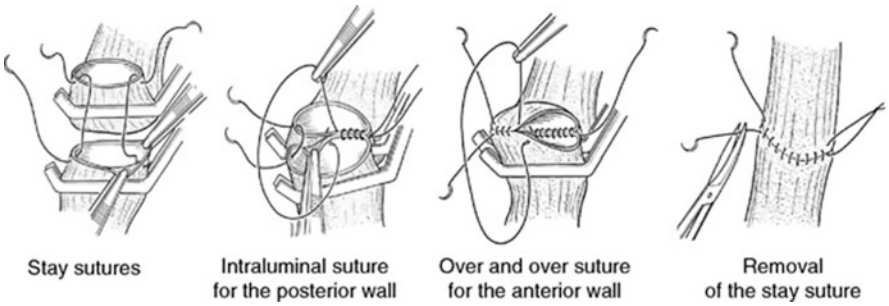

Fig. 5 Intraluminal and over-and-over techniques for SMV/PV anastomosis

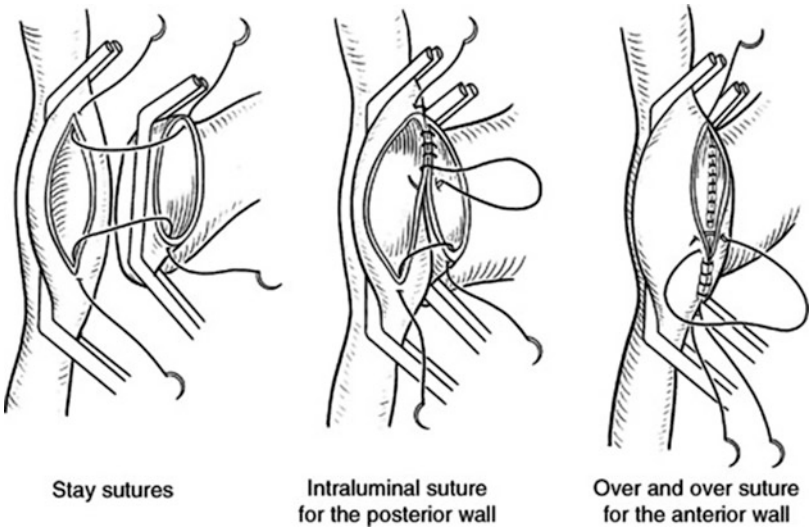

Fig. 6 End-to-side spleno-mesenteric anastomosis

When the confluence of the PV and SMV is involved, vascular clamps are placed on the splenic vein (SV), the SMV, and the PV, and the involved segment is resected (Fig. 2d). End-to-end anastomosis of the SMV and PV is first performed, a vascular clamp is placed longitudinally on the left lateral aspect of the reconstructed SMV, and end-to-side anastomosis of the SV and SMV is performed using the intraluminal suture technique for the posterior wall and the over-and-over suture technique for the anterior wall (Fig. 6). If venous congestion is not observed in the proximal organs of the SV, the division and ligation of the SV without reconstruction are a possible alternative to the abovementioned reconstruction procedure (Fig. 2d) [12]. In such cases, the formation of varices due to left-sided

portal hypertension may occur during the late phase after surgery [36, 37]. This issue will be discussed in a later chapter.

Autologous, Homologous, or Prosthetic Vein Grafting

When the resected segment of the portal vein is long and end-to-end anastomosis between the proximal and distal end cannot be performed, an autologous vein graft is interposed between the resected veins (Fig. 2e). For the autologous vein graft, the authors prefer to use the external iliac vein [32] (Fig. 7); however, other authors propose using the left renal vein [38, 39] as the autologous vein graft. There are pros and cons for both the external iliac vein and the left renal vein graft. Regarding the external iliac vein, it is possible to harvest a fairly long graft, and its diameter is almost identical to that of the PV/SMV. However, an additional skin incision is necessary to harvest the external iliac vein graft using either the intraperitoneal or extraperitoneal approach. Moreover, there is a risk of leg edema and deep venous thrombosis after harvesting an external iliac vein graft. In comparison, a left renal vein graft can be easily harvested without making a new skin incision. However, the length of the left renal vein graft is restricted by the branching of the left adrenal vein (central vein) and the gonadal vein, which should be certainly preserved to maintain venous return from the left kidney. Additionally, this type of autologous vein graft should be avoided in patients with renal dysfunction. The internal jugular vein [33, 40] and gonadal vein [41, 42] can also be used as an autologous vein graft source. The autologous vein graft should be selected considering the condition of the patients and the invaded PV/SMV. When an autologous vein graft is difficult to harvest, the parietal peritoneum [43], homologous veins [44], permanent prosthetic grafts [45], or biologic prosthetic material [46] can be used. The greatest benefit of these non-autologous vein grafts is the unlimited length of the source for

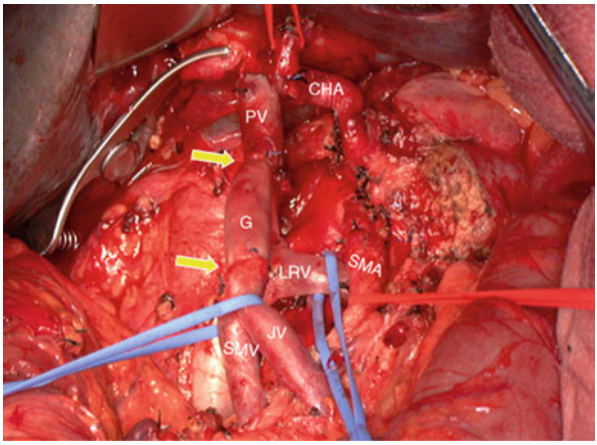

Fig. 7 Porto-mesenteric confluence resection and reconstruction using an external iliac vein graft. *PV* portal vein, *SMV* superior mesenteric vein, *JV* jejunal vein, *SMA* superior mesenteric artery, *CHA* common hepatic artery, *LRV* left renal vein, *G* external iliac vein graft. Arrows indicate the proximal and distal anastomosis of the interposed iliac vein graft. Major shunt route following splenic vein (*SV*) dissection

interposition. It should be noted, however, that the risk of thrombus formation may generally increase with the use of a non-autologous vein graft.

Vascular interposition may require a longer repair time compared with direct end-to-end anastomosis or vascular patch graft. If more than 30 min clamping is anticipated for venous reconstruction, the mesenteric flow should be bypassed to either the portal venous flow via the round ligament or systemic circulation via the greater saphenous vein to avoid severe congestion and/or ischemia of the small and large intestine [47].

Development of Left-Sided Portal Hypertension After Splenic Vein Ligation

When pancreatic head cancer invades the confluence of the SV and SMV, dissection of the SV is necessary. The SV may be reimplanted into the reconstructed SMV-PV system, but the ligation of the SV without reimplantation may also be acceptable. In such cases, the risk of left-sided portal hypertension is a controversial problem. Rosado et al. analyzed 15 patients who underwent extended pancreatoduodenectomy with PV ligation and aimed to identify postoperative venous collateral patterns and sequelae of SV ligation [48]. In all patients, the junction of the inferior mesenteric vein (IMV) with the SV or SMV was resected. In most patients (14 out of 15), a collateral route developed from the residual SV to the SMV via collateral veins in the omentum and along the colon (an inferior route; Fig. 8). At the same time, 10 out of 15 patients developed a collateral route from the residual SV to the PV via the gastric, perigastric, and coronary veins (a superior route). There were no patients who developed gastrointestinal bleeding within the study period of at least 5 months. Mean platelet count and spleen size were also unaffected. Misuta et al. reported similar surgical outcomes in 29 patients who underwent pancreatoduodenectomy with SV division [49]. They proposed that it is important to preserve the omentum [48] and transverse and right colic marginal veins to avoid the formation of varices [36]. Ligation or embolization of the splenic artery [37, 50] or anastomosis of the splenic vein to the IMV [51, 52] is another option for reducing the incidence of varices. It should be noted, however, that other reports show that the preservation of the IMV is not effective for preventing left-sided portal hypertension [53].

Complications Related to PV/SMV Resection and Reconstruction

Portal venous thrombosis is one of the most common complications following pancreatoduodenectomy with PV/SMV resection and reconstruction. The reported incidence of thrombosis following PV/SMV resection and reconstruction is 20–30% [34, 54–56], and the rate of thrombosis is lower in cases of primary end-to-end anastomosis or transverse venorrhaphy compared with interposition graft or patch venoplasty [57]. Regardless of the reconstruction method, patients who undergo preoperative chemotherapy or radiation therapy or have prolonged operative times

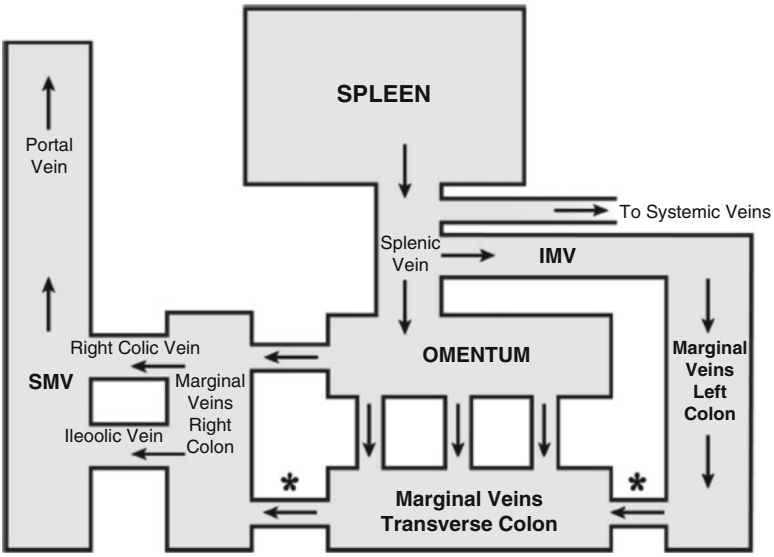

Fig. 8 Possible inferior collateral routes for decompressing the SV after ligation in an extended pancreatoduodenectomy. The SV may decompress inferiorly into the inferior mesenteric vein (*IMV*), into the omentum, or, more rarely, into the systemic circulation. Blood will flow from the IMV through the marginal veins of the colon to the superior mesenteric vein (*SMV*). If the colonic venous arcade is incomplete at the splenic flexure (*right asterisk*), this shunt may not be operative, and blood flow in the IMV will not reverse direction, or varices will format that location. Omental vessels connect to the marginal vessels of the transverse and right colon and through them and the ileocolic and right colic vessels to the SMV. Incomplete arcade at the hepatic flexure (*left asterisk*) may also result in colonic varices. IMV may rarely decompress to systemic veins. The middle colic vein is rarely available as it is almost always divided in an extended pancreatoduodenectomy with vein resection, but if present, it may decompress the marginal veins of the transverse colon. Colonic varices may also form at other locations, e.g., the cecum, depending on the completeness of the venous marginal arcade [48]

are more likely to have portal venous thrombosis [56]. When thrombosis was identified in a reconstructed PV/SMV during the postoperative course, aggressive anticoagulation therapy may be recommended unless there is a risk of bleeding complications. However, the usefulness of routine prophylactic anticoagulation therapy is controversial because the risks of thrombosis were not different between patients with and without prophylactic anticoagulation therapy in most previous reports [55, 57, 58].

Another complication after PV/SMV resection is bleeding from the anastomotic site (or other non-anastomotic site) in the PV/SMV system following pancreatectomy. This complication may be largely induced by a pancreatic fistula, in which pancreatic juice leaking from the anastomotic site melts an adjacent structure, such as the PV/SMV [59]. It is important to actively aspirate the leaking pancreatic juice using drainage catheter. However, at the same time, the catheter may tear or sometimes puncture the PV/SMV, which may lead to massive bleeding from the

PV/SMV system. Clamping a drainage catheter may be effective to stop bleeding because the intravascular pressure in the PV/SMV is not very high (approximately 5–10 mmHg) and is much lower than the arterial pressure. However, the clamping of a drainage catheter deteriorates the pancreatic fistula, which further damages the PV/SMV wall. This dilemma can be resolved by using stent graft for PV/SMV [60, 61]. The utility of stent grafting for arterial hemorrhage after pancreatectomy is widely accepted [62, 63]. In contrast, the standard procedure for postoperative PV/SMV hemorrhage is surgical repair [64, 65] when possible. However, this method is not safe when severe intra-abdominal inflammation and adhesion occur around the PV/SMV after surgery. In such cases, the stenting technique is also a feasible therapeutic option for PV/SMV hemorrhage. Regarding the PV/SMV stenting technique, a 12-Fr sheath is inserted into the main portal venous system using a transhepatic or ileocolic approach. The bleeding point is then identified with portography through the intraportal catheter or contrast radiography through the drainage tube of the pancreatic fistula (Fig. 9a). Based on the size of the PV/SMV measured with CT scanning, an appropriate stent graft size is selected to minimize endoleak (Fig. 9b, c). When the leaking point is close to the confluence of the splenic vein, gastric vein, and/or inferior mesenteric vein, these vessels can be embolized using coils and microcoils before the stent graft is deployed. The authors recommend to use anticoagulant therapy after stent graft insertion, because low pressure and slow portal venous flow may sometimes induce thrombus formation in the portal venous system.

Surgical Results (Summary of Five Meta-Analyses of Venous Resection)

Several reports have indicated that pancreatectomy with PV/SMV resection can be performed with acceptable morbidity and mortality, and survival was comparable for patients with and without PV/SMV resection [23, 24, 33, 66]. In contrast, other reports have shown poorer survival in patients who underwent PV/SMV resection compared with those who did not [67]. Presently, there is no consensus regarding which patients with pancreatic cancer benefit from PV/SMV resection. Because the pattern of PV/SMV invasion and each surgeon's ability to intraoperatively recognize the extent of PV/SMV invasion in each surgeon are variable, it is extremely difficult to perform RCTs that elucidate a clinical benefit of PV/SMV resection in pancreatic cancer patients with vascular invasion. Therefore, at this time, a systematic review that collects a large number of reports comparing the surgical outcomes of patients with and without PV/SMV resection may be one of the best ways to clarify the clinical value of combined resection of PV/SMV in pancreatic cancer patients.

Since 2006, five meta-analyses or systematic reviews comparing the clinical outcomes of patients who underwent pancreatectomy with and without synchronous PV/SMV resection have been reported [26, 68–71] (Table 2). The study years varied among these reports, ranging from 1996 to 2014. Most of the analyses included more

than 2000 pancreatic cancer patients. The rate of vascular resection ranged from 17.6 to 44.8%.

Perioperative Outcomes

Operation time and intraoperative blood loss may increase during vascular resection. However, the differences in these factors between patients who underwent vascular resection and those who did not were acceptable. According to the meta-analysis by Siriwardana et al., the mean (range) duration of PV/SMV occlusion was 20 (7–302) minutes, and the mean (range) resected length of the PV/SMV was 3.9 (0.8–10.0) cm [26]. The overall morbidity and mortality rate after surgery were generally comparable between patients who did and did not undergo PV/SMV resection. However, the most recent meta-analysis by Giovinazzo et al. showed a higher morbidity and mortality rate in patients who underwent PV/SMV resection [70]. Nevertheless, these rates are still acceptable for this type of surgery. The incidence rate of delayed gastric emptying, which is one of the most commonly observed complications, was

VR, PV, and/or SMV resection
*$p < 0.05$ versus without VR

comparable between the two groups. In contrast, the risks of pancreatic fistula were lower in patients who underwent PV/SMV resection, probably because of greater fibrotic change of the remnant pancreas resulting from the obstruction or stenosis of the main pancreatic duct.

Pathological Positivity

Patients who underwent PV/SMV resection were more likely to have a positive resection margin than patients who did not undergo venous resection. Histological evidence of PV/SMV invasion was detected in approximately 60%. In other words, in 40% of patients who underwent PV/SMV resection, the PV/SMV was not affected by the cancer but instead was probably involved in the inflammatory response of the tissue surrounding the cancer. The resection margin was positive in more than 30% of patients not only in the resected part of the PV/SMV but also in the other dissected pancreatic margins. Nodal involvement was observed in 60% to 70% of patients. Patients with PV/SMV invasion tend to have more negative pathological prognostic factors, such as positive lymph node metastasis and positive resection margins. These results indicated that when pancreatic cancer grows outside of the pancreas and reaches to PV/SMV, it is difficult to thoroughly eradicate tumor cells, even by performing radical surgery with PV/SMV resection. These clinical observations are supported by the immunohistochemical analysis of specimens from pancreatic head cancers that have invaded the PV/SMV. It was demonstrated that histological tumor invasion of the PV/SMV is characterized by aggressive biology and stromal fibroblast activation through a loss of membranous E-cadherin in tumor buds, increased vimentin expression, and activated cancer-associated fibroblasts (CAFs) [72].

Survival

According to the first large systematic review, conducted by Siriwardana et al., the median (range) survival was 13 (1–109) months for 917 patients who underwent PV/SMV resection in 31 studies [26]. The survival of patients who underwent PV/SMV resection was clearly inferior to that of patients who did not undergo PV/SMV resection. However, we should be cautious about the time frame (since 1966 to 2006) and heterogeneous study cohorts included in this meta-analysis. In fact, a more recent meta-analysis by Zhou et al. involving 19 studies (from 1994 to 2010) of pancreatectomies for pancreatic cancer and comparing 661 patients who underwent PV/SMV resection and 2247 patients who did not indicated that pancreatectomy combined with PV/SMV resection for pancreatic cancer is justified because it can have good perioperative outcomes and its long-term survival is comparable to that obtained with standard resection [68]. The meta-analysis by Yu et al. also showed compatible survival outcomes between patients with and without PV/SMV resection [69]. Other recent cohort studies also support the clinical

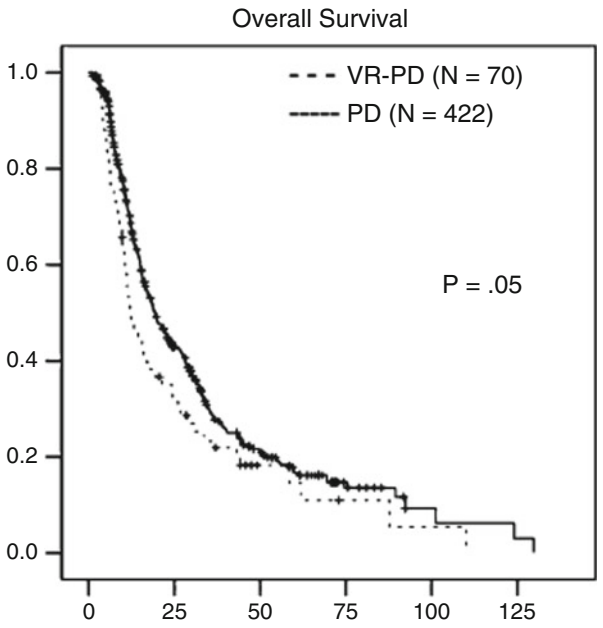

Fig. 10 Overall survival in patients undergoing pancreaticoduodenectomy with and without vein resection. *PVR-PD* vein resection combined with pancreaticoduodenectomy, *PD* pancreaticoduodenectomy without vein resection [75]

relevancy of combined PV/SMV resection for pancreatic cancer [71, 73–75]. In particular, the two largest modern multi-institutional series examining patients with or without isolated vein involvement in pancreatic cancer, conducted in the United States [75] and the United Kingdom [66], found that the oncological outcome did not differ between the patients with and without vein involvement (Fig. 10). It also should be noted, however, that the most recent meta-analysis, by Giovinazzo et al., indicated that patients with PV/SMV resection not only showed worse survival after surgery but also had higher rates of postoperative mortality and non-curative resection [70]. Taken together, the clinical benefit of PV/SMV resection for pancreatic cancer remains controversial.

Conclusion

Conflicting statements regarding the role of surgical resection of the PV/SMV during pancreatoduodenectomy have been made, and no RCTs have been conducted to clarify the surgical value of concomitant PV/SMV resection. In general, pancreatoduodenectomy with PV/SMV resection and reconstruction was not associated with increased morbidity and mortality and provided a negative surgical margin, and patients had a better survival than unresected patients. Therefore, combined PV/SMV resection and reconstruction during pancreatoduodenectomy should always be considered as an effective treatment modality for patients with pancreatic cancer adherent to the PV/SMV system in the absence of other contraindications for resection.

Key Practice Points

- The use of combined portal vein resection and reconstruction in pancreatoduodenectomy is determined preoperatively according to CT, MR, and/or portography findings.
- Intraoperatively, the type of portal vein resection and reconstruction is based on the degree of local cancer invasion of the vein.
- The types of resection and reconstruction are as follows:
  1. Wedge resection
     - Direct transverse suture
     - Patch closure
  2. Segmental resection
     - Direct end-to-end anastomosis
     - Segmental autologous vein grafting
- When the SMV/PV resection and reconstruction are performed with the ligation and division of the SV, there is a possibility that postoperative varices in the colon and esophagus will develop due to left-sided portal hypertension. Preservation of the omentum and transverse and right colic marginal vein is essential to avoid the formation of varices.
- Common complications after SMV/PV resection are thrombosis, stenosis, and hemorrhage. Thrombosis can be treated surgically and/or with anticoagulant therapy. To avoid stenosis after reconstruction, the threads used for the venous reconstruction should be loosely tied after the sufficient expansion of the anastomosed vessel with blood flow. Hemorrhage from the SMV/PV reconstruction can be treated using a full-coverage stent graft inserted via the transhepatic or ileocolic route.

Future Research Directions

- Randomized control trials are necessary to clarify the value of portal vein resection in pancreatoduodenectomy for pancreatic cancer.
- Reevaluation of the accuracy of preoperative diagnoses of portal vein invasion should be performed using modern diagnostic modalities to clarify preoperative indications for combined portal vein resection in pancreatoduodenectomy for ductal adenocarcinoma of the pancreatic head.

Controversies in Pathology Reporting and Staging

Fiona Campbell and Caroline Sophie Verbeke

Contents

Abstract

Following surgery for pancreatic cancer, it is the histopathologist who examines, dissects, and samples the resection specimen for microscopic (histologic) assessment, with the aim of producing a final pathology report that includes all the relevant prognostic information and accurate tumor staging. However, there is no universally agreed pathology protocol for the handling and sampling of pancreatic cancer resection specimens, particularly pancreatoduodenectomy specimens, and pathologists have differing opinions over what is a resection margin and

when it should be considered involved. The increasing use of neoadjuvant therapy has also led to new challenges for the pathologist. Differences in interpretation of the TNM staging system can mean that two pathologists stage the same pancreatic cancer resection specimen quite differently. This chapter discusses the pathology reporting and staging of pancreatic cancer resection specimens, with particular emphasis on the challenges and areas of controversy for the pathologist.

Introduction

The number of pancreatic resection specimens received by the pathologist has increased exponentially over the last 20 years [1]. Not all resections, however, are performed for malignancy, and, therefore, the pathologist plays an important role in establishing the correct diagnosis. Following surgery for pancreatic cancer, it is the histopathologist who examines, dissects, and samples the resection specimen for microscopic (histologic) assessment, with the aim of producing a final pathology report that includes all the relevant prognostic information and accurate tumor staging. However, there is no universally agreed pathology protocol for the handling and sampling of pancreatic cancer resection specimens, particularly pancreatoduodenectomy specimens, and pathologists have differing opinions over what is a resection margin and when it should be considered involved. There are also differences of opinion, between pathologists, in interpretation of the current AJCC/UICC TNM staging system [2, 3], which may influence future management of patients and entry into clinical trials. These differences in pathology opinion can also influence the outcome of studies on prognostic factors in pancreatic cancer, which, in turn, can prevent meaningful comparison of different studies.

This chapter will discuss the reporting and staging of resection specimens for pancreatic cancer, mainly pancreatic ductal adenocarcinoma (PDAC) and its variants, as classified by WHO 2010 [4]. The term "pancreatic cancer", however, is often used synonymously with "periampullary cancer" to denote any tumor arising in the head of the pancreas. Cancers in the head of the pancreas may arise from the duodenum, ampulla of Vater, distal bile duct, or pancreas. Distinction between these entities is important because of their differing TNM staging and prognosis, as well as their management and the entry of patients into clinical trials [2, 3]. Accurate distinction between these different cancers is also crucial for identifying possible differences in their epidemiology, etiology, and molecular biology. Errors in determining the primary origin of the tumor are highly likely to be one explanation for the considerable variation in R1 resection rates for pancreatic ductal adenocarcinoma (PDAC) in the literature. The R1 rate for true ampullary cancers is much less

than that for PDAC, while the R1 rate for distal bile duct cancer approaches that of PDAC [5–8]. Expert review of pancreatic head tumors diagnosed as PDAC has highlighted the issue of correctly establishing the primary origin of tumors in the head of the pancreas: in one review, 23% of cancers reported as PDAC were in fact carcinomas of the ampulla of Vater or of the bile duct [9].

Reported incomplete (R1) resection rates for PDAC vary considerably in the literature from 8% to 85% [10, 11]. As will become apparent from the following chapter discussion, the reasons for these different R1 rates can be multifactorial. R1 rates may be influenced by differences in specimen dissection techniques [12], differing opinions over what constitutes a resection margin, adequacy (or not) of margin sampling, definition of microscopic margin involvement [13], and, as indicated above, erroneous inclusion of primary cancers of the ampulla of Vater or distal common bile duct in studies of PDAC [9]. When a standardized pathology examination protocol is used with an agreed microscopic definition of R1, then microscopic margin involvement is a common finding in PDAC and is found to be of prognostic significance in many, if not all, studies [11, 14–16]. The high rates of R1 resections in PDAC are not a marker of low-quality surgery, but rather an indicator of high-quality pathology [14]. There are many challenges and areas of controversy for the pathologist when reporting and staging pancreatic cancer resections, including those arising from an increase in the number of resections following neoadjuvant therapy. The following sections will discuss these challenges and areas of controversy in more detail.

Dissection

The importance of the macroscopic examination and dissection of the pancreatic resection specimen (particularly the pancreatoduodenectomy specimen), by the pathologist, cannot be overemphasized [17]. The primary origin of the cancer (i.e., pancreas vs. ampulla vs. bile duct vs. duodenum), its size and extent, lymph node status, and margin status influence the TNM and R classification/staging, which, in turn, may determine further therapy and/or entry into clinical trials. There is currently no internationally accepted standardized pathology dissection protocol [7], leading to considerable variation in the reporting of factors that are of potential clinical and prognostic significance [12, 13, 18, 19].

For many years, pathologists examined the pancreatoduodenectomy specimen by inserting probes into the common bile duct and main pancreatic duct and then slicing the head of the pancreas along these probes [20]. Probing the pancreatic duct can be difficult, particularly in the distal portion, where it can be kinked, and because of its narrow bore. With increasing numbers of pancreatic resections being performed over the last 20 years [1], more pathologists have encountered these specimens and developed their own methods of dissection without the need to probe the ducts.

The main dissection approaches being used currently include bivalving or multivalving, bread loafing, and the axial slicing techniques [21–23].

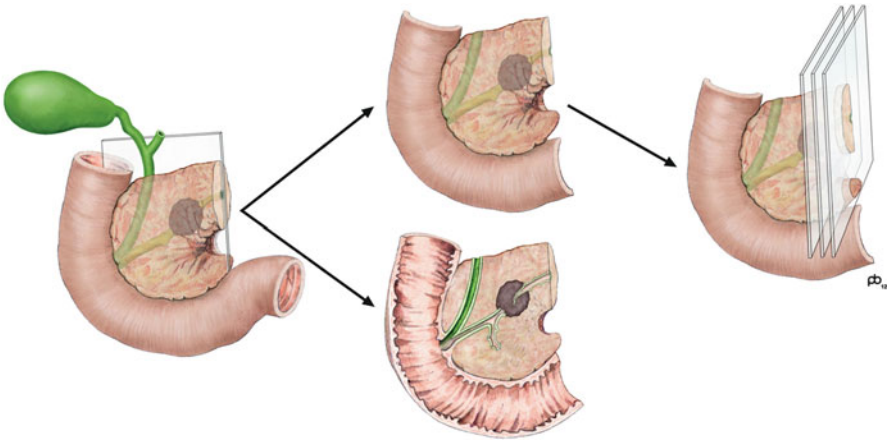

Fig. 1 In the bivalving or multivalving technique, the pancreatoduodenectomy specimen is sliced in a plane defined by probes placed in the main pancreatic duct and the common bile duct

Bivalving or Multivalving

In this technique, the main pancreatic duct and common bile duct are probed, and the specimen is sliced once (bivalving) or several times (multivalving) along the plane defined by both probes (Fig. 1). This approach can be technically difficult if one or both ducts are distorted or obstructed by tumor. Subsequent slicing of the specimen along the probes may also be challenging. Advocates of this method find it particularly helpful in the demonstration and assessment of primary ampullary tumors [24].

Bread Loaf Slicing

In the bread loaf slicing technique, the pancreatic head is serially sliced along a plane perpendicular to the longitudinal axis of the pancreatic neck (Fig. 2). With this technique, dissection of the periampullary region can be suboptimal, because the descending part of the duodenum is sliced longitudinally [17].

Axial Slicing

In this technique, the pancreatic head is serially sliced in the axial plane that is perpendicular to the descending part of the duodenum (Fig. 3). This dissection plane is identical to that of radiological imaging, i.e., computerized tomography scanning or magnetic resonance imaging, allowing correlation between radiology and pathology.

The axial slicing technique is easy to perform and can be used for all pancreatoduodenectomy specimens, regardless of the pathology encountered [17]. The

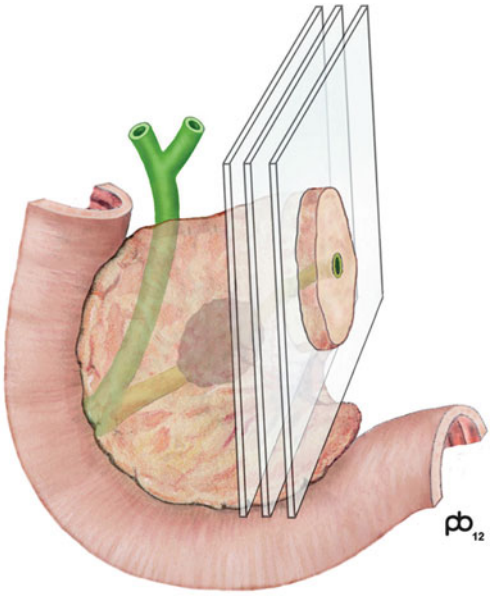

Fig. 2 In the bread loaf slicing technique, the pancreatoduodenectomy specimen is serially sliced in a plane perpendicular to the pancreatic neck

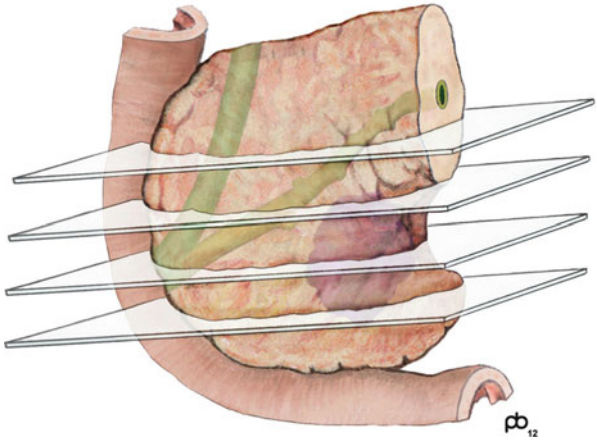

Fig. 3 In the axial slicing technique, the pancreatoduodenectomy specimen is serially sliced in a plane perpendicular to the long axis of the descending duodenum

pancreatic surface remains intact, facilitating margin assessment, and the main dissection plane is independent of the configuration of the main pancreatic duct and common bile duct, which influences the bivalving or multivalving technique. Other advantages of the axial slicing technique include the fact that the key anatomic structures (ampulla of Vater, common bile duct, main pancreatic duct) always occur at the same position in the specimen slices (allowing identification of anatomic variation and pathologic lesions), and the entire circumferential surface of the pancreas is present in each specimen slice (enabling accurate margin assessment along the entire craniocaudal length of the pancreatic head) [17].

Distal pancreatectomy specimens can be serially sliced in the sagittal plane, i.e., perpendicular to the longitudinal axis of the pancreas. This avoids the disruption of the specimen surface if the main pancreatic duct is opened longitudinally. Total pancreatectomy specimens can be dissected by a combination of axial slicing of the head and sagittal slicing of the body and tail [2].

The axial slicing technique advocated by the Japanese Pancreas Society [23] involves serially slicing the specimen perpendicular to an axis that follows the curvature of the pancreatic head. This has the disadvantage for the pathologist of producing slices that are wedge-shaped rather than uniform slices [17].

Macroscopic Assessment and Sampling

The pancreatic resection specimen can be examined fresh (e.g., for biobanking), following fixation in formalin. Prior to dissection, the different surfaces of the pancreas should be inked (according to a locally agreed color code) to facilitate identification of these surfaces during macroscopic and microscopic examination [21]. The dimensions of the pancreas, duodenum, stomach, extrapancreatic common bile duct, and other structures, such as the gallbladder or attached portion of superior mesenteric vein or portal vein, should be measured and recorded. Following dissection, the serial specimen slices can be laid out in sequential order and photographed to provide a permanent record of the gross findings. These images can be extremely helpful when interpreting the microscopic findings and when discussing the pathologic findings at clinical meetings such as the multidisciplinary team meeting.

After describing the gross appearance of the specimen, tumor, and any other pathology, tissue samples should be taken. Tissue sampling should be extensive because pancreatic ductal adenocarcinoma is highly infiltrative and invades much more widely than can be appreciated by the naked eye. It can also be difficult to distinguish carcinoma from chronic pancreatitis. The size and extent of the tumor are often underestimated on the gross examination. There is also a significant correlation between the number of tissue blocks taken and the likelihood of identifying a positive resection margin [11, 25].

The tumor should be sampled en bloc with adjacent structures and circumferential surfaces/margins, together with all lymph nodes, transection margins (pancreatic neck, common bile duct, duodenum or stomach, jejunum), the gallbladder (if present), other organs (e.g., spleen in the distal pancreatectomy), and background tissue. When a segment or sleeve of portal vein or superior mesenteric vein is present, this is best sampled en bloc with the adjacent superior mesenteric vessel groove and pancreas, to assess for tumor invasion of the vein wall. It is recommended that the entire resected vein is embedded to determine whether its adherence is due to tumor infiltration of the vessel wall or due to inflammation and fibrosis [26, 27]. When an attached segment of vein is not adherent to the superior mesenteric vessel groove over its entire length, then both cut ends (i.e., transection margins) can be sampled separately as en face tissue slices [21].

Fig. 4 Axial specimen slice with a large PDAC that infiltrates the duodenal wall (*asterix*) and main pancreatic duct (*thin arrow*), extends close to the groove of the superior mesenteric vein (*thick arrow*), but spares the common bile duct (*CBD*)

Tumor Origin

The exact location of the tumor with respect to the bile duct, ampulla, and duodenum is crucial for establishing the primary origin of the cancer (Fig. 4). However, the precise origin of a tumor may be difficult to determine, particularly when the tumor is large and involves more than one potential site of origin. The localization of the center of the tumor is the most helpful and important diagnostic criterion. This is assessed macroscopically and confirmed microscopically [19]. The presence of neoplastic precursor lesions, e.g., adenoma of the ampulla, may be helpful in identifying the primary origin of the tumor, but precursor neoplasia of the bile duct is much less commonly observed in association with bile duct cancer and usually presents as flat dysplasia rather than as an adenomatous polypoid lesion. Pancreatic intraepithelial neoplasia (PanIN) as evidence of a pancreatic origin cannot be relied upon, since it can be seen in the background pancreas of specimens with ampullary or bile duct cancer, as well as pancreatic cancer [28, 29]. In addition, cancerization of background structures (e.g., ducts or duodenal mucosa) can mimic dysplasia [30]. Although immunohistochemistry may be helpful in distinguishing intestinal-type carcinomas from pancreatobiliary-type carcinomas arising in the ampulla of Vater [31], there are currently no immunohistochemical markers that can distinguish between pancreatobiliary-type carcinomas of the ampulla and PDAC or bile duct carcinoma. Moreover, PDAC can have an intestinal morphology, thus mimicking duodenal or ampullary carcinomas [30].

Margins

Assessment of the margin status in pancreatic cancer resection specimens is the source of much controversy. Pathologists differ in what they consider to be a margin (and thus whether or not it should be sampled) and when a margin should be

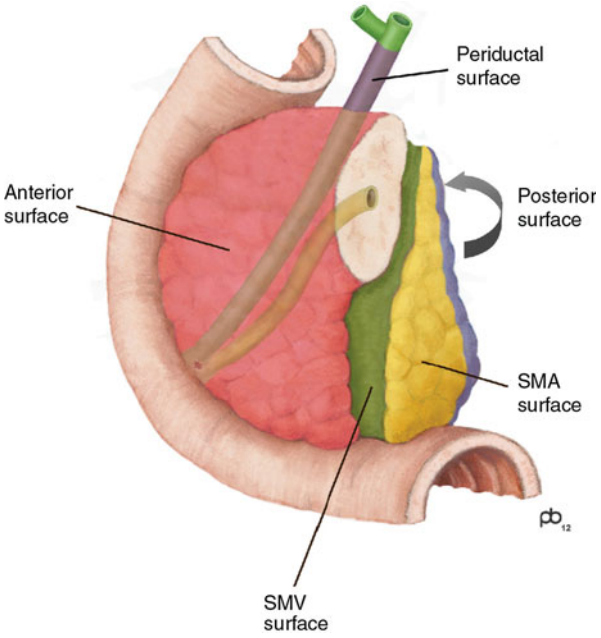

Fig. 5 The circumferential margins of a pancreatoduodenectomy specimen. The different surfaces can be inked according to a locally agreed color code

considered involved (R1) or not (R0) [13]. While all pathologists agree that the transection margins of the pancreatic neck, common bile duct, jejunum and proximal duodenum, or stomach should be sampled and evaluated, practice varies when it comes to examination of the "circumferential margins" of the pancreas. The circumferential margin of the head of the pancreas includes the anterior surface, the posterior surface, the superior mesenteric vein (SMV) groove, and the superior mesenteric artery (SMA) margin (Fig. 5). Pathologists differ in the terminology they use for the SMA margin. It is also referred to as the "retroperitoneal margin" (but the whole of the pancreas is retroperitoneal), "uncinate margin", "medial margin", "radial margin", "mesenteric margin", "mesopancreatic margin", and "posterior margin". Use of the latter term ("posterior margin") for the SMA margin means that comparisons of different published studies may not be valid if others are using the term to refer to the true posterior surface of the pancreatic head. A further circumferential margin that should also be considered in pancreatoduodenectomy specimens is the connective tissue sheath that surrounds the extrapancreatic common bile duct. This thin layer of tissue may be invaded by carcinomas arising in the extrapancreatic common bile duct or by infiltration from carcinomas of the intrapancreatic common bile duct or PDAC arising in the cranial part of the pancreatic head.

The only circumferential margin considered to be a resection margin (and therefore sampled) by some pathologists, particularly those following an American protocol [32], is the SMA margin [33, 34]. Tumor involvement of the so-called "dissection or mobilization" margins (i.e., posterior margin, SMV groove, and

around the extrapancreatic common bile duct), however, does affect survival, although it has been suggested that the influence on survival may be less than that when transection margins are involved [16]. The anterior surface is an anatomical surface rather than a true resection margin, but tumor involvement of this surface is associated with increased risk of recurrence [35], and, therefore, this surface should also be sampled and evaluated. Many current pathology guidelines now highlight the importance of evaluating all of the circumferential margins/surfaces as well as the transection margins [26, 36, 37]. In most standardized studies, the superior mesenteric vessel (medial) margin and the posterior margin are the two most commonly involved by tumor [11, 12, 14–16].

PDAC has a highly infiltrative growth pattern and often extends much further than apparent on macroscopic (gross) examination. Therefore, to assess margin status, extensive sampling of the margins should be undertaken. It has been shown that there is a significant correlation between an increasing number of tissue blocks taken from the resection specimen and an increasing likelihood of an R1 classification [11, 25]. It has also been shown that the method of dissection of pancreatoduodenectomy specimens influences R1 rates [12]. This meta-analysis found a pooled R0 rate of 29% in studies using an axial slicing technique and a definition of R1 $<$ 1 mm, while studies using other techniques and R1 $<$ 1 mm had a pooled R0 rate of 49% [12].

Completeness of excision should be assessed macroscopically and then be confirmed (or not) by microscopy. But what constitutes a microscopic complete (R0) resection or incomplete (R1) resection? The UICC TNM residual tumor (R) classification considers a resection margin involved when there is either macroscopic (R2) or microscopic (R1) transected tumor directly at a surgical resection margin (i.e., 0 mm clearance) [3]. In 2002, the Royal College of Pathologists, UK, pancreas dataset adopted the "1 mm rule" from the guidelines for reporting rectal cancer and considered PDAC within 1 mm of a margin to be an R1 resection [36]. A clearance of $<$1 mm had been shown to be associated with an increased risk of local recurrence in rectal cancer [38, 39]. However, similar studies have not been undertaken for pancreatic cancer. The growth pattern of PDAC is highly infiltrative and discontinuous, unlike that of rectal cancer. The distances between tumor cells in PDAC become significantly greater in the periphery of the tumor compared to the center. This is in contrast with colorectal cancer where there is no difference in the intercellular distances between tumor cells within the different regions of the tumor [40]. Reflecting this widely dispersed growth pattern for PDAC, others have suggested that a minimum of 1.5 mm or 2 mm clearance should be applied for an R0 resection [41–43]. These studies showed that a margin clearance of $<$1.5 mm or 2 mm was associated with a long-term survival equivalent to that of patients with directly involved (0 mm clearance) margins.

There is increasing agreement that a clearance of 0 mm is not appropriate for PDAC, but the distance required remains unknown. Current pathology guidelines [26, 36] continue to use the 1 mm rule, which has now been adopted by AJCC TNM 8 (but not UICC TNM) [44]. However, this 1 mm rule probably underestimates the presence of microscopic residual disease. It is probably more important that the

pathologist's report includes the exact measurement of the distance from the tumor to the nearest margin, so that it is clear why the resection has been considered R0 or R1.

In about 7% of pancreatic cancer resection specimens, there is no direct tumor involvement of a margin, but tumor is found at a margin within a lymph node, vascular channel, or perineural cleft [14]. One UICC TNM communication has stated that if tumor is attached to the lumen of the vessel wall or invades the vessel wall at the margin, then this should be classified as R1, but does not comment on whether lymph node or perineural involvement at a margin should also be classified as R1 [45]. Many pathologists would consider nodal or perineural deposits at a margin to be R1 [13], and some current pathology guidelines have recommended that such vessel, nodal, or perineural margin involvement is considered R1, with the caveat that this mode of margin involvement should be clearly stated as the reason for calling a resection specimen R1 in the histology report [26, 36]. However, these three modes of tumor spread are independent biological processes, recorded separately in histology reports and as optional descriptors in TNM (pV, pL, pPn), and can influence the risk of residual tumor in the patient whether or not they occur in proximity to a resection margin. For this reason, many pathologists would not consider their presence at a margin as R1, arguing that it is not appropriate to duplicate their biological risk by also classifying them as R1 [13].

Lymph Nodes

All lymph nodes present in a resection specimen should be sampled (each in its entirety, unless metastasis is seen macroscopically) by the pathologist. Lymph nodes are present in the peripancreatic tissue and the tissue surrounding the extrapancreatic common bile duct. In pancreatoduodenectomy specimens, lymph nodes may also be present in the infra-gastric and perigastric fat. Lymph nodes can be allocated to different lymph node stations using the Japanese Pancreas Society or UICC systems [3, 23]. The JPS system is much more detailed than the UICC system and allocates the lymph nodes to a larger number of different stations. The JPS system also includes distant lymph node stations, as well as regional lymph nodes [23]. Lymph nodes around the common hepatic artery are not specifically stated as regional for the pancreas in UICC TNM 7 [3], but are considered to be regional lymph nodes in AJCC TNM 7 and 8 [2, 44] and the JPS system [23]. UICC TNM 8 [46] now clearly states that common hepatic artery lymph nodes are regional, thereby removing the potential for the classification of a common hepatic artery lymph node as a distant metastasis. This anatomic division of regional lymph nodes is not necessary for TNM staging, but can act as an aide memoire to help the pathologist to locate the peripancreatic lymph nodes.

In the axial slicing technique, the lymph nodes are sampled en bloc with the adjacent pancreas and circumferential margins/surfaces. Dissection of lymph nodes from the peripancreatic fat, including by the "orange peel" method [47], prior to slicing the main specimen disrupts the specimen surface, precluding accurate margin assessment and an accurate measurement of the distance from the tumor to the

adjacent circumferential resection margin/surface. It also precludes assessment of direct tumor invasion into a lymph node (see Sect. 7). When using the axial slicing technique, careful consideration of the shape, size, and location of a lymph node in both the microscopic section and the close-up photographs of the corresponding specimen slices can help to avoid counting the same lymph node more than once.

TNM Classification/Staging

Pathologic staging (pTNM) of pancreatic ductal adenocarcinoma following resection gives an indication of the extent of the cancer and prognosis for long-term survival [48]. The two TNM classification systems used for staging are those of the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) [2, 3]. These two systems, however, do not always concur (e.g., pN staging for cancers of the ampulla of Vater in TNM 8) [44, 46].

In the currently used AJCC/UICC TNM 7 [3], the pT stage requires (macroscopic and microscopic) pathologic assessment of the size of the tumor and whether it is limited or not to the pancreas (Table 1). However, pathologists differ in their interpretation of the pT staging (Table 2).

A pT1 pancreatic ductal adenocarcinoma is limited to the pancreas and 2 cm or less in greatest dimension [2, 3]. The increasing number of resections of intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs), however, has led to the detection of small, "early" pancreatic ductal adenocarcinomas much less than 2 cm in size. This led to a proposal that pT1 pancreatic cancers should be substaged into pT1a, pT1b, and pT1c according to whether the size was $\leq$0.5 cm, $>$0.5 cm and $\leq$1 cm, and $>$1 cm and $\leq$2 cm, respectively [49, 50]. This proposal has now been accepted by AJCC and UICC in TNM 8 [44, 46].

In AJCC/UICC TNM 7, pT1 and pT2 pancreatic cancers are confined to the pancreas, whereas pT3 cancers extend beyond the pancreas but without involvement of the celiac axis or superior mesenteric artery (see Table 1) [2, 3]. The pancreas, however, does not have a capsule, and it is not always easy for the pathologist to decide what is peripancreatic tissue; the distinction between pancreas and peripancreatic soft tissue is often obscured by (chronic pancreatitis or tumor-related) fibrosis or fatty replacement [21]. There is also controversy over the pT staging of pancreatic ductal adenocarcinomas that invade the intrapancreatic common bile duct, which is a common event, even with small tumors. In UICC TNM 5, pT3 was defined as "tumor extends directly into any of the following: duodenum, bile duct, peripancreatic tissues" with the footnote that "direct invasion to bile ducts and duodenum includes involvement of the ampulla of Vater" [51]. Although some guidelines (e.g., those of the College of American Pathologists) [32] clearly state that bile duct involvement only refers to involvement of the extrapancreatic bile duct, many pathologists would consider involvement of the intrapancreatic bile duct as extension beyond the pancreas and, therefore, stage such tumors as pT3 in TNM 7 (Table 2).

Table 1 TNM staging of pancreatic cancer according to AJCC/UICC TNM 7 and 8 [2, 3, 44, 46]

AJCC/UICC TNM 7				**AJCC/UICC TNM 8**			
T1 – tumor limited to pancreas, 2 cm or less in greatest dimension				T1 – tumor 2 cm or less in greatest dimension			
				T1a – tumor 0.5 cm or less in greatest dimension			
				T1b – tumor greater than 0.5 cm and less than 1 cm in greatest dimension			
				T1c – tumor greater than 1 cm but no more than 2 cm in greatest dimension			
T2 – tumor limited to pancreas, more than 2 cm in greatest dimension				T2 – tumor more than 2 cm but no more than 4 cm in greatest dimension			
T3 – tumor extends beyond pancreas, but without involvement of celiac axis or superior mesenteric artery (SMA)				T3 – tumor more than 4 cm in greatest dimension			
T4 – tumor involves celiac axis or SMA				T4 – tumor involves celiac axis, SMA, and/or common hepatic artery			
N0 – no regional lymph node metastasis				N0 – no regional lymph node metastasis			
N1 – regional lymph node metastasis				N1 – metastasis in 1–3 regional lymph nodes			
				N2 – metastasis in 4 or more regional lymph nodes			
TNM 7 stage grouping				**TNM 8 stage grouping**			
Stage 0	Tis	N0	M0	Stage 0	Tis	N0	M0
Stage 1A	T1	N0	M0	Stage 1A	T1	N0	M0
Stage 1B	T2	N0	M0	Stage 1B	T2	N0	M0
Stage 2A	T3	N0	M0	Stage 2A	T3	N0	M0
Stage 2B	T1, T2, T3	N1	M0	Stage 2B	T1, T2, T3	N1	M0
Stage 3	T4	Any N	M0	Stage 3	T1, T2, T3	N2	M0
Stage 4	Any T	Any N	M1		T4	Any N	M0
				Stage 4	Any T	Any N	M1

Tumor extension beyond the pancreas (pT3 in TNM 7) [2, 3] has been reported in up to 90–95% of pancreatic cancer resection specimens [52, 53] leading some to suggest that tumor size should become the defining parameter for pT3 tumors. AJCC/UICC TNM 8 has subsequently accepted size criteria for pT staging of pancreatic cancer (Table 1) [54, 55]. T4 pancreatic cancers are locally advanced (involving the celiac axis or superior mesenteric artery) and in the UK and many other countries are considered to be unresectable. Invasion of the portal vein and/or superior mesenteric vein does not influence T staging.

The introduction of entirely size-based criteria for T staging in TNM 8 will mean that tumor involvement of peripancreatic tissue and/or the intrapancreatic bile duct no longer influences pT staging. However, since pT stage will depend entirely upon the size of the tumor, macroscopic assessment, sampling, and microscopic confirmation will become even more important for the pathologist. It may also be extremely difficult to assess tumor size after neoadjuvant therapy (see Sect. 8).

Table 2 Different AJCC/UICC TNM and R classification of the same pancreatic cancer by different pathologists [2, 3, 44, 46]

Tumor is 2.2 cm diameter, limited to the pancreas, invades the intrapancreatic bile duct, directly invades a single peripancreatic lymph node, and is <1 mm from the superior mesenteric artery margin. How would you stage this PDAC?					
TNM 7			**TNM 8**		
Pathologist A	**Pathologist B**	**Pathologist C**	**Pathologist A**	**Pathologist B**	**Pathologist C**
pT3	pT3	pT2	pT2	pT2	pT2
pN0	pN1	pN1	pN0	pN1	pN1
R0	R1	R0	R0	R1	R1
Stage 2A	Stage 2B	Stage 2B	Stage 1B	Stage 2B	Stage2B
AJCC/UICC TNM 7 states that direct extension into a lymph node is pN1 and that the tumor has to be at the resection margin to be R1			AJCC and UICC TNM 8 remove the ambiguity over T classification and state that direct extension into a lymph node is pN1, but AJCC TNM 8 now considers <1 mm to be a positive (R1) margin		

The accuracy of pN staging depends upon the lymph node yield. Inadequate lymph node sampling can lead to understaging [56, 57] and can also influence the lymph node ratio, which is considered by many to be a more powerful prognostic marker than the overall nodal status [58–60]. However, the number of lymph nodes that should be found (and assessed) in a resection specimen is not universally agreed upon [58, 61–63]. AJCC TNM 7 and 8 state that "optimal histological examination of a pancreatoduodenectomy specimen should include analysis of a minimum of 12 lymph nodes" to accurately stage N0 tumors [2, 44]. UICC TNM 7, however, requires a minimum of 10 lymph nodes [3], but this has been increased to 12 lymph nodes in UICC TNM 8 [46], bringing it into line with the AJCC TNM. Australian [26] guidelines have adopted a minimum of 12 lymph nodes, while the Royal College of Pathologists, UK [36], has proposed that a minimum of 15 lymph nodes should be examined.

While all pathologists agree that a discrete tumor deposit within a lymph node that is not contiguous with the main tumor mass should be considered pN1, there is disagreement whether or not direct invasion of a lymph node by the primary tumor should be considered pN1 (Table 2). Direct lymph node invasion, in the absence of a noncontiguous nodal metastasis, occurs in 9–20% of pancreatic resections. Some authors have suggested that direct invasion does not represent a lymph node metastasis and is equivalent to pN0 prognostically [64]. Others have shown that direct lymph node invasion is associated with an outcome equivalent to that of true (i.e., via lymphatic spread) pN1 [65, 66]. Direct extension of primary tumor into lymph nodes is considered pN1 by AJCC and UICC TNM, as well as by existing national guidelines (e.g., Australia, RCPath, UK) [26, 36].

There is controversy over whether extracapsular lymph node spread in pancreatic cancer is a prognostic factor [65, 67]. A very recent meta-analysis suggests that extracapsular spread is common and associated with a poorer prognosis in pancreatic

ductal adenocarcinoma [68]. However, as the authors acknowledge, there is no standard definition of extracapsular lymph node spread, and pathologists will need to sample lymph nodes with all their surrounding fat to enable such assessment, a practice that is not routinely performed by all pathologists.

The clinical significance of lymph node micrometastasis is controversial, particularly because of the different definitions for micrometastasis. The UICC TNM classification introduced the concept of "isolated tumor cells", defined as single tumor cells or small cell clusters that measure $\leq$0.2 mm in greatest dimensions and can be detected on routine H&E staining or by immunohistochemistry [3]. UICC TNM classifies lymph nodes containing isolated tumor cells as negative (pN0), but adds a suffix (i+) to indicate their presence, i.e., pN0(i+). However, many pathologists would consider such lymph node micrometastases as pN1 [53].

The total number of involved lymph nodes significantly influences survival [66]. Two very recent studies have shown that the number of positive lymph nodes is superior to the lymph node ratio in predicting survival in N1 cases and can distinguish N categories that improve prognostic accuracy [69, 70]. Although AJCC and UICC acknowledge in their general rules for TNM staging that N1, N2, and N3 can be used for "increasing number or extent of regional lymph node involvement," the current AJCC/UICC TNM 7 only uses pN0 and pN1 categories for pancreas cancer [2, 3]. UICC TNM 5 (1997) [51] did separate pN1 for pancreas cancer into pN1a (metastasis in a single regional lymph node) and pN1b (metastasis in multiple regional lymph nodes) based, in part, on the work of Hermanek [71]. Subsequently, most authors did not find significant survival differences between these groups, and both UICC TNM 6 (2002) [72] and 7 (2009) [3] have only included pN0 and pN1. The very recent studies of Strobel et al. [69] and Basturk et al. [70] have shown, with examining high numbers of lymph nodes, that the total number of positive lymph nodes is a strong prognostic predictor. AJCC and UICC TNM 8 have now introduced lymph node-positive categories based on the number of positive lymph nodes using the cutoffs of 0 (pN0) versus 1 to 3 (pN1) versus 4 or more (pN2) (Table 1) [44, 46].

Neoadjuvant Therapy

Neoadjuvant therapy is increasingly used in the treatment of patients with potentially resectable pancreatic cancer, especially patients with borderline-resectable disease, and the pathologist provides key outcome parameters in assessing the degree of tumor regression and completeness of excision in the resection specimen.

Following a response to neoadjuvant therapy, there will be a reduction in the number of tumor cells with areas of the tumor replaced by fibrosis. Macroscopic distinction between the tumor, fibrotic areas of tumor regression, and background fibrosis of (chronic or obstructive) pancreatitis can be extremely difficult, if not impossible (Fig. 6) [73]. PDAC has a highly infiltrative growth pattern, and residual tumor may still be present within macroscopically nonneoplastic tissue following neoadjuvant therapy [74]. Therefore, extensive sampling is required to assess the extent and size of the residual tumor and its relationship to the margins. Sampling the

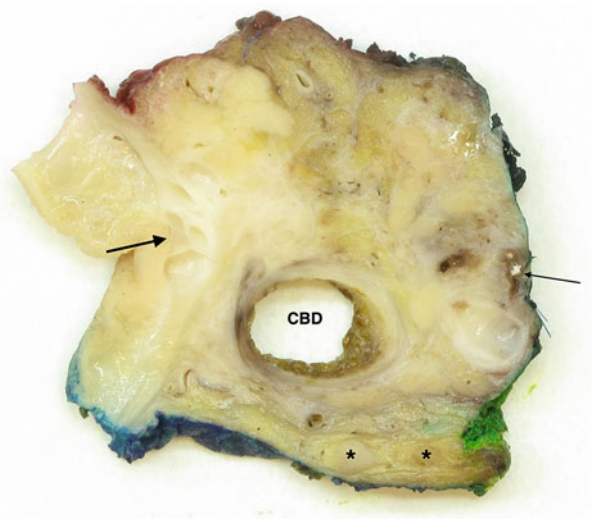

Fig. 6 Axial specimen slice following neoadjuvant therapy. Ill-defined areas of abnormal, fibrous tissue have replaced large parts of the pancreatic parenchyma and the duodenal wall. There are foci of cyst formation (*thick arrow*) and necrosis (*thin arrow*). Note the dilated common bile duct (*CBD*) as a result of metal stenting

entire resected pancreas is recommended to confirm a complete response [74]. Tumor necrosis may be a marker of therapy effect, but it also occurs in untreated cancers and, therefore, cannot be used reliably as a marker of tumor regression [75]. Following neoadjuvant therapy and a good tumor response, the pathologist is unlikely to be able to determine the primary origin of the cancer, and, therefore, bile duct cancers may be included in, and influence, studies of neoadjuvant therapy.

There are several schemes for histologic grading of tumor regression in use, based either on assessment of the amount of tumor destruction or on the amount of residual tumor [32, 75–79]. The prognostic significance of these tumor regression grading systems in post-therapy pancreatectomy specimens is largely unknown. A recent study found that patients with a complete response (Table 3) (Evans grade 4, CAP grade 0) or minimal residual disease (Evans grade 3, CAP grade 1) had better disease-free survival and overall survival than patients with moderate or no response. There was no difference in disease-free survival or overall survival between the CAP grades 2 and 3 [80]. This led the authors to propose a modified CAP grading system (Table 3) [80]. They also found that tumor regression grade is an independent prognostic factor for survival in multivariate analysis.

There are difficulties with these tumor regression grading systems, including reproducibility. Detection of residual tumor cells is straightforward, but there are no morphological features that will clearly delineate viable from nonviable tumor cells. Cytopathic effects can be seen in tumor cells following neoadjuvant therapy, but they can also be detected in untreated tumors that have been affected by inherent tumor-related ischemia [75]. The main difficulty is the assumption that the pathologist can assess the original (pre-therapy) size of the tumor and the extent of the fibrosis that is treatment-induced [74]. Extensive sampling of the resection specimen is essential for this, but distinguishing tumor-related fibrosis from neoadjuvant therapy-induced fibrosis microscopically can be just as difficult as it is macroscopically. Rates of complete

Table 3 Tumor regression grading systems for PDAC

The tumor regression grading system of Evans et al. [77]	
Grade	Extent of tumor cell destruction/residual tumor
I	Little (<10%) or no tumor destruction
2a	Destruction of 10–50% of tumor cells
2b	Destruction of 51–90% of tumor cells
3/ 3M[a]	Few (<10%) viable-appearing tumor cells
4/ 4M[a]	No viable tumor cells
The tumor regression grading system of the College of American Pathologists [32]	
Grade	Proportion of residual viable tumor
0	No viable cancer cells (complete histologic response)
1	Single cells or rare small groups of cancer cells (near complete response)
2	Residual cancer with evident tumor regression, but more than single cells or rare small groups of cancer cells (partial response)
3	Extensive residual cancer with no evident tumor regression (poor or no response)

The tumor regression grading system of Chatterjee et al. [80]	
Grade	Proportion of residual viable tumor
0	No residual cancer
1	Minimal residual cancer (single cells or small groups of cancer cells, <5% residual cancer)
2	5% or more residual cancer

[a]Addition of the M suffix indicates abundant residual mucin pools

tumor regression vary considerably in the literature, with rates ranging from <3% to >30% [74, 80, 81]. These different results are clearly influenced by the extent of tissue sampling from the resection specimen, making it difficult to compare the efficacy of different neoadjuvant therapy regimens in different studies [74].

There is currently controversy over the appropriate minimum clearance to define microscopic margin involvement (R1) in "treatment-naïve" pancreatic cancer specimens (see Sect. 5). With neoadjuvant therapy-induced destruction of tumor cells, the distances between the remaining tumor cells increase, and a minimum clearance of 1 mm cannot guarantee the absence of residual tumor beyond the resection margin [30, 74]. The appropriate minimum clearance following neoadjuvant therapy is unknown, but a distance of 5 mm has been proposed recently [82]. Reported R1 rates post neoadjuvant therapy vary from 0% to 100%, reflecting differences in margin evaluation and definitions of R1 [74].

For tumor staging following neoadjuvant therapy, only the presence of tumor cells in the resection specimen is used to determine the stage. In the current AJCC/UICC TNM 7 [2, 3], many of these post neoadjuvant therapy resection specimens are still staged as pT3 because foci of residual tumor are commonly found in the peripancreatic tissue. Implementation of TNM 8 [44, 46], where T stage for pancreatic cancer is entirely related to tumor size, will pose challenges for the pathologist in the post neoadjuvant therapy resection specimen. When there is only one focus of

residual tumor, the size of this focus can be measured to determine the ypT stage. If, however, there are multiple scattered residual tumor foci in the resection specimen, then is the size (and ypT stage) determined by the size of the largest tumor focus, the sum of the sizes of all of the foci, or the maximum dimension of the area containing residual tumor?

Conclusion

Despite much progress in the diagnosis and treatment of pancreatic cancer, there is still a lack of consensus on the assessment and classification of basic tumor characteristics such as tumor origin, tumor stage, and resection margin involvement. In 2012, Rau et al. [7] highlighted the requirement for an internationally accepted and standardized, but technically and financially feasible, pathology reporting of pancreatic cancer resection specimens. Five years on, there has been some progress, particularly with the updating of national pathology guidelines [26, 32, 36, 37] and the use of pathology reporting proformas. Use of the latter is recognized to facilitate accurate and complete pathology reports [83], but the content of these proformas still differs between the published guidelines.

There are still different protocols in use for handling and sampling pancreas cancer resection specimens, including after neoadjuvant therapy. The International Study Group for Pancreatic Surgery (ISGPS) has endorsed the use of the axial slicing technique [27], but this method is not universally accepted by pathologists. There are differing opinions over what constitutes a resection margin, when the margin should be considered involved, and how many lymph nodes should be examined. Differences in interpretation of T staging of pancreatic cancer using the current AJCC/UICC TNM 7 [2, 3] have largely been overcome by the change to T staging in AJCC/UICC TNM 8 [44, 46]. These rather dramatic changes in T staging criteria reflect the ongoing research and discussion on this important issue but, in turn, introduce new difficulties. TNM 8 is not due for implementation until January 2018. It remains to be seen whether these recent changes to TNM will correlate better with patient outcome. There still remains a need for international consensus on many aspects of pancreatic cancer pathology reporting.

Staging and Postoperative Outcomes Using the International Study Group of Pancreatic Surgery (ISGPS) Classifications

T. Welsch and J. Weitz

Contents

Abstract

The International Study Group of Pancreatic Surgery (ISGPS) established consensus definitions of postoperative pancreatic fistula (POPF), postpancreatectomy hemorrhage (PPH), and delayed gastric emptying (DGE) and thereby covered the major specific complications of pancreatic surgery. A threefold increase of the amylase content in abdominal wound drains compared with serum level on or after the third postoperative day defines POPF; early and late (>24 h) PPH is defined by mild and moderate bleeding according to the drop of hemoglobin or the need for transfusion requirement, and the inability to tolerate solid oral intake after the first postoperative week defines DGE. All three consensus definitions are classified into three grades: A, B, and C. These grades stratify the clinical effect (the illness of the patient and the need for intervention), associated mortality, hospital stay, and economic costs. All definitions have been validated using large cohorts of patients and show different outcome data at different centers, even

when high-volume centers are compared with each other. A minor degree of equivocacy of the original definitions is also acknowledged. The clinically relevant grades are most important, and the prevalence of grade B/C complications based on the ISGPS definitions occurs at the following median rates: 12–20% (POPF), 2–11% (PPH), and 6–17% (DGE).

Pancreatic surgery · Postoperative pancreatic fistula · Postpancreatectomy hemorrhage · Delayed gastric emptying · Definition

Introduction

There is no doubt that pancreatic surgery carries a relatively high risk of postoperative morbidity. Even at high-volume centers, the overall morbidity is reported at 42–56% and is substantially increased if pancreatic surgery is performed as multivisceral or extended resection [1, 2]. The most critical surgical complications are postoperative pancreatic fistula (POPF), postpancreatectomy hemorrhage (PPH), and delayed gastric emptying (DGE), which may all be related to the surgical technique but likewise may be interrelated with each other. The latter two frequently occur as a sequela of an established POPF. Because the surgical technique, surgical experience, and patient selection can significantly modulate the prevalence of the previously mentioned surgical complications, these complications have had and are still exerting an immense effect on surgical research. However, effective research and transparent benchmarking necessitates uniform and unequivocal definitions of the respective complications, i.e., the widespread use of the same "currency." A literature search in the year 2004 identified 26 different definitions of POPF resulting in a significant variation of the calculated prevalence of POPF when applied to a training set of patients [3]. Likewise, the terminology used in different studies was diverse: pancreatic leak, insufficiency, fistula, or postoperative bleeding, hemorrhage, or erosion bleed, to name only a few. In 2005, the International Study Group of Pancreatic Surgery (ISGPS) sought to put an end to the diversity and confusion of postpancreatectomy complications when publishing the consensus definition for POPF [4]. The final consensus definition was simple and easy to assess and use, and the severity based on the clinical effect was weighted into three grades: A, B, and C. Two years later, the ISGPS consensus definitions of PPH and DGE were published, and a grading A–C was introduced accordingly. Since then, the three ISGPS definitions have changed pancreatic surgery reporting and research tremendously. The present chapter underlines that the ISGPS consensus definitions have become a pivotal pillar of pancreatic surgery and enable differentiation of patient illness, hospital stay, or costs. It also becomes clear that the ISGPS definitions may require minor revision for further improvement of their use.

Postoperative Pancreatic Fistula

The ISGPS definition has been well accepted and adopted for the staging of patients with POPF. The original consensus definition publication in 2005 [4] has been cited 1,762 times (until June 9, 2016), with an average number of citations per year of 147 (Fig. 1), making it one of the most cited articles in surgical research. According to the original publication, POPF is defined as "drain output of any measurable volume of fluid on or after postoperative day 3 with an amylase content greater than three times the serum amylase activity" [4] (Table 1). Three different grades, A, B and C, delineate the effect on the patients' clinical course and are summarized in Table 1. Briefly, grade A fistulas are asymptomatic and require no change in clinical management; grade B fistulas prompt diagnostic, medical, or interventional adjustment of the standard management (e.g., antibiotics, somatostatin analogs, computed tomography [CT] scan, drain replacement), whereas patients with grade C fistulas are generally critically ill and require a major change in management and potentially a surgical reoperation plus intensive care. However, the original definition is equivocal with respect to the discrimination of grade B/C fistulas. Although the text reads that a postoperatively placed CT-guided drainage of an intra-abdominal fluid

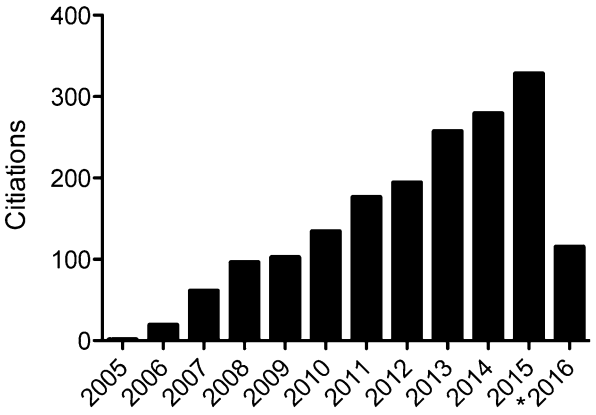

Fig. 1 Annual citations of the consensus definition of POPF since its original publication in 2005. The data were obtained from the Web of Science database. In total, there were 1,762 citations and an average number of citations of 146.8 per year. *As of June 2016

Table 1 ISGPS definition of POPF (Modified from Bassi et al. [4])

Definition		Drain output of any measurable volume of fluid on or after postoperative day 3 with an amylase content greater than three times the serum amylase activity		
Grade		Clinical condition/US/CT finding	Specific treatment/ intervention	Hospital stay
	A	Well/negative	No	Not prolonged
	B	Often well/negative or positive	Usually yes/drainage	Usually prolonged
	C	Ill appearing/positive	Yes/reoperation	Prolonged

CT computed tomography, *US* ultrasound

Table 2 ISGPS definition of PPH (Adapted from Wente et al. [17])

Grade	Time of onset and severity[a]		Clinical condition	Therapeutic consequence
	Early (≤24 h)	Late (>24 h)		
A	Mild		Well	No
B	Severe	Mild	Often well/ intermediate/very rarely life-threatening	Transfusion of fluid/blood, intensive care unit (or ICU), therapeutic endoscopy, embolization, relaparotomy for early PPH
C		Severe	Severely impaired, life-threatening	Localization of bleeding, angiography, and embolization (endoscopy) *or* relaparotomy, ICU

	Mild	Severe
Blood loss	Decrease in hemoglobin concentration <3 g/dl	Decrease in hemoglobin concentration by ≥3 g/dl
Volume resuscitation/blood transfusions	Volume resuscitation or blood transfusions (2–3 units of packed cells within 24 h of the end of operation or 1–3 units if later than 24 h after operation)	Clinically significant impairment (e.g., tachycardia, hypotension, oliguria, hypovolemic shock), need for blood transfusion (>3 units of packed cells)
Need for invasive (interventional or operative) treatment	No	Yes

[a]Severity of PPH

collection characterizes a grade C fistula, Table 2 of the original publication indicates that grade C fistulas require surgical re-exploration [4]. Consequently, some studies categorized patients with postoperative, interventional CT drainage but without re-exploration as grade B and others as grade C, leading to different outcomes. A recent retrospective analysis of 2,955 patients after pancreatic surgery at a high-volume center with a total POPF rate of 13.6% (grades A–C) proposed that cases with interventional drainage, but without re-exploration, should be assigned to grade B, and cases with surgical re-exploration be assigned to grade C only. The rationale was a significant increase in the hospital stay and POPF-associated mortality (37%) if a reoperation was performed [5]. Therefore, a future revision of the consensus definition might consider these data to minimize equivocacy.

Regardless, previous studies have demonstrated that the different grades A–C of the ISGPF definition discriminate well among the clinical condition of the patient, the need for a change in management, the associated hospital stay duration, and the economic burden [6–8]. The hospital stay duration was 8, 13, and 35 days in a US medical center and 11–15, 22–24, and 39–46 days in European centers in grade A, B, and C fistula cases, respectively. The respective associated total hospital costs were calculated to be approximately $18,100/$25,200/$119,100 and €11,700/€25,700/€59,500 for grades A, B, and C, respectively [6–8].

Before the introduction of the consensus definition, the prevalence of POPF varied significantly among different centers and was reported between 2% and 20%, and even higher [4]. The uniform use of the ISGPS definition enables meta-analysis of various studies to determine the actual POPF rate for benchmarking. One such meta-analysis was published in 2014 and included articles until the year 2011 [1]. By the year 2011, over 70% of the publications reporting on POPF had used the ISGPS consensus definition. In total, the meta-analysis identified more than 50 studies that used the ISGPS POPF definition. The analyzed studies included more than 13,000 patients after pancreatic resections. The median POPF prevalence (grades A–C) of these studies was 21.9% in retrospective and 28.6% in prospective studies [1]. Interestingly, the prevalence of symptomatic and clinically relevant grade B/C fistulas was almost equal in both study groups (12%). If a subgroup analysis was performed according to the type of surgical resection (pancreatoduodenectomy versus distal pancreatectomy), there was still a lower overall POPF prevalence in retrospective studies in the two subgroups, and prospective studies reported POPF at 26.1% (pancreatoduodenectomy) and 36.1% (distal pancreatectomy). The latter data originate from the DISPACT trial, analyzing the closure technique of the pancreatic remnant after distal pancreatectomy in a randomized, controlled design, in which the prevalence of grade B/C POPF alone was 20.5% [9].

A more recent German multicenter, randomized, controlled trial including only pancreatic head resections at academic high-volume centers (i.e., the RECOPANC trial) compared pancreaticogastrostomy with pancreatojejunostomy, and the primary outcome of the trial was the prevalence of clinically relevant grade B/C POPF [10]. Interestingly, grade B/C POPF was observed in 21% of the patients, and there was no significant difference between the two surgical techniques. The data from the two multicenter trials DISPACT and RECOPANC indicate that the rate of grade B/C fistulas is approximately 20% and had most likely been underreported in previous trials (e.g., 12%). Reasons for this discrepancy could be a less accurate monitoring in prospective or irregular data collection in retrospective trials.

The ISGPS definition of POPF also contributes to improving the data quality of studies investigating the prophylactic use of somatostatin analogs for the prevention of POPF. This controversial topic still lacks solid data because only a few of the many studies on prophylactic somatostatin analogs have applied the ISGPS definition, and most studies were in fact conducted before 2005 [8, 11]. There was only one adequately powered, randomized, controlled trial in recent years that considered the ISGPS definition, unfortunately as a secondary outcome [8, 12]. In this unicenter trial, the novel somatostatin analog pasireotide was shown to significantly lower grade B/C POPF compared with placebo treatment (7.9% versus 16.9%, $P = 0.02$) [12]. Future trials will add more evidence to prophylactic somatostatin analog treatment using the ISGPS definition.

In summary, the ISGPS definition of POPF was a major contribution to academic pancreatic surgery and is considered the international standard for data assessment and reporting. Minor modification of the exact definition of the different grades will further improve its discrimination of the clinical and economic effect. Accurate

documentation of the POPF variables (the amylase content of wound drains on or after the third postoperative day, the need for specific treatment or intervention, and the clinical condition of the patient) and exact application of the definition result in approximately 20% of grade B/C fistulas (no specific patient selection) with current best medical practice. If cases with reoperation for POPF will be classified as grade C only, then most of the 20% will be grade B fistulas.

Postpancreatectomy Hemorrhage

The definition of postpancreatectomy hemorrhage (PPH) is more complex compared with the POPF definition and requires a subdivision. It is defined by three parameters: onset ($\leq$24 h [early PPH] or >24 h [late PPH] after the index operation), location (intra- or extraluminal), and severity (mild or severe) [13]. Based on these parameters and the clinical effect, PPH is categorized into the three grades: A, B, and C (Table 2). The PPH definition had been cited 368 times between 2007 and 2016, with an average number of citations of 36.8 per year (Fig. 2). Nevertheless, the meta-analysis and review of the ISGPS consensus definitions by Harnoss et al. found that the acceptance of the PPH definition was lower compared with the POPF and DGE definitions by the year 2011 and was cited by approximately 20% of research articles reporting on PPH issues [1]. The reason for the lower acceptance is not obvious, because the definition logically characterizes and distinguishes the different types of bleeding. In particular, the clinically relevant PPH grades B/C include early severe PPH, which is often caused by technical (surgical) issues, and late severe PPH (grade C), which is generally elicited by an established POPF and erosion hemorrhage of visceral arteries. Mild late PPH was introduced to cover sentinel bleedings. However, if the definition of mild late PPH is strictly followed (drop of hemoglobin <3 g/dl or transfusion of 1–3 units of packed red blood cells [PRBC] during the hospital course >24 h after the index operation), many more (false-positive) patients in addition to the ones with a sentinel bleed are captured by the definition [14]. Therefore, a

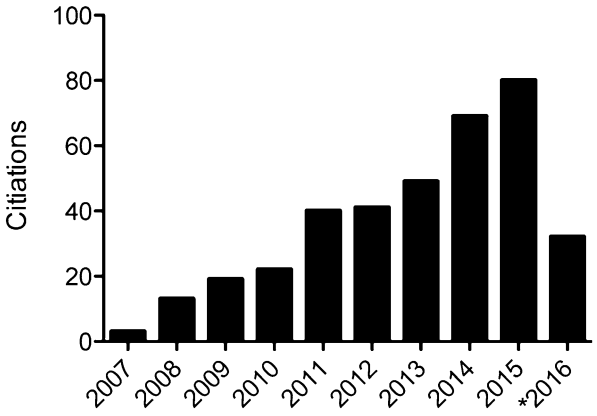

Fig. 2 Annual citations of the consensus definition of PPH since its original publication in 2007. The data were obtained from the Web of Science database. In total, there were 368 citations and an average number of citations of 36.8 per year. *As of June 2016

revision of the definition should be discussed, in which only patients with a novel, small amount of blood loss through the abdominal drains (sentinel bleeding, clinical definition) – regardless of any drop of hemoglobin or a need of transfusion requirement – are considered for the mild late PPH subgroup.

Validation studies of the PPH definition using large high-volume cohorts have demonstrated that the three PPH grades discriminate the cases well among the need for transfusion requirements, intensive care unit stay, hospital stay, and mortality [14, 15]. The prevalence of grade C POPF in the validation studies was 9.2 and 4%, and the associated mortality within this subgroup was 16.4 and >25%, respectively. The review by Harnoss et al. pointed out the difference among the retrospective (7.1%), prospective (2.2%), and validation (24.4%) use of the PPH definition for grades B and C, which prompted further discussion. Although a retrospective assessment of all PPH grades on the basis of databases can miss late mild cases (sentinel bleeding), 2.2% of clinically relevant PPH in prospective studies can be considered a very low benchmark that is not achieved in general – not even by all high-volume centers.

Importantly, the allocation to grade B/C PPH is independent of the management (operative or interventional management) of the hemorrhage, and good data exist that show no significant change in the prevalence of PPH over the last two decades, but a trend toward more interventional management of grade C PPH [16].

In summary, the PPH definition is as important as the POPF definition and discriminates well the clinical effect of the bleeding. The prevalence of clinically relevant grade B/C PPH varies at different centers and patient cohorts and resides between 2% and 11%.

Delayed Gastric Emptying

Delayed gastric emptying (DGE) is a multifactorial complication, and the pathophysiology is still not completely understood. Therefore, the definition of objective and assessable parameters is challenging. The ISGPS defined DGE as the "inability to return to a standard diet by the end of the first postoperative week and includes prolonged nasogastric intubation of the patient" [17]. Analogous to the other ISGPS definitions, the three grades A, B, and C were further defined based on the effect of the clinical course and postoperative management. Briefly, grade A DGE describes patients who are unable to tolerate solid oral intake by the first postoperative week, but require no major change of management or hospital stay. Grade B/C DGE describes the inability to tolerate solid oral intake by the second or third postoperative week and the need for medical or interventional specific treatment, respectively (Table 3). DGE itself is not life-threatening if aspiration is anticipated and avoided. However, grade B/C DGE can frequently mirror intra-abdominal hematoma or fluid collections (e.g., POPF, abscess). Therefore, the ISGPS definition describes patients with grade C DGE in a severe clinical condition and at an increased risk for critical comorbidities.

During the time period from the original publication until the composition of this article (2007–2016), the definition has been cited 562 times, or 56.2 times, per year (Fig. 3). In 2011, the acceptance of the DGE definition was as high as the POPF

Table 3 ISGPS definition of DGE (Adapted from Wente et al. [17])

DGE grade	NGT required	Unable to tolerate solid oral intake by POD	Vomiting/ gastric distension	Use of prokinetics
A	4–7 days or reinsertion > POD 3	7	±	±
B	8–14 days or reinsertion > POD 7	14	+	+
C	>14 days or reinsertion > POD 14	21	+	+

POD postoperative day, *NGT* nasogastric tube

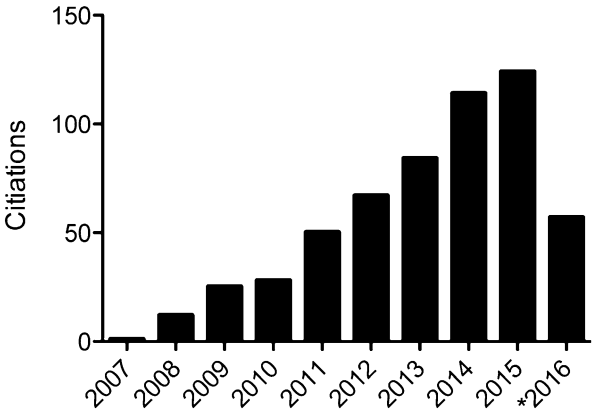

Fig. 3 Annual citations of the consensus definition of DGE since its original publication in 2007. The data were obtained from the Web of Science database. In total, there were 562 citations and an average number of citations of 56.2 per year. *As of June 2016

definition, and approximately 70% of the articles on DGE used the ISGPS definition [1]. However, the ISGPS-based prevalence of DGE was significantly different in prospective (10.8%), retrospective (20.8%), and validation studies (33.3%) [1]. Grade B/C DGE occurred at a median rate between 6 and 17%. The real prevalence of DGE might even be higher. One validation study reported DGE in 44.5% of the cases after pancreatoduodenectomy. The three grades A, B, and C are associated with prolonged total hospital stay and intensive care unit stay [18]. In the United States, the hospital charges increased over $10,000 with each severity grade [19]. It became further evident that the DGE definition is generally feasible and applicable but has limits in patients with prolonged intensive care unit (ICU) stay for other complications (e.g., parenteral nutrition, nasogastric tube placement for endotracheal intubation) [18, 19]. This is the reason why some studies introduced the term "primary DGE" when referring to DGE that is not caused or associated with other obvious complications [19]. A relative high prevalence of DGE was also reported by a recent German multicenter, randomized, controlled trial investigating pancreatojejunostomy and pancreaticogastrostomy (RECOPANC) [10]. In this trial, DGE occurred in 39% of the patients.

The physiology of "primary DGE" is incompletely understood, but data exist to show that surgical technique can affect the prevalence of the ISGPS DGE. Although there are controversial results, the antecolic reconstruction of the gastrojejunostomy appears to lower DGE after classic pancreatoduodenectomy [20, 21]. Some centers have examined the technique of pylorus ring resection over and found a significant reduction in the rate of DGE [22–24]. Furthermore, a recent meta-analysis disclosed that minimally invasive pancreatoduodenectomy also lowered the incidence of DGE [25].

Conclusions

All three ISGPS definitions are logical and feasible and can be considered standard for assessing and reporting POPF, PPH, or DGE. The definitions have been successfully validated, and the different grades discriminate well the clinical effect of the respective complication, which is generally associated with a stepwise increase in hospital stay, intensive care unit stay, mortality rate, and economic costs. There are still discrepant prevalence outcomes of POPF, PPH, and DGE when the ISGPS definitions are applied. These differences can be partly explained by interpretation of the definition or inaccurate data monitoring but also reflect different outcomes in various hospitals and centers. This was the primary aim of the ISGPS definitions: to enable benchmarking of the performance, transparency, and ways for improvement. Each of the three definitions has some minor limitations in its original form and would benefit from some minor modifications.

Borderline Resectable Pancreatic Cancer

Gauri R. Varadhachary

Contents

Abstract

Rigorous criteria are essential to define resectability of PDAC, which allows for accurate pretreatment staging and planning stage-specific therapy. Tumors of borderline resectability have emerged as a distinct subset, and these patients are at a high risk for margin positive resection. The *intergroup* criteria for BRPC includes: (1) an interface between the tumor and SMV–PV $\geq 180^{\circ}$ of the vein circumference; (2) short-segment occlusion of the SMV–PV with normal vein above and below the obstruction amenable to resection and reconstruction; (3) short-segment interface of any degree between tumor and HA with normal

artery proximal and distal to the interface amenable to arterial resection and reconstruction; and (4) interface between the tumor and SMA and/or CA measuring <180° of the circumference of the artery. Two multicytotoxic regimens approved for metastatic disease, 5-flurouracil with oxaliplatin and irinotecan (FOLFIRINOX) and gemcitabine with *nab*-paclitaxel (Gem-*nab*P), are incorporated in the preoperative management of BRPC in many centers although high-level evidence data on these regimens in the neoadjuvant setting are not yet available. Those with radiographic stability or regression and an improvement in serum tumor markers (CA19-9) may proceed to pancreatectomy and may require vascular resection and reconstruction. Prospective clinical trials with well-defined eligibility will help determine the treatment strategies. Additionally, prognostic and predictive biomarkers are urgently needed in therapy planning.

Background

Pancreatic ductal adenocarcinoma (PDAC) is a systemic disease in most patients; two thirds of patients have locally advanced or metastatic disease at the time of diagnosis. Twenty to 25% of patients present with a potentially resectable or borderline resectable pancreatic adenocarcinoma (BRPC). Although over the last two decades, there has been a small improvement in the overall 5-year survival rate of patients undergoing pancreatectomy, there is no seismic shift in the disease free interval and median overall survival of patients undergoing potentially curative resection [1–2]. Beside the concern for micro metastatic disease at the time of attempted curative resection, numerous studies have reported on poor outcomes for patients who undergo an incomplete margin positive resection, with survival similar to patients with locally advanced pancreatic cancer [3–4].

Determining resectability of the primary pancreas tumor is essential to the initial staging evaluation. This is best accomplished by a computerized tomography (CT) scan optimized for pancreatic imaging [5]. Based on this high quality CT imaging, in the past, pancreatic tumors have typically been classified as resectable, locally advanced, or metastatic. In the era of the multidetector CT optimized for pancreatic imaging, tumors of "borderline resectability" have emerged as a distinct subset of PDAC [6–10]. This distinction between resectable and BRPC is crucial to plan appropriate management algorithms that impact patient' quality of life, clinical trial designs, and eventual survival. The attempt to standardize the definition of BRPC is work in progress and has made strides in the last decade. The criteria have been modified over time, beginning with descriptions from M. D. Anderson Cancer Center (MDACC), followed by National Comprehensive Cancer Network (NCCN), and consensus conferences, the first being sponsored by the

AHPBA/SSAT/SSO and lastly with the intergroup definition which is used in currently planned prospective trials in the United States [11]. Additionally, in the last several years, two multicytotoxic regimens are approved for the management of metastatic disease, 5-flurouracil with oxaliplatin and irinotecan (FOLFIRINOX) and gemcitabine with *nab*-paclitaxel (Gem-*nab*P), and these have been incorporated in the preoperative management of BRPC with a neoadjuvant intention [12–13]. Here in, the author reviews the working definition of BRPC, including the anatomic and patient-related factors that constitute borderline resectable tumors and provide a framework for management of patients with tumors of borderline resectability. Given the lack of adequate multi-institutional prospective data, and the intrinsic heterogeneity of the disease entity, there is ongoing debate with respect to upfront resection in select patients vs. sequencing and duration of neoadjuvant therapies, standardization of surgical techniques, patient selection, and role of novel agents and biomarkers.

Preoperative Staging for Resectable and BRPC and the Role of the Multidetector CT Scan

Several modalities have been employed for the preoperative staging of pancreatic cancer including multidetector computerized tomography (MDCT), endoscopic ultrasound (EUS), endoscopic retrograde cholangiopancreatography (ERCP), magnetic resonance imaging (MRI), magnetic retrograde cholangiopancreatography (MRCP), and serum tumor markers [14–17]. There is a consensus that MDCT optimized for pancreatic imaging is the best modality to determine local tumor resectability [18]. The main limitation of this technique is its low sensitivity for low-volume hepatic or peritoneal metastases. Studies suggest that in approximately 20% of the patients who have a potentially resectable or BRPC on MDCT preoperatively, CT occult metastatic disease is found on exploration [19–20], and therefore selective application of laparoscopy and laparoscopic ultrasound is commonly performed in high volume cancer centers. It is beneficial, whenever possible, to perform a CT scan prior to biliary decompression procedures since postprocedure pancreatitis, if it occurs, may obliterate the vascular planes and preclude accurate assessment of the extent of disease. The MDCT post-processing techniques such as maximum intensity projection (MIP) images and volume rendering can help identify important vascular variants. In patients in whom CT scan suggests an isodense mass in the pancreatic head, EUS with EUS fine needle aspiration (EUS-FNA) and biopsy can confirm the diagnosis without a significant risk of acute pancreatitis and also define the relationship of the tumor to the surrounding vasculature. Raut and colleagues reported retrospective data on EUS-FNA in 233 patients who presented with CT evidence of a pancreatic mass or a malignant biliary stricture [21]. In this series, a diagnosis of cancer was established in 216 patients (93%); 15 patients (6%) were found to have benign disease, and the final diagnosis remained unknown in two patients (1%). The sensitivity, specificity, and accuracy of EUS-FNA for diagnosis of a pancreatic malignancy were 91%, 100%, and 92%, respectively.

BorderlineResectable Pancreatic Cancer: Definitions and CT Based Criteria

The purpose to establish objective radiographic criteria is to allow decisions regarding tumor resection to be made by a multidisciplinary group working jointly rather than it being purely a surgeon's prerogative with a decision made at the time of laparotomy. The definitions have evolved to remove inexact terms like "impingement", "abutment," and "involved." These definitions are very important for standardization, and therefore the conduct of clinical trials involving the use of preoperative or adjuvant therapies.

NCCN describes borderline resectable pancreatic head (and body) cancer as tumor abutment on SMA, severe unilateral SMV or PV impingement, gastroduodenal artery (GDA) encasement up to its origin from the hepatic artery, or colon and mesocolon invasion [10]. At MDACC, patients with borderline resectable pancreatic cancer include those whose tumors exhibit: short-segment encasement of the hepatic artery which is amenable to resection and reconstruction without evidence of tumor extension to the celiac axis; abutment of the SMA to involve $\leq 180^\circ$ of the circumference of the artery; or short-segment occlusion of the SMV, PV, or SMPV confluence with a suitable option for vascular reconstruction due to a normal SMV below and PV above the area of tumor involvement. The AHPBA, SSO, and SSAT Consensus Conference (2008) definition includes tumor associated deformity of the SMV–PV, abutment of the SMV–PV $\geq 180^\circ$, short-segment occlusion of the SMV–PV amenable to resection and reconstruction, short-segment involvement of the hepatic artery (HA) or its branches amenable to resection and reconstruction, and abutment of the SMA ($<180^\circ$). Most recently, several cooperative groups, including the Southwest Oncology Group, (SWOG) Eastern Cooperative Oncology Group (ECOG), and Radiation Therapy Oncology Group (RTOG), proposed a definition referred to as the *intergroup definition*, and it was used for the completed Alliance pilot trial (A021101) using preoperative modified-FOLFIRINOX followed by capecitabine based, 5040 Gy external beam radiation therapy prior to intended surgery. The intergroup criteria consists of the following: (1) an interface between the tumor and SMV–PV $\geq 180^\circ$ of the vein circumference; (2) short-segment occlusion of the SMV–PV with normal vein above and below the obstruction amenable to resection and reconstruction; (3) short-segment interface of any degree between tumor and HA with normal artery proximal and distal to the interface amenable to arterial resection and reconstruction; and (4) interface between the tumor and SMA and/or CA measuring $<180^\circ$ of the circumference of the artery (11).

Anatomic CT Based Criteria for Borderline Resectable Pancreatic Cancer: (Defined as MDACC, Type A)

Interface Between the Tumor and SMA/CA Measuring $<180^\circ$ of the Circumference of the Artery

Multiple groups have defined the tumor vessel orientation in PDAC over the last 20 years. The older classification, reported by Loyer and colleagues, categorizes the

extent of tumor abutment of the vessel wall from type A to type F [22]. In type A, there is a fat plane around the vessel; in type B, normal pancreatic parenchyma separates the tumor from the vessel; in type C, the tumor is inseparable from the vessel but the points of contact form a convexity against the vessel; in type D, partial encircling of the vessel is present and the contact point forms a concavity against the vessel wall; in type E, the tumor is completely encasing the vessel; and in type F, the tumor is completely occluding the vessel. This classification system describes tumor-vessel relationships and does not differentiate between venous and arterial involvement.

Lu and colleagues reported an alternate grading system where tumor involvement of the PV and SMV and the celiac axis, hepatic artery, and SMA is graded on a 0–4 scale based on circumferential contiguity of tumor to vessel [23]. Based on this grading system, no tumor contiguity to a vessel denotes grade 0. In grade 1, tumor is contiguous to less than one-quarter circumference of the vessel; in grade 2 the tumor is contiguous between one-quarter and one-half of the circumference; in grade 3, between one-half and three-quarters circumference; and in grade 4, the tumor contiguity is greater than three-quarters circumference of the vessel or there is vessel constriction. Using this system, they evaluated 25 patients with pancreatic adenocarcinoma who underwent preoperative pancreatic-phase thin-section helical CT followed by pancreaticoduodenectomy. Surgical results were then correlated with the CT grading system and evaluation was possible for 80 vessels. All vessels graded 0 (48 vessels) or 1 (3 vessels) were resectable, and most of those graded 3 (7/8 vessels) and all of those graded 4 (14/14 vessels) were unresectable. A threshold between grades 2 and 3, which corresponded to tumor involvement of one-half circumference of the vessel, yielded the lowest number of false-negatives and an acceptable number of false-positives for unresectability. The authors concluded that such a threshold would have yielded a sensitivity of 84%, a specificity of 98%, a positive predictive value of 95%, and a negative predictive value of 93% for unresectability of the cancer based on the vessels studied. They concluded that if tumor involves more than one-half the circumference of the vessel, it is highly specific for unresectable tumor. However, the authors did not have a standardized approach to vascular resection and there was no reported pathologic data on resection margin status (R0 vs. R1/2), making it difficult to interpret these results. In another study by Saldinger and colleagues, helical CT and CT angiography with three-dimensional reconstruction prospectively staged a total of 100 patients with periampullary neoplasms [24]. Vascular involvement was graded from 0 to 4, with grade 0 representing no vascular involvement and grade 4 representing total encasement of either the SMA or SMV. Resectability rates for grades 0, 1, 2, and 3 were 96%, 100%, 50%, and 9%, respectively, for an overall resectability rate of 76%. Valls and colleagues have reported on the presence of "reticular opacities," which are small strands arising from the tumor and abutting the vessels in some of their patients [25]. This appearance may have more significance in the setting of preoperative therapy if one believes that less viable tumor tissue may be present around the vessels after chemoradiation.

Observations from these early radiology studies and fine tuning of BRPC criteria have led experts to objectively define tumors with $\leq 180^{\circ}$ of arterial abutment

(≤50% circumferential involvement) as BRPC. As discussed below, these tumors with arterial involvement require a multimodality approach to their disease to help achieve an R0 margin resection.

Short-Segment Interface of Any Degree Between Tumor and HA

Limited or "short-segment" encasement of the common hepatic artery or the proper hepatic artery, typically at the gastroduodenal artery origin, is also included in the definition of BRPC. These patients are often candidates for vascular reconstruction with grafting. In selected patients, segmental resection with primary end-to-end anastomosis can be performed to achieve an R0 resection.

An Interface Between the Tumor and SMV–PV ≥180° of the Vein Circumference OR a Short-Segment Occlusion of the SMV–PV with Option for Reconstruction

In most patients, occlusion of the SMV or SMPV confluence by tumor suggests SMA or celiac axis involvement as well, given the proximity of the SMV to the SMA. Unfortunately for most patients, occlusion of the SMV precludes surgery since there is no patent vessel above and below the occlusion to allow interposition grafting. In a small select group of patients, short segment occlusion of the SMV with sufficient venous flow above and below the occlusion may allow them to be categorized as having BRPC. In a retrospective study recently published by Tseng and colleagues from MDACC, 141 patients who underwent vascular resection (VR) (these were not all segmental occlusions) at the time of PD were compared with patients who underwent standard PD without vascular resection [26]. Median survival was similar in both groups (23.4 months in the group that required VR and 26.5 months in the group that underwent standard surgery; $P = 0.177$). Seventy percent of patients in both groups received preoperative chemoradiation. Patients with R0 versus R1 margin had similar survival, and the authors believe this was due to the use of neoadjuvant therapy as well as meticulous margin analysis (i.e., all the R1 margin resections were truly R1 and not R2 resections). Considering the results of this retrospective study, these patients also benefit from preoperative therapy and the role of radiation is less clear.

Expanded Criteria for Borderline Resectable Pancreatic Cancer: MDACC Types B and C

Katz and colleagues have described two additional subsets, types B and C, which define borderline resectable cancer beyond the tumor-vessel orientation and anatomic criteria [27]. Most physicians have come across patients with localized pancreatic cancer who are not ready for immediate surgery. Some of these patients have subtle indeterminate subcentimeter liver or omental lesions that are suspicious for metastatic disease but the lesions are too small for FNA- biopsy or additional imaging tests (PET-CT or MRI). These patients fit the MDACC type B definition of BRPC. Type B patients may have a technically resectable or a borderline resectable

primary tumor as defined on CT images. Another subset of patients are those who have associated medical comorbidities that need further time consuming evaluation or they have a poor performance status (typically ECOG 3), albeit reversible but still risky to proceed with up-front surgery. A good example of this presentation is a patient who has had a significant decline in nutrition and performance status in the presence of obstructive jaundice and cholangitis and a steady improvement is expected after biliary decompression, better nutritional supplementation, and supportive care. This constitutes MDACC Type C subset, and patients in this category may also have had a radiographic potentially resectable or a borderline resectable primary tumor.

Role of Preoperative Therapy in Patients with Borderline Resectable Pancreatic Cancer (Types A, B, C)

Adjuvant and metastatic trials inform preoperative trials: Current trials of adjuvant therapy have clearly demonstrated a small but absolute benefit of systemic therapy for the prevention of disease recurrence. The assumption is that this benefit derives from treatment of microscopic disease that is neither clinically or radiographically apparent. The ESPAC and CONKO results have established fluoropyrimidine and gemcitabine-based chemotherapy regimens as effective in the adjuvant setting [2, 27–30]. Additionally, early preoperative trials in resectable pancreatic cancer were the building blocks to augment the rationale for neoadjuvant therapy in pancreatic cancer and for the management of BRPC [31–34]. Finally, prospective data from metastatic disease is extrapolated into locally advanced and from there, BRPC neoadjuvant setting.

***Rationale in BRPC*:** The rationale for pursuing preoperative treatment for a patient with BRPC is similar to patients with potentially resectable pancreatic cancer although with a greater emphasizes on maximizing R0 resection. Additional justification for preoperative therapy includes treating micro metastatic disease early, giving majority of the "adjuvant" therapy in a "neoadjuvant" setting when it is better tolerated. Using this approach to gauge the aggressiveness of the cancer selects patients for surgery who have the greatest likelihood of a favorable postoperative outcome especially given the morbid nature of the surgery. Data also suggests that preoperative chemoradiation may decrease the incidence of pancreaticojejunal anastomotic fistula, a common complication following PD or distal pancreatectomy. Therefore, although the sequencing and duration of preoperative treatment modalities remain elusive, most agree that a treatment schema that incorporates systemic chemotherapy with/without chemoradiation is the optimal strategy for BRPC, and this notion has been embraced by several institutions and high volume pancreatic cancer centers. At MDACC, for nonprotocol patients, patients with BRPC are presented in the multidisciplinary conference with radiology review of the pancreas protocol optimized CT; patients are categorized as borderline resectable types A, B, C, or a combination of these. A restaging CT scan is reviewed after approximately 8–10 weeks of systemic therapy. Patients with radiographic response or a

biochemical response in the presence of stable disease are candidates for more systemic therapy followed by chemoradiation or may proceed to chemoradiation or surgery [35]. If radiated, after a break of 4–6 weeks from their radiation therapy, patients who continue to show disease stability or response are candidates for surgery. The duration of systemic therapy and role of chemoradiation depends on the concern for micrometastatic disease (CA19-9, indeterminate extrapancreatic lesions) and confidence to proceed with margin negative resection (RT in select patients, if concern for R1 margin).

Retrospective Preoperative Data for Management of BRPC (Type A)

Katz et al. published the first large retrospective report of BRPC; 160 patients were identified as having BRPC and of these, 125 (78%) received preoperative therapy with mostly chemotherapy followed by chemoradiation and 66 (41%) underwent PD. [7] Twenty-seven percent (18 of 66) required vascular resections and in 94% of the patients this was an R0 resection. The median survival was 40 months for patients who underwent preoperative therapy followed by surgery and 13 months for patients who did not undergo PD ($p < 0.001$). When compared to patients who had an increase in their serum CA19-9 level over the course of induction therapy, patients whose serum CA19-9 fell were more likely to undergo pancreatectomy. The percent change in CA19-9 over the course of neoadjuvant treatment was associated with overall survival. When compared to patients who had a $> 50\%$ decrease in serum CA19-9, patients with an increase in serum CA19-9 had a greater than twofold risk of death (HR $= 2.4$, $p = 0.020$). These numbers are small though suggest that CA19-9 along with the imaging studies and host factors play a role in deciding resectability.

Chun et al. [36] reported the impact of neoadjuvant chemoradiation on margin negative resection in borderline resectable cases involving the portal or superior mesenteric vein (PV-SMV). They compared 74 preoperatively treated patients to 35 that received upfront surgery. Of those treated, 78% received gemcitabine-based chemoradiation while 22% received 5-FU based chemoradiation. They found improved survival with chemoradiation in patients with unilateral involvement of the PV-SMV (Ishikawa type II and III); however, there was not a significant survival benefit with bilateral involvement (Ishikawa type IV and V). Overall, preoperative therapy and margin negative resection status both were associated with improved survival in these cases involving the PV-SMV.

Stokes and colleagues [37] evaluated patients with borderline resectable disease by the MDACC classification who were treated with preoperative capecitabine with radiation. Among the 40 B.P. patients, 85% completed therapy and 16 underwent resection. R0 resection was achieved in 75% of surgical cases. The authors conclude that capecitabine-based chemoradiation is well tolerated and effective in selecting patients most likely to benefit from surgery.

Chuong and colleagues [38] reported sequential induction with 3 cycles of chemotherapy followed by SBRT in a cohort of BRPC patients. About 66% of patients received a combination of gemcitabine, docetaxel, and capecitabine (GTX), and the majority received gemcitabine-based therapy. Of those treated, 56% went to

surgery and 97% of those achieved an R0 resection. Among these, three patients had a pathologic complete response (pCR) and one had a near pCR.

Several small trials have reported positive outcomes with FOLFIRINOX in the preoperative setting [39–40]. Paniccia reported on a small retrospective cohort of patients who received FOLFIRINOX. Approximately half received only chemotherapy while the rest received chemotherapy followed by chemoradiation. Approximately, 90% of patients completed chemotherapy. About 85% underwent resection and all those patients achieved R0 resection. A systematic review of FOLFIRINOX in BRPC and locally advanced pancreatic cancer suggests a response rate of ~25–30% in the primary tumor although this is mostly investigator reported data [41].

These retrospective single institution studies yield valuable information, although have several limitations including unclear BRPC criteria and multiple neoadjuvant approaches. As such, it is difficult to determine what components of chemotherapy or chemoradiation are providing the most benefit. Fortunately, results from small prospective trials are emerging and several ongoing larger randomized controlled trials will further help evaluate the best sequence and duration of preoperative regimens in a background of homogenous BRPC population.

Prospective Trials in BRPC and Current Ongoing Studies

Select gemcitabine-based prospective trials: Sahora et al. published the results of two separate phase-II studies with neoadjuvant gemcitabine plus either oxaliplatin or docetaxel. In the gemcitabine and oxaliplatin (GemOx) study [42], patients received 6–9 weekly doses of GemOx with restaging and surgical exploration if evidence of response on imaging or clinically. Of the 15 patients who were classified as borderline resectable at enrollment, 47% underwent surgical exploration. R0 resection rate was 69%, and median survival was 22 months for resected versus 12 months for unresected patients. The gemcitabine and docetaxel (GemTax) trial [43] treated patients with 8 weeks (2 cycles) of GemTax prior to restaging. Patients with partial response or stable disease with improved clinical condition were taken for surgical exploration. Of the 12 patients with BRPC at study entry, 7 (58%) underwent surgical exploration and ultimately 4 (33%) were resected with curative intent. The overall R0 resection rate was 87%. Median survival among resected versus unresected patients was 16.3 months versus 12.2 months, respectively.

A separate phase II study examined the role of neoadjuvant dose-dense gemcitabine and capecitabine (GX) in locally advanced pancreatic cancer [44]. Treatment typically consisted of 2 weeks of weekly gemcitabine and daily capecitabine on a 3 week cycle (average number of treatment cycles was three). Per protocol, patients were classified as BRPC based on NCCN criteria, and 18 B.P. patients were enrolled along with 23 LAPC patients. A total of 11 (61%) underwent surgical resection and 9 of 11 (82%) were R0 resections. Interestingly, the authors also analyzed patients based on Asian Pancreatobiliary Cancer Center (APBCC) criteria, which results in 33 out of 43 patients being classified as borderline resectable. With broader inclusion criteria, a smaller proportion of patients (46%) underwent resection, yet a greater number, 13 of 15 (87%), were R0 resections. The median survival of resected

patients was 23.1 months compared with 13.4 months in unresected patients. This trial also demonstrates the importance of standardization of BRPC criteria.

In another study, 35 B.P. patients were treated with combination S-1 with gemcitabine. Twenty seven patients had no evidence of distance metastatic disease at time of resection and had a median survival of 35 months compared with 10 months for those with unresectable or metastatic disease [45]. The internal variability of results based on the borderline resectable classification system demonstrates the challenge of comparing results between trials.

Predominant chemoradiation trials: Mehta and colleagues conducted the earliest prospective trials of preoperative chemoradiation in patients with borderline resectable characteristics. Specifically, they enrolled patients with pancreatic adenocarcinoma who had >1 cm of tumor abutment, but <180° involvement of the PV, SMV, or SMA [46]. Patients received protracted 5-FU infusion with concurrent radiation totaling between 50.4 and 56 Gy. Of those treated, 60% underwent surgery, all with R0 resection and had a median survival of 30 months compared with 8 months for the remaining unresected patients.

Landry et al. reported on a randomized phase II trial comparing neoadjuvant regimens although trial was closed for poor accrual (total 21 patients) [47]. In Arm A, 10 patients received gemcitabine-based chemoradiation, and in Arm B, 11 patients received induction chemotherapy using gemcitabine + cisplatin +5-FU followed by chemoradiation with 5-FU. Three patients in Arm A and two patients in Arm B were resected. The median survival of resected patients was 26.3 months. All patients received adjuvant gemcitabine for five cycles.

A study by Takahashi et al. investigated a regimen of gemcitabine-based chemoradiation followed by gemcitabine in resectable and borderline resectable patients [48]. Of 80 B.P. patients, resection rate was 54%, and among those resected 34% were alive at 5 years. Notably, distant and peritoneal recurrence was significantly higher in the BRPC group than the baseline resectable cohort. Given higher rates of recurrence, borderline resectable patients may benefit from higher intensity chemotherapy regimens in the neoadjuvant setting.

Another trial of chemoradiation therapy with S-1 enrolled 28 patients, 25 of whom completed treatment. About 24 (85.7%) underwent surgical resection and all achieved R0 resection [49]. The large phase III trials of S-1 have taken place in Japan and there are concerns about how the toxicity profile, particularly in Western populations, may limit utilization of this drug in the Western continents. These results are encouraging, and trials of S-1 compared with the more aggressive and established neoadjuvant regimens are warranted.

FOLFIRINOX-based preoperative trials: FOLFIRINOX is commonly used in locally advanced pancreas cancer and given that BRPC bridges the continuum of resectable and LAPC, even without prospective data, the regimen is frequently used in patients with good performance status without biliary complications. In a systematic review of FOLFIRINOX trials, there were patients with BRPC and LAPC treated with this regimen for advanced localized PDAC [50]. Thirteen studies comprising 689 patients, of whom 355 (52%) patients had LAPC. Eleven studies, comprising 315 patients with LAPC, reported survival outcomes and were eligible

for patient-level meta-analysis. Median overall survival from the start of FOLFIRINOX ranged from 10.0 months (95% CI 4.0–16.0) to 32.7 months (23.1–42.3) across studies with a pooled patient-level median overall survival of 24.2 months (95% CI 21.7–26.8). In eight studies, 154 (57%) of 271 patients received radiotherapy or chemoradiotherapy after FOLFIRINOX. The pooled proportion of patients who received any radiotherapy treatment was 63.5% (95% CI 43.3–81.6, I(2) 90%). The proportion of patients who underwent surgical resection for LAPC (likely including all with BRPC criteria) ranged from 0% to 43%. In 12 studies, 91 (28%) of 325 patients underwent resection after FOLFIRINOX. R0 resection was reported in 60 (74%) of 81 patients. Given the heterogeneity, selection bias, improvements in perioperative care, and surgical skills, the added benefit of any specific modern regimen over another is difficult to interpret although all would agree that multicytotoxic therapy has likely moved the therapeutic needle compared to gemcitabine alone in the preoperative setting [51].

The only published prospective data using strict criteria is from Alliance A021101 intergroup trial for BRPC with preoperative FOLFIRINOX followed by capecitabine-based chemoradiation [52]. Twenty-nine patients were registered and 22 initiated therapy. Although 14 of the 22 patients (64%) had grade 3 or higher adverse events, 15 of the 22 patients underwent pancreatectomy. About 80% required vascular resection, 14 (93%) had microscopically negative margins, 5 (33%) had specimens that had <5% residual cancer cells, and 2 (13%) had specimens that had pathologic complete responses. The median overall survival of all patients was 21.7 months from registration.

Novel prospective trials: BRPC is an attractive platform for novel agents added to cytotoxic therapy since the resected tissue allows for extensive pharmacodynamics and pharmacogenomics and whole tumor mapping studies not feasible with core biopsies. An example is PF-04136309, a chemokine receptor type 2 (CCR2) antagonist which was studied in BRPC [53]. Activation of CCR2 mobilizes monocytes and macrophages from the bone marrow to infiltrate malignant tumors. These inflammatory monocytes appear to have tumor-promoting immunosuppressive properties. Inhibition of CCR2 with PF-04136309 resulted in enhanced antitumor immunity, decreased tumor growth, and reduced metastasis in preclinical models. A recent phase 1B trial with FOLFIRINOX and CCR2 antagonist in BRPC patients showed encouraging results with PF-04136309.

Considerations for Preoperative Therapy for BRPC

Biopsy and stent evaluation: Patients with BRPC need a cytologic diagnosis of cancer via EUS-guided FNA biopsy prior to initiating therapy. The risk of occlusion of plastic stents increases with a longer period of preoperative therapy, and biliary stent related concerns need vigilant care [54–55]. In a clinical trial of 79 patients undergoing chemotherapy with gemcitabine in combination with cisplatin followed by gemcitabine-based chemoradiation, at least one stent exchange was necessary in 46 (75%) of the 61 patients who entered the protocol with a plastic biliary stent and

self-expandable metal stents which ultimately were placed in 36 (46%) of 79 patients [33]. In the study by Katz evaluating the borderline resectable cancers, of the 125 patients who underwent a complete restaging evaluation, endobiliary stent exchange was necessary in 19 (15%) due to stent occlusion or cholangitis and most patients had a metal stent placed at the initiation of therapy [7]. Additionally, covered stents are associated with decreased tumor ingrowth and improved patency and are therefore preferred to uncovered stents [56–57].

Prehabilitation: Prehabilitation is gaining significant interest in health care and refers to enhancing a patient's functional capacity prior to medical or surgical intervention [58]. While the term originally applied to improving physical capacity, most prehabilitation programs are multidimensional and address debilitation, improving nutrition, and optimizing comorbid and psychosocial conditions. Prehabiliation therapy has shown substantive improvements in rates of postoperative recovery in colorectal cancer patients [59–60] and chemotherapy tolerance in breast cancer patients [61]. It is increasing being recognized that patients with BRPC and marginal performance status and/or reversible comorbidities are at higher risk of poor outcomes [62]. This is especially important when months of preoperative therapy is implemented with the eventual goal being to proceed with a large abdominal surgery and likely, additional systemic therapy on recovery. Currently, prospective trials are studying the role of individualized exercise programs, personal nutrition plans made by registered dieticians, medical or geriatric consultation/optimization, and psychosocial evaluations for PDAC patients with an emphasis on elderly patients [63–65]. The outcome measures include following postoperative surgical complications, length of hospitalization, quality of life, and other important results, including postoperative pain level and returning to work and leisure activities. Through creative prospective randomized trials, we can learn the impact of these measures and gauge its effect on the immune milieu in blood and tumor tissues.

Setting expectations: Forty to 60% of all patients who start preoperative therapy for BRPC eventually proceed to pancreatectomy [66]. Many relapse within 3 years of surgery and cure rate remains low. It is important to address patient expectations early and revisit goals at presentation and each restaging to minimize disappointment and caregiver stress and burnout. Most neoadjuvant programs are aggressive and prolonged (several months), and complications, particularly in high-risk patients, may interrupt or necessitate a change in plans [64].

Biomarkers and BRPC

With the current available therapies, a minority of patients achieve an excellent response to neoadjuvant therapy (<10% viable tumor cells) and eventual cure. It is difficult to identify these patients a priori, and the radiographic responses and CA19-9 serve as poor surrogates with their limitations, especially in a disease that at presentation is systemic in most patients. BRPC remains a heterogeneous entity, and prognostic or predictive biomarkers are urgently warranted.

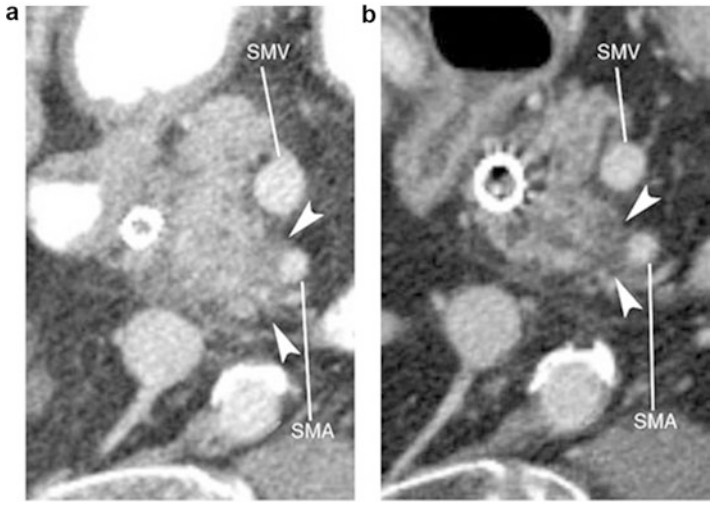

Fig. 1 Pre- and post-treatment CT scans of a 78-year-old patient presenting with tumor abutting the SMA. (**a**) Pretreatment scan shows tumor (*white arrowhead*) involving the SMA for approximately 180°. Patient's preoperative CA19-9 was 359 U/ml. Patient was treated with gemcitabine and nab-paclitaxel for two cycles and followed by gemcitabine-based chemoradiation (50.4 Gy); (**b**) after chemotherapy and chemoradiation, despite reduction in the size of the hypodense tumor, arterial abutment was still present though there was a decline in the CA19-9 to 40 U/ml. Approximately 5 months after her initial visit, patient underwent pancreaticoduodenectomy. Pathology revealed a residual infiltrating moderately differentiated adenocarcinoma of the head of the pancreas (2.0 cm), a treatment effect was seen, with 20–30% viable tumor. Proximal gastric, distal duodenal, and retroperitoneal resection margins were negative for tumor (R0 resection), and the tumor was 1.0 cm from the retroperitoneal margin. Seventeen regional lymph nodes were removed and all were negative for micrometastatic disease. Patient received adjuvant chemotherapy with single agent gemcitabine. The patient is 40 months out from completion of her treatment with no radiographic evidence of local recurrence or metastases

The role of SMAD-4 as a biomarker of disease progression and metastases needs to be studied in a prospective setting and hence, guide if it facilitates the discussion surrounding the role preoperative radiation therapy in select patients [67]. Iacobuzio-Donahue et al. performed rapid autopsies on 76 PDAC patients and at autopsy, 30% of patients died with locally destructive disease, and 70% died with widespread metastatic disease [68]. Tumor SMAD4 immunolabeling status harvested at autopsy correlated with the presence of widespread metastasis but not with locally destructive tumors ($P = 0.007$). The authors concluded that SMAD4 intact cancers may be more locally destructive and hence these patients benefit from loco-regional therapies, whereas SMAD4 deleted cancer represents an aggressive metastatic biology. Boone et al. studied 117 patients who underwent pancreaticoduodenectomy with venous resection [69]. Sixty had sufficient specimens available for SMAD4 staining. SMAD4 loss was observed in 70% of resections and was associated with earlier time to metastatic disease. Preoperative SMAD4 loss correlated well with postoperative

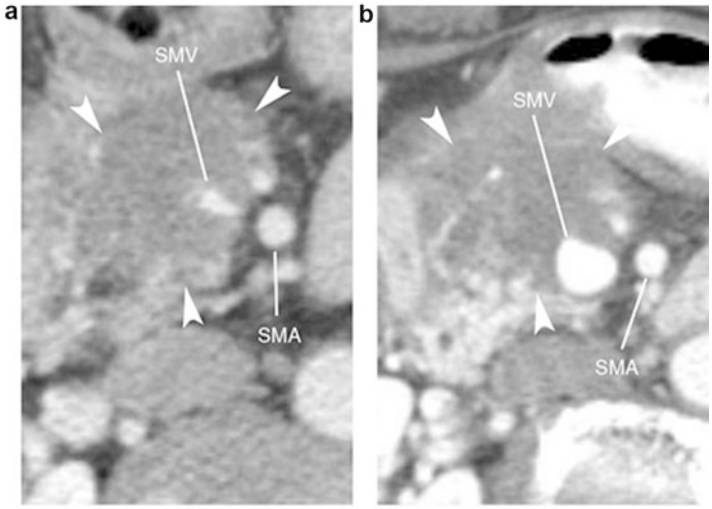

Fig. 2 Pre- and posttreatment CT scans of a 70-year-old patient presenting with segmental venous near occlusion. (**a**) Pretreatment scan shows a hypodense mass (*white arrowheads*) involving the head of the pancreas with marked narrowing of the SMV. Patient's baseline CA19-9 was 71 U/ml. Patient was treated with gemcitabine and cisplatin every 2 weeks for 4 infusions followed by capecitabine-based chemoradiation (50.4 Gy); (**b**) after chemotherapy and chemoradiation, there was significant improvement in the caliber of the SMV without much change in the tumor size and the CA19-9 was 27 U/ml. At surgery, tumor was found extending substantially to the left of the SMA for a distance of more than a centimeter. This process extended to the right to entirely encase the tributaries to the SMV such that there would be no access to a reasonable trunk of the SMV to enable venous resection. Patient is currently 24 months out from her attempted surgery and undergoing chemotherapy for progressive disease manifested by carcinomatosis

staining and was associated with 6 times higher likelihood of developing metastases. The authors concluded that preoperative SMAD4 status may be considered as one of several factors when selecting patients most likely to benefit from aggressive surgery. A recent prospective trial, RTOG 4201, in patients with locally advanced PDAC, using SMAD4 as a stratification factor, randomized patients to systemic therapy followed by RT (50.4 vs. 60 Gy) vs. systemic therapy alone – unfortunately, it was closed early due to poor accrual. Alliance 021501 is a randomized phase II trial of combination chemotherapy (mFOLFIRINOX) with or without hypofractionated radiation therapy before surgery and although the sample size is small, SMAD4 biomarker data from this study may further help define the role of SMAD4 and RT in BRPC.

Koay and colleagues have demonstrated the interpatient variability in the delivery of gemcitabine as well as in the mass transport properties of tumors as measured by computed tomography (CT) scans [70–71]. They developed a volumetric segmentation approach to measure mass transport properties from the CT scans of PDAC patients and tested interobserver agreement with this new methodology. The

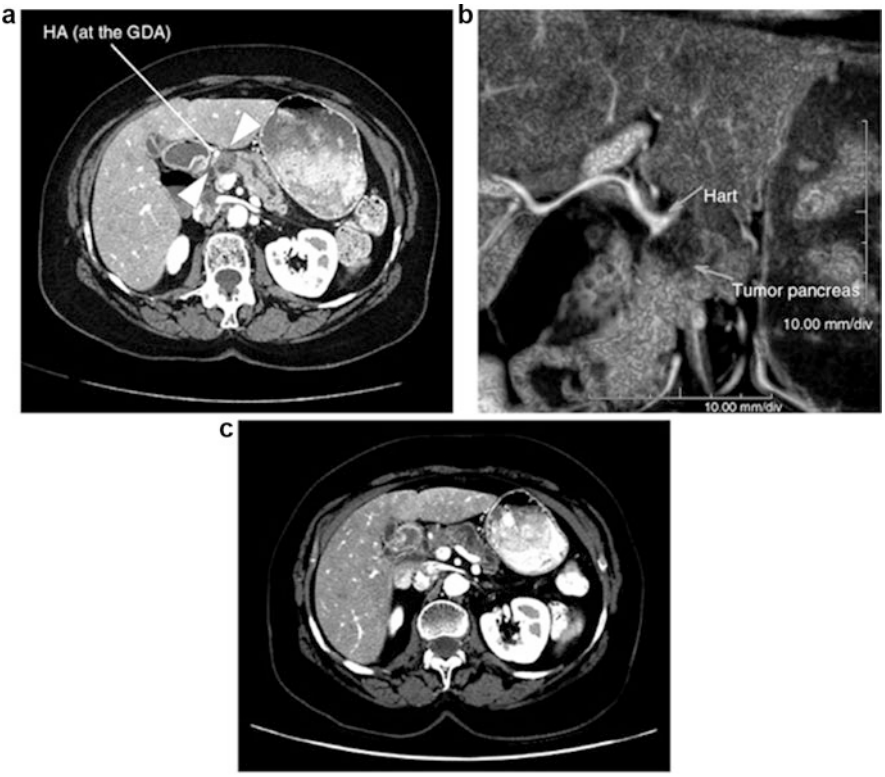

Fig. 3 Pre and posttreatment CT scans of a 74-year-old patient presenting with short-segment involvement of the hepatic artery (*HA*) at the level of the gastroduodenal artery (*GDA*). (**a**) Pretreatment scan shows tumor (*white arrowhead*) involving the HA; (**b**) the scans showed a 1.6 cm hypodense mass that was inseparable from the RHA and proximal GDA at the bifurcation as seen in the coronal view. The left HA was noted to arise from the left gastric artery. Patient was treated with capecitabine-based chemoradiation for a total dose of 50.4 Gy in 28 fractions; (**c**) postchemoradiation scan shows persistent hepatic arterial involvement. Patient underwent an R0 pancreaticoduodenectomy with resection of the hepatic artery with primary repair. Pathology showed a residual moderately differentiated ductal adenocarcinoma (1.7 cm) with perineural and lymphovascular invasion. Tumor was 1.1 cm from the retroperitoneal margin. Eighteen regional lymph nodes were removed and all were negative for micrometastatic disease. Patient completed adjuvant single agent gemcitabine chemotherapy, and interim CT scan showed no evidence of disease 1 year following pancreaticoduodenectomy

quantitative method to derive transport properties from CT scans demonstrated $<5\%$ difference in gemcitabine prediction at the average CT-derived transport value across observers. The authors concluded that with further validation as a biophysical imaging marker, transport properties of tumors (derived from standard of care CT images) may be useful in patient selection for therapy and prediction of therapeutic outcome (Figs. 1, 2, and 3).

Conclusion

Determining resectability of the primary pancreas tumor is essential to the initial staging evaluation. There is significant progress made in defining BRPC and planning early small prospective trials. The heterogeneity presents a challenge and all BRPC is not created equal and may not benefit from an identical therapy sequence. As preoperative systemic and loco-regional therapies improve, the need to use prognostic and predictive markers in BRPC will be vital to decision-making. It is imperative to plan innovative trials and to evaluate the role of liquid biopsies (exoDNA, ctDNA) and radiogenomics in this setting.

New Japanese Classification of Pancreatic Cancer

Shuji Isaji, Yasuhiro Murata, and Masashi Kishiwada

Contents

Abstract

Background: The Japanese classification of pancreatic cancer, seventh edition, has been released by Japan Pancreas Society (JPS) in July 2016.

Methods: Revision concepts and major revision points of the seventh edition of Japanese classification of the pancreatic cancers were reviewed.

Results: The principal points of revision are as follows:

Conflicts of Interest: Shuji Isaji, Yasuhiro Murata, and Masashi Kishiwada declare that they have no competing interests.

J. P. Neoptolemos et al. (eds.), *Pancreatic Cancer*,
https://doi.org/10.1007/978-1-4939-7193-0_84

1. Definition of the parts of the pancreas.
2. T category and stage grouping: consistency with those of the UICC seventh edition was obtained.
3. Reappraisal of anatomy of extrapancreatic nerve plexuses.
4. N category: classification based on numbers of lymph nodal metastasis among the regional lymph nodes; N1a, metastasis in one to three regional lymph nodes; and N1b, metastasis in four or more regional lymph nodes.
5. Histopathological classification which is consistent with the WHO classification.

The following new items have been added: (1) diagnostic guideline of tumor extension and lymph node metastasis based on multidetector CT (MD-CT), (2) objective criteria defining resectability status only based on the findings of MD-CT, (3) cytopathology guideline, and (4) criteria of histological response to drug therapy and/or radiotherapy.

Conclusion: The revised seventh edition of JPS pancreatic cancer classification focuses on establishing consistency to UICC seventh edition, while originality of JPS classification is maintained.

Keywords
Pancreatic cancer · Japanese classification · Staging system · UICC/AJCC staging system

Introduction

The purpose for establishment of pancreatic cancer classification is to make rules and guidelines so that clinicians and pathologists can compare and discuss collected cancer status and clinical outcomes based on a common criteria. As for the classification of pancreatic cancer, the first edition of the Japanese edition of the General Rules for the Study of Pancreatic Cancer was released in 1980 by the Japan Pancreas Society (JPS). The sixth edition by JPS was published in 2009 [1], and at the same year, the Union Internationale Contre le Cancer (UICC) [2] published its seventh edition. Two classifications adopted TNM classification, but they had been quite different in T category, N category, and Staging system, constituting obstacles to compare status and clinical outcomes of pancreatic cancer patients between Japan and western countries. Therefore, the revision committee of JPS (Isaji S. is the chairperson), which consists of 12 pancreatic surgeons, 4 gastroenterologists, 7 pathologists, 1 radiologist, 1 anatomist, and 1 doctor from Pancreatic Cancer Registry Committee in JPS, started its work in April 2013, and the seventh edition has been published in July 2016. The current revision by JPS focuses on establishing consistency between the Japanese and UICC classifications; however, originality of JPS classification, which is more precise and contains more information, is maintained.

In the seventh edition, major revisions have been carried out by comparing the sixth edition in the following points:

1. Definition of the portions of the pancreas: the border between the pancreatic body and tail is defined as the left side line of the abdominal aorta.
2. T category: consistency with that of the UICC seventh edition.
3. Reappraisal of anatomy of extrapancreatic nerve plexuses.
4. N category: new classification based on numbers of lymph nodal metastasis among the regional lymph nodes.
5. (5)Stage grouping: consistency with UICC staging system.
6. Histopathological classification: consistency with the WHO classification.

In the current revision, the following new items have been added: (1) criteria of diagnosis for T category based on MD-CT, (2) criteria of diagnosis for lymph nodal metastasis based on MD-CT, (3) criteria defining resectability, (4) cytopathology guideline, and (5) criteria of histological response to drug therapy and/or radiotherapy.

Definition of Parts of the Pancreas

The definition of portion of the pancreas is shown in Fig. 1. The border between pancreatic head and body is defined as the left side of the superior mesenteric vein (SMV) and portal vein (PV). The neck of the pancreas (a part anterior to the SMV and PV) and uncinate process are included in the pancreatic head. In the sixth edition by JPS, the boundary between the body and tail of the pancreas was the line dividing the distal pancreas into two equal halves. In the seventh edition, its boundary is revised as the left border of the aorta, which is the same as UICC classification. This is attributed to the fact that pancreatic cancer arising from the site between the left side of SMV/PV and left border of the aorta tends to be frequently unresectable due to the involvement of celiac axis (CA) and/or superior mesenteric artery (SMA).

Category of Tumor Extension (T)

Comparison of T categories between JPS sixth and seventh, UICC seventh edition, and the American Joint Committee on Cancer (AJCC) eighth edition is summarized in Table 1. T1 and T2 are almost the same in the three (JPS sixth and seventh and UICC seventh) classifications. T3 and T4 are quite different between JPS sixth edition and UICC seventh edition. In JPS seventh edition, however, T3 and T4 are the same as those of UICC seventh edition. Clinically, the involvement of CA and SMA is clearly defined as tumor with contact or invasion of arterial wall based on dynamic CT findings. Among T1, T1 is divided into subclassifications: T1a, 5 mm or less; T1b, more than 5 mm but 10 mm or less; and T1c, more than 10 mm but 20 mm or less.

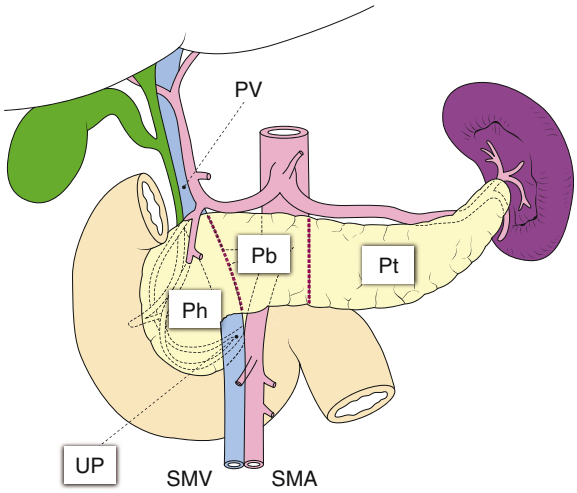

Fig. 1 Portion of pancreas in Japanese classification of pancreatic cancer, seventh edition (Kanehara & Co., Ltd., Tokyo, Japan). The border between pancreatic head and body is defined as the *left side* of SMV and PV. The neck of the pancreas (a part above SMV and PV) and the uncinate process are included in the pancreatic head. The border between pancreatic body and tail was defined as *left side line* of abdominal aorta. *Ph* pancreatic head, *Pb* pancreatic body, *Pt* pancreatic tail, *PV* portal vein, *SMA* superior mesenteric artery, *SMV* superior mesenteric vein, *UP* uncinate process

The AJCC proposed changes for T staging in its eighth edition [3]. These changes have focused on improving the reproducibility of T stage, decreasing the percentage of tumors designated as T3, because the term "extension beyond the pancreas" for description of T3 in AJCC seventh edition has been thought to be potentially inconsistent between pathologists and the T stage defined as such was not found to have any correlations with survival [4]. A revised T stage protocol was devised that defined pT1 as 2 cm or smaller, pT2 as >2–4 cm, and pT3 as larger than 4 cm. The multi-institutional comparative study proved that the proposed cutoff points for T stage were statically valid, and its utilization was more reproducible between institutions and pathologists [5].

Reappraisal of Anatomy of Extrapancreatic Nerve Plexus

From the third to sixth edition by JPS, the extrapancreatic nerve plexuses, which were originally defined in Japan according to the literature reported by Yoshioka et al. [6], were divided into seven parts of the plexus: PLphI, pancreatic head plexus I; PLphII, pancreatic head plexus II; PLsma, SMA plexus; PLcha, CHA plexus; PLhdl, plexus within the hepatoduodenal ligament; PLspa, SPA plexus; and PLce, celiac plexus. Several problems were pointed out for the scheme which had been used until the sixth edition (Fig. 2). First, PLphI and PLphII were drawn on the same

Table 1 Comparison of T categories between JPS sixth and seventh, UICC seventh edition, and AJCC eighth

	JPS sixth edition (2009)	JPS seventh edition (2016)	UICC seventh edition (2009)	AJCC eighth edition (2016)
T1	Tumor limited to pancreas, 2 cm or less in greatest dimension	Tumor limited to pancreas, 20 mm or less in greatest dimension	Tumor limited to pancreas, 2 cm or less in greatest dimension	Maximum tumor diameter <=2 cm
		T1a: 5 mm or less		
		T1b: more than 5 mm but 10 mm or less		
		T1c: more than 10 mm but 20 mm or less		
T2	Tumor limited to pancreas, more than 2 cm in greatest dimension	Tumor limited to pancreas, more than 20 mm in greatest dimension	Tumor limited to pancreas, more than 2 cm in greatest dimension	Maximum tumor diameter >2 cm < =4 cm
T3	Tumor that has extended into any of the following: bile duct (CH), duodenum (DU), peripancreatic tissue (S, RP)	Tumor extends beyond pancreas, but without involvement of celiac axis or superior mesenteric artery	Tumor extends beyond pancreas, but without involvement of celiac axis or superior mesenteric artery	Maximum tumor diameter > 4 cm
T4	Tumor that has extended into any of the following: adjacent large vessels (PV, A), extrapancreatic nerve plexus (PL), other organs (OO)	Tumor involves celiac axis or superior mesenteric artery (Tumor contant or involvement on the dynamic CT findings)	Tumor involves celiac axis or superior mesenteric artery	Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)

CH distal bile duct invasion, *DU* duodenal invasion, *S* serosal invasion, *RP* retropancreatic tissue invasion, *PV* portal venous system invasion, *A* arterial system invasion, *PL* extrapancreatic nerve plexus invasion, *OO* invasion of other organs

cross section as shown in Fig. 2a. However, it is not correct to draw these plexuses on the same cross section, because PLphI is located at the cranial side and PLphII is located at the caudal side. Second, PLphI and PLph2 were drawn just like thick nerve bundles as shown in the yellow colored site in Fig. 2b. Third, the third and fourth portion of the duodenum is located at the right side of the SMA, which is not correct anatomy (Fig. 2b).

In JPS seventh edition, anatomy of the extrapancreatic nerve plexuses had been reappraised based on cadaveric anatomical findings reported by Yi et al. [7] and several discussions between anatomists and surgeons, and finally the revision committee of JPS decided to make a new scheme as shown in Fig. 3. The current

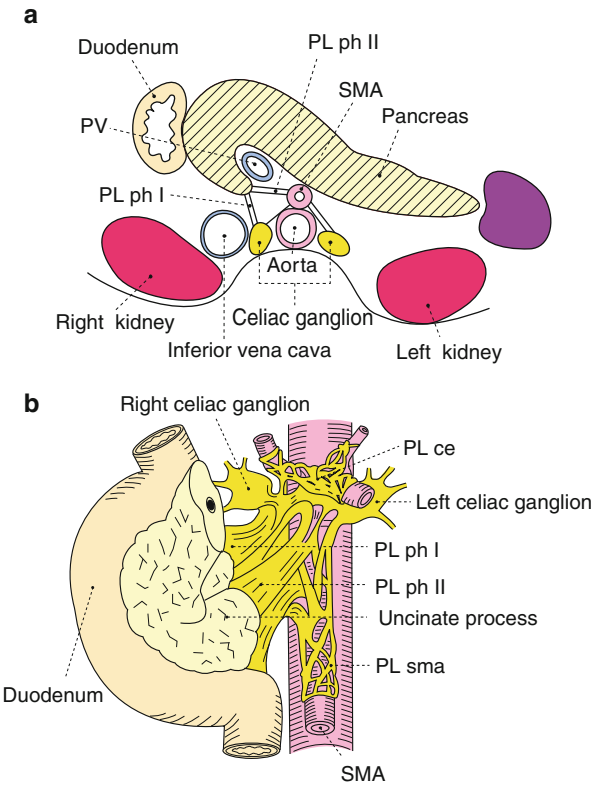

Fig. 2 Anatomical scheme of the extrapancreatic nerve plexuses including pancreatic head nerve plexuses (PLph) in Japanese classification of pancreatic cancer, sixth edition (Kanehara & Co., Ltd., Tokyo, Japan). (**a**) Pancreatic nerve plexuses (cross-sectional diagram). (**b**) Extrapancreatic nerve plexuses. *PV* portal vein, *SMA* superior mesenteric artery, *PLphI* pancreatic head plexus I, *PLphII* pancreatic head plexus II, *PLCe* celiac plexus, *Plsma* superior mesenteric arterial plexus

reappraisal of anatomy of extrapancreatic nerve plexuses has clarified that nerves within PLphI and PLphII are much less and thinner than those previously considered. Although they can be actually defined as nerve plexus from the perspective that sympathetic nerve and parasympathetic nerve cross and make a network of nerve, the membranous structures which are drawn as PLphI and PLphII have been proven to include not only nerve tissue but also fibrous tissue, capillaries, and fat tissue. Taken together with operative finding and cadaveric anatomical finding, PLphI is a region which mainly includes nerve tissue distributed to the dorsal surface of pancreatic head from the celiac plexus, while PLphII includes nerve tissue distributed to the uncinate process from the SMA plexus. Because PLphI and PLphII are frequently involved by pancreatic head carcinoma and invasion of these areas is the main cause of incomplete resection [8–10], it is very important to understand the anatomy of extrapancreatic nerve plexus for making proper diagnosis of plexus nerve invasion based on MD-CT and for determining the level of plexus nerve dissection during pancreatectomy.

In the seventh edition, the term “mesopancreas” is not adopted, because its concept and anatomical definition remain uncertain. Gockel et al. [11] has defined a membranous structure between SMA and pancreatic head as mesopancreas, which contains nerve tissue, capillaries, fibrous tissue, and fat tissue.

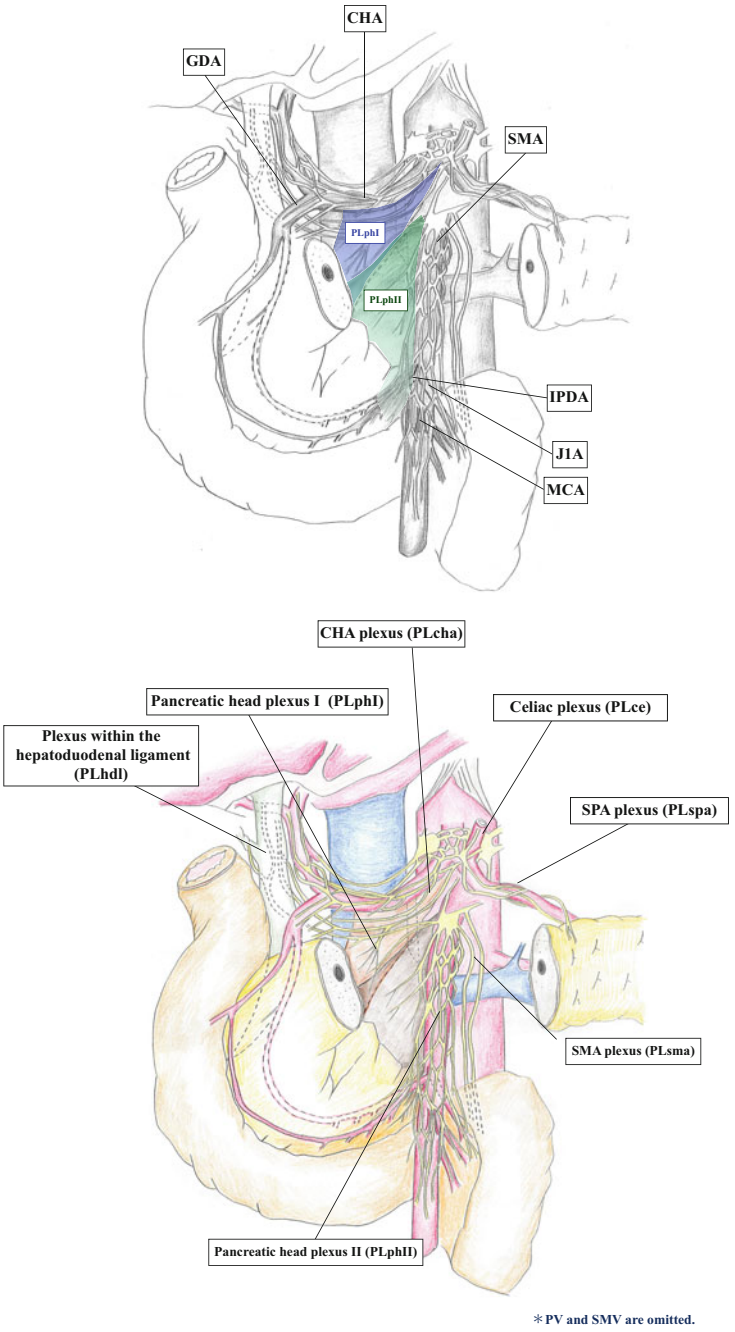

Fig. 3 Anatomical scheme of the extrapancreatic nerve plexuses including pancreatic head nerve plexuses (PLph) in Japanese classification of pancreatic cancer, seventh edition (Kanehara & Co., Ltd., Tokyo, Japan)

Mesopancreas seems to be consistent with PLphII, but they did not mention PLPhI. The term "meso" is not a proper word, because the mesentery and mesocolon contain all blood vessels and lymphatics with peritoneal attachment.

Description of Regional Lymph Nodes of the Pancreas and Lymph Node Metastasis

In the sixth edition by JPS, the lymph nodes related to the pancreas were classified into three groups: Groups 1, 2, and 3. Lymph node metastasis was described according to existence of metastasis in each group lymph nodes: N0 (no lymph node metastasis), N1 (lymph node metastasis in Group 1), N2 (lymph node metastasis in Group 2), and N3 (lymph node metastasis in Group 3). In the seventh edition, regardless of tumor location, the regional lymph nodes of the pancreas are defined as the following lymph node station numbers (Fig. 4) [12]: 5, 6, 7, 8a, 8p, 9, 10, 11p, 11d, 12a, 12b, 12p,13a, 13b,14p,14d, 17a, 17b, and 18 (Table 2). In case of metastasis in the other lymph node number (1, 2, 3, 4, 15, 16a1, 16a2, 16b1, 16b2, etc.), it is defined as M1.

The committee of JPS classification for seventh edition reevaluated the patient survival according to metastasis in the lymph node groups and the total numbers of lymph node metastasis using pancreatic cancer registry data by Japan Pancreas Society from 2001 to 2007 [13]. As a result, overall survivals between the patients with N2 and those with N3 were comparable and very poor, while there was significant difference between the patients with N0 and those with N1. According to the total numbers of lymph node metastasis, overall survival was significantly better in the patients with no lymph node metastasis followed by the patients with one to three lymph node metastases and those with four or more lymph node metastases in decreasing order (MST: 34.7, 21.9, 15.7 months, respectively) (Fig. 5). Given these results, the recording of lymph node metastasis in the seventh edition by JPS is shown as follows:

NX: Regional lymph nodes cannot be assessed.
N0: No regional lymph node metastasis.
N1: Regional lymph node metastasis.
N1a: Metastasis in one to three regional lymph nodes.
N1b: Metastasis in four or more regional lymph nodes.

Similarly, the AJCC proposed the change for N definitions in the eighth edition as follows: N0 = node negative, N1 = one to three nodes positive for metastatic disease, and N2 = four or more nodes positive for metastatic disease. The multi-institutional collected data analysis for all patients ($n = 1{,}551$) who underwent a R0 resection found that these two separate cutoffs were useful for stratification of prognosis [5].

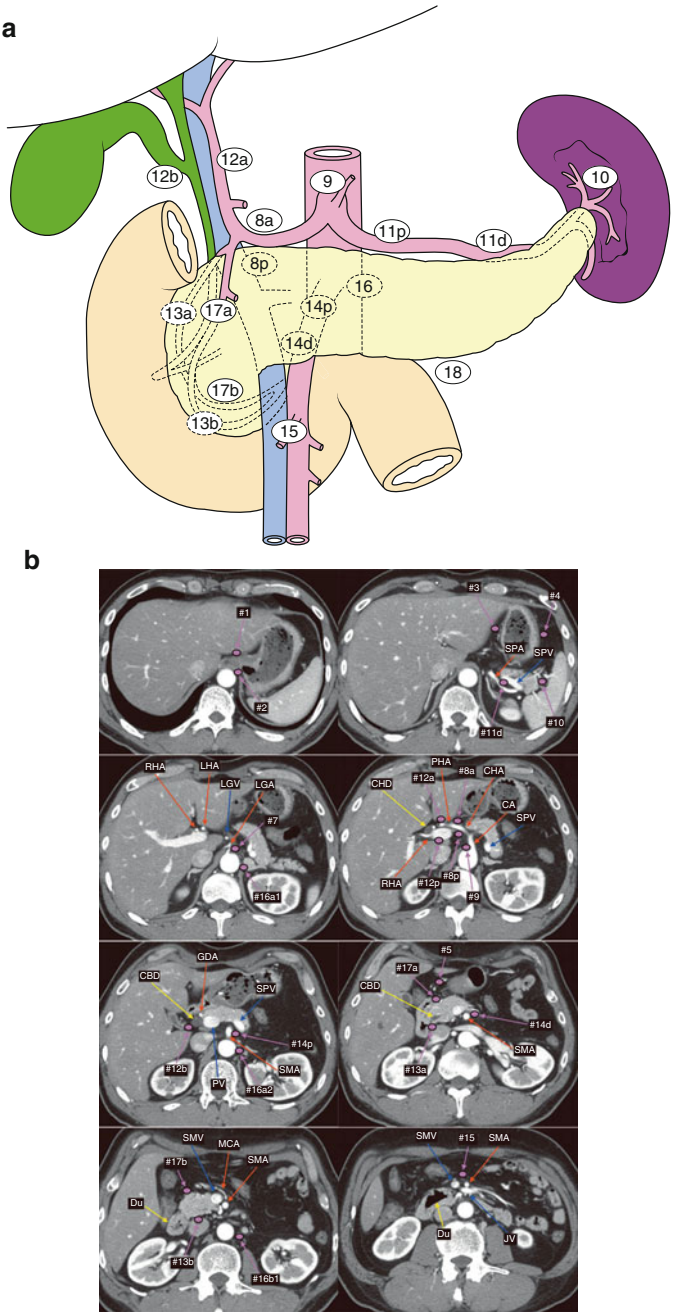

Fig. 4 Lymph node station numbers related to the pancreas in Japanese classification of pancreatic cancer, seventh edition (Kanehara & Co., Ltd., Tokyo, Japan). (**a**) Scheme of lymph node station numbers related to the pancreas. (**b**). MD-CT finding (cross section) showing peripancreatic lymph

Table 2 Numbers and names of lymph nodes related to the pancreas

Number	Name
1	Right cardial lymph nodes
2	Left cardial lymph nodes
3	Lymph nodes along the lesser curvature of the stomach
4	Lymph nodes along the greater curvature of the stomach
5[a]	Suprapyloric lymph nodes
6[a]	Infrapyloric lymph nodes
7[a]	Lymph nodes along the left gastric artery
8a[a]	Lymph nodes in the anterosuperior group along the common hepatic artery
8p[a]	Lymph nodes in the posterior group along the common hepatic artery
9[a]	Lymph nodes around the celiac axis
10[a]	Lymph nodes at the splenic hilum
11p[a]	Lymph nodes along the proximal splenic artery
11d[a]	Lymph nodes along the distal splenic artery
12a[a]	Lymph nodes along the hepatic artery
12p[a]	Lymph nodes along the portal vein
13a[a]	Lymph nodes on the posterior aspect of the superior portion of the head of the pancreas
13b[a]	Lymph nodes on the inferior aspect of the superior portion of the head of the pancreas
14p[a]	Lymph nodes along the proximal superior mesenteric artery
14d[a]	Lymph nodes along the distal superior mesenteric artery
15	Lymph nodes along the middle colic artery
16	Lymph nodes around the abdominal aorta
16a1	Lymph nodes around the aortic hiatus of the diaphragm
16a2	Lymph nodes around the abdominal aorta (from the superior margin of the celiac trunk to the inferior margin of the left renal vein
16b1	Lymph nodes around the abdominal aorta (from the inferior margin of the left renal vein to the superior margin of the inferior mesenteric artery)
16b2	Lymph nodes around the abdominal aorta (from the superior margin of the inferior mesenteric artery to the aortic bifurcation)
17a[a]	Lymph nodes on the anterior surface of the superior portion of the head of the pancreas
17b[a]	Lymph nodes on the anterior surface of the inferior portion of the head of the pancreas
18[a]	Lymph nodes along the inferior margin of the pancreas

Table 3 Stage grouping in Japanese classification of pancreatic cancer seventh edition

Stage 0	Tis	N0	M0
Stage IA	T1 (T1a, T1b, T1c)	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1 (T1a, T1b, T1c), T2, T3	N1 (N1a, N1b)	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

Stage Grouping

Stage grouping in the seventh edition by JPS is shown in Table 3. In the sixth edition, staging system was made based on data for resected cases of pancreatic cancer registry by JPS, focusing on stratification of prognosis according to each stage. In contrast, the JPS seventh edition basically adopted staging system of UICC seventh edition, focusing on enabling clinicians to decide treatment option for each stage. Roughly, stages I and II are initially resectable pancreatic cancer. Stage III is borderline resectable or locally advanced pancreatic cancer for which

	MST (mo)	1-yr	2-yr	3-yr	5-yr	
Stage IA (n=201)	69.4	95.9%	79.1%	67.1%	54.1%	
Stage IB (n=310)	36.1	84.7%	63.3%	50.0%	36.2%	p<0.0001
Stage IIA (n=615)	29.4	79.3%	56.0%	45.3%	29.9%	p=0.0757
Stage IIB (n=1367)	19.2	68.6%	39.2%	23.4%	11.8%	p<0.0001
Stage III (n=257)	18.1	68.4%	36.9%	20.4%	10.7%	p=0.4195
Stage IV (n=565)	12.7	51.5%	24.2%	12.2%	6.5%	p<0.0001

Fig. 6 Survival curves in the PDAC patients who underwent resection according to stage (Kanehara & Co., Ltd., Tokyo, Japan). Pancreatic cancer registry data by Japan Pancreas Society 2001–2007 ($n = 3315$). *PDAC* pancreatic ductal adenocarcinoma

neoadjuvant therapy may be recommended on the setting of clinical trial. Stage IV has distant metastasis for which systemic chemotherapy is recommended. When survival rates were retrospectively evaluated using pancreatic cancer registry data by JPS according to the current stage grouping, 5-year survival rates of stages IA, IB, IIA, IIB, III, and IV were 54.1, 36.2%, 29.9%, 11.8%, 10.7%, and 6.5% (Fig. 6). The significant difference of overall survival rates was found between IA and IB, IIA and IIB, and III and IV. In contrast, the survival rates were comparable between stages IIB and III: 11.8% versus 10.7% ($p = 0.4195$).

Classification of Resectability

Surgical resection is the only potentially curative therapy for long-term survival for pancreatic cancer. At the time of diagnosis of pancreatic cancer, however, only approximately 10–20% of patients are considered candidates for curative resection [14]. Therefore, it is important to define the resectability using common criteria from the perspective of determining treatment option and comparing outcomes. In the sixth edition of JPS and UICC seventh edition, there are no classification and criteria defining resectability.

The National Comprehensive Cancer Network (NCCN) has developed guidelines to define tumor resectability in pancreatic cancer based on MD-CT finding since 2006, in order to improve patient selection for surgery and to identify the likelihood of an R0 resection [15]. Using their criteria, pancreatic cancer is classified as resectable (R), borderline resectable (BR), locally unresectable (LUR), or metastatic. BR pancreatic cancer can be defined as one that increases the likelihood of an incomplete resection. On the contrary, LUR pancreatic cancer is locally advanced pancreatic cancer including tumors with SMA or CA encasement greater than 180° and unreconstructable portal vein (PV)/SMV occlusion. However, this guideline has been revised periodically and detailed, and this criteria focus on the final decision of resectability by only pancreatic surgeons. In the seventh edition by JPS, therefore, criteria defining resectability status based on the findings of dynamic CT have been established by thorough discussion among pancreatic surgeons, gastroenterologist, radiologist, and pathologist, taking NCCN guideline 2015 into consideration as follows:

Resectable: R

No tumor contact with the superior mesenteric vein (SMV) or portal vein (PV) or less than 180° contact or invasion without occlusion. Clear fat planes around the superior mesenteric artery (SMA), celiac axis (CA), and common hepatic artery (CHA), showing no contact or invasion

Borderline Resectable: BR

Subclassified according to SMV/PV invasion alone or arterial invasion

BR-PV (SMV/PV Invasion Alone)

No findings of contact and invasion of the SMA, CA, and CHA. Tumor contact or invasion of the SMV/PV of 180 or more degrees or occlusion of the SMV/PV, not exceeding the inferior border of the duodenum

BR-A (Arterial Invasion)

Tumor contact or invasion of the SMA and/or CA of less than 180° without showing stenosis or deformity. Tumor contact or invasion of the CHA without showing tumor contact or invasion of the proper hepatic artery (PHA) and/or CA

Unresectable: UR

Subclassified according to the status of distant metastasis

UR-LA (Locally Advanced)

Tumor contact or invasion of the SMV/PV of 180 or more degree or occlusion of the SMV/PV, exceeding the inferior border of the duodenum. Tumor contact or invasion of the SMA and/or CA of 180 or more degree. Tumor contact or invasion of the CHA showing tumor contact or invasion of the PHA and/or CA. Tumor contact or invasion of the aorta

UR-M (Tumor with Distant Metastasis)

Distant metastasis including non-regional lymph node metastasis.

BR pancreatic cancer is classified into the following two types according to the vascular invasion: BR-PV means the tumor whose vascular invasion is limited

within PV (portal vein) alone, and BR-A means the tumor with involvement of peripancreatic arteries such as SMA, CA, and hepatic artery (HA). This subclassification is based on the multicenter data collection by the Japanese Society of Pancreatic Surgery that BR-A increases the likelihood of an incomplete resection in comparison with BR-PV, showing significantly poor prognosis in the patients with BR-A [16, 17].

Resectability criteria of the seventh edition by JPS are considered to be utilizable for not only pancreatic surgeons but also gastroenterologist and radiologist, because they are objective criteria only based on dynamic CT findings by avoiding the subjective definitions such as "SMV/PV involvement allowing for safe and complete resection and vein reconstruction" in BR pancreatic cancer and "unreconstructible SMV/PV due to tumor involvement or occlusion" in UR pancreatic cancer [15]. Instead of these subjective definitions for SMV/PV involvement, the authors have adopted the objective definition: SMV/PV involvement exceeding or not exceeding the inferior border of the duodenum, as shown in Fig. 7. In the case of BR-PV in Fig. 7a, the tumor of pancreatic head has 180 or more degree contact/

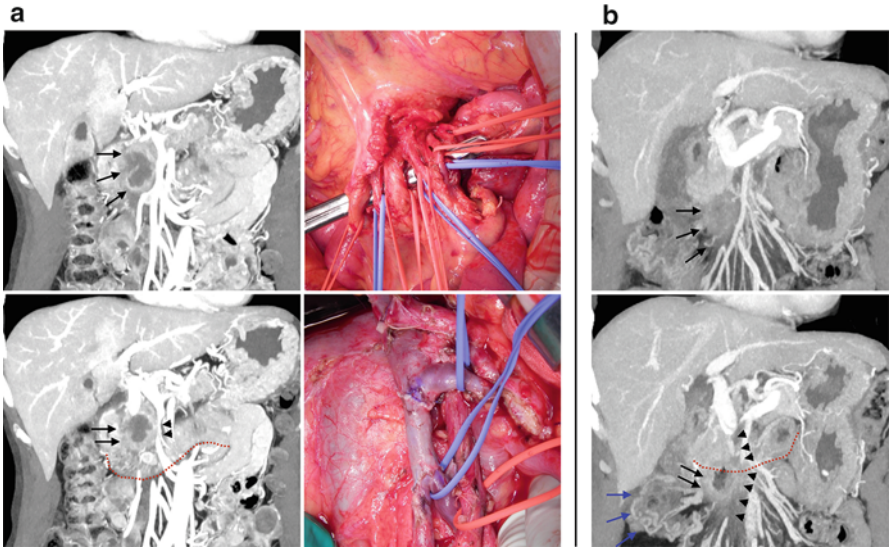

Fig. 7 Resectability criteria according to the degree of tumor invasion of the SMV/PV. (**a**) A case of BR-PV: the tumor of pancreatic head (*black arrows*) has 180 or more degrees of contact/invasion of the SMV/PV (*black arrow heads*), but not exceeding the inferior border of the duodenum (*right break line*). In this case, pancreaticoduodenectomy with combined resection of portal vein followed by reconstruction using the external iliac vein graft was performed after preoperative chemoradiotherapy in the Mie University School of Medicine, and negative surgical margin was confirmed (operative finding in middle pictures). (**b**) A case of UR-LA: the tumor of pancreatic head (*black arrows*) invades and occludes the PV/SMV, exceeding the inferior border of the duodenum (*right break line*). SMV/PV is completely occluded and collateral venous formation is found (*blue arrows*). This case was evaluated as unresectable even after chemoradiotherapy, and systemic chemotherapy was performed in the Mie University School of Medicine

invasion of the SMV/PV, but not exceeding the inferior border of the duodenum. In this case, pancreaticoduodenectomy with combined resection of portal vein followed by reconstruction using the external iliac vein graft was performed after preoperative chemoradiotherapy in the Mie University Hospital, and negative surgical margin was confirmed. In the case of UR-LA in Fig. 7b, the tumor of pancreatic head invades and occludes the PV/SMV, exceeding the inferior border of the duodenum. SMV/PV is completely occluded and collateral venous formation is found. This case was evaluated as unresectable even after chemoradiotherapy, and systemic chemotherapy was performed in the Mie University Hospital.

Criteria of Histological Response to Drug Therapy and/or Radiotherapy

Chemoradiotherapy and chemotherapy before surgery may provide for the early treatment of micrometastatic disease and allow for the identification of patients with metastatic disease and increase the R0 resection rate, resulting in a reduced risk for local recurrence and improvement in outcome. Especially for BR and UR-LA cases, systemic chemotherapy and chemoradiotherapy followed by curative-intent surgery have been widely adopted in recent years [14]. Given these background, it is required to establish uniformed criteria of histological response of drug therapy and/or radiotherapy for pancreatic cancer. The Evans grading system and the classification by the American Pathologists (CAP) grading protocol are the best studied scores [18, 19], and the relationship between histologic response and prognosis has been reported in recent years [20, 21]. The grading system of histological response in the seventh edition by JPS is shown as follows:

Grade 1: Poor or no response
Response to therapy is poor (estimated rate of residual tumor is 50% or more).
Grade 1a: estimated rate of residual tumor is 90% or more.
Grade 1b: estimated rate of residual tumor is 50% or more and less than 90%.

Grade 2: Moderate response
Cancer cells which are considered viable are moderately present (estimated rate of residual tumor is 10% or more and less than 50%).

Grade 3: Marked response
Cancer cells which are considered viable are few (estimated rate of residual tumor is less than 10%).

Grade 4: Complete response
No viable cancer cells are present.

*The estimated rate (%) of residual tumor is defined as the volume of cancer cells considered viable/the estimated tumor volume before treatment. As of host reaction to tumor destruction by preoperative therapy, xanthoglanulomatous change containing foamy histiocytes, pooling of mucin without cancer cells, infiltration of inflammatory cells, and fibrosis are important pathological features which enable us to estimate the tumor volume before treatment.

These criteria basically adopted the principle of both Evans grading system and CAP grading protocol, but they clearly describe how to estimate the rate of residual tumor cells. The estimated rate (%) of residual tumor is defined as the volume of cancer cells considered viable/the estimated tumor volume before treatment. As of host reaction to tumor destruction by preoperative therapy, xanthoglanulomatous change containing foamy histiocytes, pooling of mucin without cancer cells, infiltration of inflammatory cells, and fibrosis are important pathological features which enable us to estimate the tumor volume before treatment.

Conclusions

The revised seventh edition of JPS pancreatic cancer classification focuses on establishing consistency to UICC seventh edition, while originality of JPS classification is maintained as follows: anatomical definition of extrapancreatic nerve plexuses, N category based on numbers of lymph nodal metastasis among the regional lymph nodes, objective criteria of resectability only based on dynamic CT findings by avoiding the subjective definitions, and criteria of histological response to drug therapy and/or radiotherapy.

Abstract

Pancreatic cancer is one of the major causes of cancer death. Most patients present with advanced disease, and only 10–15% of patients can undergo resection. Survival after curative surgery is poor, as recurrences occur either locally or distantly. Adjuvant therapy has been employed in large randomized trials to treat systemic disease and hopefully improve the poor prognosis. Chemoradiation, chemotherapy using 5-fluorouracil/folinic acid (5FU/FA), S-1, gemcitabine or gemcitabine plus capecitabine, and combination therapy have all been used in the adjuvant setting.

The results of the EORTC and ESPAC-1 trials have revealed that there is no survival advantage associated with adjuvant chemoradiation following resection for pancreatic cancer compared to no chemoradiation. There is no level 1 evidence, as yet that chemoradiation is superior to chemotherapy alone following surgery. Justification for the use of combination chemoradiation with follow-on chemotherapy is based on the results of an underpowered 1987 GITSG study, which closed prematurely and compared intervention to observation. The RTOG 9704 combination study did not demonstrate a survival difference between a 5FU-based regimen compared with a gemcitabine-based chemoradiation regimen. There is no completed randomized study comparing chemotherapy versus combination therapy.

There is a clear survival advantage with adjuvant 5FU/FA and single-agent gemcitabine based on the results from the ESPAC-1 and CONKO-001 study, respectively. The ESPAC-3 trial showed that these adjuvant regimens are equally effective, but gemcitabine has a better toxicity profile. In contrast, in a Japanese population, the JASPAC-01 trial demonstrated the superiority of S1 over gemcitabine. Adjuvant combination chemotherapy with gemcitabine plus capecitabine has been recently shown to provide a survival advantage compared with gemcitabine alone in Western patients in the ESPAC-4 trial. Phase III studies investigating other combination chemotherapy regimens are ongoing and will possibly increase the number of treatment options in this setting.

Introduction

The effective treatment of pancreatic adenocarcinoma is a huge challenge. Over the past three decades, there has been considerable progress toward understanding the biology of pancreatic cancer, refining imaging systems, improving surgical outcomes, and more recently focusing on new combination treatments and biomarkers to enable targeted therapies. The worldwide incidence is 337,872 cases per year resulting in 330,391 deaths, and in Europe pancreatic cancer accounts for 103,773 new cases and 104,481deaths each year [1]. In the USA in 2016, there were around 53,070 new cases of pancreatic cancer diagnosed with 41,780 deaths [2]. The incidence of pancreatic cancer has been rising, and it is likely to be the second leading cause of cancer deaths by 2030 [3]. The American Cancer Society's estimates for pancreatic cancer in the USA for 2017 are that about 53,670 people (27,970 men and 25,700 women) will be diagnosed with pancreatic cancer and that about 43,090 people (22,300 men and 20,790 women) will die of pancreatic cancer [4]. Pancreatic cancer accounts for about 3% of all cancers in the USA and about 7% of all cancer deaths. There has been some improvement in survival outcome with the 1-year survival rate of people with pancreatic cancer who do not have surgery rising to 29% and the 5-year survival rate rising to 7% [4, 5].

The outlook for those patients who can undergo surgical resection is better. In specialized centers, resection rates of above 15% can be achieved [5, 6]. Although surgery cannot guarantee a cure, the 5-year survival does improves to around 8–10% following resection [6, 7]. Naturally, there have been many attempts to improve survival by increasing the radicality of the surgical resection including by total pancreatectomy [8], multivisceral resections [9], and extended lymphadenectomy [10–12]. A meta-analysis has shown increased postoperative morbidity for extended lymphadenectomy over standard lymphadenectomy with pancreatectomy without any survival advantage, although there is trend favoring the more extended procedure [13].

The patterns of disease recurrence following resection include both locoregional failure and distant metastases [14]. Postmortem analyses have also shown that hepatic metastases are the direct cause of death due to metastatic disease in up to 80% of cases [15]. The use of adjuvant therapy is a logical strategy to target systemic disease and thereby improve survival.

Rationale for Adjuvant Chemotherapy

Pancreatic cancer is highly resistant to many standard chemotherapy regimens relative to other gastrointestinal cancers. This is a persistent problem and may be accounted for, in part, by the underlying tumor biology of pancreatic cancer. Few chemotherapeutic

agents have been shown to have reproducible response rates of more than 10%. 5FU is an inhibitor of thymidylate synthetase (essential for synthesis of DNA nucleotides) and has been the most widely used agent in advanced pancreatic cancer, with a median survival of around 5–6 months, and is better than the best supportive care [16, 17]. The nucleoside analogue, gemcitabine, replaced 5FU as the preferred drug in 1997 as the toxicity was relatively mild and achieved a better clinical response compared to 5FU (24% vs. 5%, respectively) [18]. Although the median survival improvement in favor of gemcitabine compared with 5FU was slight (5.7 vs. 4.4 months), the 1-year survival rate was more encouraging (18% vs. 2%) [18].

Combination chemotherapy has been developed to improve the outcomes observed with gemcitabine alone. Capecitabine is an oral, fluoropyrimidine carbamate that is sequentially converted to 5FU by three enzymes located in the liver and in tumors, including pancreatic cancer. Prospective studies including two randomized trials assessing the combination of capecitabine and gemcitabine have shown promise [19–21]. Meta-analysis of gemcitabine combination studies [22, 23] has demonstrated that combination gemcitabine chemotherapy results in significant survival benefit than gemcitabine alone (HR = 0.91; 95% CI, 0.85–0.97) and the best combinations may be with capecitabine or platinum-based agents, allowing for acceptable levels of toxicity of the combinations [24, 25].

Other combination chemotherapy regimens including 5FU plus folinic acid, irinotecan and oxaliplatin (FOLFIRINOX), and gemcitabine plus *nab*-paclitaxel have been shown to be superior to single-agent gemcitabine in terms of objective response rate (31.6% vs. 9.4% and 23% vs. 7%, respectively) and survival outcomes (median overall survival 11.1 vs. 6.8 and 8.5 vs. 6.7 months, respectively) and are now standard options for the first-line treatment of patients with good performance status [26, 27].

Novel biological agents against a variety of molecular targets have yet to have an impact in improving survival in pancreatic cancer including erlotinib, bevacizumab, aflibercept, axitinib, sorafenib and cetuximab [28]. The relative effectiveness of chemotherapy in patients with advanced pancreatic cancer led to the use of 5FU in the first wave of adjuvant chemotherapy trials. The emergence of gemcitabine as the standard for patients with advanced pancreatic cancer has influenced the next generation of adjuvant studies, while, more recently, combination chemotherapy regimens have been increasingly investigated in this setting.

Randomized Controlled Trials of Adjuvant Chemotherapy

The phase III randomized studies that have assessed adjuvant systemic chemotherapy in resected pancreatic cancer are summarized in Table 1.

Bakkevold et al.

This small multicenter study [29] from Norway was conducted between 1984 and 1987 and was the earliest study to compare chemotherapy to best supportive care

Table 1 Randomized controlled trials of adjuvant systemic chemotherapy

Series	Period	No. of patients	Regimen	Median survival (months)	Actuarial survival (%) 1 year	Actuarial survival (%) 2 years	Actuarial survival (%) 3 years	Actuarial survival (%) 5 years

5FU 5-fluorouracil, *FA* folinic acid, *DOX* doxorubicin, *MMC* mitomycin C, *NS* not significant

following resection. Sixty-one patients were randomized to receive either systemic chemotherapy with 5FU (500 mg/m^2), doxorubicin (40 mg/m^2), and mitomycin C (6 mg/m^2) (FAM) ($n = 30$) or observation ($n = 31$) following pancreatic resection. There were 47 patients with pancreatic ductal adenocarcinoma, and the rest had periampullary tumors. The FAM regimen was administered every 3 weeks for a total of six cycles. There was a statistically significant survival advantage for patients in the chemotherapy arm, who had a median survival of 23 months compared to the 11 months observed in the control group ($p = 0.04$), but this was lost at 5 years (4% vs. 8% $p = 0.10$). The poor long-term survival results have to be interpreted carefully due to the high initial drop-out rate (only 24 out of the original 30 patients randomized received chemotherapy) and appreciable toxicity associated with this regimen (only 13 patients completed all six scheduled courses). A further drawback of this study was that it pooled patients with pancreas and periampullary cancer, limiting the applicability of the results to pancreas cancer.

Takada et al.

Between April 1986 and June 1992, this multicenter Japanese trial [30] enrolled 508 patients who had undergone a resection for pancreatic, gall bladder, bile duct, or ampulla of Vater cancers. Patients were randomized to either the chemotherapy arm (mitomycin C 6 mg/m^2 and 5FU 310 mg/m^2 days 1–5 and days 15–20 followed by oral 5FU 100 mg/m^2 daily) or observation following surgery. Out of 173 patients with pancreatic cancer, 158 were eligible for survival analysis. The 5-year survival rate in patients with pancreatic carcinoma was 11.5% in the chemotherapy arm and 18.0% in the control arm, and this did not represent a significant difference. There was also no difference seen between the two treatment arms for the secondary endpoints of disease-free survival and time to recurrence. The poor performance of the chemotherapy regimen in this study could be attributed to the use of oral 5FU, which because of its hepatic metabolism has very poor efficacy compared to intravenously administered 5FU or specially designed oral fluoropyrimidines.

Kosuge et al.

A recent Japanese multicenter randomized controlled trial [31] evaluated chemotherapy with 5FU (500 mg/m^2) and cisplatin (80 mg/m^2) versus observation in 89 patients with pancreas cancer, recruited between 1992 and 2000. Enrolment was restricted to patients with microscopically clear resection margins (R0), and only two cycles of chemotherapy were administered. The authors concluded that there was no survival advantage for chemotherapy (median survival 12.5 months) compared to observation (median survival 15.8 months). Of interest is the 5-year survival figure, which was higher in the chemotherapy arm (26.4%) compared to the observation arm (14.9%) though this was not statistically significant ($p = 0.94$). The drawbacks of this study are that it was probably underpowered due to an

overambitious estimated survival difference and a suboptimal duration of the chemotherapy was used.

ESPAC-1

The European Study Group for Pancreatic Cancer Trial 1 (ESPAC-1) [32, 33] was a multicenter study, which used a 2 × 2 factorial design to assess the role of adjuvant chemotherapy or chemoradiation in pancreatic cancer. Following pancreatic resection, each patient was randomized to chemotherapy (bolus 5FU 425 mg/m^2 plus folinic acid 20 mg/m^2 days 1–5, monthly for six cycles) or chemoradiation (20 Gy dose to the tumor given in 10 daily fractions over a 2-week period plus an intravenous bolus of 5 FU 500 mg/m^2 each of the first three days of radiotherapy and again after a planned break of 2 weeks) or both treatments (i.e., chemoradiation followed by chemotherapy as above) or neither treatment (i.e., observation) . Randomization was stratified according to center and resection margin status. Between 1994 and 2000, a total of 289 patients were randomized into the 2 × 2 factorial design; a further 261 patients were randomized to either chemotherapy or chemoradiation versus observation outside the original design (ESPAC-1 plus). After a median of 47 months follow-up of patients in the 2 × 2 factorial design, the median survival was 20.1 months (95% CI, 16.5–22.7) among the 147 patients who received chemotherapy and 15.5 months (95% CI, 13.0–17.7) among the 142 patients who did not receive chemotherapy (hazard ratio for death, 0.71; 95% CI, 0.55–0.92; $p = 0.009$) (Fig. 1). Two-year and 5-year survival estimates were 40% and 21%, respectively, among patients who received chemotherapy and 30% and 8%, respectively, among patients who received no chemotherapy. Independently significant prognostic factors included tumor differentiation (HR1.89, 95% CI, 1.49–2.39), tumor size (HR1.21, 95% CI, 1.08–1.36), and positive lymph nodes (HR1.57, 95% CI, 1.18–2.09). Overall the influence of the type of surgery and the presence of complications on survival (in conjunction with clinicopathological variables) were studied using the Cox proportional hazard model. Postoperative complications or the type of resection did not impact on the survival benefit seen with adjuvant chemotherapy. The primary outcome of this study supports the use of 5FU/FA as standard adjuvant therapy in resected pancreatic cancer.

CONKO-001

This multicenter German study recruited 368 patients between July 1998 and December 2004. Following R0 or R1 pancreatic resection, 179 patients were randomized to receive gemcitabine (3 weekly infusions of gemcitabine 1,000 mg/m^2 given by intravenous infusion during a 30-min period, followed by a 1-week pause), and 177 patients were randomized to surgery alone. The primary endpoint of the trial was disease-free survival. There was a significant increase in median disease-free survival with gemcitabine (13.4 months 95% CI, 11.4–15.3) compared with control (6.9 months 95% CI, 6.1–7.8) but had just failed to demonstrate a significant advantage in median overall survival ($p = 0.06$) with gemcitabine compared with

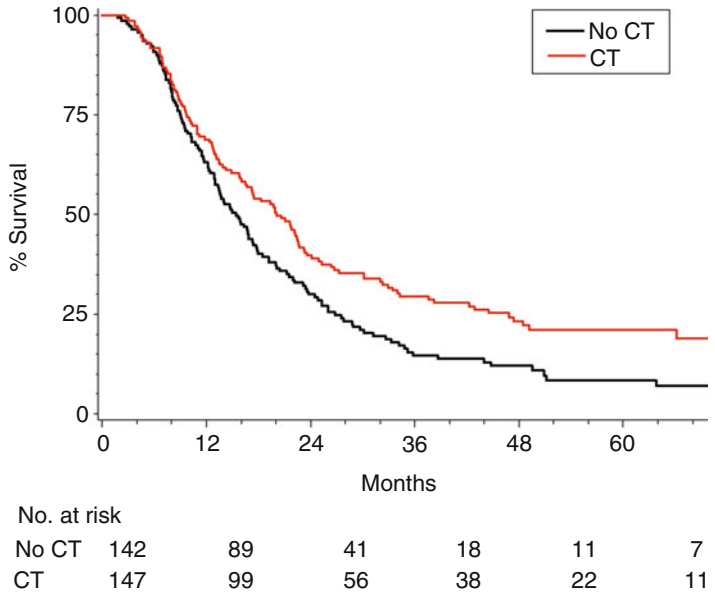

Fig. 1 Overall survival according to whether or not patients received chemotherapy (*CT*) in the ESPAC 1 trial final results, 2 × 2 factorial [32]

control [34]. However, the final analysis conducted after a median follow-up of 11 years showed also a significant advantage in overall survival [35]. Median disease-free survival for the gemcitabine group was 13.4 months compared to 6.9 months for the observation arm (HR 0.55, 95% CI, 0.44–0.69, $p < 0.001$). The estimated disease-free survival at 5 years was 16.6% in the gemcitabine group versus 7.0% in the observation group, respectively. There was a significant improvement in median overall survival with gemcitabine, 22.8 months, compared to observation alone, 20.2 months (HR 0.76, 95% CI, 0.61–0.95, $p = 0.01$). Estimated survival at 5 years was 20.7% for gemcitabine patients versus 10.4% for observation patients, respectively. The results of the CONKO-001 trial support the use of single-agent gemcitabine as an alternative option for the adjuvant treatment of pancreatic cancer.

JSAP-02

The JSAP-02 trial provided some evidence that the findings of the CONKO-001 trial could be generalized to Asian populations. This was a phase III study that was conducted in Japan and randomized macroscopically resected patients to adjuvant gemcitabine (3 weekly infusions of gemcitabine 1,000 mg/m^2 given by intravenous infusion, followed by a 1 week pause) or observation [36]. Of note, duration of treatment was shorter compared to the CONKO-001 trial with only three (instead of six) cycles of chemotherapy. The primary endpoint was overall survival and

118 eligible patients were recruited. Although a statistically significant improvement in disease-free survival was observed in favor of the chemotherapy arm (median disease-free survival 11.4 vs. 5.0 months; 2-year disease-free survival 27.2% vs. 16.7%; HR 0.60, 95% CI, 0.40–0.89, $p = 0.01$), no difference was found between arms in overall survival (median 22 overall survival 0.3 vs. 18.4 months; 5-year 23 overall survival 0.9% vs. 10.6%, HR 0.77, 95% CI, 0.51–1.14, $p = 0.19$). Given that the absolute advantage in favor of adjuvant gemcitabine in terms of both disease-free survival and overall survival appeared very similar to that reported by the investigators of the CONKO-001 trial, it is likely that the negative results of the JSAP-02 are due to the fact that the statistical design was too ambitious (i.e., target HR 0.55) and, therefore, the study underpowered to demonstrate a statistically significant difference in overall survival.

ESPAC-3

The ESPAC-3 trial was originally designed as a 3-arm, randomized, phase III trial to compare observation alone versus 24 weeks of adjuvant chemotherapy with either gemcitabine (3 weekly intravenous infusions of 1,000 mg/m^2, followed by a 1-week pause) or 5FU plus folinic acid (425 mg/m^2 and 20 mg/m^2, respectively, given as intravenous bolus on 5 consecutive days every 28 days) [37]. However, following the results of the CONKO-001 study, the observation arm was discontinued and the study continued as a 2-arm trial. The primary endpoint was overall survival. A total of 1,088 pancreatic cancer patients who had undergone a microscopically resection were enrolled. No statistically significant difference was observed between treatment arms, with median overall survival being 23.0 months (95% CI, 21.1–25.0) for patients treated with 5FU plus folinic acid and 23.6 months (95% CI, 21.4–26.4) for those randomly assigned to gemcitabine (HR 0.94, 95% CI, 0.81–1.08, $p = 0.39$). Overall survival at 2 years was 48.1% in the 5FU/folinic acid group versus 49.1% in the gemcitabine group (Fig. 2). Likewise, patients in both groups were reported to have similar outcome in terms of PFS (median and 2-year PFS 14.1 months and 30.7%, respectively, in the 5FU/folinic arm versus 14.3 months and 29.6%, respectively, in the gemcitabine arm, HR 0.96, 95% CI, 0.84–1.10, $p = 0.53$).

However, treatment with gemcitabine appeared to be better tolerated. A total of 14% of patients in the 5FU/folinic acid arm experienced a treatment-related serious adverse event compared with 7.5% in the gemcitabine arm ($p < 0.001$). Statistically significant differences in grade 3/4 toxicities between arms included leukopenia (10% vs. 6%) and thrombocytopenia (1.5% vs. 0%) which occurred more frequently in the gemcitabine group and stomatitis (10% vs. 0%) and diarrhea (13% vs. 2%) which were more common in the 5FU plus folinic acid group.

The efficacy findings of this study confirmed that gemcitabine and 5FU plus folinic acid are equally effective as adjuvant treatments for resected pancreatic cancer patients. However, the toxicity data support the contention that, in view of its more favorable safety profile, gemcitabine should be considered as the preferred therapy.

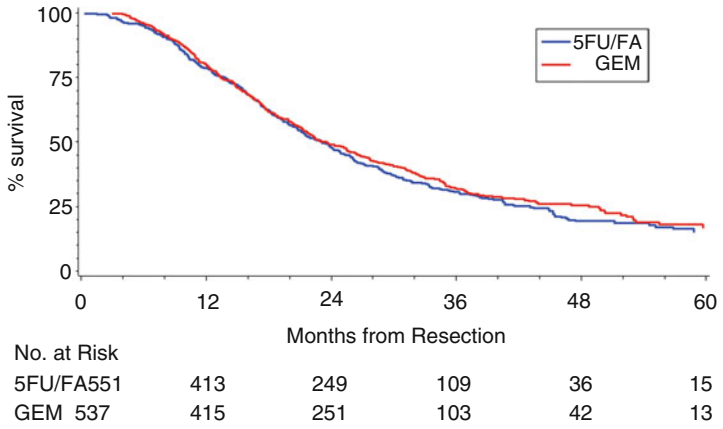

Fig. 2 Overall survival according to whether or not patients received adjuvant chemotherapy with 5-fluorouracil and folic acid (5FU FA) or gemcitabine (GEM) in the ESPAC-3 (v2) trial [37]

JASPAC-01

S-1 is an oral drug containing tegafur (a prodrug of the active compound 5FU), gimeracil (a dihydropyrimidine dehydrogenase (DPD) inhibitor), and oteracil potassium (an orotate phosphorribosyltransferase inhibitor). This combination was developed to increase the therapeutic ratio of 5FU by prolonging half-life and maintaining high levels of this agent in blood and tumor tissue while limiting the production of the same (and resulting toxicity) in the gastrointestinal tract. Further to the encouraging antitumor activity observed in studies conducted in the advanced setting, S-1 has been recently investigated as adjuvant treatment.

Japan Adjuvant Study Group of Pancreatic Cancer (JASPAC-01) was a randomized, open-label, phase III trial conducted in Japan [38]. In this study, patients who had undergone surgical resection (either R0 or R1) for stage I–III pancreatic ductal adenocarcinoma were randomized to receive standard gemcitabine (3 weekly iv infusions of gemcitabine 1,000 mg/m^2, followed by a 1-week pause) or S-1 (40–60 mg according to the BSA, twice daily for 28 days, followed by a 2-week pause) for 24 weeks. The primary endpoint was overall survival, and the study was powered to demonstrate non-inferiority of S-1. The per-protocol population included 377 patients. After a median follow-up >6 years, patients in the standard treatment arm had a median overall survival of 25.5 months and 5-year survival of 24.4% compared to 46.5 months and 44.1%, respectively, in patients who were assigned to the investigational arm. The HR for death of S-1 was 0.57 with the upper bound of the 95% CI (i.e., 0.72) being largely within the predefined non-inferiority margin (i.e., 1.25) (p value for non-inferiority <0.0001; p value for superiority <0.0001). A similar difference was observed between treatment arms with regard to relapse-free survival. Median relapse-free survival and 3-year relapse-free survival rate were 11.3 months and 22.6% in the gemcitabine group compared with 22.9 months and 39.2% in the S-1 group (HR 0.60, 95% CI 0.47–0.76, p <0.0001). Safety analysis

showed that gemcitabine treatment was associated with a statistically significantly increased risk of grade 3/4 leukopenia, neutropenia, and ALT/AST elevation, while patients randomized to S-1 experienced more grade 3/4 stomatitis and diarrhea.

The results of the JASPAC-01 trial suggest that S-1 should be the standard adjuvant treatment for pancreatic cancer in Japan and possibly in other Asian countries. Nevertheless, generalizability of these findings to Western populations is not recommended due to differences in terms of pharmacokinetic and safety of S-1 between Eastern and Western patients as previously reported in other studies.

CONKO-005

Based on the positive results of the NCIC CTG trial which demonstrated a small survival advantage for gemcitabine plus erlotinib compared to standard single-agent gemcitabine in the metastatic setting [39], the CONKO-005 trial investigated the same combination regimen as adjuvant treatment after microscopically radical (i.e., R0) resection [40]. In this phase III trial, patients were randomly assigned to receive 24 weeks of gemcitabine (3 weekly iv infusions of gemcitabine 1,000 mg/m^2, followed by a 1-week pause) or the same schedule of gemcitabine plus erlotinib (at a dose of 100 mg po, once daily). The primary endpoint was disease-free survival. A total of 436 patients were randomized. Results of this trial were presented at the 2015 ASCO Annual Meeting in Chicago, and no survival advantage from erlotinib was shown. Median disease-free survival was 11.6 months in both arms (HR 0.89, 95% CI 0.72–1.10). Also no significant difference in median overall survival was reported (24.6 months in the gemcitabine plus erlotinib arm vs 26.5 months in the gemcitabine alone arm, HR 0.90, 95% CI 0.71–1.15). Notably, a trend toward a better long-term outcome for patients who were treated with the combination treatment was observed (5-year overall survival rate 28% vs. 19%). In contrast to what was previously reported in the metastatic setting, a subgroup analysis did not confirm any correlation between grade of erlotinib-induced rash and outcome in the investigational treatment arm.

ESPAC-4

The ESPAC-4 trial was a randomized, open-label, phase III study comparing 24 weeks of standard single-agent gemcitabine (3 weekly iv infusions of gemcitabine 1,000 mg/m^2, followed by a 1-week pause) versus 24 weeks of combination chemotherapy with gemcitabine plus capecitabine (3 weekly iv infusions of gemcitabine 1,000 mg/m^2, followed by a 1-week pause and capecitabine 830 mg/m^2 twice daily orally for 21 days followed by 7 days of rest) as adjuvant treatment following macroscopically surgical resection [41]. The trial was conducted in Western countries including the UK, France, Germany, and Sweden. The primary endpoint was overall survival, and the study was powered to demonstrate a difference of 10% in a 2-year overall survival between treatment arms. A total of 722 patients were enrolled of whom 60% had undergone an R1 surgical resection

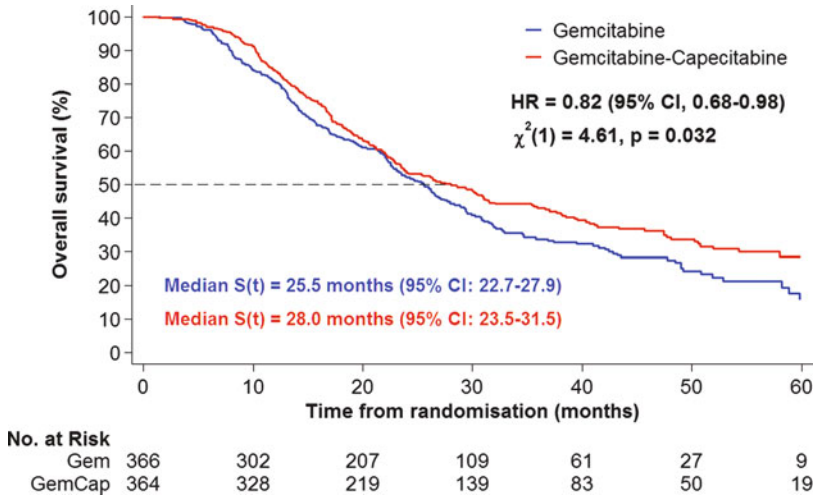

Fig. 3 Overall survival according to whether or not patients received adjuvant chemotherapy with gemcitabine (5FU FA) or gemcitabine plus capecitabine (GEM) in the ESPAC-4 trial [41]

and 80% had pathologically positive lymph nodes. The study was stopped prematurely by the Independent Data and Safety Monitoring Committee due to the positive results. Patients who were randomized to the combination treatment arm had a median overall survival of 28.0 months (95% CI 23.5–31.5) compared with 25.5 months (95% CI 22.7–27.9) for those who were treated with single-agent gemcitabine (HR 0.82, 95% CI 0.68–0.98, $p = 0.032$) (Fig. 3). At 5 years, 28.8% (95% CI 22.9–35.2) of patients in the combination therapy group were alive versus 16.3% (95% CI 10.2–23.7) in the control arm. Treatment with gemcitabine plus capecitabine was associated with an increased risk of grade ≥ 3 neutropenia (38% vs. 24%), hand-and-foot syndrome (7.0% vs. 0%), and diarrhea (5% vs. 2%), while more grade ≥ 3 infections/infestations were reported in the gemcitabine arm (7% vs. 3%). No difference in the proportion of patients experiencing a serious adverse event was observed between treatment groups (26% with gemcitabine and 24% with gemcitabine plus capecitabine).

The results of the ESPAC-4 trial set combination chemotherapy with gemcitabine plus capecitabine as a new standard of care for the adjuvant treatment of patients with curatively resected pancreatic cancer.

Predictive Biomarkers for Adjuvant Chemotherapy

There is no doubt that accurate patient selection is crucial to maximize the benefit from adjuvant chemotherapy. In this regard, studies have assessed the predictive or prognostic role of a number of tumor biomarkers in pancreatic cancer patients who are treated with curative surgical resection and adjuvant chemotherapy. Among all

biomarkers analyzed, the human equilibrative nucleoside transporter 1 (hENT1) appeared to be the most promising one. hENT1 is a membrane nucleoside transporter protein which is directly involved in the tumor cell uptake of gemcitabine. Therefore, it has been hypothesized that its expression levels could predict benefit from adjuvant gemcitabine. However, the results from retrospective analysis of randomized clinical trials have so far been contradictory.

The investigators of the ESPAC trials analyzed hENT1 expression (using the original Mackey mouse monoclonal anti-hENT1 antibody 10D7G2) in tissue microarrays from a total of 380 patients who were treated with adjuvant gemcitabine ($n = 176$), 5FU and folinic acid ($n = 176$), or observation alone ($n = 28$) within the context of the ESPAC-1 and ESPAC-3 studies [42]. They found that, among the group of gemcitabine-treated patients, those with high hENT1 expression had a significantly longer median overall survival (26.2 months) compared with patients who had low hENT1 expression (17.1 months) (HR 0.60, 95% CI 0.43–0.83, $p = 0.002$). In this group, hENT1 expression was an independent prognostic factor for overall survival ($P = 0.003$). In contrast, no difference in survival was observed according to the levels of hENT1 expression in the group of patients who received 5FU and folinic acid or no adjuvant chemotherapy.

A retrospective analysis of the CONKO-001 trial that included 156 patients (88 randomized to adjuvant gemcitabine and 68 to observation) found no association between hENT1 expression adjuvant gemcitabine and survival but used a completely different antibody (clone SP 120 rabbit antibody) [43].

Other potential candidates include dihydropyrimidine dehydrogenase, and thymidylate synthase metabolism involved in the metabolism of 5FU and carboxyl esterase-2 (CES2), which activates irinotecan into SN-38 which is part of the FOLFIRINOX regimen [28].

Future Studies

A further number of large multicenter randomized trials are actively recruiting. Addressing the question of whether combination chemotherapy regimens that have been recently shown to be superior to gemcitabine in the metastatic setting can have a role as postoperative treatments is the next logical step in the design of future adjuvant studies. In this regard, PRODIGE 24/ACCORD 24 and APACT are among the most interesting ongoing phase III studies, and the results are eagerly awaited.

PRODIGE 24/ACCORD 24 is a multicenter, randomized phase III trial investigating adjuvant treatment with a modified version of FOLFIRINOX (mFOLFIRINOX) [44]. Patients recruited in this study are randomized to standard gemcitabine (3 weekly iv infusions of 1,000 mg/m^2, followed by 1 week pause) or mFOLFIRINOX (2 weekly iv infusions of oxaliplatin 85 mg/m^2, irinotecan 150 mg/m^2, levogyre folinic acid 200 mg/m^2, and 46-h continuous infusion of 5FU 2,400 mg/m^2). The primary endpoint of the study is disease-free survival, and 490 patients are required.

APACT (ABI-007-PANC-003) is a multicenter, randomized phase III trial comparing gemcitabine plus nab-paclitaxel (3 weekly iv infusions of gemcitabine

1,000 mg/m^2 and paclitaxel 125 mg/m^2, followed by a 1-week pause) versus single-agent gemcitabine (3 weekly iv infusions of 1,000 mg/m^2, followed by a 1-week pause) [45]. Treatment duration is 24 weeks for both arms. The primary endpoint is disease-free survival, and 846 patients are required.

Rationale for Adjuvant Chemoradiation

We have robust evidence from completed large phase III trials that adjuvant chemotherapy should be used as standard for patients with resected pancreatic cancer. The argument to support the use of adjuvant chemoradiation is not quite so clear cut.

Radiation treatment after surgical resection of pancreatic cancer has been given with the idea of controlling any microscopic local residual disease. This is especially relevant considering that approximately 10–20% of resections are characterized by positive margins and recurrences following pancreaticoduodenectomy can occur at the site of resection. However, distant metastases are thought to be more common than local recurrences and account for the majority of tumor failures and cancer-related deaths in this setting.

External beam radiotherapy (EBRT) is delivered using chemosensitization (chemoradiation) usually with 5FU or gemcitabine. Although combining chemotherapy with radiation therapy can increase the risk of toxicities, chemoradiation has been shown to be superior to EBRT alone at least in the setting of locally advanced tumors [46]. Also, administering concurrent chemotherapy (despite at a low, chemoradiosensitizing dose) may potentially sterilize micrometastases and therefore reduce the risk of distant recurrence after surgical resection.

Nevertheless, compared with systemic chemotherapy, chemoradiation has been less investigated as adjuvant treatment for pancreatic cancer patients who had curative resection. Furthermore, clinical trials have so far reported contrasting results. These are reported in detail in the next paragraphs.

One of the issues associated with irradiation of the upper abdomen by external beam radiotherapy (EBRT) is the risk of considerable toxicity, especially gastrointestinal. Intraoperative radiation therapy (IORT) may be employed to reduce this by sparing normal tissues. The surrounding tissues can either be displaced or shielded, thereby allowing the delivery of larger radiotherapy doses in a single fraction to volumes harboring tumor cells. However, at the current time, there is no level 1 evidence to support its use in advanced pancreatic cancer. As most series on adjuvant IORT are dogged by small numbers, inclusion of all stages of the disease, heterogenous treatment strategies, and retrospective design, it is difficult to draw conclusions or make recommendations on IORT [47]. The one small randomized trial on IORT [48] was published in abstract form and found no difference in survival between surgery only and IORT (median survival 12 months in both groups).

Intensity-modulated radiotherapy (IMRT) could provide another option to minimize the risk of radiation treatment-related toxicities [49]. This has been increasingly

investigated in pancreatic cancer and is being used in large randomized clinical trials of adjuvant chemoradiation.

Randomized Controlled Trials of Adjuvant Chemoradiation

EORTC 40891

The role of postoperative chemoradiotherapy has been assessed in two large randomized studies (Table 2). In a multicenter prospective randomized trial, Klinkenbijl et al. [50] recruited 218 patients with either pancreatic head (stage pT1–2, pN0-1a) or periampullary cancer (stage pT1–3, pN0-1a). Randomization was to observation or radiotherapy with split course radiotherapy (40 Gy) and concurrent 5FU as continuous infusion. Median survival in the overall study population was 19 months in the observation group and 24.5 months for the treatment group (log rank $P = 0.208$). In patients with pancreatic cancer, the trend was in favor of chemoradiation, with the median overall survival being 12.6 months in the observation group and 17.1 months in the treatment group ($p = 0.099$). A subsequent report [51] on the long-term survival of patients from this trial, after a median follow-up of 11.7 years, reaffirmed that there was no difference in overall survival between the two arms (death rate ratio 0.91, 95% confidence interval 0.68–1.23; $p = 0.54$). The overall 10-year survival was 18% in the entire population and 8% in the subgroup of pancreas head cancers. The patterns of recurrent disease observed in both arms of the trial were very similar, and in each case over 70% of patients had distant metastases. These findings, again, highlight the need for a systemic component when considering adjuvant therapy for pancreatic cancer. The limitations of this study can be identified as a lack of maintenance chemotherapy and a questionable statistical design that limited its ability to detect a benefit for adjuvant chemoradiation.

ESPAC-1

As previously described, the ESPAC-1 study [32, 33] was an international multicenter randomized trial that originally used a two-by-two factorial design allocation, to address the issues of adjuvant chemotherapy and adjuvant chemoradiation in patients with resected pancreatic cancer ($n = 289$). The 2×2 factorial designs create four arms, namely, observation, chemoradiotherapy alone, chemotherapy alone, and chemoradiotherapy, followed by chemotherapy but only two permissible statistical comparisons, namely, chemotherapy versus no chemotherapy and chemoradiotherapy versus no chemoradiotherapy. Patients who were randomized to chemoradiotherapy received a dose of 40 Gy (20 Gy in 10 fractions, repeated after a 2-week pause) plus 5FU (500 mg/m^2 as a bolus infusion on the first 3 days of each cycle of radiotherapy). In the two-by-two factorial design, 145 patients were randomized to the chemoradiotherapy arm (72 of which received chemoradiotherapy followed by 5FU-based chemotherapy), while 144 were randomly assigned to no

Table 2 Adjuvant chemoradiotherapy: Randomized controlled trials

Series	Period	Number of patients	Regimen	Median survival (months)	Actuarial survival (%) 1 year	Actuarial Survival (%) 2 years	Actuarial Survival (%) 3 years	Actuarial Survival (%) 5 years
Klinkenbijl et al. [50]	1987–1995	110	40 Gy + 5FU	24.5	41	–	–	10

chemoradiotherapy (75 received 5FU-based chemotherapy and 69 observation alone). In the final analysis, the median survival was 15.9 months in the chemoradiotherapy arm and 17.9 months in the group who were not assigned to receive chemoradiotherapy (HR 1.28, 95% CI 0.99–1.66, $P = 0.05$) (Fig. 4). The estimated 5-year survival was 10% in the chemoradiotherapy arm compared to 20% in those who did not receive chemoradiotherapy ($p = 0.05$). The lack of a survival advantage following chemoradiotherapy could be due to delays in administering radiation in patients who suffered postoperative complications. This reduces the potential benefit of chemotherapy that is derived by administering it as soon as possible after resection. The arguments that the radiation given during the ESPAC1 trial was substandard or not exposed to rigorous quality control do not stand up, given that the survival in the individual groups is the same or superior to that observed in North American randomized studies and was bases on an intention to treat analysis including those who did have any chemoradiation.

The lack of convincing data from these phase III studies emphasizes the problems encountered when trying to justify the use of adjuvant chemoradiation for these patients. The possibility that in fact chemoradiation may have a negative impact on survival cannot be ignored. At the present time, the use of adjuvant chemoradiation cannot be recommended as standard therapy.

Rationale for Adjuvant Combination Therapy

The relative failure of chemoradiation to significantly improve survival following pancreatic resection led to the hypothesis that adjuvant chemoradiotherapy and follow-on chemotherapy should be a more successful approach. Evidence, however,

from meta-analysis of studies in advanced cancer has shown that there is no survival difference between chemoradiotherapy plus follow-on chemotherapy and chemotherapy alone [46]. Phase III studies have provided further evidence of the effect of chemoradiotherapy and follow-on chemotherapy in advanced pancreatic cancer; however, the message is mixed. For example, a phase III study compared chemoradiotherapy and follow-on gemcitabine with gemcitabine alone in patients with locally advanced disease [52]. The results were not encouraging as the combination therapy was more toxic and less effective than gemcitabine alone. Another randomized phase III study of 74 patients with locally advanced pancreatic cancer again compared gemcitabine versus chemoradiotherapy and follow-on gemcitabine. This study also found increased toxicity with the combination, but it was manageable. The median survival time, however, increased in the combination group versus the gemcitabine alone group (9.2 months 95% CI 7.8, 11.4 vs. 11.0 months 95% CI 8.4, 15.5 respectively). The 95% confidence intervals overlapped indicating that the difference was not statically different using a two-sided p test although the authors reported a significant difference using a one-sided p test [53].

Randomized Controlled Trials of Adjuvant Combination Therapy

GITSG 9173

The Gastrointestinal Tumor Study Group (GITSG) trial 9173 sets the trend for the use of chemoradiotherapy followed by chemotherapy in resectable disease [54, 55]. This trial randomized 43 patients either to observation or to receive combined treatment (chemoradiotherapy followed by chemotherapy) in the form of split course EBRT (40 Gy) and concurrent 5FU, followed by 5FU for 2 years (Table 3). The study was terminated prematurely both because of a low rate of accrual and because of an increasingly large difference in survival between the study arms. The median survival for the adjuvant treatment group was 20 months, significantly longer than the 11 months in the no adjuvant treatment arm. Actuarial survival rates at 2 years were 43% (95% CI 25–63) and 18% (95% CI 8–36), respectively. Because there were so few cases, a further 30 patients were registered (not randomized) to the treatment arm, and the median survival in this group was 18 months, with a 2-year survival rate of 46%. Owing to the small number of patients, the 95% confidence intervals of the survival curves were so large as to overlap with survival curves in patients receiving no additional treatment. Thus no convincing conclusion could be derived from this study, though it must be noted that the benefit from treatment could have been due to the maintenance chemotherapy used in this study.

RTOG 9704

The Radiation Therapy Oncology Group Study 9704 [56], a phase III trial, compared pre- and post-chemoradiation gemcitabine (at a dose of 1,000 mg/m^2/day) to pre-

Table 3 Adjuvant chemoradiotherapy and follow-on chemotherapy (combination therapy): Randomized controlled trials

Series	Period	Number of patients	Regimen	Median survival (months)	Actuarial survival (%) 1 year	Actuarial Survival (%) 2 years	Actuarial Survival (%) 3 years	Actuarial Survival (%) 5 years

		53	50.4 Gy + Cisplatin/5FU/ IFN α-2b followed by continuous 5FU	32.1	–	–	–	–

5FU 5fluorouracil, *Gem* gemcitabine, *CRT* chemoradiotherapy

and post-chemoradiation 5FU (at a dose of 250 mg/m^2/day given as a continuous infusion). Both arms of the study received 5FU-based chemoradiation (50.4 Gy), with the chemotherapy given for 3 weeks pre- and 12 weeks post-chemoradiation. Over 4 years, 538 patients were recruited, exceeding the planned target of 330 patients. Patients were stratified by size of the tumor, involvement of lymph nodes, and surgical resection margin. Analysis was restricted to the 451 eligible patients. Treatment groups were well balanced with the only exception of T stage, as more patients in the gemcitabine arm had T3/4 tumors compared to the 5FU arm (81% vs. 70%, $p = 0.01$). There was no difference in overall survival between the two arms (log rank $p = 0.34$). On the other hand, the rate of grade 3/4 adverse events was significantly higher in the gemcitabine arm (79% vs. 62%, $p < 0.001$), this being largely due to a significant difference in hematological toxicity (58% vs. 9%; $p < 0.001$). Of note, a subgroup analysis of the 388 patients with pancreas head cancer revealed a better survival for the gemcitabine group (i.e., median overall survival 20.5 vs. 16.9 months), and this was statistically significant after adjusting for prognostic factors (HR = 0.80; 95% CI = 0.63–1.00; $p = 0.05$). Comparison with the individual groups in the ESPAC 1 trial suggests better survival times associated with chemotherapy alone when compared with the combination group (and better survival overall), although the trial was not designed to look at this specific question (see Tables 1, 2, and 3). Good-quality data are lacking to support the use of adjuvant chemoradiation for pancreatic cancer [57]

It is now increasingly important to incorporate translational research into large prospective adjuvant studies to identify prognostic and predictive biomarkers and to better understand the underlying mechanisms of action. Two prognostic studies based on data and tissue from this trial have been completed. The RTOG 9704 study identified that the post-resection CA19.9 level was a significant predictor of overall survival [58] and that hENT1 expression of the tumor tissue using immunohistochemistry (with the original Mackey mouse monoclonal anti-hENT1 antibody 10D7G2) was an independent prognostic factor in the gemcitabine group [59].

Interferon-Based Chemoradiation

Based on the chemo- and radiosensitizing properties of interferon (IFN) as well as its ability to modulate the immune system, several phase II adjuvant studies have used IFN-based protocols in the adjuvant setting of pancreatic cancer and reported interesting results with median overall survival times of 25–27 months [60, 61]. More recently, a large randomized phase III trial compared chemoradiation with 5FU (200 mg/m^2/day, continuous infusion), cisplatin (30 mg/m^2, once a week), and IFN α-2b (3 million units, three times a week) plus EBRT (50.4 Gy) followed by two cycles of continuous 5FU versus chemotherapy with bolus 5FU and folinic acid (425 and 20 mg/m^2, respectively, on 5 consecutive days every 28 days for 6 cycles) in patients who had undergone microscopically resection for pancreatic adenocarcinoma [62]. The primary endpoint was overall survival. A total of 132 patients were randomized, while the per-protocol population consisted of 110 patients. No

difference in overall survival was found in both the intention-to-treat and per-protocol population. In the former, median survival was 26.5 months in the investigational arm compared to 28.5 months in the standard arm (HR 1.04, 95% CI 0.66–1.53, $P = 0.99$), while in the latter these figures were 32.1 months and 28.5 months, respectively ($P = 0$ 0.49). Of note, IFN-based chemoradiation was found to be significantly toxic with 85% of patients experiencing grade 3/4 adverse events compared to 16% of patients in the chemotherapy alone arm. Furthermore, investigational therapy was also associated with deterioration of a number of QoL parameters. Based on these results, the investigators themselves did not recommend further investigation of IFN-based therapies in this setting.

Future Studies

The results of the clinical trials that have been conducted so far suggest that adjuvant chemotherapy should be considered as the standard treatment for pancreatic cancer patients who undergo macroscopically radical surgical resection, regardless of the status of the surgical margins (i.e., either R0 or R1). On the other hand, the currently available data do not support the routine use of chemoradiotherapy.

One of the main concerns regarding the use of concurrent chemoradiotherapy in the adjuvant setting of pancreatic cancer is the natural course of this disease which is characterized by a high risk of postoperative metastatic dissemination. However, it is unknown whether administering chemoradiotherapy after chemotherapy may possibly confer a survival advantage.

The EORTC/FFCD/GERCOR 40013/22012/0304 phase II study randomized patients who had undergone surgical resection receive either four cycles of gemcitabine 1,000 mg/m^2 over 30 min weekly for 3 weeks and then 1-week rest (control arm) or gemcitabine 1,000 mg/m^2 for two cycles followed by weekly gemcitabine 300 mg/m^2 with concurrent radiation of 50.4 Gy given in 28 fractions of 1.8 Gy (experimental arm) [63]. This regimen was found to be feasible and well tolerated. However, no difference in both disease-free survival and overall survival was observed between treatment arms.

It is possible that the negative results are secondary to the relatively early switch to chemoradiation in the investigational arm. On the other hand, delivering chemoradiation after a reasonably long period of systemic control with adjuvant chemotherapy may allow selection of patients who are more likely to benefit from further locoregional treatment. This treatment strategy is being assessed in the randomized phase II/III clinical trial RTOG 0848/EORTC-40084-22084 [64]. In this study, patients who are disease-free after five cycles of adjuvant chemotherapy with gemcitabine plus or minus erlotinib are randomized to receive either one more cycle of adjuvant chemotherapy or the same followed by sequential fluoropyrimidine-based (i.e., 5FU or capecitabine) chemoradiotherapy (50.4 Gy). The primary endpoint of the study is overall survival, and 950 patients are estimated to be required.

Novel treatment approaches in the adjuvant setting include the investigation of immunomodulatory agents in combination with standard chemotherapy and

chemoradiotherapy. Targeting the immunosuppressive microenvironment of pancreatic cancer, a well-established contributor to the biological aggressiveness and inherent treatment resistance of this disease, is the rationale behind the use of these novel strategies. A number of agents are currently under investigation in this setting including immune checkpoint inhibitors and vaccine therapies, but these have proved to be disappointing.

The results of a phase III trial using a whole cell vaccine, the IMmunotherapy for Pancreatic RESectable cancer Study (IMPRESS), were negative [65]. This randomized phase III trial ($n = 722$) compared adjuvant chemotherapy with gemcitabine alone or in combination with 5FU-based chemoradiotherapy plus or minus algenpantucel-L, a whole cell vaccine consisting of HAPa-1 and HAPa-2, two human pancreatic cancer cell lines. The median overall survival was 30.4 months in the control arm compared with 27.3 months in the investigational arm. In the same groups, 3-year overall survival was 41.4% and 42.1%, respectively.

A combination using GVAX pancreas, based on a pancreatic cell line modified to secrete granulocyte-macrophage colony-stimulating factor (GM-CSF), an immune-stimulatory cytokine, and CRS-207 which is attenuated *Listeria monocytogenes* expressing mesothelin, another immune-stimulatory molecule had poorer survival than CRS-207 alone or chemotherapy [66]. This phase IIb ECLIPSE trial in the third line and greater setting reported a median overall survival of 3.8 months for patients treated with the GVAX pancreas and CRS-207 combination, 5.4 months for patients treated with CRS-207 alone, and 4.6 months for patients given chemotherapy.

A phase II trial evaluating necuparanib (M402), a heparinoid with antitumor activity, in combination with nab-paclitaxel and gemcitabine in patients with advanced metastatic pancreatic cancer was discontinued after an interim futility analysis of 57 deaths from 120 randomized patients showed disappointing efficacy [67].

Demcizumab (OMP-21 M18) is a humanized monoclonal antibody directed against the N-terminal epitope of Notch ligand delta-like 4 (DLL4) that binds to the membrane-binding portion of DLL4 and prevents its interaction with Notch-1 and Notch-4 receptors that mediate angiogenesis. The randomized phase II YOSEMITE trial in first-line pancreatic cancer patients with metastatic disease randomized 207 patients to nab-paclitaxel, gemcitabine plus placebo, or to nab-paclitaxel, gemcitabine plus one 70-day truncated course of demcizumab, or to nab-paclitaxel, gemcitabine plus two 70-day truncated courses of demcizumab. The trial did not meet the primary endpoint of progression-free survival, and at the interim median analysis, overall survival was 13.2 months in the pooled demcizumab arms, but had not been reached in the control arm at the time of these analyses [68].

The Role of Adjuvant Regional Therapy

Adjuvant intra-arterial chemotherapy and chemoradiation strategies have been evaluated in a number of historical studies. More recently, Hayashibe et al. treated nine patients with coeliac artery infusion of cisplatin (CDDP) and 5FU following

pancreatic resection with a median overall survival of 15.8 months [69]. Another study in non-randomized setting gave adjuvant intra-arterial chemotherapy 5-fluoruracil 750 mg/m^2, leucovorin75 mg/m^2, epirubicin 45 mg/m^2, and carboplatin 225 mg/m^2 (FLEC regimen) every 3 weeks for three cycles alone ($n = 24$) or with follow-on systemic gemcitabine ($n = 23$) after resection for pancreatic cancer [70]. The overall median disease-free survival was 18 months, and median overall survival was 29.7 months [70].

In a randomized controlled study, patients who had undergone resection for pancreatic or periampullary cancer were randomized to receive either intra-arterial mitoxantrone, 5FU, leucovorin, and cisplatin in combination with 30 × 1.8 Gy radiotherapy ($n = 59$) or no adjuvant treatment ($n = 61$) [71]. There was no significant effect on local recurrence, the development of liver metastases, and overall survival [71].

Meta-Analyses

There have been several meta-analyses of adjuvant therapy in pancreatic cancer. Composite data from the ESPAC-1 and ESPAC-3(v1) trials has confirmed a significant survival advantage of adjuvant 5-fluorouracil and folinic acid compared to observation for pancreatic cancer [72]. Stocken et al. performed a meta-analysis using individual patient data from four ($n = 875$) out of the five selected randomized controlled trials (total = 939) [73]. Assessment of adjuvant chemotherapy trials revealed a 25% reduction in the risk of death (hazard ratio = 0.75, CI: 0.64, 0.90, $P_{strat} = 0.001$) with chemotherapy compared to the no chemotherapy arm. On the other hand, there was no significant difference between chemoradiation versus no chemoradiation (hazard ratio = 1.09, 95% CI: 0.89, 1.32, $P_{strat} = 0.43$). In both the comparisons assessed, there was significant intertrial heterogeneity. On subgroup analysis, chemoradiation was more effective ($\chi^2 = 4.2$, $P = 0.04$) and chemotherapy less effective ($\chi^2 = 7.3$, $P = 0.007$) in patients with positive resection margin. These results provide strong evidence for institution of adjuvant systemic chemotherapy following curative surgery. Another more recent meta-analysis concentrated on adjuvant 5FU-based chemoradiotherapy for resectable pancreatic adenocarcinoma and found only limited benefit for adjuvant chemoradiation, essentially reinforcing the findings of Stocken et al. [74].

A meta-analysis following the publication of the CONKO-001 included five trials, with 482 patients allocated to the chemotherapy group and 469 patients to the control group [75]. Four studies were used to assess median survival which demonstrated a significant advantage for chemotherapy over control. Five studies were used to assess 5-year survival, and there was no significant difference between the chemotherapy and control, but the drawbacks include the lack of individual patient data, the omission of results from the ESPAC-1 plus patients [33], and the longer-term follow-up of the CONKO-001 trial [35] and of course could not include the very recent results of JASPAC-1 and ESPAC-4 [38, 41].

More recently, a meta-analysis of nine randomized clinical trials including 3033 patients has analyzed survival benefit and safety data associated with 6 different management options: observation, chemotherapy with 5FU, chemotherapy with gemcitabine, 5FU-based chemoradiotherapy, chemoradiotherapy plus 5FU chemotherapy, and chemoradiotherapy plus gemcitabine chemotherapy [76]. Final results showed that, compared to observation, adjuvant chemotherapy with either 5FU or gemcitabine (HR 0.62, 95% credible interval 0.42–0.88 and 0.68, 95% credible interval 0.44–1.07, respectively) and chemoradiation plus either 5FU chemotherapy or gemcitabine chemotherapy (HR 0.54, 95% credible interval 0.15–1.80 and 0.44, 95% credible interval 0.10–1.81, respectively) were associated with better overall survival. Risk reduction was statistically significant only for 5FU chemotherapy. In contrast, no improvement in overall survival was found with chemoradiotherapy (HR 0.91, 95% credible interval 0.55–1.46). The use of chemoradiation plus chemotherapy appeared to provide only a slight survival advantage compared to chemotherapy, and this was even less evident when the HRs were adjusted taking into account the proportion of patients with positive lymph nodes. Finally, an increased risk of grade 3/4 toxicities was reported with chemoradiation plus chemotherapy, and this was especially true for hematological adverse events during chemoradiation plus gemcitabine chemotherapy.

Conclusion

This is an important and encouraging time for pancreatic cancer, there are data from large randomized adjuvant studies which have been completed, further trials are under development, and further studies are currently active. This situation is a vast improvement from that a decade ago. There is a general shift in the thinking about pancreatic cancer and its treatment. Although there has been a deep divide in the approach to pancreas cancer management between Europe and America, with the former adopting adjuvant chemotherapy, and the latter continuing to promote chemoradiation with follow-on chemotherapy, these studies have contributed to a change in attitudes, such that a more common approach using systemic chemotherapy alone is evolving.

A better understanding of the biology of pancreatic cancer indicates that this is a systemic disease very early in its pathogenesis reflecting the need for systemic (chemo) therapy and also suggesting the need to explore its use in the neoadjuvant setting for resectable disease [5, 77]. This needs to be balanced however with the prospect that, at least in some cases, neoadjuvant therapy may select and promote more aggressive cancer cell clones. Thus timely surgery with adjuvant therapy must remain at the center of our logical analysis in taking this and other novel concepts forward.

Analysis of the ESPAC-3 data has shown that the most effective approach to adjuvant chemotherapy is to deliver all six cycles of chemotherapy in the adjuvant setting [78]. Survival is not influenced by whether adjuvant chemotherapy is started before eight weeks of surgery or between 8 and 12 weeks after surgery. The issue

seems to hinge on fatigue: start the chemotherapy too soon when the patient still has postoperative fatigue; then it becomes very difficult to give all six cycles. On the one hand, waiting longer for the patient to reach full recovery with little or no fatigue than most patients will be able to continue through to all six cycles.

With improving standards in surgery, the outlook in terms of survival is improving for patients with borderline resectable and locally advanced pancreatic cancer [79], and resectability is increasing with the introduction of neoadjuvant chemotherapy, most notably FOLFIRINOX [80].

More research is needed to understand the potentially negative survival effect of radiotherapy on pancreatic cancer. A recent study in genetically engineered (KPC) mice and mice with orthotopic tumor cell transplants from KPC mice tumors showed that radiation produced a higher frequency of advanced pancreatic intraepithelial lesions [81]. There were more foci of invasive cancer than pancreata of unexposed mice (controls), and radiation reduced survival time by more than 6 months. Radiation-treated mice had tumors with a higher proportion of immune-suppressive M2-like macrophages, fewer CD8(+) T cells, and greater CD4(+) T cells of T-helper 2 and T-regulatory cell phenotypes than controls. Moreover it was shown that adoptive transfer of T cells from irradiated cancers to tumors of control mice accelerated tumor growth. Radiation induced production of MCSF by the cancer cells, while a neutralizing antibody against MCSF prevented the radiation-induced tumor promoting macrophages and increased the antitumor T-cell response and slowed tumor growth [81].

There is now exceptionally good level 1 evidence for adjuvant chemotherapy in pancreatic cancer following resection, as demonstrated by two large randomized controlled trials and supported by the results of meta-analyses. Single-agent chemotherapy with either gemcitabine or 5FU plus folinic acid (with the former being preferred over the latter due to its better safety profile) has been universally accepted as a routine treatment approach based on the results of the CONKO-001 and ESPAC-1, ESPAC-3, and ESPAC-4 trials and in Japan, S-1 based on the JASPAC-1 trial.

The key to the future of adjuvant therapy in pancreatic cancer will be the identification of novel and effective agents and better biomarker technology underpinned by translational research which will inform the design of future trials. Ultimately this will ensure that patients will be able to receive selective therapy to achieve the most benefit. Finally, it is worth noting that the modest survival outcome currently achievable with the available adjuvant therapies has led to an increased interest in the investigation of neoadjuvant treatment strategies in patients who have upfront resectable or borderline resectable tumors. If these novel approaches are demonstrated to provide a better long-term tumor control, then a reappraisal of the role of adjuvant therapy within the new therapeutic algorithm of early-stage pancreatic cancer will be necessary.

The findings from the recently completed ESPAC-4 trial indicate that combination chemotherapy with gemcitabine plus capecitabine is superior to single-agent gemcitabine and therefore should be adopted as new standard of care in this setting in Western countries and is mirrored in national and international guidelines including those of the American Society of Clinical Oncology [82].

Key Practice Points

- Adjuvant gemcitabine and 5FU-based chemotherapy significantly improve survival compared to observation.
- Give all six cycles of chemotherapy after surgery.
- The start of chemotherapy can be delayed until the patient has little or no fatigue after surgery; this may be up to 12 weeks.
- Gemcitabine and 5FU-based chemotherapy do not produce different survival rates as adjuvant treatments, but the safety profile of gemcitabine is better than that of 5FU-based chemotherapy.
- Adjuvant combination chemotherapy with gemcitabine plus capecitabine significantly improves survival compared to single-agent gemcitabine.
- Adjuvant chemotherapy with S-1 significantly improves survival compared to single-agent gemcitabine in Japanese patients.
- Adjuvant chemoradiation has not been shown to improve survival
- Adjuvant chemoradiation after adjuvant chemotherapy may not offer improved survival compared to chemotherapy alone – trial results are still awaited from the RTOG 0848 trial [64].

Future Research Directions

- Improved predictive biomarkers
- Improved combination chemotherapies
- Neoadjuvant plus adjuvant therapy
- Integrated translational research
- Development of biological therapies
- Development of immunotherapies
- Improved prognostic biomarkers
- Standardized pathological assessment

Adjuvant Chemoradiation Therapy for Pancreatic Cancer

Adeel Kaiser, William F. Regine, Naimish Pandya, and Michael C. Garofalo

Contents

Abstract

Despite newer treatment modalities, overall outcome for pancreatic cancer remains poor and has changed very little during the past 30 years. Surgery remains the mainstay, but delivery of adjuvant postoperative therapy has been shown to be essential for long-term survival. Large, prospective randomized studies have revealed conflicting data on whether chemotherapy alone or combination chemoradiation is optimal. They have also triggered debates regarding the sequencing of adjuvant therapy strategies. Unfortunately, marked discrepancies exist with patient selection as well as trial design among these studies, resulting in inadequate comparisons of their conclusions. Nevertheless, like other gastrointestinal malignancies, it appears that adjuvant combination chemoradiation is superior to chemotherapy alone when the data is critically analyzed. This critical

Introduction

It is estimated that more than 53,000 Americans will be diagnosed with cancer of the pancreas in 2016 [1] . The incidence of pancreatic cancer continues to rise on an annual basis. This is matched by an equally horrifying and also increasing estimated death rate. In 2016, it is anticipated that more than 41,000 deaths will occur as a result of this cancer. Long-term survival continues to remain very dismal and is less than 5%. Despite modern therapies, overall outcome has changed very little during the past quarter century. Surgery continues to remain the key therapeutic intervention for improved long-term outcome; however, only 10–20% of newly diagnosed pancreatic cancer patients are even surgical candidates [2]. Therefore, it is imperative to widen the number of durable survivors from this small pool of resectable patients. Experiments with newer therapeutics and altered treatment strategies are ongoing to accomplish this. The use of adjuvant therapy after surgery is becoming more established to improve long-term outcome. However, numerous randomized clinical trials in this realm have provided conflicting results regarding the role of chemotherapy versus chemoradiotherapy in the adjuvant setting. After decades of using 5-flurouracil (5-FU), gemcitabine has established superiority. Enhancement in the delivery of the radiation therapy is minimizing toxicity and also contributing to improved overall outcome. The ideal time sequence of combined adjuvant therapies is also an area of active deliberation. This chapter will review the historical trials that have defined the potential benefits for adjuvant chemoradiation and examine the evidence on hand that establish its advantage over adjuvant chemotherapy alone.

Rationale for Adjuvant Chemoradiation in Pancreatic Cancer

Though only a small percentage of patients are eligible to undergo pancreatoduodenctomy, an even smaller percentage of pancreatic cancer patients go on to have a definitive cure from this surgery. Unfortunately, even a pathological R0 resection will not guarantee long-term survival, as many patients eventually fail and ultimately die of disease progression [3]. Available data indicate only a 27.8 month median survival when margin negative surgery is completed [4]. Furthermore, up to 75% of

these recurrent pancreatic cancer patients will have a component of local failure after their resection and about 25% will be local failures only [5]. The high rate of both locoregional and distant recurrences among pancreatic cancer patients following surgery is the impetus to developing aggressive adjuvant treatment strategies and improving overall survival [6–8].

Pancreatic ductal carcinomas frequently harbor genetic alterations that have been shown to predict for local failure. These mutations are being studied now as a mean to stratify patients who would benefit most from local therapy. In general, many pancreatic cancers harbor KRAS, CDKN2A/p16, TP53, and SMAD4/DPC mutations [9, 10]. Of these, SMAD4, a tumor suppressor gene, is inactivated in 53–67% of cases.

Though the role of adjuvant therapy is more established today, the type of adjuvant treatment strategy continues to remain in controversy and evolve, while continued investigations into combinations of chemotherapy, radiation therapy, and biologic therapy are ongoing [11]. The retroperitoneal location of the pancreas and its proximity to major neurovascular structures make resections with wide negative margins challenging, and often result in close or microscopically positive surgical margins (R1 resection). As demonstrated in other gastrointestinal malignancies, residual microscopic locoregional disease can be eradicated by adjuvant chemoradiation. The locoregional control benefits conveyed by adjuvant chemoradiation have been proven in phase III esophageal, stomach, and rectal cancer trials, which have subsequently translated into improved overall survival [12, 13]. During the past two decades, various randomized prospective clinical trials have attempted to determine the optimal adjuvant therapy, and though the debate still rages, it is becoming clearer that proper patient selection remains the key to achieving the most favorable long-term outcome. Initial investigations among inoperable locally advanced pancreatic cancers revealed the benefit of the use of chemoradiotherapy [14, 15]. This led to three randomized trials that incorporated this strategy among operable cases [16–18]. However, competing with this notion, two other randomized European trials espouse that radiation may not be crucial in the adjuvant setting [19, 20]. Nevertheless, data from recent trials support the use of radiation, but optimal patient selection remains imperative.

Randomized Prospective Trials

GITSG Trial

The GITSG trial [16] was the first of such trials that randomized pancreatic cancer patients to chemoradiation or observation among those who had undergone a potentially curative (R0) resection with negative surgical margins. Treatment included a split-course of 40 Gy of external beam radiation therapy (EBRT) delivered over 6 weeks. The treatment delivered the first 20 Gy of EBRT over 2 weeks with concurrent bolus 5-FU chemotherapy (500 mg/m^2) during the first 3 days. This was repeated again during weeks 5 and 6 after a 2-week break. This was then followed by weekly bolus 5-FU given as maintenance chemotherapy for 2 years or

until disease progression. Although the trial was slow to accrue and a marked difference in survival led to its early closing, a 43 patient analysis revealed a statistically significant doubling in median overall survival and modest improvement in 5-year survival for patients receiving adjuvant split-course chemoradiation. The 21 patients randomized to adjuvant split-course chemoradiation had a median survival, 2-year survival, and 5-year survival of 21 months, 43%, and 19% compared to 11 months, 18%, and 5%, respectively, for the observation group ($p = 0.03$). There were no long-term life threatening complications or deaths attributable to therapy and only 2 of the 51 total treated patients (4%) in the GITSG study developed late treatment-related complications [21]. However, the predominant critiques of this trial include its limited power, inadequate quality assurance of radiation delivered and the inability to complete the maintenance chemotherapy treatment by a significant number of its patients. To compensate for the small patient population and verify its results, the GITSG treated a nonrandomized cohort of 32 patients similar to the adjuvant chemoradiotherapy treatment arm of its original trial. This cohort achieved similar results, with median, 2-year, and 5-year survivals of 18 months, 46%, and 17%, respectively [16]. These additional results further validated the benefit seen with adjuvant chemoradiation and led to the adoption of adjuvant chemoradiation as the standard of care in the United States.

EORTC Trial

The European Organization for Research and Treatment of Cancer (EORTC) conducted an analogous multicenter study to evaluate the potential benefit of adjuvant chemoradiation by randomizing resected patients to chemoradiation or observation [15, 17]. Unlike the GITSG trial, the EORTC treated both pancreatic and periampullary adenocarcinoma and allowed both R0 and R1 surgical resections. Of the 207 patients, 103 were randomized to observation and 104 to the split-course chemoradiotherapy regimen similar to that used in the GITSG study. However, their chemotherapy consisted of continuous infusion of 5-FU (25 mg/kg/day) instead of the bolus dosing concurrently with the radiation, and also did not include maintenance 2-year chemotherapy after completing the chemoradiotherapy treatment. The results revealed a statistically insignificant lack of improvement in median overall survival, 2-year survival, or 5-year survival, with 24.5 months, 51%, and 28% for the treatment arm, compared with 19 months, 41%, and 22% in the observation group, respectively. A sub-analysis of only pancreatic head cancer revealed the median duration of overall survival and 2-year and 5-year survivals to be 17.1 months, 37% and 20% within the treatment arm compared to 12.6 months, 23%, and 10% for the observation arm, which were also not statistically significant. Though the authors questioned the utility of chemoradiotherapy as adjuvant treatment based on their results, a reanalysis using a one-sided log-rank test demonstrated a 14% survival difference from the observation, which was statistically significant ($p = 0.049$) [22].

The discrepancy between the EORTC and GITSG trial results can likely be explained by its different patient population and modified treatment algorithm. Approximately 20% of the enrolled patients had an R1 resection, which are known to have a poorer prognosis [23]. Whereas a little less than 50% of the enrollees were

found to have periampullary adenocarcinoma, which portend a better long-term survival [24]. The EORTC study did not include systemic maintenance 5-FU chemotherapy after completion of combination therapy, though systemic 5-FU has not demonstrated significant survival benefit among pancreatic cancer patients. Furthermore, 20% of its patients did not receive any adjuvant therapy among the treatment arm and up to 44% had not received the intended chemotherapy. When the analysis was limited to those patients with only pancreatic head adenocarcinoma, the results of the treatment arm were slightly inferior to the GITSG trial. Finally, both studies were under-powered to offer any definitive results.

ESPAC-1 Trial

The European Study Group for Pancreatic Cancer (ESPAC) conducted the prospective multicenter ESPAC-1 trial in Europe in an attempt to clarify the need for radiation in adjuvant therapy in resected pancreatic cancer [19, 25]. The trial enrolled 541 patients with pancreatic adenocarcinoma only, who underwent a potentially curative resection, irrespective of the margin status. Patients within this trial underwent a double randomization of chemotherapy versus chemoradiotherapy and yes versus no to each option using a 2 × 2 factorial design that created four groups: (a) observation, (b) chemotherapy alone, (c) chemoradiotherapy, and (d) chemoradiotherapy followed by maintenance chemotherapy. The chemoradiotherapy used in two of the arms of the study modeled the GITSG and EORTC split-course therapy of 40 Gy over 6 weeks with concomitant 5-FU chemotherapy (500 mg/m^2) on days 1–3 of weeks 1 and 5. The chemotherapy used in one arm and the maintenance chemotherapy that followed chemoradiotherapy in another arm was modeled after the Mayo regimen, using daily bolus 5-FU (425 mg/m^2) for the first five consecutive days in a 28-day cycle for a total of six cycles. The design and the statistical analysis of the study were highly complex, but intended to compare no chemotherapy (groups a + c above) versus chemotherapy (groups b + d) and chemoradiotherapy (groups c + d) versus no chemoradiotherapy (groups a + b). After a median follow-up of 47 months, the estimated 5-year survival of patients randomized to chemoradiotherapy was 10% versus 20% for no chemoradiotherapy. The patients who received chemotherapy had a significantly higher 5-year survival when compared with those who did not receive chemotherapy (21% vs. 8%). Detailed results of this complicated trial can be found within Table 1.

Based on the results of this trial, the authors of ESPAC-1 concluded that adjuvant chemotherapy was beneficial and chemoradiotherapy detrimental to overall survival among resected pancreatic cancer patients. However, though this had been a bold effort to define adjuvant therapy, the trial suffered from numerous shortcomings [31]. First, it endured a complex trial design that not only led to creating inadequately powered four separate groups, but the combination analysis among the groups did not allow for a clear delineation of the effects of chemotherapy alone or chemoradiotherapy alone. Additionally, the clinicians were allowed to administer chemotherapy or chemoradiotherapy ("backdrop therapy") prior to enrolling the patient into the trial. This clearly confounded end results as not only does it create a selection bias by the clinician but the "background therapy" confounds the effects

of the investigative treatment. Finally, no quality control of radiation treatment was performed, leading to under dosing and heterogeneous radiation treatment fields. Also, the time interval to begin adjuvant therapy markedly varied between arms, again leading to selection bias of delayed treatment for poorer performance status patients. The specific reasons for the inferior radiation results in ESPAC-1 are unclear, but the fact that the median overall survival (16.9 months) for observation arm was much better than that seen in the GITSG (10.9 months) or EORTC (12.6 months) trials also remains unexplained. Thus, the unique results of ESPAC-1 need further validation before any conclusions can be drawn regarding the role of chemotherapy or chemoradiation in the adjuvant setting.

RTOG 97-04 Trial

The Radiation Therapy Oncology Group (RTOG) led a collaborative cooperative group effort in further delineating the optimal adjuvant treatment for resected pancreatic cancer patients [18]. This study was intended to evaluate the addition and determine the superior chemotherapy treatment to the optimal dose of 50.4 Gy of radiation with concurrent 5-FU continuous infusion. This study also included R0 and R1 resected patients, but only allowed pancreatic adenocarcinoma histology. After surgical resection, patients received one cycle of chemotherapy, then chemoradiation, followed by three additional cycles of chemotherapy. The chemotherapy cycles consisted of either gemcitabine (1,000 mg/m^2) given once weekly for 3 weeks with 1 week off or continuous infusion 5-FU (250 mg/m^2/day) for 3 weeks followed by a week off. In both arms, EBRT was delivered continuously for a total dose of 50.4 Gy combined with concomitant 5-FU (250 mg/m^2/day) delivered by continuous infusion throughout the duration of the radiation treatment. Following an initial dose of 45 Gy, a final 5.4 Gy was delivered to a "boost" field of the tumor bed as defined by the preoperative tumor volume. A total of 451 randomized surgically

resected patients were analyzed, of which 230 were randomly assigned to the 5-FU-based regimen and 221 were assigned to the gemcitabine arm. Patients were stratified according to surgical margins (R0 vs. R1 vs. Unknown), tumor diameter ($<$3 cm vs. $\geq$3 cm), and nodal status (N0 vs. N1). Results of pancreatic head cancers revealed a median and 3-year overall survival for patients treated with gemcitabine-based chemoradiotherapy to be 20.5 months and 31% versus 16.9 months and 22%, respectively, for the 5-FU-based arm, which were not statistically significant. When adjusting for surgical resection status, tumor diameter, and nodal status, a statistically significant difference was observed favoring the gemcitabine arm. Based on these results, the authors concluded that gemcitabine was superior to 5-FU when added to chemoradiation, and that future adjuvant chemoradiotherapy trials should build upon a gemcitabine-based chemoradiotherapy backbone.

One of the key differences of the RTOG trial and its predecessors was the utility of central quality assurance of the radiation treatment. Prior studies were found to have an unacceptable protocol variance which led to inequity in the treatment delivered. The impact of RT quality assurance and compliance among RTOG 97-04 patients showed a statistically increased ($p = 0.0077$) median survival for those patients undergoing radiation per protocol (1.74 years) versus substandard radiation (1.46 years) [32]. In fact, the quality of radiation correlated more strongly with survival than the assigned treatment artm ($p = 0.014$). Also, when comparing the 5-FU arm of the RTOG trial with the GITSG and EORTC trials, the median OS was inferior. This is likely accounted by the greater number of patients with a R1 or unknown surgical resection margin, which are known to have poorer prognosis. Nevertheless, this trial and the CONKO-001 (discussed below) substantiate the use of gemcitabine-based chemotherapy in the adjuvant setting ahead of 5-FU. Finally, since no chemotherapy alone arm was included in this trial, no definite conclusions could be drawn from this trial about the role of chemotherapy alone as adjuvant therapy.

CONKO-001 Trial

The Charité Onkologie group conducted a large European multi-institutional prospectively randomized trial that addressed the question of only adjuvant chemotherapy and no radiation. No chemoradiation was utilized in this trial. Three hundred sixty-eight resected pancreatic adenocarcinoma patients were enrolled and stratified among the treatment and observation arms. Only surgically resected patients with known margins were allowed to enter the trial. Also, patients with CA 19-9 greater than 2.5 times the upper limit of normal were excluded from the trial. Randomization occurred into two arms, one received six cycles of systemic chemotherapy given once weekly for 3 weeks of gemcitabine (1,000 mg/m^2) followed by 1 week off or the other which was an observation arm with no adjuvant therapy. Contrary to the other randomized trials, the CONKO-001 investigators powered their study to determine a difference in the disease free interval between the two arms. At a median follow-up of 136 months, the median disease free survival was 13.4 months in the adjuvant treatment group versus 6.7 months in the observation group. Median overall survival was also found to statistically improve with chemotherapy. Median

overall survival and 5-year and 10-year survival were 22.8 months, 20.7% and 12.2% versus 20.2 months, 10.4% and 7.7%, respectively, for the observation arm [33]. When stratified by subpopulations of Node negative versus Node positive, both disease free survival and overall survival endpoints were markedly superior for the former category.

When attempting to determine whether radiation therapy imparts any survival benefit among resected pancreatic cancer patients using the RTOG 9704 and CONKO-001 trials, it is crucial to note the differences among the patient population enrolled in each trial. Enrollment of definitive R0 resected patients within the RTOG 9704 trial was approximately 50% lower than the CONKO-001 trial. The latter trial also used biomarkers (specifically CEA and CA 19-9) as exclusion criteria, thereby preselecting a patient population clinically destined to have better survival. Low levels of postresection serum CA 19-9 predicts for increased sensitivity to chemoradiotherapy and improved survival [34]. Indeed when CA 19-9 level is less than 90, median overall survival and 3-year survival improved to 23 months and 32%, respectively, among RTOG 9704 patients [34].

IMPRESS Trial

In 2013, a multi-institutional trial was completed examining adjuvant treatment with the winning regimen from RTOG 9704 (gemcitabine plus 5-FU chemoradiation) plus Algenpantucel-L immunotherapy [35], an allogeneic vaccine consisting of two irradiated prostate cancer cell lines reengineered to express the murine α-1,3-galactosyltransferase gene. With a median follow-up of 21 months, 70 patients treated with this combination showed an improvement in 1-year survival to 86% in comparison to 69% in the gemcitabine arm of RTOG 9704 [18]. These results prompted the initiation of the phase 3 IMPRESS (Immunotherapy for Pancreatic Resectable Cancer Study) trial. In this study, 722 patients were randomized 1:1 to gemcitabine with or without 5-FU-based chemoradiation or the same plus Algenpantucel-L. However, the phase 3 trial did not demonstrate a statistically significant difference in overall survival with immunotherapy, which was 33% at 4 years in both experimental and control arms [36].

Nonrandomized Trials

Several nonrandomized trials have been conducted at various institutions across the world in an attempt to improve outcomes among surgically resected pancreatic cancer patients. Recognizing the limitations of any interpretation that can be made from these trials, among which include limited power, patient selection bias, varied inclusion criteria, and diverse treatment protocols, it is worth noting the results of some larger and interesting studies. A retrospective analysis of 1092 patients treated at the Johns-Hopkins Hospital and Mayo Clinic between 1993 and 2005 was performed to determine the benefits of adjuvant radiation among their pancreatic adenocarcinoma patients [27]. Just about 50% of these patients underwent 5-FU-based chemoradiotherapy after surgery, while the rest had no adjuvant therapy. Median overall survival and the 2-year

and 5-year survival among the chemoradiotherapy treated patients was 21.1 months, 44.7% and 22.3% when compared to 15.5 months, 34.6% and 16.1%, respectively, among the nonradiation treated patients. Age, resection margin, T-stage, and nodal status were all crucial factors in improving overall outcome. What is not clear is whether the any proportion of patients within the nonradiation treated cohort received any systemic chemotherapy alone. Recognizing that variation within treatment protocols as well as selection bias of healthier patients receiving more aggressive therapy likely exists in this analysis, it is still interesting to note a marked and sustained improvement in survival among patients who received some duration of radiation in the adjuvant setting.

The ACOSOG Z05031 multicenter phase II trial attempted to determine if an aggressive chemotherapeutic regimen with radiation would not only be feasible but also improve outcome [28]. Eighty-nine patients were enrolled in this trial in which they were treated with continuous infusion 5-FU (200 mg/m^2) with concurrent radiation (50.4 Gy) along with weekly cisplatin (30 mg/m^2) and interferon- radiation*6*] units three times a week. This was then followed by two 6-week cycle of continuous infusion 5-FU (200 mg/m^2). Though the trial did not complete its projected enrollment and had to be terminated early from marked grade 3 toxicity, median overall survival, and the 2-year survival among those that enrolled was 25.4 months and 59%, respectively. Although resection margin status had an impact on survival, it was not statistically significant (R0 vs. R1, median OS 31.9 vs. 18.9 months, $p = 0.103$). Nonetheless, this treatment protocol was deemed too toxic to pursue for phase III evaluation.

Investigators at the Stanford University Medical Center reported on the use of adjuvant chemoradiotherapy using only continuous infusion 5-FU (200–250 mg/m^2) with 54 Gy EBRT [29]. Fifty-two patients were treated and completed this protocol resulting in the median overall survival and the 2-year and 3-year survivals of 32 months, 62% and 39%, respectively. Since no significant toxicities were seen for this protocol, further studies with dose intensification are being proposed. An Italian study conducted a feasibility study using cisplatin (40 mg/m^2), epirubicin (40 mg/m^2), gemcitabine (600 mg/m^2), and continuous infusion 5-FU (200 mg/m^2) followed by radiation therapy [30]. Results confirm tolerability of the regimen, with median overall survival and 2-year and 5-year survivals to be 27 months and 53% and 22%, respectively. The results of this trial are very similar to the ACOSOG Z05031 trial substantiating the use of a 5-FU- and cisplatin-based regimen concurrently with radiation therapy.

A Surveillance, Epidemiology, and End Results (SEER) analysis confirmed the benefit of adjuvant radiation treatment among resected pancreatic cancer patients [37]. More than 3,300 patients were identified from the SEER registry who had undergone surgical resection for nonmetastatic pancreatic cancer between 1998 and 2006. Among these, 48% underwent adjuvant radiation therapy and were found to have a significant improvement in median overall survival when compared to those who did not have radiation therapy (19 vs. 14 months, $p < 0.001$). Use of chemotherapy was not specified for either cohort. Nevertheless, use of adjuvant radiation therapy was determined to be an independent predictor of survival among resected pancreatic adenocarcinoma patients.

Finally, in a retrospective National Cancer Data Base study examining 6165 patients treated with adjuvant chemotherapy ($n = 2334$, 38%) versus chemoradiotherapy ($n = 383$, 62%), the addition of radiation improved median survival from 20 to 22.3 months ($p < 0.001$) [38]. This survival benefit remained significant even when subset analyses were performed for R0, R1, pT3, pN0, or pN1 patient groups.

Conclusion

Based on the results of these trials (Table 1), it is clear that resected pancreatic adenocarcinoma patients have improved survival with adjuvant therapy. Notwithstanding the results of the ESPAC-1 trial, all other studies undoubtedly revealed a marked improvement in median survival and 3- or 5-year survival among their treatment arm when compared to the control arm (usually no adjuvant therapy). Furthermore, apart from the EORTC analysis, all studies, including the RTOG 9704 (when accounting for a similar selection criterion as the CONKO-001), revealed statistically significant benefit in survival when compared to no adjuvant therapy. When accounting for a similar criterion of low postresection serum CA 19-9 level, there was more than 2 month improvement in median survival with the use of radiation in a gemcitabine-based adjuvant protocol. Moreover, data from institutional trials, as well as retrospective analysis and SEER analysis all point to an improvement in both disease free survival and overall survival with the use of radiation in the adjuvant setting. The more recent CONKO-001 and the RTOG 9704 studies corroborate the superiority of a gemcitabine-based chemotherapy over a 5-FU-based regimen. Smaller trials even confirm the feasibility of using gemcitabine concurrently with radiation as well, instead of the continuous infusion of 5-FU used in all of the randomized trials [39–41]. At present, the role of adjuvant therapy in pancreatic cancer continues to evolve. However, based on the available information to date, a gemcitabine-based chemoradiotherapy regimen has been established as the "backbone" therapy upon which future trials will likely be conducted.

Patient selection remains a key factor in both performing adequate clinical trials as well as effectively formulating treatment plans that are appropriate for each pancreatic cancer patient. Further critical analysis of all randomized trials discussed above note that inadequate patient selection is likely the common deficiency of each of them. Indeed, it is argued that every one of these trials had a heterogeneous mix of patients, among which included those who truly had a completely resected disease, some with persistent local disease, and possibly some with micrometastatic disease [42]. Since the overall survival is markedly varied among each of these patient populations, evaluation of the true benefit of the treatment arm for each trial must really be questioned. Indeed, no trial reveals results that extend a profound survival improvement when the treatment arms are compared to each other. Failure to distinguish among these patient populations is likely due to the lack of adequate pre- and postoperative imaging studies, inadequate quality control of surgical techniques, and the lack of quality control in pathological evaluation specifically related to margin status. There is sufficient evidence that incomplete surgical resections lead to median survival rates

comparable to inoperable locally advanced pancreatic cancer [26, 43, 44]. Furthermore, recent data suggests positive surgical margins occur often than previously reported [44–46]. This discrepancy among positive surgical margins exists within the adjuvant trials as well. Even though the ESPAC-1 authors reportedly enrolled a high number of R0 resected patients within their trial, the final results revealed greater than 62% of patients had local recurrence with 35% demonstrating local failure only [25]. This high rate of local recurrence implies that a greater number of true R1 and R2 resections were likely present within the trial. Similarly, the CONKO-001 trial also had high local failure rates (34% among gemcitabine treated patients and 41% among the observation cohort) [20]. This trial also failed to define local failure and had inadequate postoperative follow-up evaluations. The recommendation of a CT scan within 6 months of enrollment likely resulted in late detection of any persistent disease postoperatively. Finally, the RTOG 97-04 trial had a high 33% positive surgical margin rate; however, a pretreatment CT scan and radiation quality control perhaps contributed to the lower local recurrence rates (28% among the 5-FU arm vs. 23% among the gemcitabine arm) in this trial [18]. Lack of radiation quality control among the GITSG, EORTC, and ESPAC-1 trials probably further added to the discrepancies in delivering equivalent adjuvant chemoradiation among each of these trials. Therefore, strict patient selection criteria need to be established in order to determine the true benefits of adjuvant chemoradiation among the true R0 resected pancreatic cancer patients.

Despite evidence from these and many other smaller studies revealing substantial benefit of chemoradiotherapy in the adjuvant setting, long-term prognosis for pancreatic cancer patients continues to remain grim. It is becoming clearer that appropriate patient selection for both surgical resection as well as adjuvant chemoradiotherapy will identify a subpopulation of patients who will benefit the most from such aggressive measures. Further studies need to occur in attempting to delineate various patient populations that separate those with poorer prognosis from others. Future adjuvant trials should employ modern imaging techniques in the preoperative setting to identify the truly resectable versus the locally advanced pancreatic cancer cases, by using specific anatomic determinants [47, 48]. In addition, future trials should also employ strict surgical and pathological quality control along with postoperative imaging in order to further select out specific patients and then interpret the true benefits of adjuvant therapy. Lastly, development of newer chemotherapeutics and biological agents, a better understanding of the basic molecular profile of pancreatic cancer, along with improved radiation techniques (e.g., Intensity Modulated Radiation Therapy) should increase our armamentarium in fighting this deadly disease.

Key Practice Points

- Adjuvant therapy after pancreaticoduodenectomy increases survival
- Using a gemcitabine-based “backbone” chemotherapy is superior to using a 5-flurouracil-based chemotherapy in the adjuvant setting
- Negative surgical resection margins (R0 Resection) lead to improved survival

- Adjuvant combination chemoradiation may provide superior results to chemotherapy alone
- Optimal dose of radiation is considered to be in the range of 45–54 Gy

Key Research Points

- Establish precise pathologic criteria for enrollment into adjuvant therapy clinical trials
- Require accurate pathologic margin status with robust quality control for trial enrollment
- Establish strict quality control measures for delivery of radiation treatments
- Equal randomization of chemotherapy versus chemoradiation to confirm superiority
- Rigorous central review of patient enrollment, optimal delivery of treatment, and eventual reporting of trials data

Future Research Directions

- Utilizing a multidisciplinary approach to the treatment of pancreatic cancer
- Determining the optimal candidate for pancreaticoduodenectomy by establishing strict surgical resection criteria using improved diagnostic radiographs
- Employing innovative radiation techniques, such as IMRT, to minimize toxicity and intensify either radiation or chemotherapy treatments or both
- Utilizing novel chemotherapeutics and biologics based on specific molecular targets
- Improving surgical outcomes utilizing multimodality therapy in the neoadjuvant setting

Abstract

Pancreatic cancer surgery is the only potentially curative approach for this disease and remains a formidable challenge. Better perioperative management, increased experience and advanced surgical techniques, and centralization of care have significantly reduced morbidity and mortality rates of major pancreatic resection. Together with more active and effective chemotherapeutic and radiotherapeutic regimen, this has led to an increase use of resectional procedures in borderline resectable and locally advanced unresectable tumors. Especially for the latter, arterial resection is often necessary to achieve clear margins. However, this approach is currently under debate with higher rates of complications reported. In this chapter, an overview is provided of potential indications and techniques as well as short- and long-term outcomes associated with these procedures.

Keywords

Pancreatic cancer · Arterial resection · Appleby procedure · Locally advanced · Neoadjuvant therapy

Introduction

Surgical resection is the only potential curative treatment of pancreatic cancer. The pancreas has an abundant and complex vascular supply (Fig. 1). Unfortunately due to this, pancreatic cancers often grow close to or invade the superior mesenteric vein/portal vein or superior mesenteric artery/celiac trunk/hepatic artery [1]. In most cases, this either defines locally advanced unresectable tumors or requires vascular resection to achieve macroscopic tumor clearance, i.e., R0/R1 resections. Arterial resection for pancreatic cancer, however, has been labeled as potentially harmful, by the 2014 consensus statement from the International Study Group of Pancreas Surgery (ISGPS) [2]. Their review of the evidence cited the increased mortality and morbidity of the surgery, without evidence of increased survival in comparison to resection alone. However, a head-to-head comparison of tumor resection with arterial resection versus *no* resection has not been carried out. The consensus view

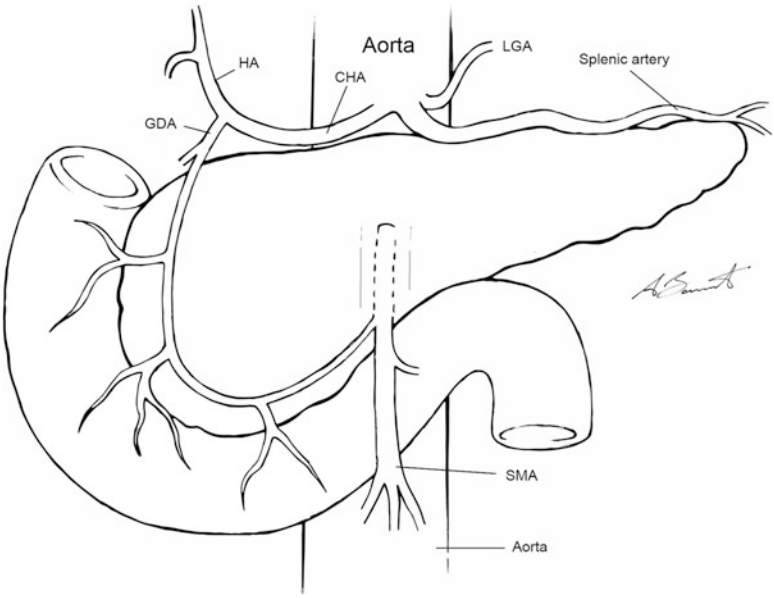

Fig. 1 Arterial supply of the pancreas. *HA* hepatic artery, *CHA* common hepatic artery, *LGA* left gastric artery, *GDA* gastroduodenal artery, *SMA* superior mesenteric artery

is that definitive arterial involvement should be considered locally advanced unresectable and thus managed with palliative intent in most cases [2, 3]. This however is based on the available evidence, which includes just a few hundred reported cases in the literature, mostly from small retrospective case series conducted over a long time period [4], and recent data has challenged this view with reported resectability rates of 60% in initially locally advanced unresectable cases that underwent induction FOLFIRINOX therapy [5]. As such, a degree of caution has to be applied to the conclusions, allowing for variation in approach taking into account more recent data and novel multimodal and technical approaches.

Despite the ISGPS consensus, arterial resections for pancreatic cancer have been increasingly published [3, 6–8]. However, these are not reporting the standard of care in most centers worldwide, but an available approach in highly selective individuals. While routine arterial resection is not advocated, it may be appropriate for a selected group of patients. This group may become more prevalent as more effective methods of tumor downstaging become available and experience with the technical challenges advances. The best predictor of survival following a diagnosis of pancreatic cancer is a successful (R0) resection [9], although R1 resections are also effective in providing long-term benefit together with adjuvant therapy [10, 11]. While rare, there is some reported long-term survival following arterial

resection [12]. Here an overview is presented on arterial resection following pancreatic cancer surgery, including indications, technical aspects, and outcome.

Preoperative Assessment and Patient Selection

The need for arterial resection should ideally be identified preoperatively [3], and all such cases should be managed in high-volume centers, within specialist multidisciplinary teams. This management should include high-quality CT scanning with mandatory pancreatic protocol to assess resectability. The National Comprehensive Cancer Network (NCCN) guidelines of CT classification of resectability have largely gained acceptance (Table 1) and were supported by the ISGPS in 2014 [2]. All cases where there is a possible need for arterial reconstruction should therefore be considered either locally advanced, unresectable (most cases), or borderline resectable on preoperative imaging [2, 3].

The potential need for arterial resection should prompt consideration of a different management approach. Arterial infiltration by pancreatic cancer can be seen as a marker of a biologically aggressive tumor [2, 4, 13], although this has not been convincingly proven on a molecular level. Presumed vascular involvement is not confirmed in a relevant proportion intraoperatively or on histology, especially after neoadjuvant therapy. Further, tumor cells tend to grow along nerve plexuses around the superior mesenteric artery/celiac trunk without true infiltration [14]. Where

Table 1 NCCN/ISGPS guidelines defining resectability status [2]

Localized and resectable	Borderline resectable	Locally advanced, unresectable[a]
No distant metastasis	No distant metastasis	No distant metastasis
No radiographic evidence of SMV or PV distortion	Venous involvement of the SMV or PV with distortion or narrowing of the vein or occlusion of the vein with suitable vessel proximal and distal, allowing for safe resection and replacement	Unreconstructible SMV/portal occlusion
Clear fat planes around CA, HA, and SMA	GA encasement up to the hepatic artery with either short segment encasement or direct abutment of the HA without extension to the CA	Any celiac abutment
	Tumor abutment of the SMA not to exceed 180° of the circumference of the vessel wall	Greater than 180° SMA encasement
		Aortic/IVC invasion or encasement

[a]Criteria are given only for cancers of the head

vessels are truly involved in pancreatic cancer, the cancer tends to infiltrate along the intimal surface of the vessels [15].

Studies investigating the use of arterial resection have suggested reservation of the technique for those less likely to develop (or harbor) systemic disease. Consequently most clinicians would advocate neoadjuvant therapy in these patients [16–19], even though there is insufficient evidence to recommend neoadjuvant therapy in resectable or borderline resectable patients [2]. One accepted rationale of neoadjuvant therapy is to select those cases with systemically progressing tumors who would not benefit from major resectional surgery.

Those advocating neoadjuvant therapy in locally advanced unresectable or borderline resectable pancreatic cancer with suspected arterial involvement have utilized a variety of chemotherapeutic agents and radiotherapy protocols [16–19], with different durations and doses, consequently making it very difficult to offer evidence based recommendations. Ideally where neoadjuvant therapy is undertaken in such patients, it should be in the context of clinical trials, so that suitable regimens can be identified. Clinical trials in progress may provide further clarification on this issue (e.g., ESPAC-5F or NEOPAN).

Where neoadjuvant therapy has been undertaken, it is considered important to operatively explore all patients in whom disease remains localized without evidence of metastatic spread [2]. This is following several reports suggesting that post-therapy changes after neoadjuvant treatment are currently not distinguishable from neoplastic disease on imaging and that R0 resection may be possible on surgical exploration even in cases that remain formally unresectable on restaging [20–22].

When formulating a preoperative plan in a patient where arterial resection is planned, the need for concurrent portal vein venous resection is an important component of the plan [23]. This is especially true for lesions where hepatic artery or coeliac axis resection is being planned. Given the dual blood supply of the liver, reconstruction of the hepatic artery may not always be necessary, especially in cases where gastroduodenal arterial flow is preserved or where aberrant arterial anatomy preserves a degree of hepatic arterial flow (e.g., replaced right hepatic artery) [16]. However, where concurrent portal vein resection is undertaken, there should be a lower threshold for performing arterial reconstruction [23]. This is because during the vein resection the liver will suffer an ischemic insult, and arterial compromise could exacerbate the insult. For this reason where resection (with reconstruction) of both arterial and portal supply to the liver is planned, it should be performed in a sequential manner, to minimize the ischemic insult [24, 25].

Arterial Resections

There are two broad situations where arterial resection may be considered in pancreatic cancer surgery. Coeliac axis resection may be undertaken in left-sided pancreatic resections and in right-sided pancreatic resections either common hepatic artery resection or superior mesenteric artery resection.

Coeliac Axis Resection in Left-Sided Pancreatic Resections

Unfortunately most patients with distal pancreatic cancer present at a later stage of disease, meaning that tumor involvement of the coeliac axis is not uncommon [19]. However, it is possible to resect the distal pancreas with the entire coeliac axis (DP-CAR) without reconstruction, due to the development of collateral supply via the gastroduodenal artery [19, 26]. The procedure was first described in 1953, by Lyon Appleby, as part of a resection undertaken for an advanced gastric cancer necessitating en bloc distal pancreatectomy [27]. A modification of this procedure shown in Fig. 2 has subsequently been employed to facilitate achieving an R0 resection in highly selective cases [8, 18, 28–30].

The DP-CAR is the most commonly performed arterial resection in pancreatic cancer [4]. Despite this, just 240 cases over a time period of 1975–2014 were identified in a recent systematic review [26]. Many of these studies were conducted over wide time periods, in highly varied clinical settings, meaning that their relevance to modern practice is limited. The most recent large series reported only 20 DP-CAR cases within an overall series of 822 patients undergoing a distal pancreatectomy [31].

Methods reported to decrease the ischemic complications of coeliac artery resection include preoperative embolization of the common hepatic artery (PHAE) and reports of laparoscopic ligation of the coeliac axis [32–34]. However, a recent systematic review of DP-CAR identified that only 55 of 155 cases (where it was reported) underwent PHAE, with ischemic complications occurring in 21 of 233 cases, with no obvious identified benefit in the PHAE patients [26]. There are limited reports of DP-CAR with hepatic arterial reconstruction, and it has been advocated that reconstruction should be guided by the drop of flow within the hepatic artery following coeliac axis clamping as measured by common hepatic artery pressure or if there is a loss of biphasic arterial flow [16, 34]. An intraoperative measurement of the intrahepatic blood flow using a duplex ultrasonography will certainly have a role in this. A suggested level at which arterial reconstruction should be considered was a reduction in pressure by 25% following coeliac axis clamping [34]. Currently however there is insufficient data to support adoption of this technique, especially given the potential risk for increased vessel trauma. Approaches to arterial reconstruction are discussed below, as they are most frequently necessitated in right-sided pancreatic resections [4].

The most recent series report 30-day mortality for DP-CAR at 10% compared to 1% in standard distal pancreatectomy [31]. This higher mortality is at odds with systematic reviews suggesting a perioperative mortality of 3.0–3.5% [8, 26]. Of note, median hospital stay is reported at 32 days, which is much higher than typical pancreatic cancer resections [26], especially for left-sided tumors. Despite the limited evidence base, it is reasonable to accept that a DP-CAR is associated with a significant increase to the risk of perioperative mortality, though the exact level of this is difficult to quantify, and will be highly dependent on individual cases and institutions.

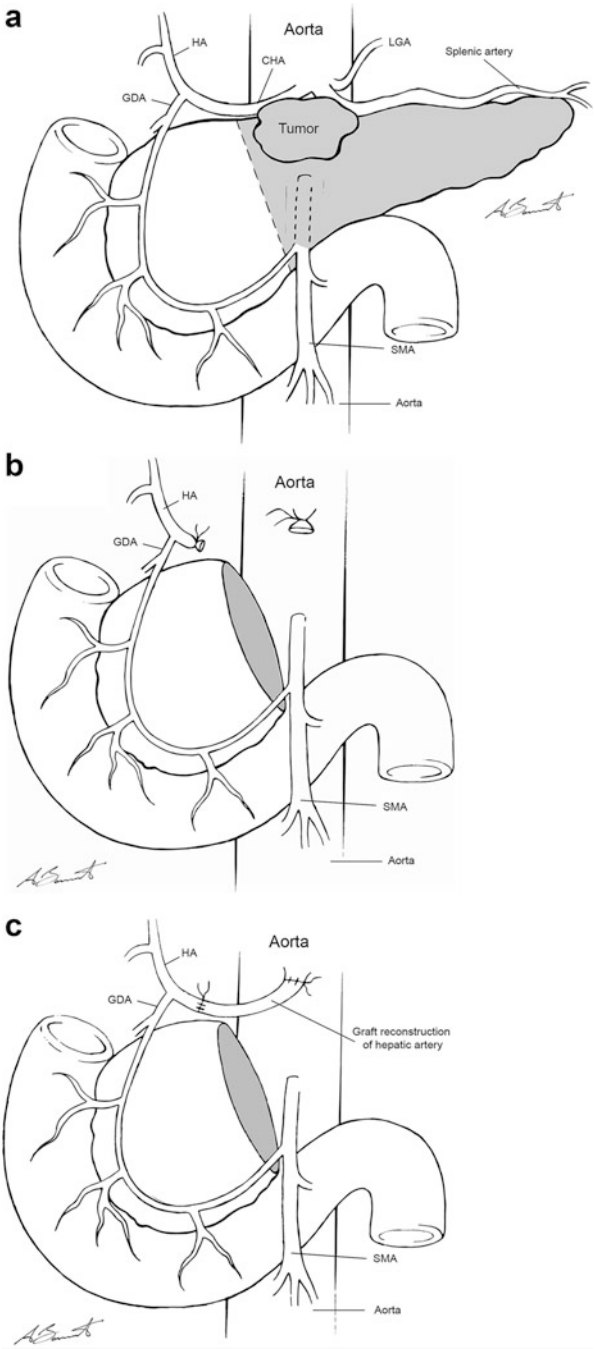

Fig. 2 Schematic of Appleby resection including coeliac axis (**a**). Appleby resection without reconstruction (**b**). Appleby resection with graft reconstruction of hepatic artery (**c**). *HA* hepatic artery, *CHA* common hepatic artery, *LGA* left gastric artery, *GDA* gastroduodenal artery, *SMA* superior mesenteric artery

A large multicenter study compared DP versus DP-CAR. In this study, overall morbidity was comparable (36% vs. 35%) [31]. Major complication following DP-CAR can be expected at a rate of approximately 30% of patients [26]. Of particular concern following DP-CAR are ischemic complications that are not typical for standard DP. These include complications ranging from ischemic gastropathy to gastric, hepatic, or gallbladder necrosis [26]. The overall rate of ischemic complications is seen in around 8% of patients [26].

Achieving an R0 resection is seen as the primary aim of the extended arterial resection in pancreatic cancer. This was achieved in 152 of 204 of cases, which is lower than could be expected in typical distal pancreatectomies [35]. However, given this is locally advanced, irresectable disease by definition an R0 rate of approaching 75% can be seen as a significant technical achievement [26].

The primary advantage of a DP-CAR is achieving an R0 resection; however, one potential advantage of the approach has been the potential improvement in the typical epigastric pain seen in many patients [28, 36]. The intractable pain in pancreatic cancer is likely due to tumor involvement of the coeliac plexus and coeliac ganglions. These are resected in a modified Appleby procedure. It is thought that the improved pain is mediated through this mechanism [36]. Unfortunately, the majority of studies do not report on quality of life measures, so meaningful analysis of the affect this may have on overall quality of life is not possible.

Arterial Resection in Right-Sided Pancreatic Cancer Resections

The majority of patients undergoing curative intent surgery for pancreatic cancer have right-sided pancreatic lesions [9]. However, when examining patients undergoing arterial resection for pancreatic cancer, the majority tend to have left-sided resections [4]. The proximity of major vascular structures to the right-sided pancreatic lesions means that arterial involvement is not uncommon and has been defined as a reason for unresectability [2, 37, 38]. Indeed, more tumors are borderline resectable or locally advanced unresectable and then resectable at the time of presentation.

Arterial resections are much less frequently performed in patients undergoing right-sided pancreatic resection [4, 6]. In the published literature, only a third of patients undergoing arterial resection have a right-sided resection [4, 6]. This is due to the increased complexity of arterial resection in association with pancreatic head resection [24]. Arterial resection in right-sided pancreatic lesions typically necessitates reconstruction to restore arterial flow in either the superior mesenteric artery or common hepatic artery, so as to prevent catastrophic ischemic complications [39, 40]. One such resection and reconstruction technique is demonstrated in Fig. 3. Occasionally due to aberrant hepatic arterial anatomy,

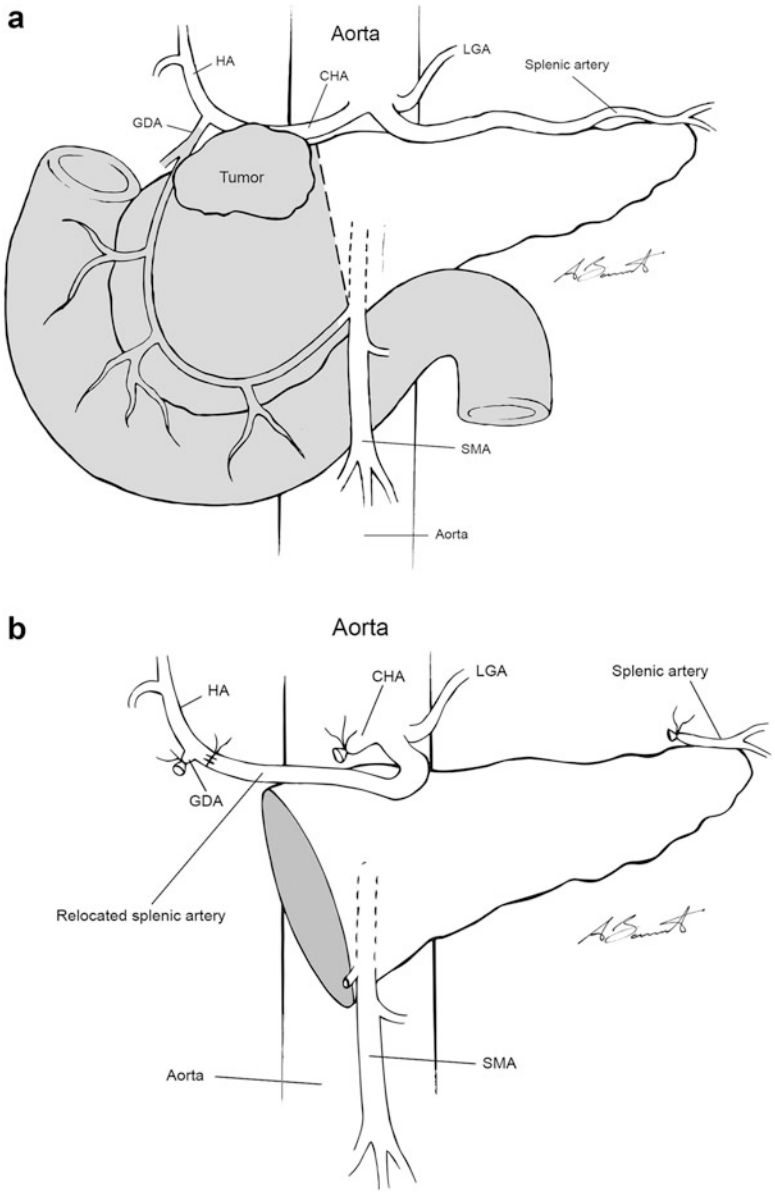

Fig. 3 Schematic of pancreas head resection including common hepatic artery (**a**). One possible reconstructive technique where splenic artery is mobilized to reconstruct common hepatic artery (**b**). *HA* hepatic artery, *CHA* common hepatic artery, *LGA* left gastric artery, *GDA* gastroduodenal artery, *SMA* superior mesenteric artery

resection can be performed without reconstruction such as in cases of a replaced right hepatic artery [25].

Very few studies have concentrated on arterial resection and reconstruction in right-sided pancreatic cancer, and consequently the evidence base looking at post-operative morbidity and mortality is limited [2, 24].

Arterial Reconstruction Techniques

A variety of approaches to arterial reconstruction have been applied [4]. The three main approaches include primary reconstruction with end-to-end anastomosis, vein interposition grafts, and arterial interposition grafts [4]. Arterial bypass techniques have also been performed, but typically this is for inadvertent arterial injury during pancreatic resection [12].

Primary End-to-End Reconstruction

The most commonly performed arterial reconstruction is primary resection and end-to-end anastomosis [4]. Performing an end-to-end reconstruction requires suitably mobile arterial lengths that are comparable in size. This is so that an anastomosis can be constructed without tension. Consequently end-to-end primary repairs are typically suitable for small segment arterial involvement and resection.

Vein Interposition Graft

When primary repair is not feasible, such as in extensive vascular resections, venous interposition grafts can be performed. Typically the saphenous vessels are harvested and arterial flow restored [25, 41]. These can either be bridging the gap of resected vessels or by creating an alternative flow from neighboring vessels such as the left gastric artery or from the SMA to the CHA [25, 34]. They can also be reconstructed directly from the aorta.

Artery Interposition Graft

Where primary end-to-end arterial anastomosis is not possible, arterial interposition grafts can be carried out. These are typically autografts, with the use of splenic artery or internal iliac artery [24]. The use of splenic artery as an interpositional graft has been reported in case of pancreatic body carcinoma with the involvement of coeliac axis, common hepatic artery, and the gastroduodenal artery, where a total pancreatectomy with coeliac axis resection is required [42]. When autografts are not used, cryopreserved blood type matched vessels can be another option [6].

Perioperative Management

When performing arterial resection in pancreatic cancer, there are a number of specific complexities that need to be considered. Currently the evidence base upon which clinical practice can be guided is limited, and much of the evidence to guide practice in such cases is taken from other areas of clinical practice.

Even brief periods of hypotension could lead to severe consequences. These could be induced if there is further ischemic compromise of intra-abdominal organs in cases without reconstruction or through inducing thrombosis in cases with arterial reconstruction. Unfortunately intra-abdominal ischemia may be difficult to distinguish from postoperative pain, and the opportunity to intervene may be missed before the diagnosis is made [43, 44]. To aid early diagnosis, it is essential to maintain a low index of suspicion and have access to high-quality CT angiography and ultrasound duplex imaging at all times [43]. Centers should not undertake cases without 24-h access to such imaging modalities and access to full compliment of interventional radiological techniques.

In patients with an arterial reconstruction, an early thrombosis represents a major perioperative risk, with likely high mortality and morbidity [43]. Consequently, therapeutic anticoagulation may be considered, though this may increase the risk of postoperative bleeding [45]. It may be that anticoagulation can be reserved for those deemed to be at high risk of thrombosis. In the transplant setting, the use of blood transfusion and technical challenges in the resection have been identified as risk factors for concerns [43]. A focus of future research should be to identify the optimal patients and regimen for postoperative anticoagulation. Currently, management must be based on clinical judgment in individual cases, with therapeutic anticoagulation reserved for those deemed to be at higher risk of thrombotic complications.

A final consideration is the presence of other nonvascular anastomoses. In right-sided pancreatic resections, there are typically a number of anastomoses, in comparison to left-sided resections where they are not typical [46]. Anastomotic leak is one of the most prevalent significant complications following pancreatic resection and a major source of morbidity and mortality [47]. Arterial resection could be seen as putting patients at increased risk of anastomotic breakdown given the increased blood loss, longer operative time, and the ischemic insult during the resection [4]. Anastomotic breakdown is also a risk factor for increased delayed postoperative bleeding [43]. These factors may underpin the higher reoperation rates in patients undergoing arterial resection [4]. When performing major vascular resection, a total pancreatectomy may be preferable, to avoid the need for a pancreatic anastomosis and hence increase its associated morbidities

Prognosis

Very few studies report on 5-year survival for patients undergoing arterial resection in surgery [4, 26, 28, 40, 48, 49]. The few studies reporting it offer 5-year survival of between 0% and 15% [2]. Median survival is reported in more studies and typically

is reported at between 12 and 22 months, with weighted median survival in DP-CAR reported at 14.4 months [4, 26]. This survival must obviously be viewed in context.

It would be unfair to compare such survival with the overall survival of patients with minimal histological or clinical features predictive of poor outcome. Indeed work has suggested that patients with very favorable clinical and pathological features can have 5-year survival approaching 60% [50]. The need for an arterial resection should be seen in the context of advanced disease, and comparisons if any should be drawn from other locally advanced and unresectable cases. In patients with inoperable pancreatic cancer at laparotomy with or without bypass procedures, who go on to have palliative chemotherapy, median survival is 14.4–16.3 months [51], which seems to be superior to patients who undergo palliative (i.e., R2) resection, underlining the key requirement of obtaining an R0 resection when considering arterial resection [52]. Further, a recent meta-analysis of locally advanced pancreatic cancer patients treated with FOLFIRINOX and of whom only around 25% were resected, median survival was 24.2 months [53]. However, this is comparing data of most effective chemotherapy with advanced surgery without therapy or with less effective therapy. Obviously, the best available therapy plus advanced and safe surgery should be put into the equation. When the median survival of patients undergoing arterial resection is viewed in this light, it does not appear as bleak.

Importantly resection remains the only curative treatment for pancreatic cancer, and when offered to patients, that small chance of survival may to an individual be deemed worth the surgical risk.

Conclusion

Arterial resection should only be considered in a highly selected group of physically fit patients and in patients where there is a high chance of obtaining an R0 resection [52]. Centers performing such surgery should carry out a high volume of major pancreatic resections and have a comprehensive multidisciplinary approach and support for their service. In particular, 24-h access to a full compliment of radiological imaging and intervention should be seen as essential.

Patients should probably only undergo resection if disease is stable or responding to neoadjuvant therapy, without evidence of distant metastases. All patients should be considered for current clinical trials to further the evidence base for such resections. While these are a highly selective group of patients at present, as the chemotherapeutic armamentarium advances, it is likely that the frequency for combined pancreatic and arterial resections will increase.

Treatment of Recurrent Pancreatic Cancer After Surgery

Oliver Strobel, Willem Niesen, and Markus W. Büchler

Contents

Abstract

The majority of patients with pancreatic cancer eventually develop and die from recurrence even after successful surgical resection and adjuvant therapy. Pancreatic cancer recurrence and its treatment are, therefore, very relevant clinical concerns. For several reasons there is a striking lack of knowledge and evidence with respect to the incidence and pattern, the detection, and the management of pancreatic cancer recurrence. This chapter summarizes available data on the incidence, timing, and pattern of recurrence, discusses the need for and the potential of structured surveillance programs, and provides an overview of treatment options for pancreatic cancer recurrence. While most patients will eventually die from systemic recurrences, a relevant subgroup of 20–30% of

patients at first present with isolated local recurrence. For systemic recurrences chemotherapy is the only treatment option. However, data from observational cohort studies suggest that treatment strategies that include local approaches may be associated with prolonged survival patients with isolated local recurrences. In order to improve the treatment of both local and systemic recurrence of pancreatic cancer and to enable clinical trials, it will be important to establish surveillance programs after resection and to address treatment options for recurrence in future guidelines.

Introduction

Management of pancreatic ductal adenocarcinoma (PDAC) recurrence is a very relevant topic because even after successful resection and administration of adjuvant therapy, PDAC recurs in the majority of cases. Most patients eventually succumb to local, metastatic, or combined tumor recurrences resulting in a median survival of only 20–25 months and 5-year survival rates around 20% [1, 2]. Three main reasons contribute to the high recurrence rate and poor prognosis of PDAC:

(i) An obvious reason for local recurrences is insufficient resection margin clearance reflected by the high rate of R1 resections identified by stringent margin assessment [3–6]. The high rates of R1 resection are not caused by inappropriate surgical technique but explained by the tumor biology of PDAC with extrapancreatic and extratumoral perineural spread toward the arteries identified in 60–70% of cases [7].

(ii) Even more importantly most patients die from early metastatic recurrence. Undetectable micrometastatic disease at the time of resection is thought to be the main reason for this systemic failure. While this provides a clear rational for the administration of systemic therapies in the adjuvant or neoadjuvant settings (see chapters "▶ Adjuvant Chemotherapy in Pancreatic Cancer" and "▶ Neoadjuvant Chemotherapy in Pancreatic Cancer"), the follow-up data derived from randomized controlled trials on adjuvant therapy show that the tested therapy regimens can significantly delay but not prevent recurrence (see Table 1) [8–17].

(iii) The aggressive tumor biology and high chemoresistance of PDAC are thought to be main reasons for the failure of available regimens for adjuvant therapy to achieve a sustained local and systemic control [2].

With significant improvements in the surgical therapy and in accompanying (neoadjuvant or adjuvant) systemic treatment options, the long-lasting controversy on the role of surgery in resectable PDAC has been resolved [1]. High-volume centers have reported actuarial 5-year survival rates after resection of 20% overall and of up to 60% in patient subgroups with a favorable combination of prognostic factors [6, 18–20]. More recently, the JASPAC-1 study has marked a significant advance in adjuvant treatment with S1 resulting in a 5-year survival rate of 44% [16]. Today it is undisputed that surgical resection in combination with systemic treatment remains the only chance of long-term survival or cure in patients with primary PDAC.

In contrast, although PDAC recurrence is a pressing problem affecting the majority of resected patients, its management is poorly studied and highly controversial. A part of the underlying problem is a certain therapeutic nihilism toward PDAC recurrence that is reflected by the fact that most current treatment guidelines do not recommend structured surveillance programs after resection due to a lack of evidence for effective treatment options for recurrence or lack of a survival benefit by regular follow-up exams (see Table 2) [21–26]. Of note, some current guidelines do not even address the problem of PDAC recurrence and its management.

This chapter aims to provide an overview of current treatment options for PDAC recurrence with a special focus on isolated local recurrence. The chapter also addresses several aspects that are relevant in the context of PDAC recurrence, including incidence and pattern of recurrence after resection, and the potential value of structured surveillance after resection.

Incidence and Pattern of Recurrence

The knowledge about the incidence, timing, and pattern of recurrence is vague as surveillance programs are not generally recommended in current clinical guidelines resulting in a lack of follow-up data from large patient cohorts. The best information on clinically detected recurrence is probably available from randomized controlled trials on resection and adjuvant therapy (Table 1 [8–16]**)** with some additional data available from the few observational studies dedicated to the topic of recurrence [27]. A few available autopsy series provide important data on the pathological pattern of recurrence after resection [28–30].

Data from randomized controlled trials (RCTs) provide the best indication of the "clinical" pattern of recurrence detectable by structured follow-up programs with assessment of patient history, physical examination, cross-sectional imaging (usually contrast-enhanced computed tomography (CT)), and serum values of tumor markers,

Table 2 Recommendations on surveillance after resection for pancreatic cancer in selected recent clinical guidelines

Guideline	Recommendation	Level of recommendation	Level of evidence
AWMF Germany 2013 [22]	*9.33*:	A	5
	Structured surveillance programs for PDAC are not recommended as there are no available data that regular staging examinations are associated with a survival benefit	Consistent level 1 studies *According to Oxford Centre for Evidence-Based Medicine*	Expert opinion without explicit appraisal or based on physiology, bench research, or "first principles"
NCCN USA (2016) [21]	*MS-43/PANC-6*:	Category 2B	Lower level
	History and physical examination for symptom assessment, CA 19-9 testing, and follow-up CT scans every 3–6 months, then every 6–12 months	Based upon lower-level evidence, there is NCCN consensus that the intervention is appropriate	
	Are category 2B recommendations, because data are not available to show that earlier treatment of recurrences leads to better patient outcomes		
ASCO USA (2016) [23]	*6.1*:	Moderate	Low
	In the absence of RCT evidence, the panel recommends that patients who have completed treatment of potentially curable pancreatic cancer and have no evidence of disease be monitored for recovery of treatment-related toxicities and recurrence. Visits may be offered at 3- to 6-month intervals; the role of serial cross-sectional imaging, the extent to which surveillance intervals should be prolonged over time, and the duration of recommended surveillance are all undefined	Informal consensus, benefits outweigh harms The available evidence was deemed insufficient to inform a recommendation to guide clinical practice. The recommendation is considered the best current guidance for practice, based on informal consensus of the expert panel	Low confidence that the available evidence reflects the true magnitude and direction of the net effect. Further research may change either the magnitude and/or direction this net effect

especially of carbohydrate antigen 19-9 (CA 19-9). The follow-up results of selected RCTs on resection and adjuvant therapy are summarized in Table 1. These data allow several important conclusions on incidence, timing, and pattern of recurrence after resection for PDAC. Data on disease-free survival from RCTs comparing adjuvant therapy versus observation show that without adjuvant therapy 50% of patients develop clinically detectable cancer recurrence within 5–10 months [8, 10, 12]. Adjuvant chemotherapy with gemcitabine or 5-fluorouracil [5-FU] monotherapy cannot prevent but delay recurrence to 11–15 months. With patient selection based on known prognostic factors, recurrence is observed later, at 14.4 months without and at 18 months with adjuvant therapy [9]. Even in the more recent RCTs, the median disease-free survival remains at 12–15 months [13, 15]. Up to 90% of patients without and about 70% with adjuvant therapy develop PDAC recurrence within a follow-up time of 30–50 months. More recently, the JASPAC-1 study marked an exceptional advance, at least for Asian patients, with a median disease-free survival of 22.9 months and 5-year disease-free survival rate of 33.3% after resection and adjuvant therapy with S1 [16].

While the reporting on the pattern of recurrence in different RCTs is rather heterogeneous and the majority of patients presents with systemic progression, 20–30% of patients are consistently found to primarily present with isolated local recurrence (Table 1). In summary, the data on recurrence from RCTs demonstrate that even with adjuvant therapy, most patients develop recurrence within 1.5 years after resection. The data also suggests that based on structured surveillance programs, it may be possible to identify a subgroup of 20–30% of patients who first develop isolated local recurrence (as detectable by current imaging technology).

A multicenter observational study in 1130 patients undergoing resection between 2000 and 2010 reported a median actuarial overall survival of 25.9 months (median follow-up 18 months) [27]. Based on radiographic evidence, pathologic confirmation, and/or tumor marker elevation, the local recurrence rate in this study was 22%, and metastatic recurrence was detected in 41% of patients, confirming the clinically detectable recurrence patterns observed in RCTs. The identification of positive lymph node status as most relevant risk factor for local recurrence [27] suggests that many patients with "local recurrence" may in fact have progression of pre-existing lymph node metastases and may be good candidates for re-resection.

Only the few available autopsy series can demonstrate the "true" pathological pattern of recurrence and the relevance of the sites of recurrence for death. In an autopsy study in 24 patients who died after resection of pancreatic cancer, 75% of patients had local recurrence, 75% had distant metastases, and the local recurrence was the cause of death in 17% of patients [28]. Another autopsy study in patients with PDAC included 22 patients after resection [29]. At autopsy, two patients (9%) had died of unrelated causes and had no evidence of recurrence, three (14%) had isolated local recurrence, four (18%) had only metastatic recurrence, and 13 (59%) had both local and systemic recurrence. In this study, expression of DPC4 in the tumor was highly correlated with metastatic but not with localized disease [29]. These autopsy studies confirm that after resection and adjuvant therapy for pancreatic cancer, most patients die from systemic disease, but a subgroup of patients develop and die from isolated local recurrence, and molecular properties of the tumor appear to contribute to the pattern of recurrence.

It will be interesting to see how the neoadjuvant or adjuvant administration of more aggressive chemotherapy regimens such as S1 [16] and FOLFIRINOX [31–33] and advances in radiation oncology will affect incidence, timing, and pattern of PDAC recurrence. Translational studies characterizing the molecular properties of PDAC in the context of the pattern of disease may identify biomarkers associated with systemic progression that may become useful for personalized decision-making in the management of PDAC recurrence.

Surveillance After Resection for Pancreatic Cancer

The effectiveness of surveillance after PDAC resection is highly controversial, and in most countries structured surveillance programs are not established. While some of the available treatment guidelines for PDAC do not even address this relevant topic, several "evidence-based" guidelines give out different recommendations with respect to follow-up after potentially curative surgery (Table 2). Based on very similar literature, the German S3 guidelines do not recommend structured surveillance programs for PDAC due to a lack of evidence of positive effects of surveillance on prolonging survival after the completion of adjuvant chemotherapy [22], while the North American NCCN guidelines acknowledge the lack of evidence but still recommend CA 19-9 examination and cross-sectional imaging every 3–6 months for the first 2 years. The latter recommendation was based on the consensus that earlier

detection of recurrence may facilitate patient eligibility for investigational studies or other forms of treatment [21]. However, a cost-effectiveness analysis revealed higher costs without any survival benefit from a regular follow-up program that included abdominal imaging [34].

On the one hand, it should be acknowledged that clinical guidelines have to be based on current evidence and have to include socioeconomic considerations and that there is at present little evidence for the benefit of surveillance. On the other hand, structured surveillance programs are needed to enable studies investigating the potential survival benefit from early detection and timely therapy of PDAC recurrence.

Although regular surveillance is not generally recommended and usually not paid by the health insurances, some centers offer a structured follow-up with physical examination, blood tests (including CA 19-9 levels), and abdominal imaging to all patients who undergo PDAC resection. In a recent analysis of 940 postoperative follow-up visits performed in 618 pancreatic patients over a 1-year period, recurrences were detected in 74 (40%) of 184 patients in follow-up after PDAC resection, of whom only 26% had symptoms [35]. In all of these patients, a cancer-directed therapy was initiated. Importantly, 12 (75%) of 16 patients with isolated local recurrence were without symptoms and 11 were referred for re-resection [35]. The comparison of sequential follow-up CT scans allows for early detection of local recurrences by identification of subtle but progressive changes at typical predilection sites for local recurrences (Fig. 1) [36]. The value of CT scans in the early detection of local recurrence was recently confirmed in an independent series [37].

These data have important implications, because they show that most recurrences are at first asymptomatic and will be detected earlier with regular surveillance including cross-sectional imaging, and this offers the opportunity for earlier initiation of cancer-directed therapy. While it appears logical that earlier detection of recurrence and initiation of therapy may result in better outcomes, future studies will have to assess how the treatment options discussed below affect survival and quality of life of patients with PDAC recurrence.

The development of tools for screening of risk populations and for early detection of PDAC is an area of intensive research. Novel analytic targets such as exosomal markers and cell-free DNA that are currently being evaluated for early detection of PDAC may also be promising tools for post-resection surveillance [38, 39]. The potential of structured surveillance programs after resection will have to be redefined in the future as better diagnostic tools, and more effective systemic therapies will hopefully become available.

Treatment of Recurrence of Pancreatic Cancer

The treatment of pancreatic cancer recurrence is based on very limited evidence. The available literature is restricted to mostly small retrospective studies in selected patients and/or multiple case reports, suggesting a considerable publication bias.

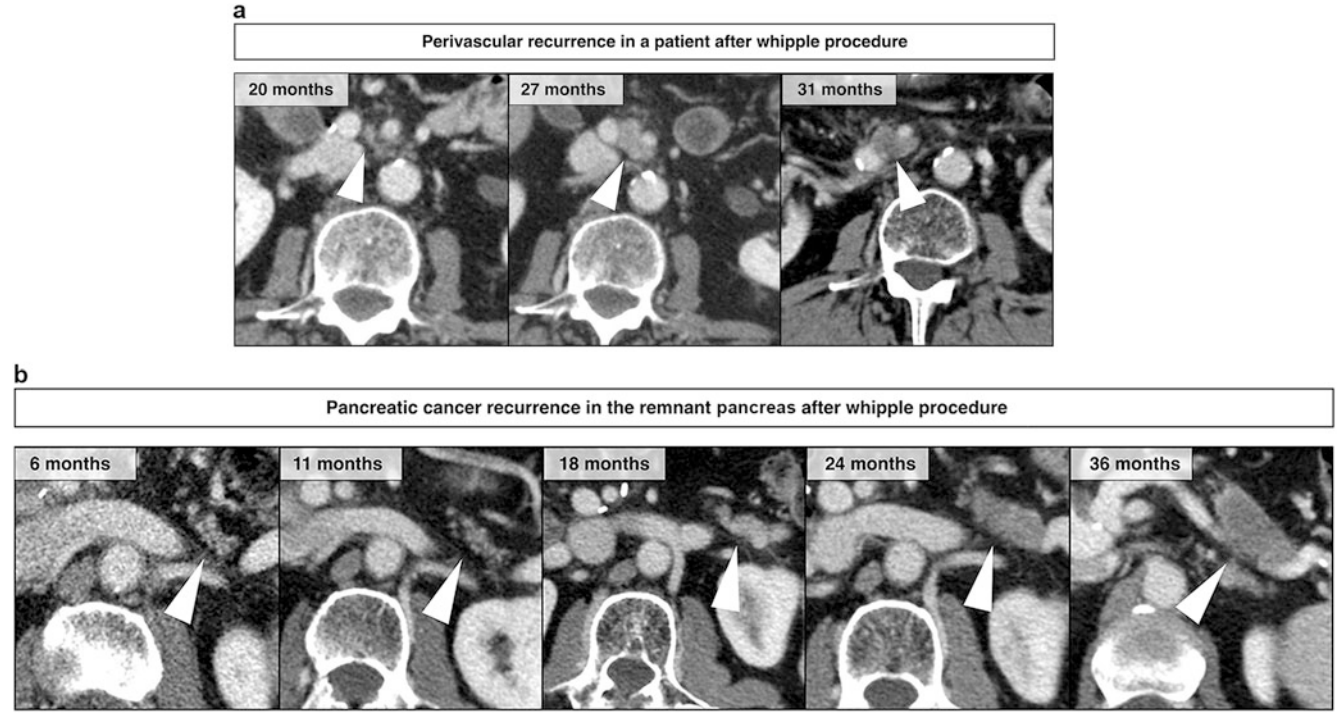

Fig. 1 Typical findings of local recurrence in sequential CT scans for surveillance after resection for pancreatic adenocarcinoma. (**a**) Perivascular recurrence at different time points after pancreatoduodenectomy for pT3pN1R1 ductal adenocarcinoma in a 64-year-old patient. Unsuspicious findings at 20 months. At 27 months increase of dense tissue between the superior mesenteric artery and vein with further increase and hypodense changes after 31 months. The patient underwent successful re-resection with intraoperative radiation therapy (*IORT*). (**b**) Local tumor recurrence involving the pancreatic remnant after pancreatoduodenectomy for pT3N1R1 ductal adenocarcinoma. Unsuspicious findings until 18 months after resection. Hypodens changes in the pancreatic remnant at 24 months with increase after 36 months. The patient underwent re-resection with completion pancreatectomy and adrenalectomy

While several of the current treatment guidelines do not even address the topic of treatment of PDAC recurrence, the German S3 [22] and the NCCN guidelines [21] mention several treatment options dependent on the pattern of recurrence including local therapy for local recurrences (Table 3) [21–26]. Based on common sense rather than on actual evidence, the pattern of recurrence defines the potential benefit of additional local versus merely systemic treatment. The appropriate treatment options further depend on multiple parameters including the exact localization of recurrence, the clinical performance status and comorbidity of the patient, previous cancer-directed treatment (i.e., neoadjuvant and/or adjuvant treatment regimens), and timing of recurrence (i.e., interval between resection and recurrence and timing in relation to adjuvant therapy).

Available treatment options described in the literature are summarized in Table 4 in the context of the pattern of recurrence The following paragraphs address treatment options for systemic recurrence and isolated local recurrence separately.

Treatment of Systemic Recurrence

As discussed above, the majority of patients with recurrence after PDAC resection present with systemic disease. Clearly, systemic chemotherapy is the appropriate cancer-directed therapy for the majority of these patients. There is little evidence from the literature as to the best regimen in this situation. However, this is a palliative situation, and depending on the timing of recurrence (during or after adjuvant therapy), the regimen used for neoadjuvant and/or adjuvant therapy, and the performance status of the patients, the same principles as outlined for second-line chemotherapy in advanced disease and for palliative treatment may be recommended (see chapters ▶ "Palliative Management of Pancreatic Cancer" and ▶ "Chemotherapy for Advanced Pancreatic Cancer"). Among current treatment guidelines, the NCCN guidelines provide the most detailed recommendations adjusted to the possible clinical scenarios (Table 4) [21]. With respect to quality of life, adequate pain therapy, management of cancer complications, and supportive care are very important aspects of palliative therapy in patients with PDAC recurrence (see chapter ▶ "Palliative Management of Pancreatic Cancer").

Oligometastatic Recurrence

None of the current guidelines specifically address the situation of oligometastatic recurrence of PDAC in their main recommendations, because the evidence on the management of this condition is limited to small case series and case reports of oligometastatic recurrence in the liver and lungs. Metastasectomy for both initially systemic disease and systemic PDAC recurrence is highly controversial. However, recent reports suggest that such operations are increasingly performed [40–43]. Data on resection of metachronous liver metastases is limited to case reports and subgroup analyses of small series. The few available series on resection for liver metastases of PDAC mainly analyze synchronous resection and resection in patients with good response to chemotherapy, and the median survival of 14–15 months is not very

Table 3 Recommendations on treatment of recurrent pancreatic cancer in selected recent clinical guidelines

Guideline	Recommendation	Level of recommendation	Level of evidence
AWMF Germany (2013) [22]	*7.13*:	GCP – strong consensus	NA
	Local recurrence: In case of isolated local recurrence for pancreatic cancer, all possibilities for local therapy should be considered		
	Systemic recurrence: Not specifically addressed		
NCCN USA (2016) [21]	*MS-44/PANC-10*:	Category 2B	Lower level
	Confirmatory biopsy		
	All cases of recurrent disease	Category 2A	
	➔ Clinical trial is preferred option	Based upon lower-level evidence, there is uniform NCCN consensus that the intervention is appropriate	
	➔ Palliative and best supportive care without additional therapy should also be an option		
	Local recurrence:		
	Chemoradiation can be considered in patients with local disease recurrence only, if not previously administered		
	An alternative chemotherapy regimen can be given		
	Surgical resection may be considered in select cases (i.e., good performance status, location of recurrence is favorable), though there is currently no evidence to support this recommendation		
	Systemic recurrence:		
	<6 months after adjuvant therapy → alternative chemotherapy		
	6 months after adjuvant therapy → systemic therapy as previously administered or an alternative systemic regimen		
	Previous adjuvant treatment and good performance status → gemcitabine/nab-paclitaxel and FOLFIRINOX		
ASCO USA (2016) [23]	Not addressed	NA	NA

AWMF Arbeitsgemeinschaft der Wissenschaftlichen Medizinischen Fachgemeinschaften e.V. (Version 1.0 October 2013), *NCCN* National Comprehensive Cancer Network (Version 2.2016), *ASCO* American Society of Clinical Oncology (2016), *ESMO* European Society for Medical Oncology (2015), *NCI* National Cancer Institute, *IAP* International Association of Pancreatology, *EPC* European Pancreatic Club, *GCP* good clinical practice

encouraging [40, 41]. In 23 patients who underwent resection for metachronous metastases of PDAC, the median survival after diagnosis of liver metastases was 14.5 months (unpublished data) in line with the published series.

In contrast, favorable survival has consistently been reported after resection of the rare event of isolated lung metastases including metastatic pulmonary recurrences [42, 44–47]. PDAC with isolated pulmonary metastases appears to identify a subgroup with favorable prognosis, probably explained by unique molecular properties of these tumors [43, 48, 49]. The favorable survival observed after resection of pulmonary metastases may, thus, at least in part be explained by a selection bias.

While there is no evidence for a survival benefit of local therapies for metastatic disease, metastasectomy may be considered in selected patients with oligometastatic hepatic and particularly pulmonary recurrences, especially in patients with good performance status and a long interval between resection and diagnosis of the metastatic recurrence. Other local treatment options such as locally ablative therapies or radiation therapy may also be considered.

Treatment of Isolated Local Recurrence

The evidence on treatment of isolated local recurrence of PDAC is limited, but there are promising results from several retrospective cohort studies or case series for multimodal concepts including chemoradiation and surgical re-resection (Tables 5 and 6) [46, 50–61]. The use of local ablation therapies such as irreversible

Table 4 Cancer-directed treatment options for recurrent pancreatic cancer

Type of recurrence	Possible treatment	Intention	Comments
Isolated local recurrence	Chemotherapy	Palliation	Considered the standard therapy for any kind of recurrence without curative intention
			Data based on cohort studies
	Chemoradiation	Palliation/ local control/ pain therapy	Considered by many as only alternative treatment option that includes a local therapy
			Data based on cohort studies (see Table 5)
	Re-resection in combination with chemotherapy or chemoradiation	Potential cure/medium- to long-term control	Re-resection in a multimodal setting in combination with chemotherapy/chemoradiation is the only potentially curative treatment option. Performed in highly specialized surgical centers
			Data based on cohort studies (see Table 6)
	Locally ablative therapies in combination with chemotherapy	Palliation/ local control	Experimental treatment options (including irreversible electroporation, radiofrequency ablation, etc.). Data mainly extrapolated from cohort studies in unresectable disease. Only case reports in the setting of isolated local recurrence
Oligometastatic systemic recurrence	Chemotherapy	Palliation	Standard treatment for metastatic recurrence
			Data based on cohort studies in recurrence. Preferred regimens mainly extrapolated from studies on second-line treatments for primarily unresectable/metastatic disease
	Metastasectomy in combination with chemotherapy	Medium- to long-term control	May be appropriate for selected patients
			Limited data from small retrospective cohort studies. Best data for pulmonary metastases
	Locally ablative therapies in combination with chemotherapy	Medium- to long-term control	May be appropriate for selected patients
			Data restricted to case reports

				S1 ($n = 7$)	PFS: 6.9 months
Zeng [54]	2016	24 ($n = 5$ additional metastases)	SBRT 45 (42–50) Gy	Reported in $n = 3$	OS: 12.2. months
					PFS: NA
					CR: $n = 5$ (21%)

Included are studies with >5 patients undergoing chemoradiation
SBRT stereotactic body radiation therapy, *OS* overall survival, *PFS* progression-free survival, *CR* complete response (clinical). Updated from Strobel and Büchler [17]
[a]Study includes $n = 3$ patients after definitive chemoradiation (no resection) for locally advanced disease

electroporation and radiofrequency ablation may represent another strategy worth testing for isolated local recurrences (Table 4). However, as data on local ablation therapies are restricted to case reports, the following paragraphs will focus on radiation therapy and surgical re-resection.

Only two of the analyzed guidelines specifically address the treatment of isolated local recurrence (Table 3). The current German S3 guidelines recommend the evaluation of available local therapies and mention the options of re-resection and chemoradiation in the supporting discussion [22]. The NCCN guidelines are more specific and recommend first inclusion in clinical trials (preferred), the administration of chemoradiation (if not previously done), a change of the regimen of systemic chemotherapy, or palliative and best supportive care. In their 2/2016 version, the NCCN guidelines for the first time mention the option of surgical re-resection in the supporting discussion, but continue with the statement that "there is currently no evidence to support this recommendation" [21].

Given the available data on radiation therapy and re-resection discussed below and summarized in Tables 5 and 6, this preference of chemoradiation over re-resection is somewhat startling and may point to a certain dominance of radio-oncologists in the guideline panels.

Rational for Local Therapy

Undisputedly, most pancreatic cancer patients will eventually die from metastatic spread even after potentially curative resection. However, it has been generally accepted that in primary pancreatic cancer, surgical resection in combination with systemic chemotherapy (or chemoradiation) is currently the only therapy option offering long-term survival and, in rare cases, even cure [2].

With advances in both safety and radicality, the limits of surgical resection are today being pushed toward extended resections [62] or resections after aggressive neoadjuvant therapies for locally advanced PDAC [31, 32] with promising results. Strategies of neoadjuvant treatment offer the advantage to select patients without progression for surgical resection, while patients with early systemic progression are selected out. Similarly, an isolated local recurrence may identify patients with tumors of a less aggressive phenotype resulting in slower systemic progression and better prognosis [29, 57]. This notion provides a good rational to test localized treatments such as re-resection and chemoradiation in this selected subgroup of patients with a localized disease pattern. However, the majority of patients presenting with suspected isolated local recurrence may also have occult systemic disease and may develop systemic progression later in the course of their disease. Therefore, as for primary pancreatic cancer, local therapies for recurrence must always be embedded in multimodal treatment strategies that include systemic chemotherapy.

Radiation Therapy for Isolated Local Recurrence

Radiation therapy/chemoradiation is often discussed as the main alternative to merely palliative chemotherapy for treatment of local recurrence [21]. The evidence for chemoradiation is based on only few retrospective series of limited size (Table 5) [50–54]. The actuarial overall median survival reported for different radiation therapy protocols ranges between 8.8 and 17.5 months. The three series using chemoradiation report longer median survival around 15.9–17.6 [50, 52, 53] compared to the two series on stereotactic body radiation therapy (SBRT, 8.8 and 12.2 months) [51, 54], probably because fewer patients received additional systemic

Included are studies with >5 patients undergoing re-resection

OS overall survival, *DFS* disease-free survival, *ILR* isolated local recurrence without evidence of systemic disease confirmed by surgical exploration. Updated from Strobel and Büchler [17]

[a]The cohort by Kleeff et al. is from the same center and included in the follow-up study by Strobel et al.

[b]Mixed cohort of local and distant recurrence. Only data of patients with local recurrence included here

chemotherapy in the latter two studies. Data on progression-free survival, local control rates, toxicity, and symptom relief are all inconsistently reported among the available studies. It should be noted that three studies report complete radiologic response rates of 15–33% [50, 52, 54].

With clear evidence for local efficacy in all studies and overall survival rates of up to 18 months, treatment strategies that include radiation therapy to improve local control should be further tested in patients with isolated local recurrence after resection of PDAC. However, the data also suggest that local radiation has to be accompanied by systemic chemotherapy to achieve adequate progression-free and overall survival.

Re-resection for Isolated Local Recurrence

Very similar to the situation described for radiotherapy, the evidence for re-resection for isolated local PDAC recurrence is based on retrospective series of limited sample size (Table 6) [46, 55–61]. However, the reported outcome with median overall survival rates of 25 to >30 months after re-resection in four of the more recent series [57–60] is superior to the outcome reported after chemoradiation. These differences can in part be explained by bias due to the exclusion of patients with radiologically undetectable metastatic disease in the resected subgroups. While most series did not report on resection rates, the series from Heidelberg initially reported a resection rate of 50%, which dropped to 42.3% in the larger follow-up study, mainly due to intraoperative diagnosis of metastases [55, 57]. Overall, the available series clearly show that re-resection for isolated local recurrence is feasible and safe (low mortality rates of 0–2%) and associated with encouraging survival results. However, it should be emphasized that these results are based on cohorts of highly selected patients treated in specialized referral centers for pancreatic surgery and may not be commonly applicable.

The initial experience with re-resection at Heidelberg University Hospital was reported in 2007 [55], and the so far largest series on re-resection for isolated local PDAC recurrence was published in 2013 [57]. Of 97 patients with preoperatively suspected isolated local recurrence and histologic proof of recurrence, 57 (59%) had isolated local recurrence by surgical exploration, while distant metastases were identified in 40 (41%) patients. This highlights the necessity of better diagnostic tools to detect small metastatic deposits, a problem known from staging of primary PDAC. Of 57 isolated local recurrences, 41 (72%) were resected (Fig. 2), while 16 (28%) were locally unresectable. Median postoperative survival was 16.4 months in confirmed isolated local recurrence versus 9.4 months in metastatic recurrence, confirming the better prognosis associated with localized disease pattern observed in other studies [63]. Importantly, median survival in isolated local recurrence was significantly longer after re-resection compared to locally unresectable recurrences (26.0 vs. 10.8 months). This observation in surgically confirmed isolated local recurrence clearly points to a potential survival benefit from re-resection. R0 re-resection in 18 patients was associated with a favorable median survival of

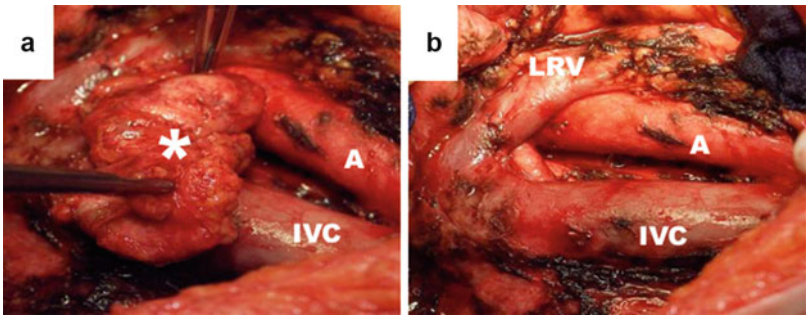

Fig. 2 Intraoperative findings in a patient with isolated locoregional recurrence in a typical predilection site after resection for adenocarcinoma of the pancreatic head, interaortocaval lymph nodes below the left renal vein. (**a**) Location of the recurrence (*) after exposure and dissection. (**b**) Operative site after tumor removal and retroperitoneal lymphadenectomy. *A* abdominal aorta, *IVC* inferior caval vein, *LRV* left renal vein

30.5 months [57]. While a true benefit of re-resection can only be demonstrated by RCTs, these results suggest that selected patients with suspected isolated local PDAC recurrence may benefit from re-resection.

Only one study [61] that did not report on administration of systemic therapy reports a sobering median survival of 8.9 months after re-resection for PDAC recurrence. This again points toward the need to embed re-resection in a multimodal treatment strategy that includes systemic chemotherapy in order to achieve long-term survival.

Overall, the available series on re-resection clearly demonstrate that this concept is promising and should be tested in selected patients. A direct comparison of survival outcomes reported for radiation therapy and re-resection is not scientifically sound and should not be made. However, it is very clear that the available evidence for re-resection is at least equal, if not superior, to the evidence on radiation therapy in terms of the numbers and sample size of studies as well as with respect to reported survival outcomes.

Selection of Patients for Local Therapy

The identification and selection of patients that benefit from a treatment that includes local therapy are very relevant in the context of PDAC recurrence. Clearly, patients with a localized disease pattern without systemic progression, in whom the local recurrence may define prognosis, are the most likely to benefit from local therapy.

To identify these patients, early detection of the local recurrence by adequate surveillance and a thorough diagnostic workup to minimize the risk of occult metastatic disease are necessary. However, as discussed above, the rate of undetected metastatic disease is high [57]. While PET-CT is a currently available technology which holds promise in detection of local and distant PDAC recurrence and warrants

further investigation [64], better tools for detection of metastatic disease are needed in the future.

The larger available series on treatment of local PDAC recurrence analyzed parameters that are associated with survival and may be useful for patient selection. The interval between primary tumor resection and detection of recurrence [46, 53, 55, 58] and CA 19-9 serum levels [57] are two parameters that may be useful, but the available data do not yet allow to determine cutoff values to support decision-making. In the absence of clear evidence, patients with a long interval between primary tumor resection and detection of local recurrence, low tumor markers, good performance status, and low comorbidity are probably the best candidates for local therapies based on common sense.

There is accumulating evidence that molecular properties of the primary tumor define the pattern of localized versus metastatic disease and even the distribution of metastatic disease between organs (e.g., liver and lung) [29, 48, 49]. Recently, several distinct molecular subtypes of pancreatic cancer that are associated with treatment response and prognosis have been identified [65–68]. Similar studies may allow for identification of molecular signatures associated with localized disease or systemic progression and serve as new powerful tools for patient selection in the future.

Conclusions

Pancreatic cancer recurrence is a pressing problem that affects the vast majority of patients even after successful resection and completion of adjuvant chemotherapy. It is, therefore, surprising how little evidence there is with respect to the management of pancreatic cancer recurrence, and it is concerning that this important topic is still missing in many current clinical practice guidelines for pancreatic cancer. While the majority of patients develop metastatic recurrence, a significant subgroup of 20–30% of patients first develop isolated local recurrence. These patients appear to have tumors of less aggressive subtypes with slower systemic progression and may benefit from local therapy. As most recurrences are at first asymptomatic, structured follow-up programs are needed for earlier detection and timely initiation of therapy. However, in the absence of evidence, structured surveillance programs are currently not recommended. Although the literature provides little evidence with respect to the management of isolated PDAC recurrence, both chemoradiation and surgical re-resection appear to be safe and effective based on several retrospective series. The best "standard" management for isolated PDAC recurrence can only be determined based on RCTs which are unlikely to be conducted for this indication. More likely, the therapy for PDAC recurrence will remain a matter of interdisciplinary, personalized decision-making. Novel biomarkers for early detection of PDAC and the development of more effective systemic treatments will hopefully also advance surveillance after PDAC resection and treatment of PDAC recurrence.

Abstract

The management of cystic pancreatic lesions fundamentally depends on knowing the cyst type and the risk or presence of malignancy. Only serous cystic neoplasms (SCN) are generally benign lesions, while mucinous cystic neoplasms (MCN) and intraductal papillary mucinous neoplasms (IPMN) as the most common cystic lesion and solid-pseudopapillary neoplasm (SPN) show different risk profiles for the development of invasive cancer. Once a cystic lesion is detected, the clinical decision is necessary if an upfront resection with the inherent morbidity of pancreatic surgery should be performed or if an observational management can be preferred. Whereas these strategies are clearly defined for certain cystic lesions including SCN, MCN, and SPN, the management of IPMN, especially with regard to the branch-duct type, remains partly controversial, and current guidelines differ with regard to indications for surgery and/or surveillance. The present chapter gives an overview on the different types of pancreatic cystic neoplasms and current diagnostic modalities. Furthermore, the indications for surgery, the variety of surgical resections, and the surveillance/follow-up strategies are discussed in the light of the current literature and guidelines.

Introduction

For pancreatic cysts, an overall prevalence of 2.5% is estimated in recent reports from the United States. In MRI studies, they may be seen in 14–20% up to 50–70% in people aged >70 years [1, 2]. A former postmortem study describes pancreatic cysts <1 cm in app 25% of cases [3]. Most of them are asymptomatic incidental findings, more and more detected by increased use of improved imaging. The meaning of these features depends on the potential of the different types to develop malignancy. Arising awareness leads to a worldwide discussion in literature and expert meetings with lots of effort to acquire guidelines concerning diagnostics, risk factors, course, and management of each form of pancreatic cystic lesions, guided by symptoms and risk of malignancy.

In contrast to real cystic lesions of the pancreas, pseudocysts should be sharply distinguished. Pseudocysts can mostly be found as sequela of inflammation or trauma and are easy to differentiate and to diagnose. Due to their size and their almost extrapancreatic appearance, pseudocysts were frequent findings also in times of moderate accuracy of imaging, and therefore it formerly was assumed that most cystic lesions of the pancreas were pseudocysts. Their clinical relevancies being benign residual lesions concern only symptoms and signs of inflammation to indicate any form of therapy. Therefore, they will not be subject of this chapter.

Under consideration of the wide range of different cystic neoplasms, the most frequently resected and clinically relevant entities include intraductal papillary mucinous neoplasm (IPMN), mucinous cystic neoplasm (MCN), serous cystic neoplasm (SCN), and solid-pseudopapillary neoplasm (SPN). In large collectives of patients who underwent resections for cystic pancreatic lesions ($n > 400$, from the Memorial Sloan Kettering Cancer Center New York and >800 from Harvard, Boston), IPMN was documented in 23–38%, MCN in 11–23%, SCN in 16–23%, and SPN in 2–3% [4, 5]. They differ in incidence, localization, and age and sex correlation and show specific gene alterations. Only SCN is considered to be benign, while IPMN, MCN, and SPN show different malignant potentials, which are associated with their mucinous components. Different types of IPMN can be found in the Wirsung or Santorini duct (main duct, MD-IPMN) as well as in the branch ducts of the pancreas (BD-IPMN) and are of high interest for recent research due to their risk to become pancreatic cancer which can be estimated at 70% and 25–30%, respectively, for MD- and BD-IPMN.

This chapter gives an overview to the current knowledge of diagnostics and behavior of the different cystic lesions of the pancreas, which is the basis for understanding their relevance and for developing individual therapy strategies. The first part comprises the knowledge for each type of cystic pancreatic neoplasms under consideration of large patient series. Diagnostic procedures are summarized and discussed within the second part with respect to the accuracy of preoperative diagnostics, as the key tool for further management. In the third section, the controversial possibilities and opinions on how to handle pancreatic cystic lesions once they are detected – surveillance versus resection – are highlighted under consideration of recent guidelines.

Characterization of the Different Types of Pancreatic Cysts

Dilated Branch Ducts

Dilation of branch ducts of the pancreas is a very common incidental finding in CT or MRI scans with increasing prevalence. Seventeen percent of all people show these changes with increasing age [2, 6]. The terminology of BD dilation describes all visible cystic BD lesions of <10 mm in diameter. They are not associated with any abdominal symptoms, and annual control by MRI or EUS is adequate (see Sect. 4). Their role as precursors to BD-IPMN and the natural course in terms of growth dynamics are not totally understood yet. Despite this currently incomplete understanding, they are also described as "incipient IPMN" by a recent and new histological definition [7]. Once their diameter exceeds 10 mm, these lesions fulfill imaging criteria of BD-IPMN.

Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasms (IPMN) account for approximately 35% of all cystic pancreatic tumors and consequently represent the largest subgroup. IPMNs are characterized by production of mucin as well as intraductal and papillary growth of the ductal epithelium. With regard to their location in the pancreatic duct system, they are subclassified into main-duct (MD), branch-duct (BD), or mixed-type IPMN, involving both the main duct and the side branches [4, 7]. To date, it remains controversial whether mixed-type IPMNs primarily arise from the main pancreatic duct and from side branches or if both structures are simultaneously affected, and they therefore represent a distinct subtype of IPMN. IPMNs have to be clearly differentiated from pancreatic intraepithelial neoplasms (PanINs) as another precursor lesion to pancreatic ductal adenocarcinoma (PDAC).

MD- and mixed-type IPMNs are characterized by a dilation of the main pancreatic duct >5 mm without any sign of an external obstruction, which can be found only segmentally or diffusely. The neoplastic papillary epithelium produces abundant mucin with a high viscosity which cannot be drained sufficiently and leads to obstruction and secondary dilation of the affected parts of the duct system. BD-IPMNs are defined as cysts >10 mm communicating with the pancreatic main duct without its dilation (Fig. 1) [8]. Although most IPMNs are primarily noninvasive, they show a potential for a malignant transformation over time following an "adenoma-carcinoma" sequence via three or four grades (low-grade, (formerly also borderline), high-grade dysplasia, and invasive cancer [7].

Four main aspects characterize the natural history of IPMN patients:

- Morphological type (MD-, BD- or mixed-type IPMN)
- Age at the time of diagnosis and the time course of the disease
- Histological subtype (intestinal, pancreatobiliary, oncocytic, gastric differentiation)
- Grade of dysplasia (low-grade, borderline, high-grade dysplasia, invasive cancer)

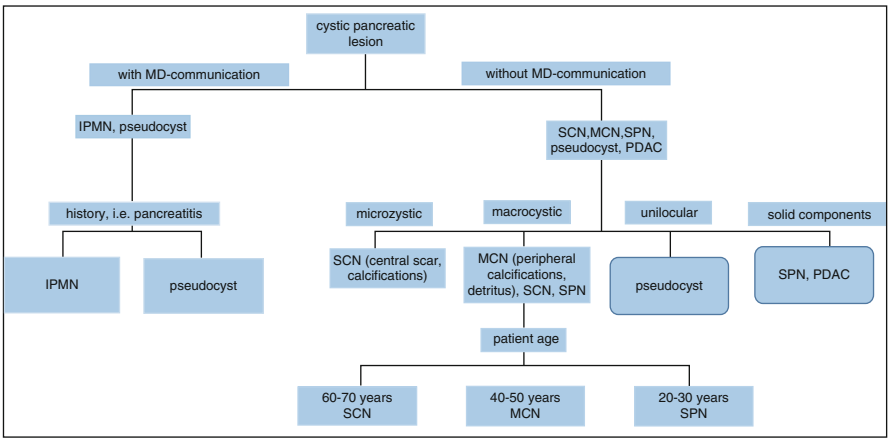

Fig. 1 Radiological flowchart for the diagnostic algorithm of cystic pancreatic lesions (Adopted from [6])

Morphological Type (MD-, BD- or Mixed-Type IPMN)

A recent and comprehensive meta-analysis on the incidence of malignancy in IPMN has shown a rate of 43% for invasive cancer in MD- and mixed-type IPMNs, whereas this is found in app. 17% of BD-IPMNs [9]. In addition to true invasive cancer, lesions with high-grade dysplasia are also regarded as "malignant" by many authors due to the consideration that high-grade dysplasia reflects a situation where there is no more time to waste as the inherent progression to invasive cancer may occur very soon [10]. Consequently, including high-grade dysplasia lesions, MD-IPMNs show an overall risk of malignancy of 60%, whereas BD-IPMNs show malignant transformation in 20–25% of all cases. Mixed-type IPMNs seem to be associated with the highest risk of malignancy which is estimated to be app. 70% in large study populations [8]. The dynamic and time frame of progression for the different morphological IPMN types is not completely understood yet, as especially for MD- and mixed-type IPMN – which are basically resected by the time of diagnosis – no reliable data are available. Furthermore, it has to be considered that radiologically defined findings of BD-IPMN may contain a mixed-type component in the histological workup when they are resected. This underlines the difficulty to evaluate an individual patient's risk on the basis of morphological characteristics.

Patient Age at the Time of Diagnosis

The median age of patients presenting with benign IPMNs compared to malignant IPMNs shows significant differences in two cohort studies of 140 resected MD- and mixed-duct IPMNs by Salvia et al. [11] as well as in 136 resected MD-IPMNs by Sohn et al. [12]. From both studies, the progression to invasive IPMN can be estimated at 5–6 years as patients with benign IPMNs showed a median age of 61 and 63 years, compared to 67 and 68 years for patients with malignant findings [11, 12]. This estimation can certainly only be regarded as a surrogate parameter, and an

already longer subclinical course of preceding IPMN development by the time of diagnosis must be considered. Another corresponding observation is the correlation between duct diameter and the risk of malignancy in MD-IPMNs, underlining that a potentially longer course of the disease reflected by the increased duct size leads to a higher proportion of malignant findings [13].

Progression rates of BD-IPMN under observation have been reported in large studies by Sahora et al. [14] and Maguchi et al. [15]. Among 411 resp. 349 patients, signs of progression occurred in a proportion of 18% during a median follow-up time of 26 months and 44 months, respectively. Malignant histological features after resection of these patients were finally found in 9% and 15% of the patients. Furthermore, both studies demonstrated the development of "remote" lesions – both IPMN and PDAC – distant from the index lesion during the observation. This underlines that the phenomenon of IPMN may not be a focal and localized defect, but the entire pancreas may be affected by a genetic "field defect" with a disparate penetrance in different regions of the gland. This hypothesis is also supported by the synchronous occurrence of multiple BD-IPMNs observed in a certain proportion of patients [16]. Patients with multifocal lesions are generally older than those with solitary IPMN findings, and although multiple lesions are likely to increase the long-term risk of malignant transformation, it remains controversially debated whether multifocal IPMNs have a higher risk of malignancy compared to unifocal lesions [16]. The additional 10-year risk for IPMN patients to develop concomitant PDAC can be estimated between 3% and 9% [17]. If IPMN might play a promoting role in the development of PDAC remains unclear.

Histological Subtypes

Four histological IPMN subtypes with a relevant prognostic impact can be differentiated, namely, intestinal, pancreatobiliary, oncocytic, and gastric subtype. The *intestinal* subtype which displays malignant features in app. 50% of all cases is characterized by neoplastic epithelial cells expressing MUC2, MUC5AC, and CDX2 as typical markers and is mainly found in MD-IPMN [17]. Invasive cancers arising from intestinal-type IPMN are usually colloidal carcinomas and show a better median survival compared to PDAC (107 vs. 20 months) [18]. The *pancreatobiliary* subtype shows branched papillary epithelia with high-grade atypia and an immunohistochemical positivity for MUC1 and MUC5AC. Ninety percent of all IPMNs of this subtype show an associated invasive component, typically tubular adenocarcinomas, which is the most aggressive IPMN-associated cancer and very similar to PDAC in morphology and prognosis [19]. The *oncocytic* subtype is characterized by eosinophil cytoplasm, goblet cells, and complex branched papillary epithelia expressing MUC1 and MUC6. This subtype is rare as well as a malignant transformation into an oncocytic carcinoma which shows a prognosis similar to patients with a colloid carcinoma [19]. BD-IPMNs usually show a *gastric* subtype morphology with multiple small cysts with foveolar gland epithelium, resembling glands of the gastric antrum. A tubular adenocarcinoma can eventually arise from these IPMNs and is associated with an intermediate prognosis with a mean survival of only 45 months [20].

Grade of Dysplasia

Patients after resection of any type of noninvasive IPMNs (only low-grade and high-grade dysplasia according to the recent Baltimore guidelines [7]) show an excellent overall and disease-specific 10-years survival of 95–100% for both MD- and BD-IPMN [17]. In invasive IPMN, poor prognosis is closely related to disease stage, positive resection margins, and N1 status [17, 21]. Early stages of IPMN-associated cancer including pT1 and pN0 show a much more favorable prognosis compared to sporadic PDAC. However, once advanced stages (pT2–pT4) and especially lymph node metastases are found, survival decreases significantly, and the prognosis is not superior to sporadic PDAC [21].

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCNs) are typically found in perimenopausal women with a median age of 48 years and are often located in the distal body or the tail of the pancreas (>90%) with a mean diameter of 6 cm at the time of diagnosis. MCNs show a uni- or multicystic pattern with a thick wall and can display solid components. The important differentiation to BD-IPMN is the lack of any communication to the pancreatic duct system. The typical and pathognomonic histopathological finding is an ovarian-like stroma in these lesions [22].

Similar to IPMNs, most MCNs are noninvasive but show a risk of an "adenoma-carcinoma" sequence over time. In larger series on resected MCNs, in 15–20% of all cases an invasive component is found [23]. Since patients with an invasive MCN are significantly older (median 3–10 years) than those with a noninvasive MCN, a time-dependent tumor progression is likely, comparable to that in IPMN [8]. Although the impact of the ectopic ovarian stroma in MCN remains unclear, a hormone- and growth factor-dependent induction with a consecutive progression from pancreatic epithelium to cystic lesions is discussed. This potential correlation is supported by the observation of a rapid growth of pancreatic MCNs in women during pregnancy. Features of potential malignancy in MCN are mural nodules on imaging, lesion size >6 cm, and calcification of the cyst wall [24]. Once an MCN is diagnosed, a surgical resection is indicated in most cases due to the young age of the patients and the present inability to differentiate securely between a benign and a malign lesion. The 5-year overall survival of patients presenting with invasive MCN is app. 60%, being worse for elderly patients and for patients with more advanced tumor stages [25].

Serous Cystic Neoplasms

Serous cystic neoplasms (SCNs) are mostly found in the pancreatic body and tail and lack a significant potential for malignant transformation. The incidence of SCNs is slightly higher in women than in men with a peak at the age of 60 years. In cross-sectional imaging and in resection specimen, SCNs have a micro- or macrocystic appearance with a typical finding of a central scar structure. Histopathologically,

they are composed of cysts lined by a single layer of glycogen-rich cuboid epithelial cells [26]. A preoperative distinction of SCN from MCN is possible in most cases due to significant differences in imaging. Besides sporadic SCNs, which represent the most common entity, there is an association with von Hippel-Lindau syndrome in some patients. In von Hippel-Lindau patients, SCNs are commonly multiple, whereas sporadic SCNs are mostly single lesions. Sporadic SCNs have a somatic mutation of the VHL gene in up to 50% with an inactivation of the VHL tumor suppressor protein [26–28] and often show a mutation in the TBC1D3 gene, also known as PRC17, but no mutations in the genes typically mutated in mucinous neoplasms, such as KRAS, RNF43, or TP53 [28, 29].

At the time of diagnosis, SCNs have a mean size of 4–6 cm and half of the patients are asymptomatic [26]. Depending on the localization and size of the lesion, symptoms including abdominal pain, discomfort, jaundice, or fatigue may occur. Malignant transformation of SCN leading to a serous cystic adenocarcinoma is very rare and has only been described in few case reports [30]. Thus, for asymptomatic patients with an SCN of <4 cm in diameter and without criteria for malignancy on preoperative imaging, only surveillance is indicated. The natural course of SCN is characterized by a gradual increase in diameter (0.6 cm/year in average). The growth rate seems to be size depending as small SCNs (<4 cm) show a significantly slower growth rate of 1–2 mm/year than larger lesions (>4 cm) in which annual growth rates of up to 2 cm can be found. Consequently, besides the size itself, growth rate during surveillance may have an influence on the decision for surgery to avoid local complications due to compression. Following resection, recurrence risk is extremely low and no structured follow-up is recommended [31].

Solid-Pseudopapillary Neoplasm (Frantz Tumor)

Initially described in 1959, solid-pseudopapillary neoplasms (SPNs, Frantz tumors) are rare cystic neoplasms and account for approximately 1–2% of all pancreatic tumors [32]. They are usually found in young women with a median age of 30 years and are most frequently located in the tail of the pancreas. SPNs show the potential of lymphatic spread, recurrence, and distant metastases and are therefore classified as malignant lesions [33]. Nearly all reported series on SPN include surgical patients who underwent resection, and nonsurgical management has been described only anecdotally. Consequently, the natural history of SPN in terms of growth dynamics and malignant progression remains unclear. Although long-term survival with locally limited tumor manifestation seems possible, also aggressive systemic spread with short survival times are found underlining the malignant potential of *SPNs*.

SPNs have a mean size of 8 cm by the time of diagnosis and are mainly (60%) located in the body and tail of the pancreas [33]. Their macroscopic appearance shows a combination of solid and cystic components, and nearly all tumors show characteristic mutations in exon 3 of the β-catenin gene [34]. A specific absence of other common mutations, such as KRAS, SMAD4, or TP53, distinguishes SPNs from other neoplasms of the pancreas [35].

The long-term prognosis of SPN after resection is excellent although app. 6% of the patients show locally advanced tumors with vascular involvement or lymph node metastases and 8% present with distant metastases [33]. A recent review including more than 2 200 resected patients shows that 96% of the patients are disease-free during long-term observation. The time to recurrence in the remaining 4% of the patients is more than 4 years, and the overall disease-specific mortality is 1.5% [33]. Despite this general favorable prognosis, SPN are basically malignant tumors and complete surgical resection is indicated as well as a lifelong follow-up (i.e., annually) [32].

Diagnostic Modalities

In general, pancreatic cysts are classified as either nonneoplastic or neoplastic. Nonneoplastic cysts include pseudocysts, retention cysts, and benign epithelial or lymphoepithelial cysts and are not associated with any tendency for progression to malignancy, whereas in neoplastic cysts, the differentiation between serous and mucinous lesions is essential to evaluate the risk of malignant transformation. Mucinous cysts are more common and harbor a certain risk of malignancy, depending on various criteria which include type of lesion and size as well as other features specified in detail for every entity above.

Diagnostic Modalities 1: The Radiological View

Contrast-enhanced CT scan and MRI are the preferable cross-sectional imaging modalities for the clarification of cystic neoplasms of the pancreas. As MRI offers a very good visualization of fluid and soft tissues, this modality is superior in showing septation, debris, and nodules and often allows a more specific diagnosis than CT. For demonstrating a communication of the cyst with the pancreatic ductal system, magnetic resonance cholangiopancreaticography (MRCP) is the imaging tool of choice. In cases of difficulties in detecting the communication, secretin given during the MRCP may be helpful [6].

Beyond visualization of the pancreatic duct system, this specific advantage of MRI, CT, and MRI is equally effective. Moreover, CT is superior in detection of calcification of pancreatic cysts compared to MRI [36] and offers the advantages of lower costs and broad availability. However, it has to be considered that radiation exposure associated with repeated CT examinations limits its suitability for long-term surveillance of cystic lesions. Therefore, when frequent imaging is required, this exposure can be avoided by using MRI with MRCP.

The first step in the radiological differentiation of a pancreas cyst in MRI is to estimate its communication with the main pancreatic duct, which is the precondition for distinguishing an IPMN from other cystic lesions. Only pseudocysts are to consider as a differential diagnosis, communicating also sometimes with the pancreatic ductal system [37].

Secondly, the radiologist has to proof the morphology of the pancreatic cysts [6]:

- *Unilocular cysts* show no septs or solid portions; this feature is mostly seen in pseudocysts and rarely in SCN, MCN, and IPMN.
- *Microcystic lesions* show single small cysts <2 cm and are mostly found in SCN or BD-IPMN.
- *Macrocystic lesions* consist of less but bigger compartments (>2 cm) than microcystic lesions. Normally, they can be demonstrated in MCN or IPMN and rarely in neuroendocrine tumors or lymphangioma.
- Cysts with *solid contents* are often found in SPN, but also in MCN and IPMN or degenerative altered cysts. Solid contents are generally suspicious of a malignant potential.
- *Calcifications* located in the middle of a cyst are suggestive of SCN, while calcifications built like peripheral eggshells are specific for MCN.

The third aspect in radiologic diagnostic is to consider the cyst's localization within the pancreas combined with certain clinical characteristics including age, sex, history of pancreatitis, and elevation of laboratory blood values, which should be taken into account. SCNs are often found in elderly women ("grandmother tumor"). Macrocystic lesions in the corpus or tail of the pancreas in fertile women often turn out to be MCN ("mother tumor"), while macrocystic lesions in the pancreatic head of an elder man are highly suspicious to be an IPMN. In contrast, SPNs are typical for young women ("daughter tumor") [33]. For unilocular cysts, first of all an underlying pancreatitis should be excluded via history and blood analysis [6].

MD-IPMNs are mainly not presenting "classical" cystic features from the radiological point of view but are diagnosed by imaging as a dilation of the MPD ≥5 mm, either segmental or diffuse, without identifiable reason for an external pancreatic duct obstruction and without signs of pancreatic branch-duct dilation. If combined with one or more dilated branch ducts (≥10 mm), they fulfill the criteria of a mixed-type IPMN.

For the differentiation between benign and potentially malignant IPMN and therefore the management decision (resection vs. surveillance), specific radiologic criteria have to be considered, which were initially defined in the IAP consensus guidelines in 2006 [8] and have been updated in the following Fukuoka meeting in 2012 [9] (Table 1). Figure 1 gives an overview of the diagnostic radiological modalities.

Diagnostic Modalities 2: The Endoscopic View

Endoscopic ultrasound (EUS) is a well-established examination modality, which allows a transluminal high-resolution diagnostic examination of the pancreatic parenchyma and the ductal system. Evaluation of a pancreatic mass or pancreatic cyst is the most common indication for EUS of the upper gastrointestinal tract [38]. As the differential diagnosis of cystic lesions which are asymptomatic often requires

Table 1 Radiologic criteria for clinical decision-making on how to manage BD-IPMN and estimation of their malignant potential [9]

Worrisome features	High-risk stigmata
Non-enhancing mural nodes	Enhancing solid components
Main-duct diameter 5–9 mm	Main-duct diameter ≥10 mm
Abrupt change in main-duct caliber with distal parenchyma atrophy	
Thickened/enhancing cyst wall	
Cyst size ≥3 cm	

additional diagnostic tools after an initial cross-sectional imaging (CT scan or MRI), EUS offers a cost-effective approach to decide whether surgery is warranted or radiologic and clinical surveillance can be recommended [39].

EUS is particularly valuable in evaluating diagnostic features and potential risk factors for malignancy as it has been shown to have a high sensitivity and specificity for these questions, including size and number of cysts, thick vs. thin cyst wall, nodules, septa, solid contents, diameter of the main pancreatic duct, and its communication with the cyst as far as the presence of lymph nodes [40]. In general, EUS is not superior but comparable to MRI for identifying main-duct involvement and the communication with the cyst and for detecting mural nodes missed in CT/MRI. Furthermore, EUS offers the possibility of fine needle aspiration (FNA) and characterization of a pancreatic cystic lesion by obtaining cyst fluid analysis, which may be helpful for clinical decision-making. The fluid can be evaluated for tumor markers, as well as cytopathologic, biochemical, and molecular analysis. For the tumor marker **CEA**, the initial study by Brugge et al. could demonstrate that an optimal cutoff value of 192 mg/mL is associated with a diagnostic accuracy of 79% for detection of mucinous cysts and the differentiation from serous – and consequently harmless – cysts [41]. Recent analyses studying the value of CEA in cyst fluid calculated a positive predictive value of 96% for CEA levels greater than 400 ng/ml and a negative predictive value of 98% for CEA levels below 5 ng/ml [42]. To note, the level of CEA in cyst fluid does not correlate with malignancy but may only be used for the characterization of a mucinous nature of the cystic lesion [43]. In contrast, carbohydrate antigen (CA) 19-9 does not have any significant predictive value in the diagnosis of a mucinous lesion [44].

Fluid cytology can detect malignant cells, MUC-containing cells (IPMN and MCN mentioned above), glycogen-rich cuboidal cells (SCN), branching papillae with myxoid stroma (SPN), and abundant anucleate squamous cells and debris (lymphoepithelial cysts) [38]. The accuracy for the detection of mucinous cysts resp. malignancy is shown to be 58% resp. 75%.The analysis of cyst fluid **DNA** is often performed for detection of KRAS mutation, which is highly specific for a mucinous cyst (96%) [44].

In general, the use of fluid cytology is not regarded as a standard to date, regardless if the cystic lesion shows worrisome imaging features or not [45]. According to several reports, the sensitivity in determining malignancy in pancreatic cysts using EUS-FNA is 50% or even less [42]. The abovementioned limitations in the currently available analysis of cyst fluid underline the need for improved diagnostic tools. Recent studies could demonstrate the potential impact of **novel molecular markers**, including VEGF, GNAS, mi-RNA, mucic stain, or inflammatory mediator proteins [46, 47]. Consequently, the value of analysis of cyst fluids retrieved by FNA is currently still in a preclinical stage for the safe determination of pre-malignancy or malignancy but a specific field of ongoing intense research [40].

A further aspect is the option of an EUS-guided therapy with **cyst ablation**, which may provide a minimally invasive alternative to surgery in patients not suitable for an operation. First results on small patient collectives show complete cyst resolution in <40% of patients using ethanol installation, also in long-term follow-up, and cyst resolution with minimal residuum of the cyst in app. 60–80% in patients after injection of paclitaxel [40]. However, this procedure should not be considered as an alternative to surgery as it is still unclear concerning the effects on the natural history of cysts and the long-term outcomes. It should therefore only be performed after critical evaluation in individual cases when patients are not suitable candidates for a surgical approach.

Moreover, to date not every center can provide EUS facilities which limit its widespread use. Another potential shortcoming of EUS is the lack of reproducibility and the high dependency of quality and results on the expertise of the examining physician. Considering these aspects, EUS – with or without FNA – is not suitable as an exclusive but as an additional diagnostic tool as it may improve the diagnostic accuracy of cross-sectional imaging for pancreatic cystic lesions. Also ERCP is not utilized as a routine examination tool for the differentiation of pancreatic cystic lesions [43, 48]. In some cases, mucous secretion into the duodenum, highly suspicious for MD-IPMN, can be seen by ERCP or esophagogastroscopy [43].

Diagnostic Modalities 3: The Pathologic View, Including Genetic Aspects

The first step to differentiate pancreatic cysts after their resection is the distinction in neoplastic and nonneoplastic (congenital, lymphoepithelial, enterogene, endometrial, lymphangioma, hemangioma, sarcoma) as far as epithelial and non-epithelial (pseudocysts and parasitic cysts). All pancreatic cysts mentioned in this chapter are neoplastic and of epithelial origin [49]. The epithelial cells differ in appearance (i.e., columnar in IPMN and MCN, cuboidal in SCN) and express different glycoproteins (several types of the so-called MUC). They produce an either serous or mucinous cyst fluid, the latter associated with a higher risk for malignancy. Further immunohistopathologic parameters possibly expressed by the different cyst epithelia include CEA, α-inhibin, neurospecific enolase (NSE), caudal homeobox protein (CDX)-2,

Table 2 Histomorphological and genetic patterns of different pancreatic cysts (Adopted from [49])

Pancreatic cyst	Histopathology	Immunoprofile	Genetics	Differential diagnosis
IPMN	Mucin-producing epithelium with typical cystic dilation of the pancreatic ducts	MUC expression:	Mutations of KRAS, GNAS (intestine IPMN), RNF 43	MCN
		Gastric type: MUC5		
		Intestine type: MUC 2 + 5, CDX2		
		Pancreatic type: MUC 1 + 5		
		Oncocytic type: MUC 1, 2, 5, 6		
MCN	Mucin-producing epithelium, "ovarian" stroma	*Epithelium*: CEA + MUC5 + *Stroma:* progesterone and estrogen receptor+, a-inhibine+		IPMN
SCN	Multicystic low epithelium	*Serous epithelium*: MUC1+, MUC6+ α-inhibine +		NCC metastasis, BD-IPMN
SPN	Eosinophil epithelium, hyaline stroma	Vimentin + CD10+ progesterone receptor + β-catenin nuclear +	Mutation CTNNB1-gene (exon 3)	NET, acinar cell carcinoma

vimentin, CD10, and β-catenin. In addition, the cyst stroma appearance between the cells of the pancreatic cysts widely differs, i.e., ovarian-like in MCN and hyaline in SPN. Considering genetic aspects, KRAS, GNAS, and RNF43 mutations are common pathological findings (Table 2).

IPMN in the general pathologic view is defined as *a grossly visible*, *predominantly papillary*, *or – more rarely – flat*, *noninvasive mucin-producing epithelial neoplasm arising in the main pancreatic duct or branch ducts*. Macroscopically – as ideally in the radiological imagings already described – they are found intraductal either affecting the main pancreatic duct or the branch ducts. For further differentiation of IPMN, four microscopic **subtypes** are of interest: the *gastric type* is found in BD-IPMN [20], while the largest proportion (36%) of MD-IPMNs shows an *intestinal type* (36%). A *pancreatobiliary* resp. *oncocytic* subtype accounts for 7–8% of all IPMN each [19]. The term **incipient IPMN** describes branch-duct lesions between 0.5 and 1.0 cm in diameter with intestinal or oncocytic differentiation or with a GNAS mutations, which typically occur in intestinal and gastric IPMN subtypes [7]. Furthermore, the **grade of dysplasia** is an important topic in the pathologic examination with respect to therapy and prognosis. It represents the epithelial changes on the way to malignancy of IPMN and MCN, which are well-characterized in terms of an adenoma-carcinoma sequence and are reflected by an increasing number of genetic alterations. Concerning recent guidelines for both IPMN and MCN, low-grade dysplasia has to be differentiated from high-grade

dysplasia and invasive cancer [7]. In some centers, still the former classification including borderline between low- and high-grade dysplasia is used.

Accuracy of Preoperative Diagnostics According to the Definitive Histopathologic Result

The management of pancreatic cysts fundamentally depends on knowing the cyst type and the risk or presence of malignancy. This underlines the importance of a correct diagnosis at the time of detection. Salvia et al. could show an accuracy of 78% for preoperative diagnosis of any cystic pancreatic lesion in 476 resected patients when they matched preoperative and final pathologic diagnosis in a retrospective approach [50]. The best results were achieved for SPN (95%) and for IPMN with main-duct involvement (81%). EUS showed no additional diagnostic benefit. In another series including 334 patients, IPMN with main-duct involvement was correctly diagnosed in the preoperative cross-sectional imaging in 71% [52]. Jang et al. compared the results of preoperative CT, MRI, and EUS findings in 318 Korean patients with the final pathology after resection of pancreatic cysts [53]. The sensitivity to predict the type of pancreatic cysts was 83% vs. 94% and 89% for CT alone vs. CT and additional MRI or EUS, and the specificity was 70% vs. 59% and 53%, respectively. The diagnostic accuracy of a combination of CT and MRI (81%) was superior to CT alone (61%) and EUS (70%). In distinguishing mucinous from non-mucinous cysts in a multicenter trial of 341 patients, EUS accuracy was only 51% [41], while other authors describe an accuracy up to 73% [50–54]. **In conclusion**, MRI is the tool of choice for the differentiation and diagnosis of cystic pancreatic lesions, preferable to CT, and potentially supplemented by EUS with or without FNA.

Management of Pancreatic Cystic Lesions

As described for each cystic entity above, the malignant potential is essential for the further clinical decision with regard to surveillance or an upfront operation as well as for surveillance and follow-up intervals and duration, respectively. Furthermore, the malignant potential needs to be considered with regard to the extent of resection if an operation is indicated. Other important aspects in the decision-making process concerning an operation are age and comorbidity of the patient, and no prophylactic resection is indicated in patients with a higher risk of perioperative life-threating complications than for experiencing the malignant transformation of their pancreatic cyst to PDAC. Consequently, although general indications for surgery in specific cystic lesions exist, individual decisions are possible, which is reflected in all current guidelines as recommendations always refer to “patients who qualify for surgery” or “patients fit for surgery” [31, 55].

Option 1: Operation

Indications for Surgery

Surgery is indicated in SCN only if patients are symptomatic, the lesion exceeds 4 cm in diameter, or there is a clear progression with an annual growth of >6 mm [30].

In contrast, MCN resection is basically indicated by the time of diagnosis, independently of symptoms or size [9, 31]. Although a current publication including a large collective of 349 MCN patients challenges this general recommendation [56, 57], international guidelines are not adopted yet, and the indication for resection seems to be unquestionable to date [57].

A similar general recommendation for resection is given for all MD- and mixed-type IPMNs with a main pancreatic duct diameter of ≥10 mm [9, 31]. A recent study, showing that MD- and mixed-type IPMNs with a duct diameter below 10 mm bear a significant risk of malignancy as well [58], raises the question if the threshold for resection should potentially be lowered in updated guidelines. However, this remains a point of controversy to date.

The most controversial current aspect is the indication for and the timing of resection in BD-IPMN. Based on the 2012 consensus guidelines [9], the so-called "Sendai" criteria have been established to describe the risk of malignancy in these lesions. The guidelines recommend the resection of branch-duct IPMN of more than 3 cm in diameter in general. Smaller branch-duct IPMN should only be resected in the presence of "high-risk" stigmata including mural nodules, positive cytology, symptoms, or a synchronously dilated main duct. However, there is growing evidence that these guidelines are not sufficient enough in order to recognize all premalignant lesions in time. In different larger surgical series examining resected IPMN, the incidence of malignant branch-duct IPMN (including in situ and invasive carcinoma) was approximately 25% among all IPMN below 3 cm without any reliable cutoff in diameter [10, 59, 60] (Table 3). Although these are certainly selected collectives of patients, the findings of malignant potential in a relevant proportion of the patients underline that a clear stratification and decision for conservative or surgical treatment is very difficult up to the present. Neither the existence of mural nodules as a guideline predictor of malignancy nor the existence of clinical symptoms did correlate with malignancy. These findings underline that size alone and currently established markers of potential malignancy are not reliable predictors and that even small branch-duct IPMNs have a relevant risk of malignancy. Individual decisions for resection based on an evaluation of all morphological and clinical factors (including imaging, tumor markers, symptoms, progression, and prior patient history) seem to offer the best approach at the moment.

Finally, for all SPN, there is an agreement that a surgical resection is indicated by the time of diagnosis, regardless of any additional symptoms or associated findings [31].

Table 3 Reported rates of malignancy in various series of small branch-duct IPMN in retrospective surgical collectives

Study	n	Malignancy rate (high-grade dysplasia or invasive cancer)			
		<1 cm	1–2 cm	2–3 cm	Total <3 cm

Types of Surgical Resection

Formal Resections

Standard procedures for surgery of cystic lesions include partial, distal, and total pancreatectomy [61]. These operations can be performed for any type of cystic entity (SCN, MCN, IPMN, SPN), depending on the localization and size of the lesion. For findings limited to the pancreatic head, pylorus-preserving pancreatoduodenectomy is the routine approach. A classical pancreatoduodenectomy with stomach resection is rarely required and should be restricted to situations where the lesion extends toward the pylorus and gastric antrum. Preservation of the pylorus offers the advantage of physiological food passage and is therefore regarded as superior regarding weight loss and quality of life in the long-term outcome, which may be especially important for patients resected for benign pancreatic lesions with a good prognosis. In case of suspected MD-IPMN, after completion of the resection, it is mandatory to perform an examination of the pancreatic resection margin by intraoperative frozen section. The surgical strategy has to be adjusted afterwards. In case of IPMN-free cut margins, no further resection is required. In contrast, when IPMN manifestations are found at the site of transection, this implies that completion pancreatectomy should be considered, depending on various factors. These include the grade of dysplasia at the transection site, the localization on IPMN spread in the parenchyma or in the main pancreatic duct, the age of the patient, and the finding in the resected pancreatic head. In case of IPMN-associated invasive cancer in the resected specimen, an individual decision has to be made as the prognosis is determined by this invasive component and is not dependent on the remaining IPMN tissue which implies that the pancreatic remnant may be preserved. An oncological lymphadenectomy should always accompany formal resections of main-duct IPMN and SPN according to their malignant potential. This comprises the lymph nodes of the hepatoduodenal ligament as well as the lymph nodes along the right side of the celiac axis and the superior mesenteric artery. The reconstruction includes pancreaticojejunostomy or pancreaticogastrostomy, hepaticojejunostomy, and duodeno- or gastrojejunostomy.

If the cyst is located in the pancreatic body or tail, distal pancreatectomy is the standard resection [61, 62]. For MD-IPMN and SPN, this operation is again performed following oncological principles, including lymphadenectomy along the left side of the celiac axis, the superior mesenteric artery, and the hepatoduodenal ligament as well as splenectomy. In case of benign IPMN or MCN, spleen preservation is possible, either with or without preservation of the splenic vessels.

Division of the pancreas above the portal vein/superior mesenteric vein axis can be done by stapling devices or scalpel followed by suture closure of the remnant. Coverage of the resection margin by patches (e.g., jejunum/teres hepatis ligament, artificial patches) or a pancreaticojejunostomy to avoid postoperative pancreatic fistula is optional. Especially coverage by a teres ligament flap has the potential to reduce associated clinical complications [63]; however, none of the mentioned methods has yet been proven to actually decrease the overall POPF incidence, which ranges between 30% and 50%.

Total pancreatectomy is required for diffuse main-duct IPMN or – rarely – for extended manifestations of multifocal BD-IPMNs. It is performed either as a primary en bloc resection if the IPMN extension is preoperatively assessed throughout the entire gland or as a sequential procedure in situations where intraoperative frozen sections show IPMN progression after partial pancreatectomy, as described above. A splenectomy and lymphadenectomy combining the lymph node regions of partial pancreaticoduodenectomy and distal pancreatectomy are required, as total pancreatectomy should also be carried out oncologically.

Parenchyma-Sparing Resections

Parenchyma-sparing resections comprise enucleation and central pancreatectomy. Enucleation is a suitable approach for small (<3 cm) cystic lesions that are located in a subcapsular position and show an adequate (3 mm) distance to the main pancreatic duct. This distance is essential as it has been shown that "deep" enucleation for lesions with a distance of less than 3 mm to the pancreatic duct is associated with a significantly higher risk for POPF and should be evaluated carefully against the possibility of a formal resection [64]. Predominantly, enucleation is feasible for SCN and BD-IPMN. It can be performed if the benign character of the excised lesion is confirmed by intraoperative frozen section and when the location and morphology of the cystic lesion are suitable for this procedure. In order to evaluate this adequately, an accurate localization of the cystic lesion is essential. Besides preoperative imaging, the most important tool for tumor location is the experience of the surgeon performing the exploration [65, 66]. Mobilization of the pancreas and a careful digital examination of the suspected lesion are supplemented by intraoperative ultrasound examination if necessary. By means of intraoperative ultrasound, not only an identification of the cystic lesion is feasible but moreover the relation and distance to the pancreatic duct can only be clarified [65]. During enucleation itself, careful attention needs to be paid to the connection of the cyst to the pancreatic duct.

This should be identified and closed by clip or suture ligation to avoid high-volume enzyme leakage. A tumor size of 3 cm in diameter can be regarded as the limit for a safely performed enucleation. Tumors measuring more than 3 cm in size show malignant histological changes significantly more often, making a local surgical approach impossible. Besides, tissue trauma and wound surface following an enucleation reach a critical size for the development of fistulas or other complications, including bleeding or postoperative pancreatitis. The resected cyst should always be examined by intraoperative frozen section to confirm its benign nature. In the case of unexpected malignancy, a more extended oncological resection must be chosen. Drain placement at the end of the operation is recommended as fistula rates of approximately 30% are currently reported; however, most of them are clinically irrelevant [65, 66].

The second limited and parenchyma-sparing resection approach for localized and benign pancreatic cysts located in the body of the pancreas is central pancreatectomy. A segment between the level of the superior mesenteric vein/portal vein axis and the remaining tail of the gland can be resected under preservation of all healthy tissue [67, 68]. Pancreatic transection toward the pancreatic head is performed similar to distal pancreatectomy, mostly by stapler or by scalpel with a consequent suture closure. Toward the pancreatic tail, the transection is performed in a way, comparable to partial pancreaticoduodenectomy, mostly by sharply to avoid tissue damage on the cut margin. After removing the cyst-bearing segment, the distal stump of the pancreas is further mobilized from the splenic vessels over a 2 cm distance to allow a safe anastomosis. Reconstruction is accomplished with a retrocolic Roux-en-Y loop of the jejunum. Alternatively, a pancreaticogastrostomy is possible. The already closed pancreatic head remnant can finally be covered with the same jejunal loop by sutures between the seromuscular layer of the jejunum and the capsule of the pancreas. Another possibility to reduce clinically relevant POPF-associated complications is the use of a ligamentum teres flap for covering of the stump, which has been shown to be beneficial in distal pancreatectomy and can be used in central pancreatectomy as well [63].

Reconstruction is completed by an infracolic Roux-en-Y enteroenterostomy in case of pancreaticojejunostomy as the method of reconstruction [68]. To date, fistula rates of approximately 40% are reported for central pancreatectomy. Comparable to enucleation, most of these fistulas are uncomplicated, do not lead to consecutive complications, and can be treated conservatively [67, 68].

Parenchyma-sparing resections have been described for MCN and SPN in the past in several series. As MCN is comparable to BD-IPMN in terms of malignancy risk, these procedures are a suitable possibility for this entity, presumed that the benign character of the lesion is confirmed intraoperatively. In contrast, for SPN, non-oncological resections have to be evaluated critically, as the nature of the lesion cannot be predicted in most cases, and the impact of lymph node dissection remains unclear. Due to the small reported patient numbers, valid data on this topic are not available to date.

Laparoscopic Surgery

Laparoscopic pancreatic surgery has become increasingly important during the last decade. Cystic lesions are findings that specifically qualify for this approach, as the procedure is technically not burdened by peripancreatic tissue alterations which are commonly found in chronic pancreatitis or pancreatic cancer, but are not present in cystic lesions. Laparoscopic distal pancreatectomy is the most commonly performed procedure for cystic neoplasms today. Although no randomized controlled trials have shown superiority of laparoscopic distal pancreatectomy compared to the open approach, the minimally invasive procedure is regarded as a standard of care in most centers, especially for benign indications. The extent of resection in the laparoscopic setting is similar to the open procedure with regard to lymphadenectomy and splenectomy vs. splenic preservation depending on the dignity of the removed cystic lesion.

Besides distal pancreatectomy, enucleation and central pancreatectomy are infrequently performed laparoscopically; the available literature demonstrates the technical feasibility and perioperative safety of both – laparoscopic enucleation and central pancreatectomy – but is dominated by case series data and most commonly limited to 5–30 patients [69–71].

Option 2: Surveillance

In general, all pancreatic cysts should be discussed in multidisciplinary boards in specialized centers for pancreatic diseases. Currently, it could be shown in a large survey in the Netherlands that despite of varying guidelines, the risk of malignancy is underestimated by a significant proportion of physicians, and a majority suggests abdominal ultrasound as an adequate surveillance tool in cysts of 10 mm [72]. These results may reflect a substantial lack of awareness for the malignant potential of IPMN, MCN, and SPN. Especially in the United States, the recent guidelines of the AGA [55] have induced an important and controversial discussion about the surveillance management, as the recommendations do not match those of other international guidelines [31, 73], and the statements of a reduced or even no surveillance for asymptomatic small cyst under consideration of the health care costs are not in accordance with long-term results of various studies showing an ongoing and potentially increasing risk of malignancy, even beyond a 5-year period.

As pointed out above, only asymptomatic SCN <4 cm and some BD-IPMNs show no indication for an upfront operation. For these entities, structured lifelong surveillance is recommended in 6 monthly up to annual intervals, depending on the nature and course of the cysts. As the time from the first diagnosis of an MD-IPMN to development of an invasive IPMN can be estimated at 5–6 years [11, 12], for BD-IPMN, no data exist, but progression in 18% of BD-IPMN patients during a median follow-up time of 26 months and 44 months was observed [14, 15], indicating the

high likelihood in an unknown part of BD-IPMNs for a slow development of malignancy with unknown point of no return. Thus, especially for middle-aged patients, even shorter surveillance intervals (6 monthly) are discussed initially after 5 years, during those one observation visit per year could be sufficient. In case of SCN, besides the size itself, the growth rate triggers the decision for surgery to avoid complications caused by local compression.

Every surveillance visit should cover MRI/MRCP, alternatively EUS in experienced hands, a physical examination, and a blood analysis, containing routine parameters and HbA1c, CEA, and CA 19-9. Moreover, the individual history of pain or even pancreatitis must be considered. In any case of deterioration – if new pancreas-related symptoms, new-onset diabetes, weight loss, increase of the tumor markers without any other cause, increasing of cyst size, or other changes in imaging as radiologic criteria of possible malignancy (newly detected worrisome features or high-risk stigmata according to [8]) are observed – an operation has to be evaluated.

For patients who are not fit for surgery at the time of diagnosis of a pancreatic cystic neoplasm without signs of malignancy but an indication for resection, a surveillance strategy should be chosen, which is adapted to the specific physical and psychosocial condition of each individual patient. In case of a progress of the lesion and if a suspicion of malignancy occurs, a biopsy and histopathological workup are required. In case of a confirmation of invasive cancer, chemotherapy with or without radiation should be discussed depending on the physical performance status of the patient.

Postoperative Follow-Up

As all types of IPMN as far as MCN and SPN must be considered as a chronic and lifelong disease – unless a total pancreatectomy has been performed – the natural course of these entities requires regular postoperative follow-up regarding to international guidelines [9, 31, 55]. Lately, published follow-up data from surgical IPMN patients showed that 17% of 381 patients after resection of invasive and noninvasive IPMN had a recurrence of the IPMN after a median of 17 months [74]. Within this study, 33 patients had only partial resection of the multifocal disease with mixed-type as well as BD-IPMN. The residual BD-IPMNs with a median size of 10 mm at the date of resection grew within a follow-up of median 5 years to a median size of 13 mm. In another cohort of 130 patients who had undergone partial pancreatic resections for noninvasive IPMNs, He et al. showed that 17% of the patients developed lesions suspicious for new or progressive IPMN within a median time of 46 months [73]. Within this disease progression cohort, some patients developed high-grade dysplasia and invasive cancer. Another 12% of the cohort showed neither new IPMN nor progression in known residual IPMNs. Although within the literature the recurrence rates vary between 8% and 57% [11, 44, 73], even patients with noninvasive IPMN might have an estimated average recurrence rate of 25% of remote IPMN and 7% for developing pancreatic cancer within 5 years after resection. For MCN, the risk for recurrence seems to be lower than for IPMN as

noninvasive MCNs show no recurrences after complete resection and do not require a structured postoperative surveillance [9, 31]. In contrast, follow-up after resection of invasive MCN should be performed similar to PDAC [31].

After resection of SPN, a recurrence rate of 4 up to 11% is described with a mean time to recurrence of 1 to >4 years [30, 72, 73]; therefore, a long-term follow-up 1–2×/year is recommended [31, 73].

Comparable to the recommendations for surveillance of cystic lesions without primary operation indication shown in Table 4, postoperative follow-up visits for noninvasive pancreatic cysts should also include MRI (alternatively by endosonographic ultrasound in experienced hands), physical examination, and blood analysis. Also the loss of function after pancreas resection is considered in this postoperative setting. In addition for IPMN patients, regular endoscopic controls focused on colorectal adenomas and Barrett dysplasia of the esophagus are recommended as both pathologies are increasingly observed in IPMN patients [20, 21]. The recommended intervals per cyst entity are shown in Table 4.

In conclusion, recent results underline the necessity of a structured and long-term follow-up after resection of every pancreatic cyst, except for SCN. In the case of confirmed recurrence, surgical re-resection should be attempted according to the recommendations given above. Depending on the extent of the prior resection, this implies the performance of a remnant pancreatectomy in a considerable number of patients.

Table 4 Proposal of a management algorithm for cystic pancreatic lesions and postoperative follow-up: time intervals and imaging modalities [9, 31, 74, 77]

		Proceeding (time interval in months)		Postop. follow-up (time interval in months)
Diagnosis		Surveillance (MRI/EUS)	Resection	MRI (CT)
Serous cystic neoplasm (SCN)	<4 cm, asymptomatic	6, 18, 30, . . .annually		
	Symptomatic or >4 cm		x	None
Mucinous cystic neoplasm (MCN)			x	None
Dilated branch ducts		12, 24, 36, . . .annually		
BD-IPMN	Without worrisome features*	12, 24, 36, . . .annually		
	With worrisome features*		x	MRI: 6, 18, 30, . . .annually
MD-IPMN			x	MRI: 6, 12, 18, 24, . . .6 monthly
Mixed-type IPMN			x	MRI: 6, 12, 18, 24, . . .6 monthly

*see table 1

Conclusion

Pancreatic cysts are common entities and are increasingly found due to improved imaging modalities. As they bear a certain risk of malignancy, the indication for surgery has to be evaluated by the time of diagnosis; however, not all cystic lesions require a surgical intervention. While there are clear recommendations with regard to the management of SCN, MCN, and SPN, clinical decision-making in IPMN remains controversial. The current knowledge on the risk of malignancy in IPMN is mostly based on retrospective surgical series although recently an increasing number of publications deal with the natural course of IPMNs under a watch-and-wait strategy. Main-duct and mixed-type IPMNs are clear surgical diseases that require an oncological resection, while guideline recommendations for BD-IPMN are currently being discussed – especially with the regard to a defined size cutoff and other features of pre-malignancy. Therefore, individual decision-making is possible, and besides imaging features and potential symptoms, all other patient-related factors including age and comorbidities have to be weighed. In all types of IPMN, a lifelong surveillance or postoperative follow-up of the pancreatic remnant, respectively, is essential.

Laparoscopic Surgery for Pancreatic Neoplasms

Santiago Sánchez Cabús and Laureano Fernández-Cruz

Contents

Abstract

After 20 years since its introduction, the laparoscopic approach has shown to be safe and reproducible in the surgical treatment of lesions in the pancreas, with the added benefits of reduced intraoperative blood loss and a shorter hospital stay. These benefits have been equally reproduced with surgical treatment of patients with pancreatic neoplasms. In the case of localized lesions in the body or tail of the pancreas, laparoscopic surgical treatment has proved equally effective as conventional open surgery in the short term, obtaining equivalent results from the oncological point of view. As for the laparoscopic surgical treatment of pancreatic head injuries, there is still a lack of available scientific evidence, but reported data show similar results to conventional surgery. Anyway, more studies

Introduction

The first laparoscopic pancreatic resections were performed in 1994, when Gagner et al. [1] reported a total laparoscopic pancreaticoduodenectomy (LPD), and Cushieri et al. [2] published the first cases of laparoscopic distal pancreatectomy (LDP). Since then the interest on this type of resections grew exponentially, mainly for benign lesions due to uncertainty regarding oncologic outcomes. With the development and refinement of laparoscopic pancreatic surgery, parenchyma-sparing techniques such laparoscopic enucleation and central pancreatectomy extended the indications for the treatment of benign or borderline malignant pancreatic lesions.

In this chapter the current laparoscopic surgical techniques for the treatment of benign and malignant tumors of the pancreas will be discussed.

Laparoscopic Surgery for Exocrine Pancreatic Tumors

Twenty years after the introduction of laparoscopic surgery for exocrine pancreatic tumors, LDP has become a reality and is regarded by many as the standard of care for the treatment of left-sided pancreatic lesions. A recent meta-analysis from Mehrabi et al. [3] demonstrated the superiority of LDP over open distal pancreatectomy (ODP) in terms of blood loss, earlier oral intake, and length of hospital stay, without significant differences in terms of pancreatic fistula (PF) (21.8% vs. 21.6%) postoperative morbidity (34% vs. 38%), and mortality (0.4% vs. 1.1%). However, there is still a lack of randomized controlled trials between LDP and ODP, and it is very likely that such a trial will never be conducted.

Another important issue is the preservation of the spleen in LDP. The spleen does play an important immunological role; however preservation of the spleen at the time of LDP is controversial. Splenectomy has been reportedly associated with an increased postoperative morbidity, hematologic complications, and impaired primary immune response, as well as long-term increased risk for the development of certain malignancies [4, 5]. Therefore, spleen should be preserved whenever possible. Spleen-preserving DP (SPDP) is considered nowadays the procedure of choice for patients with benign or borderline malignant tumors of the pancreatic body and tail, as the majority of pancreatic neuroendocrine tumors (pNETs), although some authors have pointed out that it might be associated with an increased morbidity [6].

This procedure can be performed with or without splenic vessels preservation; the latter technique was described by Warshaw [7] where the splenic vascularization is fully dependent on the short gastric vessels. Adam et al. [8] published the combined experience of SPDP from Bordeaux and Barcelona comparing SPDP with and without splenic vessel preservation, and they observed equivalent results in operative time, blood loss, and conversion rate, but in the Warshaw technique (WT), they found a significant increase of splenic complications and a lower spleen preserving rate. Beane et al. [4] also found a significant advantage in clinically relevant PF, splenic infarction, overall morbidity, need for postoperative drainage placement, and shorter hospital stay in SPDP with vessel preservation. In addition, Fernandez-Cruz et al. [6] assumed that splenomegaly is a contraindication for VL-SPLDP due to insufficient nourishment of an increased mass by the short gastric vessels. On the other hand, SPDP seems to be associated with an increased risk for developing splenic vein thrombosis and subsequent left-sided portal hypertension, although the risk of variceal bleeding is unclear [9, 10].

Recently Sánchez Cabús et al. [11] published results after 115 consecutive LDP. SPDP was performed in 55.7% of the patients, with major postoperative complications in 25% of the patients and a clinically relevant PF rate of 11.3%, with a median postoperative hospital stay of 11 days. An additional analysis of that series of patients revealed that spleen preservation was associated with less major postoperative complications, independently of the surgical technique used, and authors identified splenectomy as an independent risk factor of postoperative major complications ($p = 0.019$, HR (95% CI): 4.617 (1.292–16.497)) [12]. Goh et al. [13] recently have published a comparative study of LPD (31 patients) versus robotic distal pancreatectomy (RDP, eight patients), finding equivalent outcomes but with an added advantage of RDP over LDP in terms of spleen preservation (3 (37.5%) vs. 25 (80.6%), $P = 0.016$) and splenic vessel preservation (5 (62.5%) vs. 4 (12.9%), $P = 0.003$), although associated with a longer median operation time (452.5 (range, 300–685) vs. 245 min (range, 85–430), $P = 0.001$).

The technical complexity of an LDP has been evaluated in terms of the learning curve, which is believed to be around ten cases, according to Braga et al. [14] and Ricci et al.'s [15] reports, although there are other factors that may influence this learning curve, such as the previous experience of the surgeons in both laparoscopy and pancreatic surgery. The issue of the closure of the pancreatic stump in LDP has been a matter of controversy. Pancreatic transection and stapler closure of the pancreas are widely adopted as the method of choice in LDP. Braga et al. [16] compared 100 LDP with 100 ODP, with a PF rate between the groups similar: 53% in the LDP group versus 51% in the ODP group, with 70% of PF in both groups being grade A, with stapler being used over 85% of the patients.

Whether these results might be applicable to patients with pancreatic ductal adenocarcinoma (PDAC) is a matter of controversy. In 2003, Strasberg described the radical antegrade modular pancreatosplenectomy (RAMPS), a new surgical technique for treating left-sided pancreatic cancer, which later has been adopted by the majority of groups and considered to be the gold standard procedure [17]. It aims to achieve a complete oncologic resection by keeping dissection into anatomical

planes and thus providing a radical operation. In addition, left-sided cancer is frequently associated to other organ infiltration, such as transverse colon or mesocolon or stomach. The RAMPS technique aims to increase the R0 resection rate and maximize the lymph node resection of the surgical specimen. There have been recently reports with few patients on the results of the laparoscopic RAMPS procedure for PDAC: Fernández-Cruz et al. [6] reported their results after laparoscopic RAMPS on ten patients obtaining free surgical margins in 90% of the patients and a median survival of 14 months. Song et al. [18] performed laparoscopic RAMPS in 24 patients with PDAC, with 22 out of 24 patients reaching R0 resection, a mean number of harvested lymph nodes of 10.3 ± 8.6, with a 2-year overall survival of 85.2%. Abu-Hilal et al. [19] have recently reported a R0 rate of 76% with a median node sample of 15 nodes and 1-year survival rate of 88%. Finally, a multicenter cohort study from four centers was published in 2015 by Sahakyan et al. [20] showing results after laparoscopic resection on 196 patients with PDAC, revealed a conversion rate of 2.6%, a clinically relevant postoperative pancreatic fistula (POPF) rate of 15.7%, with a median survival of 31.3 months, and an overall 5-year survival rate of 30%.

In 2010 Kooby et al. [21] published a retrospective study with data from nine academical centers in the United States comparing results from OPD with LDP. They were not able to find any differences neither in the positive margin rate or node retrieval nor in overall survival. They concluded that long-term survival was not influenced by the surgical approach. These findings were later confirmed by Magge et al. [22] in a comparative study with 62 patients with PDAC finding no differences in overall survival between both groups. Recently Sharpe et al. [23] published their study comparing 145 LDP with 625 ODP for PDAC again with no differences in terms of lymph node count, 30-day unplanned readmission, and 30-day mortality, with the added benefit of shorter hospital stay in LDP patients (6.8 ± 4.6 vs. 8.9 ± 7.5 days, $P < .001$). Finally, in 2015, Shin et al. [24] conducted a propensity score-matched analysis of PDAC patients resected by the ODP versus LDP with 51 patients in every group. Their results showed equivalent results in terms of primary outcomes of operative time, number of harvested lymph nodes, resection margin status, and secondary outcomes of frequency of POPF and complications, with no differences in patient survival. Stauffer et al. [25] reported in 2016 a comparative study of LDP versus ODP for PDAC, finding no differences in operative time, conversion to open surgery, POPF rate, and major postoperative complications. However, LDP was associated with a shorter hospital stay (5.1 vs. 9.4 days, $p = 0.0001$) and time to initiate adjuvant therapy (69.4 vs. 95.6 days, $p = 0.0441$). In addition, LDP was associated with more resected lymph nodes than ODP (25.9 vs. 12.7, $p = 0.0001$). Interestingly, survival rates at 1, 3, and 5 years were similar between LDP and ODP (69% vs. 78%, 41% vs. 44%, and 41% vs. 32%, respectively). Riviere et al. [26] published in 2016 a systematic review of data from 12 studies including 1,576 patients, 394 undergoing LDP, and 1,182 ODP for PDAC. None of the studies were randomized controlled trials, with all the evidence coming from retrospective cohort-like studies or case-control studies. Both techniques had equivalent outcomes in (LDP vs. ODP): short-term mortality (0.5% vs.

1%; odds ratio (OR) 0.48), serious adverse events (8.8% vs. 5.1%; OR 1.79), and clinically significant POPF (7.7% vs. 6.6%). Mean length of hospital stay was shorter by 2.43 days in the laparoscopic group than in the open group (MD −2.43 days). The results from all these studies are favorable to LDP and should ideally be confirmed in a randomized controlled trial. Tumors larger than 5–6 cm can be safely resected laparoscopically by the use of determinate surgical techniques that allow for a complete resection, as shown in a recent study by Fernández-Cruz et al. [27] showing results after LDP in 18 patients having tumors with a median size of 7 cm. R1 resections for exocrine pancreatic malignancies were found in 50% of patients. Morbidity (grade > II) was found in 16.6% of patients and 30-day mortality in one patient, with an overall median survival of 50 months and 29 months for patients with exocrine pancreatic malignancies.

Despite all these promising results, recently, De Rooij et al. [28] published a Dutch nationwide comparison of open versus LDP for both benign and malignant disease showing that LDP was associated with fewer major complications (16% vs. 29%; p: 0.02) and a shorter median hospital stay, but it only accounted for a 10% of all DP, so LDP is not universally accepted.

LPD is more technically demanding than LDP and is currently performed in few centers in the world. Liao et al. [29] published in 2016 a systematic review of minimally invasive PD (MIPD) reporting a conversion of 9.1%, average operative time of 422.6 min and average blood loss of 321.1 mL. The mean harvested lymph nodes were 17.1, and the rate of microscopically positive tumor margins was 8.4%. The cumulative morbidity was 35.9%, and a POPF was reported in 17.0% of cases. The average length of hospital stay was 12.4 days, and the mortality rate was 2.2%. Doula et al. [30] performed a systematic review of comparative studies between OPD with minimally invasive PD (LPD and robotic PD) including 14 articles. The conversion rate in LPD was between 0% and 15%, but the authors did not find any significant differences in resection margins, rates of POPF formation, bile leak, and delayed gastric emptying, reoperation rates, and intraoperative and postoperative mortality. The learning curve for LPD was studied by Wang et al. [31], which performed a CUSUM analysis and divided the learning curve into three separate phases: phase I was the initial learning period (cases 1–11), phase II represented the technical competence period (cases 12–38), and phase III was regarded as the challenging period (cases 39–57). They suggested that to attain a technical competence for performing LPD, a minimum of 40 cases should be required.

With respect to results after LPD for PDAC, there is less evidence than with LDP, and also there are no randomized controlled studies comparing open and laparoscopic approaches, only comparative and case-control studies. Adam et al. [32] conducted a study comparing OPD (6,078 patients) and minimally invasive PD (MIPD, 983 patients) with data from the National Cancer Database including years 2010 and 2011. The majority of hospitals (92%) performing MIPD were low volume (≤10 cases/2 years). The unadjusted 30-day mortality rate was 5.1% for MIPD versus 3.1% after open surgery. For patients with PDAC, there were no differences between MIPD and open PD after multivariable adjustment in number of lymph nodes removed, rate of positive surgical margins, length of stay, or readmissions.

However, 30-day mortality was higher for patients undergoing MIPD (OR 1.87 (95% CI 1.25–2.80), $p = 0.002$). De Rooij et al. [33] published in 2016 a systematic review and meta-analysis of comparative cohort and registry studies which included 1,833 patients. No differences were found in mortality or POPF. LPD was associated with prolonged operative, but lower intraoperative blood, less delayed gastric emptying, and shorter hospital stay. In addition, they found an increase in postoperative mortality in low-volume centers, which emphasizes the importance of high-volume centers on reaching good results. However, Dokmak et al. [34] published a comparative study between 46 patients undergoing LPD and 46 OPD. They found higher severe morbidity (28% vs. 20%, p: 0.32) in LPD due to grade C POPF (24% vs. 6%, p: 0.007), bleeding (24% vs. 7%, p: 0.02), and revision surgery (24% vs. 11%, p: 0.09), without any differences regarding the pathological reports between both approaches. Due to their results, these authors suggested that LPD should not be routinely performed for periampullary tumors. Experienced laparoscopic surgeons from the Mayo Clinic have shown the feasibility and safety of LPD compared to OPD for patients with PDAC [35–37], even in patients requiring major vascular resection and reconstruction. They found favorable results in LPD patients observing a significant reduction in blood loss (842 vs. 1,452 mL, $p < 0.001$), as in median hospital stay, (6 vs. 9 days, $p = 0.006$); no significant differences in the total number of complications (35% vs. 48%, $p = 0.24$) or severe complications ($\geq$ Clavien-Dindo III) (6.4% vs. 3.4%, $p = 0.51$) between the two groups. In their study, patients operated on for PDAC from LPD spent less time from surgery until the start of adjuvant chemotherapy than OPD patients (48 vs. 59 days, $p = 0.001$). These authors suggested that receiving adjuvant treatment in a timely and complete fashion should be an additional advantage of the laparoscopic approach.

One of the most important early steps in the performance of a PD consists of the correct assessment of SMA infiltration using the SMA first approach [38, 39], which is a technical modification of the standard PD. This has been a surgical step considered difficult by the laparoscopic approach. Recently, Pittau et al. have recently proved that the SMA first approach is feasible and safe to perform laparoscopically [40], helping to avoid futile resections.

In conclusion, the available evidence suggests that for patients having PDAC in the body/tail of the pancreas, LDP is a safe procedure and has shown benefits when compared to ODP in terms of blood loss and postoperative hospital stay without compromising long-term oncologic results. LPD for PDAC seems to be feasible, safe, and advantageous over OPD as well, but there is definitively less evidence in the literature.

Laparoscopic Surgery for Pancreatic Neuroendocrine Tumors

Pancreatic neuroendocrine tumors (pNETs) have been one of the most frequent indications for laparoscopic pancreatic surgery; the majority are benign or borderline malignant. In addition, some of these lesions are single and small that allow conservative pancreatic surgery, such as enucleation and central pancreatic resection.

In 2005 a European multicenter study on laparoscopic pancreatic surgery was published, which was one of the first reports to provide information about what was being performed at the time. The results showed that the majority of the cases reported (50/127 cases) were pNETs [41]. A recent study by de Rooij et al. [28] compared the Dutch experience between OPD and LDP showing that pNETs were the main indication for laparoscopic pancreatic resection (38%).

Indications for surgery for pNETs are well established [42–44], regardless that the resection is performed with conventional open or laparoscopic surgery. In functioning pNETs (F-pNETs), surgical resection is the treatment of election, and it is recommended for patients with single, sporadic tumors regardless of its size, since it eliminates or improves the symptomatology, even if the patient has distant metastases. However, even though the surgical approach should not modify the indications for resection, there are some F-pNETs that are better suited for laparoscopic resection than other tumors. For instance, insulinomas are tumors generally single and benignant without lymph node invasion. Therefore, due to its benign nature and if conditions are met, enucleation is a treatment of choice, avoiding the need for a more aggressive resection. On the other hand, other F-pNETs, such as gastrinoma, are not generally considered a good indication for laparoscopic surgery, since they can arise in the so-called gastrinoma triangle, and surgical exploration of duodenum is necessary in a large proportion of these patients [45].

In nonfunctioning pNETs (NF-pNETs), surgical indication is somewhat more controversial than for F-pNETs. Surgery is generally not indicated in small NF-pNETs (less than 2 cm), because they are asymptomatic, almost always discovered incidentally, and their probability of malignancy is believed to be very low. Edil et al. [46] showed that tumor size was associated with lymph node metastasis: <1 cm: 14%; 1–1.9 cm: 9%; 2–2.9 cm: 37%; 3–3.9 cm: 56%; 4–4.9 cm: 72%; and ≥ 5 cm: 56%. Thus, the accepted threshold for indicating resection is 2 cm, which is a size that associates greater proportion of nodal involvement. Another point of controversy is the surgical procedure needed for performing the resection, which depends on the size, main pancreatic duct involvement, location within the pancreatic gland, and, if available, results of preoperative biopsy. In general, parenchyma-preserving resection is indicated in small lesions, while more aggressive pancreatectomies should be recommended in larger lesions or when there is suspicion of a malignant tumor. Long-term results of laparoscopic pNETs resection were evaluated by Haugvik et al. [35], with an overall 5-year disease-specific survival rate of 90%, finding R2 resections, Ki67 $\geq$ 5%, and T4 tumors as bad prognosis risk factors.

Fernández-Cruz et al. [47] published their results after laparoscopic resection of pNETs. Laparoscopic enucleation resulted in the less blood loss compared with other techniques, but with a significantly higher postoperative morbidity due to a higher PF rate. Spleen-preserving DP also had higher complication rates than the conventional LDP due to spleen-related complications. However, results were excellent in terms of R0 resection, even in malignant tumors. Authors concluded that the benefits of minimally invasive surgery were manifested in the short hospital stay and acceptable pancreas-related complications in high-risk patients, with a high negative margin rate in patients with malignant tumors. Fernández-Cruz et al. [48] published

their results after laparoscopic enucleation for NF-pNETs in 30 patients. Clinically relevant PF, which is a main issue in this type of resection, occurred in 6.6% of the patients, and after a median follow-up of 48 months, only one patient developed lymph node and liver metastases.

In 2014, Drymousis et al. [49] published a systematic review on laparoscopic versus open surgery for pNETs. They included 906 patients, 22% of them resected laparoscopically, finding the known advantages of less intraoperative blood loss, less morbidity, and a shorter postoperative hospital stay. They were not able to find any differences on the PF rate, operative time or mortality between groups, even though the majority of the patients were resected by means of laparoscopic DP or enucleation.

In conclusion, laparoscopic pancreatic surgery has proven to be a feasible and safe approach and should be considered the standard of care in the management of patients with pNETs.

Conclusion

According to the available scientific evidence, laparoscopic surgery has been shown to be safe and effective for the treatment of neoplastic lesions of the pancreas, with the added short-term benefit of less intraoperative blood loss and a shorter hospital stay, obtaining similar long-term oncological results to those after conventional surgery, both for pancreatic ductal adenocarcinoma and pancreatic neuroendocrine tumors. However, the existence of stronger evidence from randomized controlled trials that definitely elucidate the role of laparoscopic surgery for the treatment of pancreatic neoplasms is still necessary.

Modern Japanese Approach to Pancreatic Cancer

Takao Ohtsuka and Masao Tanaka

Contents

Abstract

Principal clues to early diagnosis of pancreatic cancer including pancreatic duct dilation, diabetes, and intraductal papillary mucinous neoplasms are discussed, referring to Japanese contributions. The Japan Pancreas Society (JPS) has revised fourth edition of Clinical Guidelines for Management of Pancreatic Cancer, providing 51 clinical questions with graded evidence-based recommendations in 2016, and diagnosis, chemotherapy, radiation therapy, surgical resection, adjuvant treatments,

and supportive therapy are addressed. “Borderline resectable (BR)” pancreatic cancer is a new concept, and JPS makes two categories of BR pancreatic cancer such as involvement of only portal vein (BR-PV) and involvement of major artery (BR-A). Extended resection cannot be actively advocated in patients with pancreatic cancer in the present daily practice, because several prospective randomized trials did not confirm the survival benefit of extended resection compared to standard resection. The analysis using data of the JPS Pancreatic Cancer Registry indicates that the 5-year survival rate of patients after resection of pancreatic cancer has been significantly improved after the introduction of gemcitabine into Japan. More recently, a Japanese group has demonstrated that S-1 adjuvant chemotherapy is superior to gemcitabine. Recent great interest in Japan is to clarify the significance of neoadjuvant treatments in resectable and BR pancreatic cancer.

Current Status of Pancreatic Cancer in Japan

The number of pancreatic cancer-related death in Japan has increased to 31,716 in 2014, indicating that this disease has become the fourth leading cause of cancer death in Japan [1]. According to database of nationwide Pancreatic Cancer Registry conducted by the Japan Pancreatic Society (JPS) since 1981, the 5-year survival rate of overall patients with invasive pancreatic cancer has gradually increased from 6.7% to 13.0% during the recent three decades, and that of the patients who underwent pancreatectomy for invasive cancer has also increased from 10.9% to 18.8% [2] (Fig. 1). Despite the recent advances in imaging modalities and surgical techniques and the development of new anticancer agents, most pancreatic cancer patients have been still diagnosed as having a far advanced lesion, resulting in the poor prognosis. These data indicate the necessity of the establishments of diagnostic strategy for early-stage pancreatic cancer and multidisciplinary treatment strategy including resection for advanced pancreatic cancer to be cured.

Clinical Guidelines for Management of Pancreatic Cancer

The JPS published the first edition of evidence-based guidelines for the management of pancreatic cancer in 2006 [3] and fourth revised version in 2016 [4]. The first edited guidelines provided 29 clinical questions, while in the fourth edition, a total of 51 clinical questions are presented, indicating that management options and unresolved issues in the daily practice of the pancreatic cancer have been increasing. Answers are given to each clinical question with recommendations appropriately, graded based on evidences reported in relevant world literature.

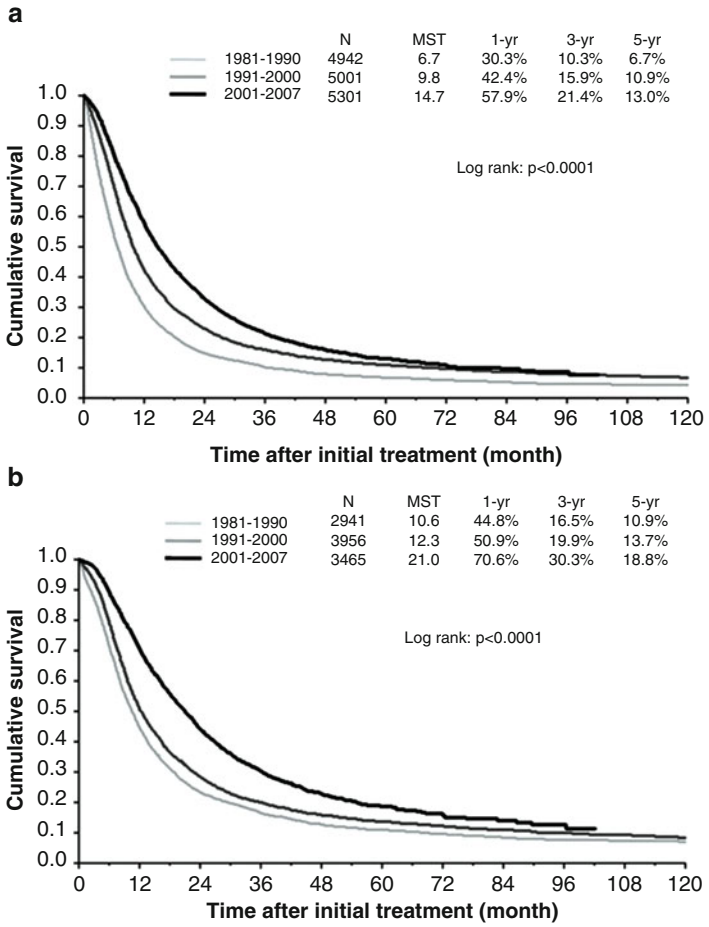

Fig. 1 Survival curves of overall patients with invasive pancreatic cancer (**a**) and those who underwent resection of invasive pancreatic cancer (**b**) in three periods. A table inset shows the number of patients (*N*), median survival time (*MST*) in months, and 1-year, 2-year, 3-year, and 5-year survival rates in each study period group (These figures are cited with permission from Ref. [2])

References with structured abstracts remade by the committee and contained in an attached CDROM are cited adequately. The entire guidelines cannot be translated here, but the clinical questions in the fourth edition are described in Table 1. Almost all aspects of the management of pancreatic cancer are addressed, including diagnosis, chemotherapy, radiation therapy, surgical treatments, adjuvant therapy, and supportive therapy. The guidelines also include some "perspectives" of the committee members, although this may be unusual for guidelines. Details of the "best supportive care" have been also described in the fourth edition of the guidelines. Algorithms for the diagnosis and treatment principals of pancreatic

Table 1 Fifty-one clinical questions in clinical guidelines for the management of pancreatic cancer 2016

1. Disease concept		
	I. Disease concept (DC)	
	DC-1	What are the risk factors to develop pancreatic cancer?
	DC-2	What is familial pancreatic cancer?
	DC-3	What is borderline resectable pancreatic cancer?
2. Diagnosis		
	II. Diagnosis (D)	
	D-1	How to detect pancreatic cancer?
	D-2	Diagnostic modality when pancreatic cancer is suspected
	D-2-1	Are CT and MRI useful to diagnose pancreatic cancer, when suspected?
	D-2-2	Is EUS useful to diagnose pancreatic cancer, when suspected?
	D-3	Next step to diagnose pancreatic cancer
	D-3-1	Is ERCP useful to diagnose pancreatic cancer?
	D-3-2	Is PET useful to diagnose pancreatic cancer?
	D-3-3	Is cytology/histology useful to diagnose pancreatic cancer?
	D-4	How to determine the stage of pancreatic cancer?
	D-5	How to determine the resectability of pancreatic cancer?
	D 6	Is it better to perform staging laparoscopy to determine the stage of pancreatic cancer?
	D-7	How to diagnose early stage pancreatic cancer possibly leading to long-term survival?
3. Treatment		
	A. Treatment of "resectable" pancreatic cancer (R)	
	III. Surgery (RS)	
	RS-1	Is resection recommended for resectable pancreatic cancer?
	RS-2	Is resection at high volume centers recommended for pancreatic cancer?
	RS-3	Does multidisciplinary treatment have a significant role in borderline resectable pancreatic cancer?
	RS-4	Does surgical resection have a significant role in pancreatic cancer with positive intraabdominal irrigation cytology?
	RS-5	Does preservation of the stomach have a significant role in pancreatoduodenectomy for pancreatic cancer?
	RS-6	Does combined resection of portal vein improve survival after resection of pancreatic cancer?
	RS-7	Does extended resection of retroperitoneal lymph nodes and neural plexus have a significant role in surgical treatment of pancreatic cancer?
	RS-8	Is prophylactic bypass recommended in pancreatic cancer proven to be unresectable during laparotomy?
	RS-9	Does laparoscopic pancreatectomy have a significant role in pancreatic cancer?
	RS-10	How to survey the patients undergoing resection of pancreatic cancer?
	RS-11	Is nutritional support recommended after resection of pancreatic cancer?

(*continued*)

Table 1 (continued)

IV. Adjuvant treatment (A)		
	RA-1	Is neoadjuvant therapy (chemoradiotherapy or chemotherapy) recommended for resectable pancreatic cancer?
	RA-2	Is intraoperative radiotherapy recommended for resectable pancreatic cancer?
	RA-3	Is postoperative adjuvant chemoradiotherapy recommended after resection of pancreatic cancer?
	RA-4	Is postoperative adjuvant chemotherapy recommended after resection of pancreatic cancer?
B. Treatment of locally advanced pancreatic cancer (LA)		
	LA-1	What is the primary treatment of unresectable locally advanced pancreatic cancer?
V. Radiation (LAR)		
	LAR-1	What kind of chemoradiotherapy is recommended for unresectable pancreatic cancer?
	LAR-2	How to determine the clinical target volume of external radiation therapy for unresectable pancreatic cancer?
	LAR-3	Does induction chemotherapy have a significant role in chemoradiotherapy for unresectable pancreatic cancer?
	LAR-4	Does intraoperative radiation therapy have an effect on unresectable pancreatic cancer?
	LAR-5	Does radiation therapy or chemoradiotherapy improve QOL of the patients with unresectable pancreatic cancer?
VI. Chemotherapy (LAC)		
	LAC-1	What is the primary agent of chemotherapy for unresectable locally advanced pancreatic cancer?
	LAC-2	(MC-2) Is secondary chemotherapy recommended for unresectable pancreatic cancer?
	LAC-3	(MC-3) What is the recommended period of chemotherapy for unresectable pancreatic cancer?
	LAC-4	(MC-4) Is immunotherapy recommended for unresectable pancreatic cancer?
C. Treatment of metastatic pancreatic cancer (M)		
VI. Chemotherapy (MC)		
	MC-1	What is the primary agent of chemotherapy for unresectable pancreatic cancer with distant metastasis?
	MC-2	(LAC-2) Is secondary chemotherapy recommended for unresectable pancreatic cancer?
	MC-3	(LAC-3) What is the recommended period of chemotherapy for unresectable pancreatic cancer?
	MC-4	(LAC-4) Is immunotherapy recommended for unresectable pancreatic cancer?
V. Radiation (MR)		
	MR-1	Is radiation therapy useful for bone metastasis from pancreatic cancer?
4. Supportive therapy		
VII. Stent insertion (ST)		
	ST-1	Is biliary drainage recommended for unresectable pancreatic cancer with obstructive jaundice?
	ST-2	Which is better as an approach of biliary drainage for unresectable pancreatic cancer with obstructive jaundice, percutaneous or endoscopic?

(*continued*)

Table 1 (continued)

	ST3-1	What kind of stent is recommended for preoperative biliary drainage in pancreatic cancer with obstructive jaundice?
	ST3-2	What kind of stent is recommended for biliary drainage in unresectbale pancreatic cancer with obstructive jaundice?
	ST-4	Which is recommended for gastric outlet obstruction in unresectable pancreatic cancer, gastrojejunostomy or stent?
VIII. Palliative medicine (PM)		
	PM-1	What is the effective care for psychological stress in pancreatic cancer patients and their family?
	PM-2	What is the effective treatment of upper abdominal pain and back pain in pancreatic cancer patients?
	PM-3	Is elemental diet support effective for the improvement of the condition of patients with unresectable pancreatic cancer?

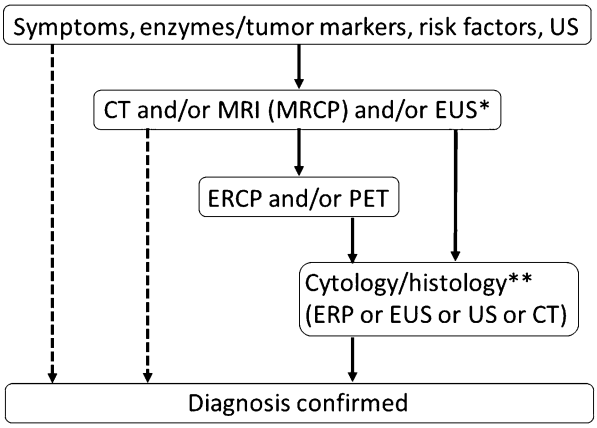

Fig. 2 Diagnostic algorithm (This figure is translated and cited with permission from Ref. [4]). *US* (percutaneous) ultrasonography, *CT* computed tomography, *MRI* magnetic resonance imaging, *MRCP* magnetic resonance cholangiopancreatography, *EUS* endoscopic ultrasonography, *ERCP* endoscopic retrograde cholangiopancreatography, *PET* positron emission tomography. *Enhanced CT and enhanced MRI + MRCP are preferable. EUS is possible at experienced institution. **Pathological diagnosis is preferable whenever possible

cancer presented in the guidelines are shown in Figs. 2 and 3. Briefly, any patients with symptoms suggestive of pancreatic cancer, elevation of serum and/or urinary amylase and/or tumor markers such as carbohydrate antigen 19-9 (CA19-9) and carcinoembryonic antigen (CEA), presence of multiple risk factors such as strong family history of pancreatic cancer, hereditary pancreatic cancer syndrome, diabetes mellitus, chronic pancreatitis, hereditary chronic pancreatitis, and cigarette smoking, and/or percutaneous ultrasonographic findings suggestive of pancreatic cancer should undergo enhanced computed tomography (CT) and/or magnetic

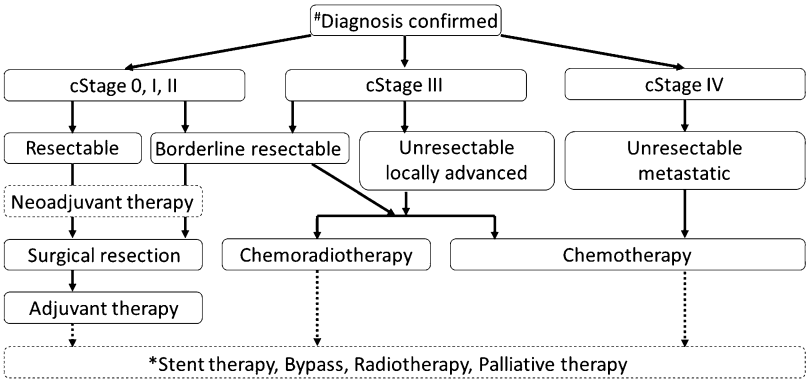

Fig. 3 Therapeutic algorithm (This figure is translated and cited with permission from Ref. [4]). Clinical stage (cStage) is determined according to the General Rules of Surgical and Pathologic Studies on Cancer of the Pancreas (seventh edition) (Ref. [5]). #Supportive treatment for pain, malabsorption, diabetes, anxiety is usually needed from the time of initial diagnosis. *Sometimes indicated in selected patients

resonance imaging/cholangiopancreatography (MRI/MRCP) and/or endoscopic ultrasonography (EUS). If these imaging studies have not confirmed the diagnosis, then the patients should be subjected to ERCP and/or positron emission tomography (PET). Pathological assessment (cytology/histology) under ERCP, EUS, or CT should be performed as much as possible (Fig. 2).

Seventh edition of General Rules of Surgical and Pathologic Studies on Cancer of the Pancreas [5] published by the JPS in 2016 has changed the classification of the location of pancreatic cancer (Fig. 4) and TNM classification (Fig. 5) to ensure the integrity with the Union for International Cancer Control (UICC) classification [6], and fourth edition of JPS guidelines for the management of pancreatic cancer [4] follows these revised classifications. The borderline between the pancreatic body and tail is set at left outer edge of aorta in the current rules, although this was previously set at the midline between the left outer edge of superior mesenteric vein/portal vein (SMV/PV) and left outer edge of pancreatic parenchyma. The category of T factor is almost the same with that of UICC [6], while the Japanese category divides T1 factor into three subcategories according to the tumor size and N1 factor into two subcategories according to the number of the metastatic lymph nodes, based on the assessment of the survival data between 2001 and 2007 in JPS Pancreatic Cancer Registry (Fig. 5) [5]. The JPS classification of peripancreatic lymph nodes is also demonstrated in Fig. 6. Nodal stations are classified into three groups according to the location of the lesion, either the head or body and tail of the pancreas or both (entire pancreas) (Fig. 7). Regional lymph node station includes Group 1 and 2. Stage IVA of locally advanced pancreatic cancer which was previously great concern of Japanese physicians in terms of the treatment strategy is currently compatible for stage IIA, IIB, or III in the seventh edition of JPS classification [5]. Of note, positive result of intraoperative irrigation cytology (CY1) does not yet belong to “M1” in the

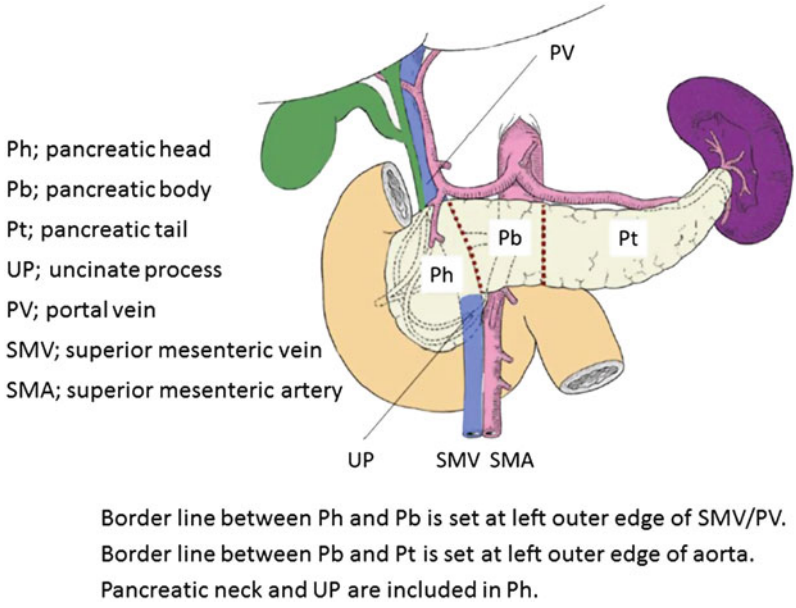

Fig. 4 Nomenclature of location of the tumor (This figure is translated and cited with permission from Ref. [5])

Primary tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to the pancreas, 2cm or less in greatest diameter
T1a	Tumor 5mm or less in greatest diameter
T1b	More than 5mm but 10mm or less in greatest diameter
T1c	More than 10mm but 20mm or less in greatest diameter
T2	Tumor limited to the pancreas, more than 2cm in greatest diameter
T3	Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
T4	Tumor involves the celiac axis or the superior mesenteric artery

Distant metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	1 to 3 lymph nodes involvement
N1b	4 or more lymph nodes involvement

Stage

Stage 0	Tis	N0	M0
Stage IA	T1 (T1a, T1b, T1c)	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1 (T1a, T1b, T1c), T2, T3	N1 (N1a, N1b)	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

Fig. 5 The stage of the disease in the Japan Pancreas Society (*JPS*) system according to the General Rules of Surgical and Pathologic Studies on Cancer of the Pancreas (seventh edition) [5]. This figure is translated and cited with permission from Ref. [5]. This classification ensures the integrity with the Union for International Cancer Control (*UICC*) classification [6]. The category of T factor is almost the same with that of UICC, while the JPS category divides T1 factor into three categories according to the tumor size, and N1 factor into two categories according to the number of the metastatic lymph nodes. Of note, positive result of intraoperative irrigation cytology (*CY1*) does not yet belong to "M1" in the seventh edited JPS classification

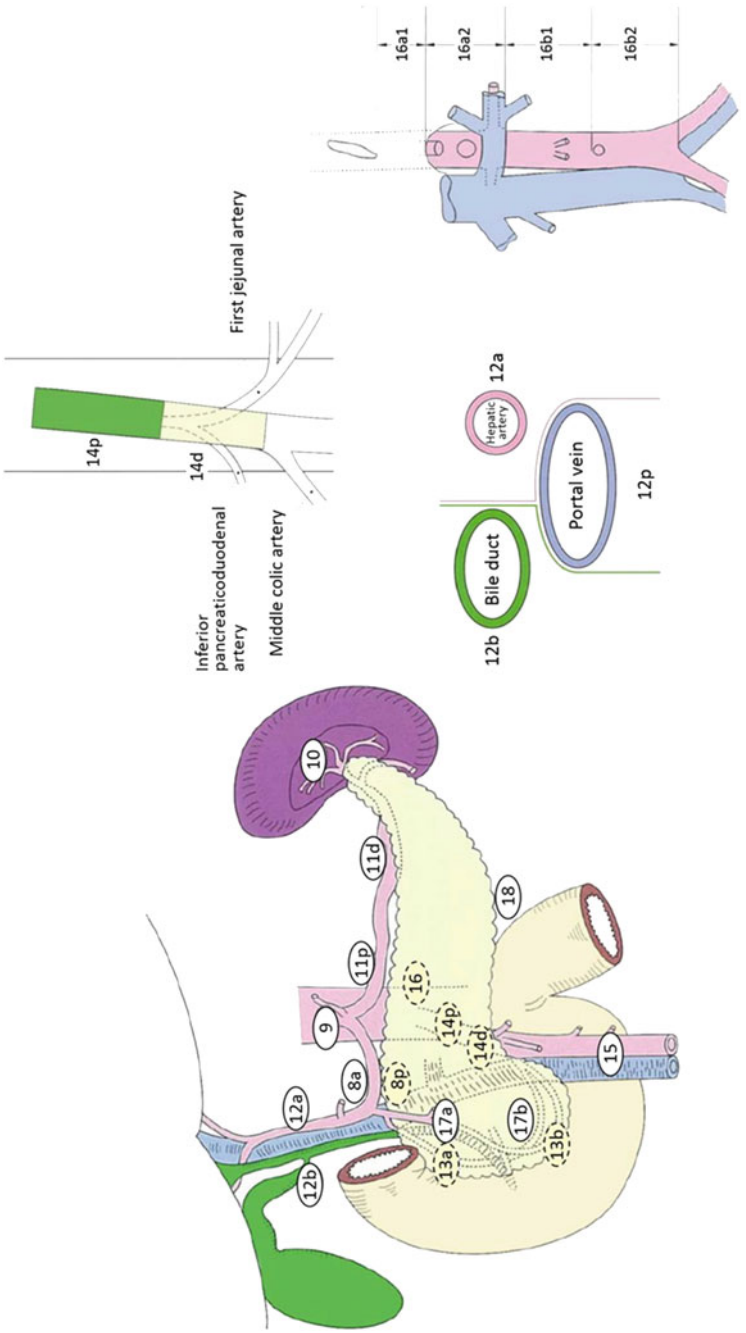

Fig. 6 Nomenclature of lymph node stations in the peri-pancreatic region (This figure is cited with permission from Ref. [5])

	Total pancreatectomy	Pancreato-duodenectomy	Distal pancreatectomy
Group 1	8a, 8p,10, 11p, 11d, 13a, 13b, 17a, 17b, 18	8a, 8p, 13a, 13b, 17a, 17b	10, 11p, 11d, 18
Group 2	5, 6, 7, 9, 12a, 12b, 12p, 14p, 14d	5, 6, 12a, 12b 12p, 14p, 14d	7, 8a, 8p, 9, 14p 14d
Group 3	1, 2, 3, 4, 15 16a2, 16b1	1, 2, 3, 4, 7, 9, 10, 11p, 11d, 15, 16a2, 16b1, 18	5, 6, 12a, 12b, 12p, 13a, 13b, 15, 17a, 17b, 16a2, 16b1

Fig. 7 Nomenclature of lymph node stations in the peri-pancreatic region and group numbers, according to the type of the operation (This figure is cited with permission from Ref. [5]). Regional lymph node station to determine the "N" factor includes Group 1 and 2

seventh edition of JPS TNM classification, because of the lack of evidences emphasizing the effects of CY1 on postoperative survival [7, 8].

Another new concept is "borderline resectable (BR)" pancreatic cancer. There are several definitions of BR-pancreatic cancer in Western countries [9, 10], while the JPS has made two categories of BR pancreatic cancer such as involvement of only PV/SMV (BR-PV/SMV) and involvement of major arteries (BR-A) irrespective of the presence or absence of PV/SMV involvement [4, 5], because Japanese surgeons aggressively perform pancreatectomy with combined resection of PV/SMV and usually determine the resectability based on the arterial involvement, not only on the PV/SMV involvement [11, 12]. BR-PV/SMV indicates the tumor involvement of PV/SMV less than 180° without invasion to or contact with superior mesenteric artery (SMA), celiac artery (CA), and common hepatic artery (CHA) and superior to the inferior margin of the duodenum, because reconstruction of SMV distal to the inferior margin of the duodenum is technically difficult [4, 5]. BR-A indicates tumor invasion to or contact with SMA or CA but without stenosis or deformity of SMA or CA or tumor invasion to or contact with CHA without invasion to or contact with proper hepatic artery and CA [4, 5]. If the tumor spread is matched with the criteria of both BR-PV/SMV and BR-A, then that will be managed as BR-A.

Clues to Early Diagnosis of Pancreatic Cancer

There have been a number of factors possibly leading to the diagnosis of pancreatic cancer. However, none have been successful to detect pancreatic cancer in early stages. Apart from well-known risk factors such as family history, chronic pancreatitis, cigarette smoking, etc., the following three factors (dilation of pancreatic duct, diabetes

mellitus, and intraductal papillary mucinous neoplasm of the pancreas) would deserve particular emphasis, because all of these are frequently encountered in clinical practice.

Dilatation of Pancreatic Duct

Dilation of the main pancreatic duct (MPD) can easily be demonstrated by ultrasonography and/or CT and may be the first sign to detect pancreatic cancer. However, specificity of this sign for the diagnosis of pancreatic cancer is rather low, since chronic pancreatitis also causes dilation of the MPD. As the most highly refined method to delineate the changes in the MPD, Inoue et al. [13] developed balloon catheter pancreatography and examined its diagnostic utility. The degree, length, and luminal deviation of a stenosis of the MPD as well as several branch duct findings such as paucity of branches around the MPD stenosis and irregular caliber changes were evaluated in 21 patients with pancreatic cancer and in 27 patients with chronic pancreatitis. Multivariate regression analysis demonstrated that only two findings were statistically significant in the differentiation of benign and malignant stenosis, i.e., severe stenosis and marked dilation of the upstream MPD [13]. These significant findings can now be evaluated by MRCP, and the role of ERCP is changing to sampling of the pancreatic juice for cytology and determination of molecular markers such as telomerase, hTERT, K-RAS, microRNA, etc. [14–21]. On the other hand, Iiboshi et al. [22] have recently demonstrated that endoscopic placement of naso-pancreatic drainage (ENPD) tube and subsequent pancreatic juice cytology in patients with MPD stricture increases sensitivity to detect pancreatic cancer. They examined 20 patients who had focal stenosis and distal dilation of the MPD by repeated pancreatic juice cytology via ENPD tube (average 5.3 time, range 2–11 times) and showed that the sensitivity, specificity, and accuracy of the cytological results of pancreatic juice were 100%, 83%, and 95%, respectively. Of note, among 15 patients with positive cytology via the ENPD tube subsequently diagnosed as having pancreatic cancer on resected specimen, seven had noninvasive carcinoma, all of whom had normal serum tumor marker levels and negative radiological mass finding. Kimura et al. [23] also reported their experiences of 24 patients with stage 0 and I pancreatic cancer according to JPS classification [5] and demonstrated that cytological examination during ERCP was 65% sensitive in preoperative diagnosis of such early-stage pancreatic cancer, whereas other imaging modalities were only 29–38% sensitive. Of note, 9 of 24 early-stage pancreatic cancers were diagnosed by ERCP/cytology alone. Despite the risk of acute pancreatitis, pancreatic juice cytology during ERCP still has important roles in the diagnosis of early-stage pancreatic cancer, which cannot be detected by any other imaging modalities.

Diabetes Mellitus

Diabetes mellitus is diagnosed in more than 50% of patients with pancreatic cancer and has long been considered to be one of factors to indicate the diagnosis of

pancreatic cancer. Ogawa et al. [24] prospectively studied 86 type 2 diabetic patients by ERCP and found six patients (7.1%) with pancreatic cancer. This very high prevalence was achieved by selection of patients using several criteria including (1) the onset of diabetes after the age of 55 without obesity, family history, or excessive alcohol ingestion, (2) acute exacerbation of preexistent diabetes, (3) loss of body weight despite good control of diabetes, (4) increased serum levels of amylase (>200 IU/L) and/or CA19–9 (>300 U/mL), and (5) ultrasonographic abnormalities of the pancreas. The study was continued until the total number of patients reached 197 and yielded the final prevalence of pancreatic cancer of 11.2% (data published only in Japanese). However, the most pancreatic cancers were diagnosed as advanced or unresectable condition, and thus, another screening system to detect early-stage pancreatic cancer in diabetic patients should be established. Chari et al. [25] reported that approximately 1% of diabetic subjects aged ≥50 years would be diagnosed with pancreatic cancer within 3 years of first meeting criteria for diabetes. The difference of these prevalence rates may be explained by more detailed criteria for patient selection.

Intraductal Papillary Mucinous Neoplasm (IPMN)

IPMN is a new clue to the diagnosis of pancreatic cancer [26]. Since Tanaka et al. first demonstrated case reports of pancreatic cancer concomitant with IPMN [27, 28], many other Japanese investigators have been much interested in this unique combination, and the reported incidence of concomitant pancreatic cancer ranges from 2.0% to 9.9% or 1.1% per year [29–32]. Kamata et al. [33] have recently conducted a prospective surveillance study of 102 IPMN patients and reported metachronous development of seven concomitant pancreatic cancers (7%). In this report, they showed the utility of EUS for the early detection of concomitant pancreatic cancers which were not diagnosed by CT and MRI/MRCP. On the other hand, Ohtsuka et al. [34] found 23 synchronous or metachronous pancreatic cancers occurring in 20 patients in a series of 179 patients who underwent resection of IPMNs. Seven of the 23 pancreatic cancers (30%) were of early stages (stage 0 to I according to JPS classification [5]), and sensitivities of CT, MRI/MRCP, and EUS to detect the stage 0 to I concomitant pancreatic cancers were 16%, 29%, and 29%, respectively, while sensitivity of ERCP/pancreatic juice cytology was 86%. Of note, three early-stage pancreatic cancers were diagnosed by ERCP/cytology alone, indicating that ERCP has an important role in the early diagnosis of distinct pancreatic cancers in patients with IPMNs. Ideno et al. found that IPMNs having concomitant pancreatic cancer are frequently of branch duct type, MUC2-negative gastric subtype, and of GNAS wild-type [35], and these molecular characteristics may lead to some insights to establish the diagnostic strategy for early detection of pancreatic cancer in patients with IPMNs. The JPS is now conducting a prospective multicenter surveillance study of branch duct IPMNs, and over 2,300 patients have been

registered between 2012 and 2014 (UMIN000007349). They will be surveyed for 5 years, using alternate CT and MRCP/EUS at every 6 months. Then, important informations with a high evidence level regarding the incidence of concomitant pancreatic cancer in patients with branch duct IPMNs and effects of alternate CT and MRCP/EUS on the early detection of concomitant pancreatic cancer will be obtained in 2019.

Strategy Against Locally Advanced Pancreatic Cancer

Extended Resection Versus Standard Resection

The treatment strategy for the Clinical Stage IVA pancreatic cancer in the previous sixth edition of JPS classification, indicating Clinical Stage IIA, IIB, and III in the current seventh edition, [5] remains controversial. This category includes resectable, borderline resectable, and unresectable locally advanced pancreatic cancers. Patients without invasion to major arteries (CHA in pancreatic head cancer, SMA in all pancreatic cancers) should undergo resection rather than chemoradiation. One prospective randomized study from Japan clearly showed a survival benefit of surgical resection compared to chemoradiation alone in patients with locally advanced pancreatic cancer invading to pancreatic capsule without involvement of the SMA or CHA and without distant metastasis [36, 37]. PV/SMV involvement does not preclude the indication for pancreatic resection as described above [11, 12], but the survival benefit of combined resection of the PV/SMV has not been proven yet. With regard to surgical treatments of pancreatic cancer, Japanese surgeons used to pursue cure of their patients with pancreatic cancer by means of extended resection with complete dissection of retroperitoneal lymph nodes and neural plexus in 1980s. One prospective randomized multi-institutional comparison conducted in Japan yielded no significant difference in overall 5-year survival rates between standard (No.13, 17 lymph node stations) (16%) and extended resection (No. 8, 9, 12, 13, 14, 16a2, 16b1, 17 lymph node stations, and circumferential nerve plexus of SMA) (6%) for pancreatic head adenocarcinoma [38]. Postoperative quality of life tended to be worse in the extended resection group as expected. In view of these results, the guidelines state [4] that extended resection cannot be actively advocated in patients with pancreatic cancer in the current daily practice. More recently, a Korean group has followed this Japanese investigation and demonstrated that extended resection (No. 5, 6, 8, 9, 12, 13, 14, 16a2, 16b1, 17 lymph node stations, and right-side nerve plexus of the SMA) does not provide a significant survival benefit compared with standard resection (No. 12 in part, 13, 17 lymph node stations) [39].

The survival benefit of extended resection in patients with lymph node metastasis may still justify the performance of D2 lymph node dissection (removal of Group 1 and 2 lymph nodes), because the precise status of lymph node metastasis can only be examined after surgery. In addition, the role of extended resection may

still have to be explored in earlier stage pancreatic cancer. Recent Japanese surgeons consider that standard resection includes pancreatectomy with lymph node dissection of Group 1 and 2 (D2), and therefore, the present JPS classification [5] defines the "regional" lymph nodes as Group 1 and 2 lymph nodes. Then, they limit the range of dissection area within Group 1 or extend the resection area to No.16 lymph node station, nerve plexus of the SMA, combined resection of PV/SMV, and sometimes CHA, according to the tumor spread as well as patients' general condition. Distal pancreatectomy with en bloc celiac axis resection is the representative extended pancreatectomy for pancreatic cancer designed by Japanese surgeons [40].

Adjuvant Treatment

Since the application of gemcitabine as a primary agent for the treatment of unresectable pancreatic cancer and as an adjuvant agent after resection of pancreatic cancer [41, 42], survival rates of overall patients as well as of those who underwent pancreatectomy have been gradually improving as described above (Fig. 1). More recently, Uesaka et al. [43] have conducted a randomized phase III trial of adjuvant chemotherapy comparing gemcitabine versus S-1 for patients with resected pancreatic cancer (JASPAC-01 study) and shown that hazard ratio for S-1 to gemcitabine was 0.56 (95% CI, 0.42–0.74, $p < 0.0001$ for non-inferiority, $p < 0.0001$ for superiority) based on the interim analysis. The 2-year survival rates were 53% (95% CI, 46–60) for gemcitabine and 70% (63–76) for S-1. These data indicate that S-1 adjuvant chemotherapy is superior to gemcitabine, and fourth edited JPS guidelines [4] recommend S-1 as the first choice of an adjuvant chemotherapeutic agent after resection of pancreatic cancer.

Because the effect of adjuvant therapy for pancreatic cancer is still limited, recent interest of Japanese investigators has been shifted to neoadjuvant therapy. Several Japanese prospective studies have shown the possible usefulness of neoadjuvant treatment for resectable or borderline resectable pancreatic cancer, using gemcitabine-based chemoradiation [44], gemcitabine plus S-1 [45], or carbon-ion radiotherapy [46], and lots of prospective randomized phase III trials are going on.

Conclusion

Japanese investigators have recently made great efforts to conduct multicenter or nationwide projects to provide high-quality evidences for the early diagnosis or the adequate treatment of pancreatic cancer, providing worldwide new insights as well as guidelines in accordance with Japanese situation. JPS plays important roles to arrange the clinical guidelines and the general rule of surgical and pathologic studies for the adequate management of Japanese patients with pancreatic cancer.

Key Practice Points

1. Pancreatic duct dilation, diabetes mellitus, and IPMNs may be clues to early diagnosis of pancreatic cancer.
2. Patients with locally advanced pancreatic cancer with no major arterial invasion should undergo resection rather than chemoradiation for better survival.
3. Definition of BR pancreatic cancer is different between Japan and Western countries, and the significance of this category during management of pancreatic cancer remains an unresolved issue.
4. Extended resection including para-aortic lymph nodes and neural plexus around the SMA has no overall survival benefit compared to standard resection.
5. The survival benefit of extended resection in patients with lymph node metastasis may still justify the performance of D2 lymph node dissection, because the precise status of lymph node metastasis can only be examined after dissection.
6. Adjuvant chemotherapy with S-1 or gemcitabine is recommended after resection of pancreatic cancer.

Future Research Directions

1. A breakthrough to more efficient methods for early detection of pancreatic cancer is urgently needed.
2. High-risk factors predisposing to pancreatic cancer must be recognized more widely to subject patients to imaging studies of the pancreas.
3. The role of extended resection may still have to be explored in earlier stages of pancreatic cancer.
4. Effects of neoadjuvant treatments to further improve the prognosis of resected pancreatic cancer should be investigated in prospective randomized trials.

Neoadjuvant Chemotherapy in Pancreatic Cancer

Theodoros Michelakos and Cristina R. Ferrone

Contents

Abstract

More than 30% of pancreatic ductal adenocarcinoma (PDAC) patients present with borderline resectable (BR) or locally advanced (LA) disease. Historically, this patient population had a poor prognosis, with the majority not being offered an operation. Following the promising results of modern combination regimens such as FOLFIRINOX (5-FU, oxaliplatin and irinotecan) and gemcitabine plus nab-paclitaxel for patients with metastatic PDAC, these regimens have been utilized in patients with BR or LA disease to render them resectable. Indeed, neoadjuvant FOLFIRINOX increases resectability of LA PDAC up to 44%, with

margin-negative resection rates and overall survival rates comparable to upfront resectable patients. Neoadjuvant chemotherapy also aids in obviating adjuvant therapy, which is frequently not initiated or completed due to the morbidity associated with pancreatic operations. Based on the encouraging results in locally advanced and borderline patients, neoadjuvant chemotherapy may also be of use in patients presenting with resectable disease. Neoadjuvant therapy may aid in screening patients with aggressive disease who progress on neoadjuvant therapy, and therefore may not benefit from an operation. Clinical trials currently underway will provide further information on the efficacy of modern neoadjuvant therapies for PDAC patients.

Introduction

The incidence of pancreatic ductal adenocarcinoma (PDAC) continues to increase worldwide. In the United States, it is currently the third leading cause of cancer death [1]. Approximately, 15%–20% of patients present with resectable disease, yet 80% of these patients already have cancer in their locoregional lymph nodes [2, 3]. More than 30% of PDAC patients present with borderline resectable (BR) or locally advanced (LA) disease [4]. Historically, these patients have a poor survival of only 8–12 months from the time of diagnosis [2, 5]. In the majority of cases, gemcitabine and/or 5-FU-based chemoradiation was utilized in an attempt to render patients resectable, but often the therapy was palliative with less than one-third of patients down-staged and resected [5–7]. Even after resection, survival remained poor with a median of 20 months (range 9–62 months) [5, 7].

In 2011, the PRODIGE 4/ACCORD 11 trial [8] demonstrated that the combination of 5-FU, oxaliplatin, and irinotecan (FOLFIRINOX) led to improved overall and progression-free survival compared to gemcitabine alone for patients with metastatic PDAC. Based on these results, FOLFIRINOX became the standard of care for patients with metastatic PDAC. With the promising outcomes in the metastatic setting, FOLFIRINOX has been utilized in patients with BR or LA disease. Many of these patients also received chemoradiation, in an attempt to render them resectable. While no results from randomized control trials evaluating the efficacy and safety of FOLFIRINOX in the neoadjuvant setting have been published, retrospective studies have demonstrated encouraging results [9–13].

Similarly, nab-paclitaxel in combination with gemcitabine in the MPACT trial [14] demonstrated an improved overall survival and progression-free survival when compared to gemcitabine alone for the treatment of metastatic PDAC. Subsequently, this combination therapy has also been utilized in the neoadjuvant setting for patients

with borderline or LA disease. Other gemcitabine-based neoadjuvant regimens, such as gemcitabine plus S1 [15] and gemcitabine plus oxaliplatin [16], have also been evaluated in clinical trials with promising results.

Definitions

Resectable/Borderline Resectable/Locally Advanced

Accurate staging and selection of patients is crucial to maximizing the benefits and minimizing the risks of treatment. PDAC can be classified in a spectrum from resectable to unresectable, based on the presence of distant metastases and the tumor's relationship to vascular structures and other organs. It is important that the classification and management of each patient is discussed in a multidisciplinary team. The PDAC multidisciplinary board at the Massachusetts General Hospital (MGH) consists of two or more pancreatic surgeons, one or more gastrointestinal radiologists, two or more medical oncologists, and one or more gastrointestinal radiation oncologist. To determine resectability, the Americas Hepato-Pancreato-Biliary Association (AHPBA)/Society of Surgical Oncology (SSO)/Society for Surgery of the Alimentary Tract (SSAT) consensus criteria [17] are used.

Rationale for the use of Neoadjuvant Therapy in PDAC

Resection offers the only chance for potential cure of patients with PDAC. Additionally, patients who have not received neoadjuvant therapy and are resected with a negative resection margin >1 mm survive significantly longer than patients with an R1 resection or unresectable LA disease [18] (Fig. 1). Therefore, it is extrapolated that neoadjuvant therapy which down-stages patients, so that a margin negative resection can be achieved, could be beneficial.

Similar to other cancers, effective neoadjuvant therapy does not only down-stage cancers and treat undetected early micro-metastases, but also aids in patient selection. While the operative outcomes of pancreatic resections continue to improve, there is still a relatively high morbidity (30–60%) and mortality (1–5%) at high volume centers [19–21]. Neoadjuvant therapy can aid in selecting the best candidates for surgical resection by offering those with good biology who respond to neoadjuvant therapy an operation, while avoiding a resection in patients with aggressive biology which progresses on neoadjuvant therapy. Neoadjuvant therapy may also obviate the need for additional adjuvant therapy. In large trials, such as ESPAC-3 and CONKO 1, adjuvant therapy was not initiated or completed in approximately 10% and 40% of patients, respectively, due to complications associated with the pancreatic operations, disease progression, patients' decision, or toxicity [22, 23].

Patients for whom neoadjuvant therapy is considered should first obtain a tissue diagnosis to confirm the diagnosis. Second, eligible patients should have an adequate

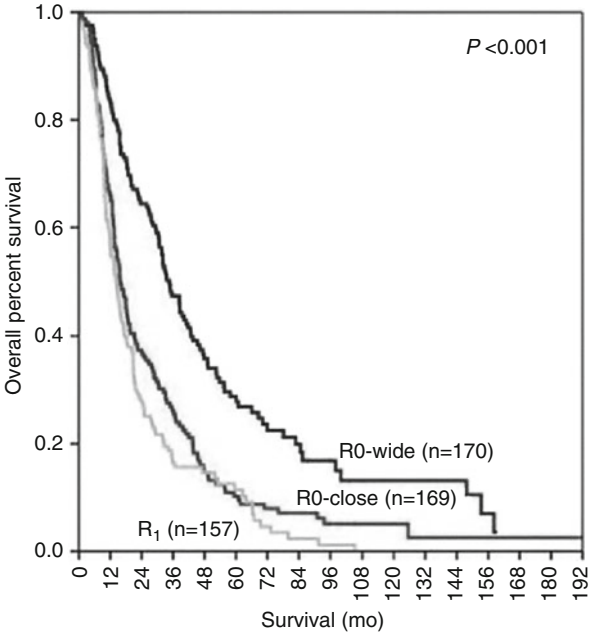

Fig. 1 Improved overall survival of PDAC patients with margins > 1 mm. Kaplan-Meier overall survival curve: R0 resection with wide margin >1 mm versus R0 resection with close (1 mm) margin versus R1. Median survival was 35 versus 16 versus 14 months, respectively. P < 0.001 (Konstantinidis et al. [18])

performance status to withstand neoadjuvant regiments (Eastern Cooperative Oncology Group [ECOG] 0 or 1 [24]). Third, patients should undergo biliary drainage if they present with obstructive jaundice.

Locally Advanced PDAC

No prospective randomized trials with modern chemotherapy have been completed in patients with LA PDAC. FOLFIRINOX is the most widely studied modern neoadjuvant combination regimen, yet the data are mainly derived from small-sample retrospective studies (Table 1). Even fewer data are available for gemcitabine plus nab-paclitaxel. Among patients with BR or LA PDAC who received neoadjuvant FOLFIRINOX alone, 0%–33% were down-staged and resected [25–28]. When FOLFIRINOX was followed by neoadjuvant chemoradiation, the frequency of resectability is increased up to 44% [9–12, 29–34].

Neoadjuvant FOLFIRINOX seems to increase the frequency of negative resection margins. In cohorts of resected FOLFIRINOX patients, an R0 margin was achieved in 41–100% of patients [3, 9–12, 28–32, 34–36]. Rombouts et al. in a systematic review of 14 studies calculated that the total R0 frequency was 77% [37]. The MGH experience in 110 patients was an R0 (>1 mm) resection rate of 81% (unpublished data). This compares favorably with resectable patients who went directly to the operating room and had an R0 rate of approximately 70–80% [22,

23, 38] as well as those who underwent only neoadjuvant chemoradiation where an R0 of 11%–32% was achieved [39].

Survival

A recent patient-level meta-analysis including 13 studies with 355 patients with LA PDAC treated with FOLFIRINOX +/− chemoradiation [13] reported a pooled median overall survival calculated from the start of FOLFIRINOX of 24.2 months (range 10.0–32.7 months) and a progression-free survival of 15.0 months (range 3.0–20.4 months). In the MGH experience of 141 BR/LA PDAC patients, a median overall survival of 34.2 months (interquartile range: 19.9–55.5) from the time of diagnosis was observed. Survival was even better for resected patients who reached an overall survival of 37.7 months (interquartile range: 23.0–55.5) (Fig. 2) and a disease-free survival of 29.1 months (interquartile range: 15.6-not reached) (unpublished data). Although these results are not derived from clinical trials and might suffer from selection bias, they are clearly better than those from historic studies treating LA PDAC patients [5, 7].

Toxicity

The main drawback of combination therapies such as FOLFIRINOX or gemcitabine plus nab-paclitaxel is their high frequency of toxicities when compared to

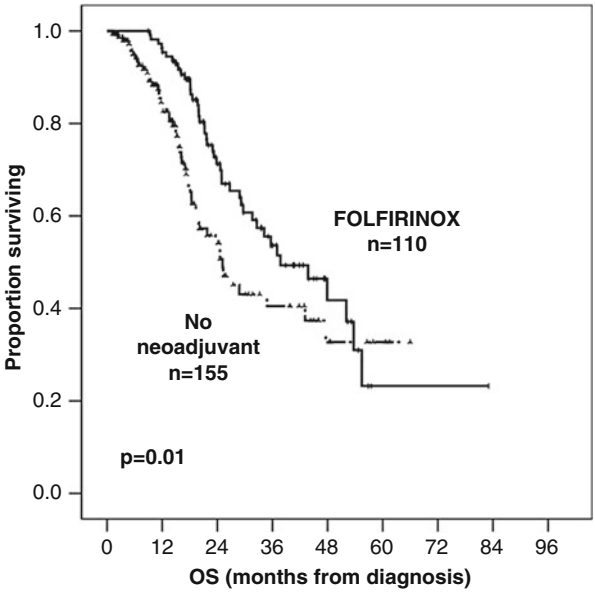

Fig. 2 BR/LA PDAC patients who received neoadjuvant FOLFIRINOX followed by resection had a better overall survival compared to resectable patients who underwent upfront resection. Kaplan-Meier overall survival curves: BR/LA who received neoadjuvant FOLFIRINOX followed by resection versus resectable patients who underwent upfront resection. Median overall survival from diagnosis was 37.7 (interquartile range 23.0–55.5) versus 25.1 months (interquartile range 15.4–not reached), respectively. P = 0.01

monotherapies. The PRODIGE 4/ACCORD 11 trial demonstrated increased toxicity for FOLFIRINOX when compared to gemcitabine for metastatic PDAC [8]. The most common side effects encountered with FOLFIRINOX are neutropenia, thrombocytopenia, diarrhea, vomiting, sensory neuropathy, and fatigue. Specifically, a systematic review of studies on neoadjuvant FOLFIRINOX therapy of LA PDAC [37] calculated a total frequency of grade 3–4 toxicity of 23% (51/220), while according to a recent meta-analysis [13], the pooled grade 3–4 adverse rate was 19.6% for neutropenia, 5.9% for thrombocytopenia, 8.2% for diarrhea, 8.8% for emesis, and 11.7% for fatigue. Interestingly, in the PRODIGE 4/ACCORD 11 trial, FOLFIRINOX reduced the quality of life impairment compared to gemcitabine, making patients actually feel better despite the toxicity associated with the chemotherapy [40].

Borderline Resectable PDAC

In an attempt to increase the rate of margin-negative resections and to improve outcomes, neoadjuvant chemotherapy has been suggested not only in LA PDAC patients, but also in borderline resectable patients. Although many studies have examined neoadjuvant therapy in this population, most are small single-center retrospective studies with mixed borderline/locally advanced cases [41–50].

In the largest study including only BR cases by Katz et al. [51], 125 of 160 BR PDAC patients completed neoadjuvant therapy (chemotherapy, chemoradiation, or both) and restaging. Of those, 79/125 (63%) underwent an operation after neoadjuvant therapy and 66/125 (42%) were resected. Negative margins were achieved in 94% of resected patients and overall survival for resected patients was 40 months.

In the era of modern neoadjuvant chemotherapy, only limited number of cases have been reported [44–50]. In a patient-level meta-analysis (presented as poster at the 2017 Pancreas Club by Suker et al.) including 17 studies with 250 borderline patients, the median OS was 18 months and the margin-negative resection rates ranged from 50% to 100% [52]. Furthermore, the initial results of the Alliance for Clinical Trials in Oncology Trial A021101 [47] demonstrated that of the 22 BR PDAC patients who received modified FOLFIRINOX followed by chemoradiation, 15 (68%) underwent an operation and 12 (80%) had negative margins (>1 mm). The median overall survival was 22 months from the registration to the trial.

Resectable PDAC

The best performers, resectable patients, have historically been the minority of patients who present to the physician. Unfortunately, even in this cohort of patients, 25% die within 12 months of their pancreatic resection (Fig. 3) [38]. Improved patient selection is desperately needed to avoid subjecting patients to a large and complex operation associated with significant morbidity and mortality [53]. Neoadjuvant chemotherapy is one approach to improve patient selection.

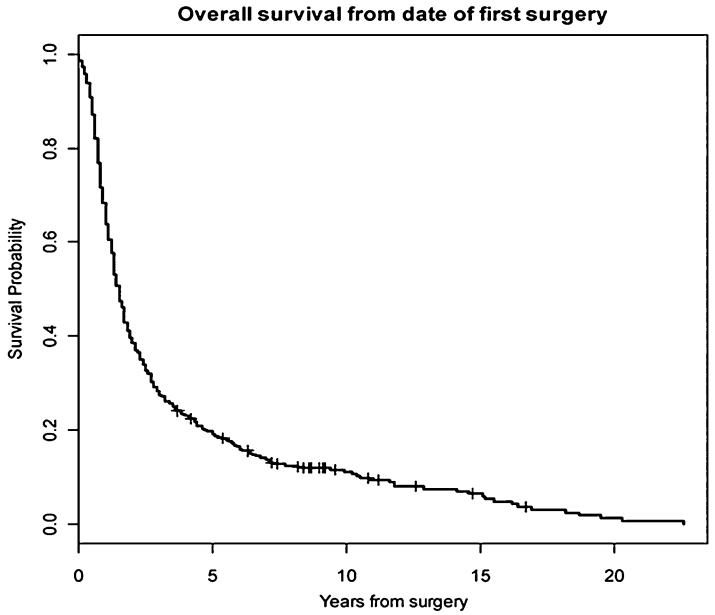

Fig. 3 Pancreatic ductal adenocarcinoma has poor prognosis. Kaplan-Meier overall survival curve: 499 patients who underwent an operation for their PDAC at MGH between 1985 and 2006. Actual survival rate at 5 and 10 years was 19% and 10%, respectively (Ferrone et al. [53])

At least three meta-analyses have investigated the role of neoadjuvant therapy in patients presenting with resectable disease [5, 7, 54]. The pooled frequency of resected patients ranged from 66% to 82% and pooled R0 rates ranged from 82% to 89%. In the meta-analysis by Gillen et al. [5], the pooled median survival of patients initially deemed resectable was 23.3 months for those who were resected and 8.4 months for those who were not. Among prospective studies [7], the weighted mean of the median survival was 18.8 months for all patients initially deemed resectable (resected or not resected), while in the meta-analysis of phase II trials [54], the median survival of this patient population was 23.0 months from diagnosis or the start of neoadjuvant therapy.

Utilizing data from the National Cancer Database in a propensity score-matched analysis [55], resectable Stage I/II patients receiving neoadjuvant therapy followed by an operation had a better survival compared to those who underwent upfront resection (26 vs. 21 months). Additionally, patients in the neoadjuvant group had a lower T stage, lower frequency of lymph node positivity (48% vs. 73%), and a higher negative margin resection rate (83% vs. 76%).

Neoadjuvant Therapy for Resectable PDAC in the era of FOLFIRINOX

As demonstrated above, patients who initially presented with BR or LA advanced disease received neoadjuvant FOLFIRINOX prior to being resected, than patients

with initially resectable disease who received no neoadjuvant therapy [3]. Indeed, the pooled median overall survival of 24.2 months reported in the LA PDAC patient-level meta-analysis by Suker et al. [13] is comparable to the 23.6 months documented in resectable PDAC patients receiving adjuvant gemcitabine in the ESPAC-3 trial [23]. Based on these findings, it has been advocated that neoadjuvant FOLFIRINOX could be used routinely in patients with resectable PDAC [56–58]. Currently, several clinical trials (NCT02782182, NCT02178709, NCT02172976, NCT01560949, NCT02959879, NCT02047474, NCT01660711, NCT02345460) are assessing the benefit of neoadjuvant FOLFIRINOX in the setting of resectable PDAC. Furthermore, for initially resectable patients, NCT02243007 performed at MGH and the SWOG S1505 trial (NCT02562716) are comparing perioperative FOLFIRINOX versus gemcitabine plus nab-paclitaxel. The ESPAC-5F trial (ISRCTN89500674) is comparing resection followed by adjuvant 5-FU versus neoadjuvant gemcitabine plus capecitabine followed by operation versus neoadjuvant FOLFIRINOX followed by resection versus chemoradiation followed by resection.

Response and Follow-up

If patients treated neoadjuvantly progress during treatment, the treatment regimen should be altered. Currently, there is no consensus regarding adjuvant therapy in patients receiving neoadjuvant therapy. MGH follows the NCCN guidelines and checks CA 19–9 every 3 months and imaging every 6 months.

Predictors of Response and Resectability

Several studies [3, 59, 60] have demonstrated that radiological imaging after the completion of neoadjuvant therapy is not a reliable predictor of resectability. Specifically, in the MGH experience including 40 borderline and LA PDAC patients treated neoadjuvantly with FOLFIRINOX +/− chemoradiation, 30% were classified as resectable preoperatively, but 92% of patients underwent an R0 resection. Along the same lines, Katz et al. demonstrated that among patients with borderline PDAC treated neoadjuvantly with gemcitabine-based therapy +/− CRT or CRT alone, only 0.8% of tumors were deemed radiologically resectable preoperatively, but 66% underwent a resection. The inability of radiologic imaging to determine resectability could be attributed to the significant fibrosis which replaces viable tumor tissue in response to neoadjuvant therapy [61, 62]. Currently, imaging is not able to differentiate between viable tumor and fibrosis (Fig. 4).

Several studies have attempted to identify predictors of response to neoadjuvant therapy. Hohla et al. [27] suggested that female gender might be a predictor of

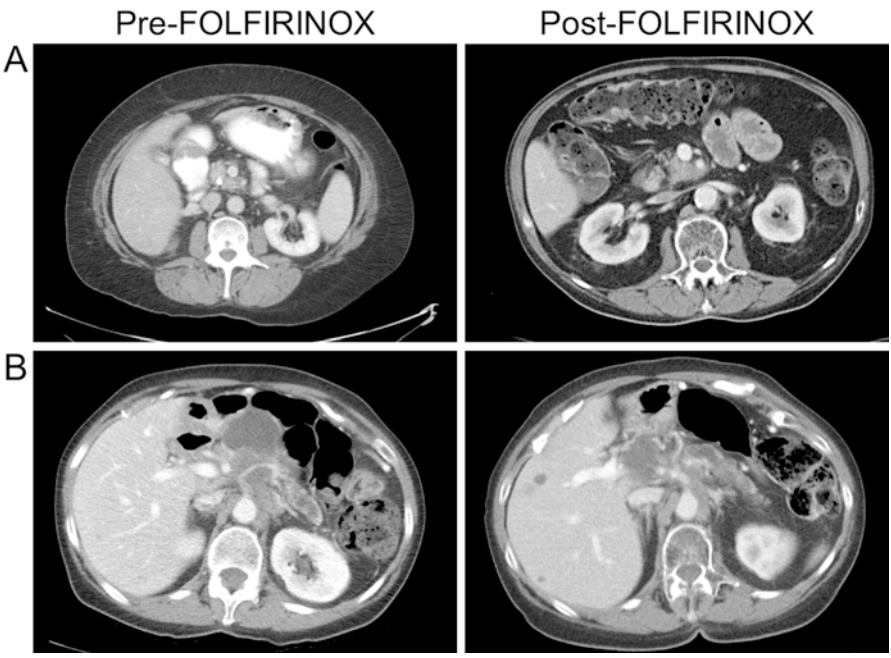

Fig. 4 Imaging does not predict resectability after neoadjuvant FOLFIRINOX. (**a**) 41-year-old female presenting with a 3.6 cm pancreatic mass involving the superior mesenteric artery. CA 19–9 at presentation was 985 U/mL. After 4 months of FOLFIRINOX and 50.4Gy of chemoradiation, her CA 19–9 was 37 U/mL. Final pathology revealed a 1.6 cm T2N0M0 PDAC with negative margins. (**b**) 69-year-old female presenting with a 4.1 cm pancreatic mass involving of the celiac trunk. CA19–9 at presentation was 13,735 U/mL. After 4 months of FOLFIRINOX and 50.4Gy of chemoradiation, her CA 19–9 was 25 U/mL. The CT scan demonstrated a 1.9 cm pancreatic lesion. Final pathology revealed a 2 cm T2N0M0 PDAC with negative margins

response since females had a significantly higher disease control rate of 91.7% compared to 48.0% in male patients ($p = 0.001$). More recently, Bednar et al. [63] demonstrated that pancreatic head/neck lesions (OR 0.307, $P = 0.033$) and SMA involvement (OR 0.285, $P = 0.023$) were independent predictors of resection in LA PDAC patients treated neoadjuvantly with FOLFIRINOX or nab-paclitaxel plus gemcitabine. CA 19–9 levels have also been suggested as a marker of resectability: Boone et al. [64] demonstrated that in borderline resectable patients treated with neoadjuvant therapy (Gemcitabine-based or FOLFIRINOX), a CA 19–9 response of >50% predicted an R0 resection (odds ratio 4.2; $p = 0.05$), while in borderline resectable patients who had an increase in CA 19–9, none of the five (0%) underwent an R0 resection compared with 80% of the remaining cohort ($p = 0.001$). Similarly, Aldakkak et al. [65] demonstrated a correlation between post-neoadjuvant CA-19-9 levels and completion of intended therapy including

resection. Katz et al. [66] demonstrated that post-neoadjuvant CA 19–9 < 61 U/mL in upfront resectable patients receiving neoadjuvant chemoradiation had a high positive predictive value for undergoing resection, but a limited negative predictive value.

On the cellular and molecular level, predictive markers are also lacking [67]. Capello [68] and colleagues demonstrated in a comprehensive study that high expression of carboxylesterase 2 might be a predictor of response to FOLFIRINOX, on the basis that carboxylesterase 2 converts irinotecan into its active form, SN-38, which induces apoptosis in PDAC cells. Based on the absence of a reliable marker of resectability as described above, aggressive management of PDACs which have not progressed on neoadjuvant therapy is encouraged. Patients in whom there is no evidence of metastases and a decrease in CA19–9 should be offered a surgical exploration. Determination of resectability should be performed intraoperatively. It is suggested that involved or narrowed vascular structures are examined by serial frozen-section biopsies and that resection is aborted in cases of positive biopsies.

Conclusion

Neoadjuvant therapy may benefit PDAC patients within the whole spectrum of resectability. Patients with locally advanced PDAC may be rendered resectable and offered an operation with a high R0 rate, leading to a survival comparable to upfront resectable patients who offered an operation followed by adjuvant chemotherapy. In borderline resectable PDAC patients, neoadjuvant therapy may increase the frequency of margin-negative resections and improve outcomes. Lastly, in patients presenting with resectable disease, neoadjuvant chemotherapy may aid in selecting surgical candidates by avoiding an operation with high postoperative morbidity and mortality in patients with poor tumor biology. Combination regimens such as FOLFIRINOX and gemcitabine/nab-paclitaxel are preferred over monotherapies in patients who have a good performance status. In the absence of reliable predictors of resectability following neoadjuvant chemotherapy, surgical exploration of all patients who have not disease progression is encouraged. As ongoing neoadjuvant trials for PDAC mature, the impact of neoadjuvant therapy will help us better guide PDAC patients.

Differential Therapy Based on Tumor Heterogeneity in Pancreatic Cancer

Juan Iovanna, Benjamin Bian, Martin Bigonnet, and Nelson Dusetti

Contents

Abstract

A major impediment to the effective treatment of patients with pancreatic ductal adenocarcinoma (PDAC) is its molecular heterogeneity, which is reflected in an equally diverse pattern of clinical outcomes and in response to therapies. An efficient strategy in which PDAC samples were collected by endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) or surgery and preserved as patient-derived xenografts (PDX) and as a primary culture of epithelial cells was developed. Multiomics analysis, including transcriptomic and pharmacological studies, was performed on these PDX. As expected, significant molecular and phenotypic heterogeneity was observed. However, bioinformatic analysis was able

to discriminate between patients with bad or better prognosis. Primary cultures of cells allowed to analyze their relative sensitivity to standard drugs (gemcitabine, 5FU, oxaliplatin, irinotecan active metabolite SN-38, and docetaxel), as well as more original anticancer drugs such as 5-aza-2′-deoxycytidine (5-AZA-dC) or the nicotinamide phosphoribosyltransferase (NAMPT) inhibitor FK866. The establishment of chemograms in vitro allowed to identify individual profiles of drug sensitivity. Remarkably, the response was extremely heterogeneous and patient dependent. It was also found that transcriptome analysis predicts the anticancer drug sensitivity of PDAC cells. Furthermore, an original strategy to identify PDAC dependent on the MYC oncogene and consequently more sensitive to bromodomain and extraterminal inhibitors (BETi) was developed. In conclusion, using this original approach, it was found that multiomics analysis of PDX could predict the clinical outcome of patients, the sensitivity to anticancer drugs, and the pharmacological response to new therapeutic strategies. This opens up a future setting in individualized medicine, aiming to stratify patients in order to select the most appropriate treatments for each group.

Introduction

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal human malignancies and a major health problem, causing around 300,000 deaths per year worldwide [1]. Despite considerable research efforts in the past decades, conventional treatment approaches have had limited impact, including surgery, radiation, chemotherapy, or a combination of these. The prognosis is poor with only 20% of patients alive 1 year after diagnosis [1]. Given this scenario, the search for new treatments that will counter PDAC progression and increase patient life expectancy has been given high priority. Particularly, future therapeutic agents are expected to be "molecularly targeted" in order to specifically affect PDAC cells while leaving normal tissues undamaged. Recent phase III clinical trials in unselected PDAC populations tested bevacizumab, erlotinib, and axitinib, which are molecularly targeted agents, combined with gemcitabine. These trials did not show robust survival benefits, probably because they were tested in unselected PDAC populations that were highly heterogeneous [2–4]. In fact, a major impediment to the effective treatment of PDAC is the molecular heterogeneity of the disease, reflected in diverse clinical response patterns to therapy. This heterogeneity is shown by the heterogeneous evolution observed in patients with PDAC, with a survival from 2 to 3 months to more than 5 years after diagnosis, and with a strong difference in susceptibility to classical as well as novel drugs. This may be explained

by the fact that each PDAC has a combination of several modifications to intracellular pathways that will result in variable susceptibility to drugs, metastasis development, and therefore survival [5–7]. Currently, no proposed treatments have taken into account this heterogeneity. In fact, the drugs received by patients suffering from PDAC are chosen according to their general performance status and the stage of their disease. No study of the tumor can predict its responsiveness to the treatment nor give a prognosis to the disease progression. For example, objective response rates of 31.6% in FOLFIRINOX-treated patients and 9.4% in patients treated with gemcitabine have been reported, showing that around 70–90% of patients are non-responders, respectively [8, 9].

Toward a Molecular Pathology Field: Transcriptome of the PDAC is Correlated with Clinical Outcome

Molecular heterogeneity of PDAC has been extensively reported [10–13]. The transcriptome analysis of a cohort of pancreatic PDX revealed a significant correlation between the PDAC phenotype and its clinical outcome [14]. A clustering analysis, using an unsupervised approach, revealed two groups of patients characterized by a bad or a better prognosis. Around 500 transcripts were overexpressed, whereas around 400 transcripts were downregulated in short-term survivors compared with long-term survivors (Fig. 1). Importantly, gene ontology analysis on

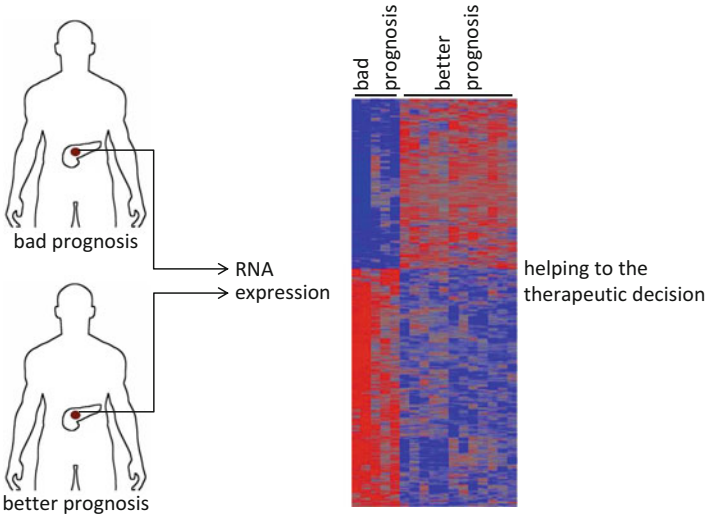

Fig. 1 *RNA expression analysis of PDAC predicts the clinical outcome*. Heat map shows the RNA expression profile of patients with bad and better prognosis

differentially expressed genes showed a significant enrichment in biological processes associated with cancer such as cell cycle, mitosis, response to cellular stresses, DNA metabolism, chromosome organization, and cellular metabolism, with a false discovery rate of >0.001. This indicates that these pathways were preferentially activated [14]. Analysis of clinical data from short-term and long-term survival patients showed that the first group had poorly differentiated tumors whereas long-term survival patients presented partially or well-differentiated tumors. Therefore, these data are not surprising since poorly differentiated tumors are expected to be associated with bad prognosis compared with well-differentiated tumors [15–18]. This correlation between tumor differentiation and prognosis has been previously documented. Wasif et al. described a correlation between tumor differentiation and patient survival time, as well as using tumor differentiation as a value to predict response to treatment [19]. In fact, tumor differentiation, or "grade," is increasingly used as an independent prognostic factor; it appears with as much impact as prognostic tumor size or lymph node metastatic invasion [20]. Although the grade of differentiation can be estimated by the pathologist after a pancreatectomy, this is only possible in about 15% of patients. However, using a set of molecular markers identified in recent works, the grade of the PDAC could be estimated in only a small number of cells obtained by endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA). This is almost impossible to determine by microscopy analysis alone on these small samples. In fact, based on these results, it seems evident that using expression of some of these molecular indicators on small PDAC samples obtained by EUS-FNA would help in predicting the behavior of the PDAC and shape the therapeutic strategy. In theory, the microscopic analysis of small PDAC samples could be replaced by a molecular analysis combined with nanotechnologies, e.g., NanoString. Although this novel approach is promising, it must be validated in independent cohorts of patients.

The PDAC Phenotype is Associated with Chemosensitivity

In a recent study, the sensitivity of PDAC primary cell lines derived from PDX to five gold standard chemotherapies (gemcitabine, 5FU, oxaliplatin, docetaxel, and the irinotecan active metabolite named SN-38) was analyzed, with drug concentrations ranging from 0.001 to 1000 μM. These personalized chemograms allowed to obtain a dose-response curve characterizing each patient [14]. These results demonstrated that each patient-derived cell line shows its own chemogram profile, indicating that each PDAC has a particular and specific profile of response (Fig. 2). This is clinically relevant since sensitivity or resistance to one drug does not predict sensitivity or resistance to another. Another important point to be noted is that after incubation with some drugs, it was almost impossible to kill all the cells even with very high concentrations such as 1000 μM for gemcitabine, oxaliplatin, docetaxel, or 5FU or 100 μM for SN-38. For example, 20–50% of cells were resistant to 1000 μM of gemcitabine, 5–30% remained alive when treated with 100 μM of SN-38, 10–70%

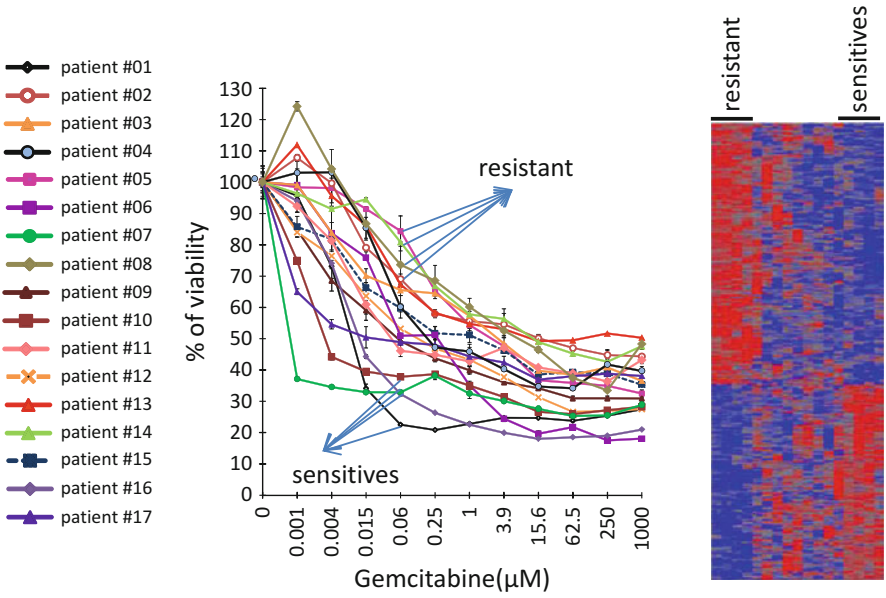

Fig. 2 *Chemograms*. PDAC-derived cells were treated with increasing concentrations of gemcitabine, and the surviving cells were measured after 72 h of treatment. A sensitivity profile was obtained for each patient. *RNA expression and drug sensitivity*. The heat map is showing the RNA expression profiles of PDAC-derived cells with resistance or sensitivity to the treatment with gemcitabine

when treated with 1000 μM 5FU, and 0–25% with 1000 μM oxaliplatin. An exception was found when cells were treated with docetaxel, where doses as low as 0.001 μM were able to kill from 20% to 90%, depending on the primary culture, and almost all cells were killed by 62.5 μM. This observation can be explained by the fact that primary cultures are representative of the different cell populations present in the tumor, as PDAC is known to be heterogeneous [21]. This emphasizes clinical applicability because the chemogram may detect the percentage of sensitive and resistant cells to a drug and therefore be a helpful tool to the oncologist selecting the second line of treatment for a given patient.

Then it was studied the correlation between drug response and PDAC phenotype by performing a clustering analysis of each PDX transcriptome (Fig. 2). Surprisingly, some sets of genes were identified as specifically overexpressed or underexpressed in resistant and in sensitive cells, respectively [14]. Importantly, it was observed that a small number of common genes associated with drug resistance or sensitivity, suggesting that the phenotype of the sensitivity or resistance is specific for each drug [14]. Finally, it was noted that the genes associated with sensitivity or resistance to treatment are different to the genes associated with bad or better prognosis. This indicates that survival and drug sensitivity are regulated by independent mechanisms [14].

Repositioning Unusual Anticancer Drugs for Treating a Selected Subgroup of Patients with PDAC

The Example of 5-AZA-dC

5-AZA-dC (5-aza-2′-deoxycytidine) is a DNA methyltransferase (DNMT) inhibitor incorporated into DNA as a deoxycytidine analogue, forming irreversible covalent bonds with DNMT at cytosine sites targeted for methylation [22]. 5-AZA-dC demonstrates activity against hematological malignancy [23] and is used as the first line of treatment in acute myeloid leukemia patients over 65 years old who are not candidates for intensive chemotherapy [24]. However, its efficacy in solid tumors seems to be limited [25]. The rationale to use methyltransferase inhibitors to treat tumors is that neoplastic cells exhibit global hypomethylation with localized hypermethylation of CpG islands and increased levels of methyltransferases activity [26]. Moreover, aberrant hypermethylation of CpG islands is associated with transcriptional silencing of genes, which not only plays a role in tumorigenesis but may also influence response to anticancer agents [27, 28]. Therefore, reversing gene methylation and epigenetic silencing has the potential to influence tumor growth, sensitivity to anticancer agents, and ultimately clinical outcome [29]. Several studies have documented the relevance of epigenetic alterations in pancreatic cancer and the effect of 5-AZA-dC on pancreatic tumor cells [30]. In clinical trials, although the 5-AZA-dC has shown an objective response in some patients, its overall efficacy remains relatively low. For these reasons, 5-AZA-dC is not used in the treatment of patients with PDAC. Therefore, this drug has been selected as a proof of concept to study whether a drug with a relevant mode of action is efficacious in a particular subgroup of PDAC patients and whether that group can be identified by specific markers. Several primary cultures of PDAC cancer cells were subjected to increasing concentrations (from 0 to 80 μM) of 5-AZA-dC in order to study their sensitivity and to obtain a dose-response curve. Using this approach, it was possible to compare these PDAC-derived primary cultures and estimate their relative chemosensitivity. As with the gold standard anticancer drugs, each patient-derived primary culture showed a different pattern of chemosensitivity with an IC_{50} ranging from 0.29 μM to $>$80 μM, which is a range of more than 275-fold. Then their relative sensitivity in vivo using pancreatic PDX was validated [31].

This strong variability in response to the drug encouraged to go forward with this study, trying to find molecular markers that may identify sensitive patients. Surprisingly, there is no correlation between sensitivity to 5-AZA-dC and DNMT1, DNMT3A, or DNMT3B at the expression level. In addition, expression of other molecules associated with DNA methylation, such as Mecp2 (methyl-CpG-binding protein 2) or polycomb-group proteins including SUZ12, EED, EZH1, and EZH2, does not correlate with the 5-AZA-dC sensitivity. These results are interesting and original because they show that the effect of the drug is not systematically dependent on the level of its target, indicating that sensitivity is dependent on other cellular mechanisms. This is reflected in the lack of literature associating efficacy of 5-AZA-dC and levels of DNMT1 expression in tumors, with the exception of data

obtained by Li et al. This concluded that PDAC-derived cells with low DNMT1 expression tend to be sensitive to low doses of 5-AZA-dC [32]. Altogether, these results strongly suggest that there is little to no correlation with their targets. However, it has been found that sensitivity to 5-AZA-dC treatment does correlate with long-term survival in patients carrying well- and moderately differentiated tumors. This is in agreement with the fact that some genes typically expressed in poorly differentiated PDAC, such as MUC3A, MUC5AC, GATA6, or HNF4A, are differentially overexpressed in sensitive PDAC-derived cells compared with resistant PDAC-derived cells. These data strongly suggest that 5-AZA-dC treatment should be more efficient against well- and moderately differentiated tumors than against the poorly differentiated ones.

The Example of the NAMPT Inhibitor FK866

Nicotinamide phosphoribosyltransferase (NAMPT) catalyzes the rate-limiting step of nicotinamide condensation with 5-phosphoribosyl-1-pyrophosphate to yield nicotinamide mononucleotide and is overexpressed in several tumors. FK866 ([3,5-bis(trifluoromethyl)phenyl][(2R)-2-(3-hydroxy-4-methylbenzyl)-4-{2-[(2S)-2-(methoxymethyl)morpholin-4-yl]ethyl}piperazin-1-yl]methanone dihydrochloride) is a noncompetitive highly specific inhibitor of NAMPT and is clinically interesting as it is a potent antitumor drug both in vitro and in vivo [33]. Many recent studies provide evidence that it selectively inhibits growth of various types of cancer cells, with no effect on normal cells [34]. It causes cellular death by apoptosis [35] and induces autophagy. Clinical studies have revealed that FK866 induces toxicity to proliferating hematopoietic cells, due to its short half-life in circulation and the resulting prolonged treatment regimens. Therefore, the efficiency of NAD+ (nicotinamide adenine dinucleotide)-depleting drugs, such as NAMPT inhibitors, when used alone is expected to be low due to insufficient tumor selectivity [36–38]. For this reason, FK866 has mainly been tested as an additive drug to other well-known chemotherapies. It increased the chemosensitivity of gastric cancer cells to 5FU [39], potentiated the effects of cisplatin and etoposide in neuroblastoma cell lines [40], and massively reduced the overall metabolic activity in xenografts, impairing PDAC growth [41].

It was studied the effect of the NAMPT-inhibitor FK866 in PDAC-derived cells. Primary cultures of PDAC-derived cells were exposed to increasing concentrations of FK866 (from 0 to 1000 nM) to determine their sensitivity by plotting dose-response curves. Using this approach, it was estimated the relative chemosensitivity of the different PDAC-derived cell cultures by comparing the resulting IC_{50} values. These data reveal that each PDAC-derived cell culture has its own sensitivity to FK866 with a huge range of IC_{50} values (from 0.30 to >1000 nM), suggesting a very high response variability among patients [42]. This has also been described for the gold standard drugs and 5-AZA-dC. Next, it was hypothesized that NAMPT level, as a specific target of FK866, could predict drug sensitivity. Consequently, it was quantified NAMPT at the transcriptional level in pancreatic PDX. The mRNA

expression level was then plotted, and the FK866 IC_{50} values were used to investigate and compare the global sensitivity of PDAC cells. These results showed that resistance to FK866 positively correlates with the expression level of NAMPT transcript indicating that PDAC expressing higher levels of NAMPT has an increased resistance to FK866 treatment, possibly for a stoichiometric reason.

It is unlikely that NAMPT inhibition could be used as a monotherapy for treating patients with a PDAC since FK866 at high concentrations is very toxic, due to its mechanism of action affecting basic functions of both cancerous and normal cells. Therefore, the only possibility is to use FK866 in combination with cytotoxic drugs to potentiate their effect. Consequently, it was studied the sensitivity of PDAC to the treatments with gemcitabine alone or gemcitabine combined with FK866 in several PDAC-derived primary cultures [42]. The combined treatment (gemcitabine + FK866) synergistically decreased the cell viability of 70% of the primary cultures compared with treatment with gemcitabine alone. Surprisingly, this added benefit was almost negligible when combined with 5FU or oxaliplatin [42]. Then it was analyzed the effect of FK866 alone or combined with gemcitabine on the intracellular levels of NAD+ and found a significant correlation between low levels of NAD + in pancreatic PDX and its sensitivity to the treatment. Overall, these results suggest that most PDAC patients could take advantage of co-treatment with gemcitabine + FK866. In addition, quantification of NAMPT mRNA expression or NAD+ concentration in PDAC could be used as potential biomarkers for determining their sensitivity to the co-treatment of gemcitabine + FK866.

Identifying Novel Personalized Targets for Treating Patients with PDAC

Like other malignant diseases, PDAC results from a complex combination of genetic, epigenetic, and environmental factors, which gives rise to a particularly heterogeneous disease [43–45]. Consequently, this heterogeneity highlights the need to stratify patients with the goal of predicting better responses to therapies. One strategy to discover potential markers for patient stratification is to focus on identifying pathways that are deregulated in tumors, particularly when tumor cell survival depends on keeping these alterations (e.g., oncogene "dependence" to survive and grow) [46, 47]. Therefore, it is logical to assume that targeting of these pathways with specific inhibitors, when available, should lead to cell growth arrest, death, and tumor regression. Using this rationale, it should be possible to select, by means of a few markers, a particular subgroup of patients whose tumor cells are "addicted" to certain pathways, and use appropriate inhibitors to treat these patients' tumors, which is the major goal of modern individualized medicine.

In this way, a frequently deregulated, though insufficiently therapeutically exploited, pathway in PDAC involves "dependence" on the *c-Myc* oncogene [48]. This transcription factor influences the expression of a significant number of genes involved in cell growth, proliferation, and apoptosis [49–52]. In fact, this oncogene has been implicated in the pathogenesis of one-third of all human malignancies.

Early studies confirmed the oncogenic role of c-MYC in PDAC using genetically engineered mouse models, which upon overexpression of this gene display increased pancreatic tumorigenesis [53]. In addition, using a variety of experimental models, it has been shown that upregulation of MYC is sufficient to induce the formation of PDAC without additional genetic manipulation of any cell survival pathways [54], and deletion of one *c-Myc* allele decelerates tumor development in vivo [55]. Based on these data, in recent work, Wirth et al. propose to use MYC as a stratification marker of PDAC [56]. Altogether, these features indicate that *c-Myc* behaves as a cancer driver gene for PDAC. Consequently, many efforts have been dedicated to identify potent MYC inhibitors as new therapeutic options [57–60]. Key to these efforts has been the discovery that the bromodomain and extraterminal family of proteins (BET) are necessary for MYC activity [61, 62]. These proteins are efficiently inhibited by BET inhibitors (BETi), such as JQ1, suppressing PDAC development in mice by inhibiting both MYC activity and inflammatory signals [63]. In addition, inhibition of MYC expression is thought to be an essential mechanism by which BETi suppress tumor progression [64–66]. Thus, identifying a subgroup of PDAC patients based on their c-MYC-high status and testing their response to BETi could be of paramount medical importance. Consequently, this hypothesis was recently tested [67].

To this end, a learning cohort of 55 pancreatic PDX was created and characterized and gene expression profiling performed using an Affymetrix platform. From this dataset, a panel of 239 RNAs known to be regulated by MYC was selected and performed a hierarchical clustering analysis. The obtained dendrogram indicates the presence of two major subgroups that were logically defined as MYC high and MYC low. Interestingly, it was observed that around of 30% of patients are characterized by an increase in the expression of MYC target RNAs. In addition, it was also found that the tumors of the MYC-high subgroup showed lower differentiation, proliferated more, and presented a shorter survival time (median is 9.2 months for the MYC-high subgroup vs. 18.8 months for the MYC-low subgroup). Moreover, the relapse-free survival median is 5.6 months and 11.5 months for MYC-high and MYC-low subgroups, respectively. These results indicate that PDAC of the MYC-high subgroup is more aggressive. To optimize the response to BETi treatment, a minimal specific MYC signature was defined to be used to stratify PDAC tumors as MYC high or MYC low. A total of 16 genes were selected, 10 were identified from the gene set corresponding to the upregulated genes in the MYC-high group, and 6 were the top-scoring downregulated genes in the MYC-high patients, found from the whole gene expression profile. An algorithm was developed by using the ratio of both up- and downregulated genes to identify PDAC tumors with either MYC-high or MYC-low phenotypes (Fig. 3). The accuracy of this algorithm was confirmed using an independent validation cohort. Therefore, it was concluded that the algorithm based on these small numbers of transcripts is reliable for identifying tumor subtypes based on their c-MYC status.

Accordingly, it has been assumed that the subgroup of PDAC belonging to the MYC-high phenotype should be more sensitive to the pharmacological inhibition of MYC activity. This currently cannot be targeted directly but instead is targeted

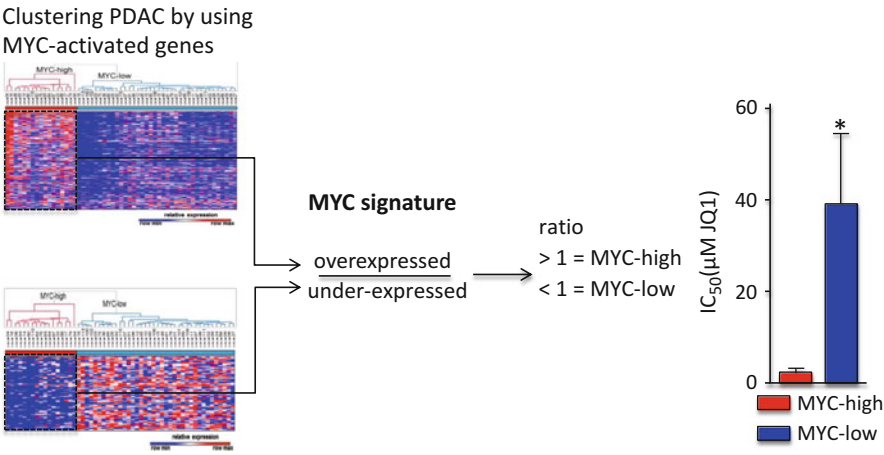

Fig. 3 *MYC signatures predict sensitivity to BETi*. MYC controls the expression of a large panel of target genes that characterize tumor phenotypes. A 16-transcript signature classifies a MYC-dependent (MYC high) PDAC subgroup by performing the ratio of overexpressed over underexpressed genes after normalization. Ratio > 1 indicates a MYC-high profile, and ratio < 1 corresponds to MYC-low profile. MYC-high tumors are more sensitive to JQ1 treatment, a well-described bromodomain inhibitor

through the inactivation of BET proteins. To test the hypothesis, a panel of pancreatic PDX-derived primary cultures has been treated with the well-characterized BETi compound JQ1. Cells were incubated with a large range of drug concentrations, and it has been found that MYC-high cells exhibit higher sensitivity to the BETi treatment compared with the MYC-low cells. The mean IC_{50} for the MYC-high cells was 2.3 µM $\pm$ 0.8, whereas the corresponding IC_{50} for the MYC-low cells was 39.22 µM $\pm$ 16. Then, a preclinical analysis was performed by treating PDX presenting MYC-high or MYC-low phenotypes with JQ1 to validate the in vitro results. As expected, MYC-high samples responded efficiently to the treatment, whereas samples with the MYC-low phenotype were more resistant. Altogether, from the in vitro and in vivo results, it can be assumed that MYC-high tumors are more sensitive to BETi. The main conclusion is that having tools to determine tumors with high MYC activity is of clinical interest in order to identify patients sensitive to BETi. These results also suggest that a similar strategy may be useful in designing individualized medicine efforts aimed at stratifying patients to novel treatments.

Conclusion

Determination of efficient molecular signatures is clinically useful for detecting patients having a particular pattern of sensitivity to a given treatment. The approaches presented here are easily applicable and low cost. This is particularly

beneficial in nonoperable tumors, which represent around 85% of PDAC. Currently, in these patients, a biopsy is systematically taken by EUS-FNA as a diagnosis confirmation procedure prior to treatment. These biopsies represent a valuable source of cancer cells, which may serve as the source of tumor macromolecules such as RNA. In turn, this RNA may be used for measuring expression of RNA sets of interest (expression signatures) to determine a particular phenotype. Unfortunately, one of the main difficulties found with biopsies is that they are systematically contaminated by blood, stroma, and, in some cases, normal pancreatic or gastrointestinal cells, which may make molecular analyses difficult. The preparation of PDX from biopsies in order to obtain sufficient clean material is technically feasible, but it would take nearly 6 months. This delay is incompatible with clinical application. The alternative is to prepare organoids directly from biopsies. This allows amplification by cell replication and purity because only epithelial cancerous cells will grow in the selective culture media. It is possible to obtain suitable material within 2–3 weeks of culture. Then, it is easy to purify RNA from organoids and measure expression of several informative transcripts using the NanoString platform (Fig. 4). This approach of transcriptional level quantification presents a great advantage in that it does not require previous amplification, which can introduce unwanted

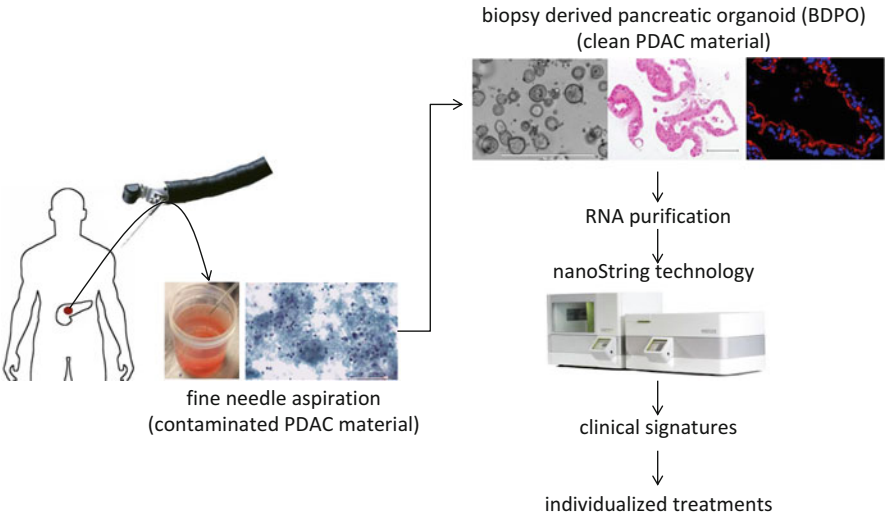

Fig. 4 *Molecular signatures of PDAC tumors will be routinely performed for individualized treatment approaches in the near future*. It will be of particular interest for non-operable patients which represent about 85% of PDAC. Currently, in these patients, a biopsy is systematically taken by EUS-FNA before starting the antitumor treatment as a diagnosis confirmation procedure. These biopsies represent a valuable source of cancer cells which may serve as the source of RNA. But the material obtained is largely contaminated by blood and tumor stroma or neighbor tissues. The alternative is to prepare organoids directly from biopsies that allows amplification by cell replication and purity since only epithelial cancerous cells are growing in the selective culture media. Sufficient organoids can be obtained within 2–3 weeks of culture. RNA from organoids can be easily purified and expression of several informative transcripts measured by a NanoString platform

technical bias. Importantly, all these manipulations take only 3 additional days. It is very probable that in the near future, the treatment of cancer will be preceded by a precise and extensive molecular characterization of cancer cells in order to select the most appropriate treatments, creating an individualized medicine approach. PDAC is undoubtedly one of the malignant diseases that most urgently needs this approach, since treatment with standard drugs is inefficient. Although this chapter was focused on PDAC, a similar strategy could also be applied to other cancer types.

Neoadjuvant Chemoradiation for Operable Pancreatic Cancer: The Importance of Local Disease Control

Chad A. Barnes, Susan Tsai, William A. Hall, Beth A. Erickson, and Douglas B. Evans

Contents

Abstract

Pancreatic cancer (PC) is one of the most neuroinvasive tumors of the gastrointestinal tract, and perineural invasion is associated with high rates of local-regional

recurrence. Historically, the goal of local-regional control in patients with PC has largely been secondary to the prevention of metastatic disease progression. However, with improving systemic therapies, patients are now experiencing unprecedented survivals and are living long enough to be susceptible to local recurrence. Such local recurrences usually occur in the neural tissue enveloping the celiac artery, superior mesenteric artery, or hepatic artery. The use of neoadjuvant chemoradiation has been effective in decreasing perineural invasion and may be particularly effective when given preoperatively prior to the immune suppressive effects of surgery and the hypoxic tissue disruption that occurs following pancreatectomy. This chapter focuses on the rationale and importance of neoadjuvant radiation therapy in the treatment of localized, potentially operable PC and provides an introduction to current neoadjuvant radiation therapy techniques, including intensity modulated radiation therapy and stereotactic body radiation therapy.

Introduction

Optimal treatment sequencing for patients with localized, operable pancreatic cancer (PC) is the subject of intense investigation as it is now appreciated that almost all patients have radiographically occult metastatic disease at the time of diagnosis [1]. Multimodality therapy has become the standard; for example, in patients treated with a surgery-first approach, all current guidelines recommend 6 months of postoperative (adjuvant) therapy, regardless of final pathologic stage [2]. Unfortunately, the delivery of adjuvant therapy following pancreatectomy is unpredictable, as approximately 40–60% of patients will not receive adjuvant therapy due to perioperative morbidity or failure to adequately recover from surgery [3, 4]. The inability to deliver adjuvant therapy to patients with a high probability of harboring micrometastatic disease has fueled an interest in alternative treatment sequencing. Preoperative (neoadjuvant) therapy is a logical alternative to surgery-first treatment sequencing. Inherent to a neoadjuvant approach is the immediate delivery of systemic therapy to a population of patients at high risk of harboring disease outside of the primary pancreatic tumor. It also allows for a 3–5 month period of treatment during which patients will evidence response or progression [5]. Among patients who complete all intended neoadjuvant therapy and surgery, the median overall survival has been reported to range from 34 to 45 months, suggesting that early delivery of systemic therapy prior to surgery may be even more effective than adjuvant therapy [6, 7]. The timing or sequencing of systemic therapy in operable patients may have oncologic value beyond just the receipt of systemic therapy. As survival duration increases, local disease control will become even more important as patients will live long enough to be susceptible to local recurrence. An obvious

clinical reality is that only patients who are alive and free from distant metastatic disease-related death are prone to local recurrence. The short survival experienced by most patients after a potentially curable operation for PC, due to early metastatic disease progression, has made assessment of local disease control impossible. Isolated local recurrences (after pancreatic resection) virtually always arise within the perineurium of the autonomic nerves which surround the celiac, hepatic, or superior mesenteric arteries. Such recurrences are difficult to treat and prevention is the preferred strategy. This chapter will focus on the pathophysiology of local perineural recurrence and the importance of radiation therapy in its prevention.

Brief Update on Pretreatment Staging

Historically, resectability was determined at the time of operation for patients with localized PC; if the surgeon felt the tumor was resectable, the tumor was removed and the patient was declared to have had resectable disease. If at the time of operation the tumor was not felt to be resectable, the patient was declared to have locally advanced disease. Subsequently, an objective CT-based staging system was developed to improve the classification of patients eligible for neoadjuvant clinical trials, where a preoperative definition of resectable disease was needed to identify eligible patients for trial enrollment [8]. The benefit of such an objectively defined staging system for patients and physicians is obvious – the goals of therapy can be specifically defined at the time of diagnosis and optimal treatment sequencing can be initiated. To the extent that surgery is necessary (albeit usually not sufficient) for cure, patients who may be eligible for potentially curative surgery can be accurately defined; and those patients with locally advanced (nonoperable) disease are also identified. Historically, among patients who have locally advanced PC as defined by preoperative imaging, surgery was not felt to be possible. However, it soon became clear that a gray-zone existed between the definitions of resectable and locally advanced PC. Borderline resectable disease was used to define patients with arterial abutment and short segment venous (superior mesenteric–portal vein [SMV-PV]) occlusion who, in the past, would have been considered locally advanced [9]. However, after neoadjuvant therapy the borderline classification was developed for patients who demonstrated a response to treatment, as measured by clinical benefit, improved imaging, and a decline in tumor marker profile, and were being considered for surgery [10]. Patients with borderline resectable PC are at the highest possible risk for a positive margin of resection due to tumor-artery abutment, require a more complex operation usually involving vascular resection and reconstruction, and may be at higher risk for harboring radiographically occult distant metastatic disease. For these reasons, at the Medical College of Wisconsin (MCW), induction therapy consisting of chemotherapy followed by chemoradiation is the preferred treatment sequence in this patient population. The chemoradiation portion of induction therapy is thought to be particularly important for those patients with

arterial abutment in the hope of sterilizing at least the periphery of the tumor and thereby preventing a positive margin of resection.

The staging system used for clinical trial enrollment at MCW is illustrated in Table 1 and incorporates an expanded description of locally advanced disease which

Table 1 Staging classification of localized PC

Vascular structures which determine the stage of disease for localized pancreatic cancer		Resectable	Borderline resectable	Locally advanced	
				Type A	Type B
Tumor-artery anatomy	SMA (usually pertains to a tumor of the head or uncinate process)	No radiographic evidence of abutment or encasement	≤180° (abutment)	>180° (encasement) but ≤270°	>270° encasement
	Celiac artery (usually pertains to a tumor of the pancreatic body)	No radiographic evidence of abutment or encasement	≤180° (abutment)	>180° (encasement) but does not extend to the aorta and amenable to celiac resection (with or without reconstruction)	>180° and abutment/ encasement of the aorta
	Hepatic Artery (HA) (usually pertains to a tumor of the pancreatic neck/head)	No radiographic evidence of abutment or encasement	Short segment abutment/ encasement without extension to celiac artery or HA bifurcation	>180° encasement with extension to celiac artery and amenable to vascular reconstruction	>180° encasement with extension beyond bifurcation of proper HA into right and left hepatic arteries
Tumor-vein anatomy	SMV-PV	≤50% narrowing of SMV, PV, SMV/PV	>50% narrowing of SMV, PV, SMV/PV **with** a distal and proximal target for reconstruction	Occlusion **without** option for reconstruction	
Traditionally considered for resection after neoadjuvant therapy		**Yes**	**Yes**	**Yes**	**No**

has been termed Type A and Type B [11]. Patients with Type A locally advanced disease may be candidates for surgical resection of their tumor after induction therapy, whereas surgery will likely never be possible in those patients with Type B disease. Because the visceral arteries have a perineural sheath which envelopes them, there is often a plane of dissection between the adventitia of the artery and the neural sheath which allows for sharp dissection of the tumor off the artery. In contrast, complete 360° encasement would require that one cuts through tumor to separate the superior mesenteric artery (SMA) from the tumor, SMA encasement of this magnitude is considered nonoperable at MCW. With regard to the celiac artery, increasing experience has demonstrated the safety of celiac resection in carefully selected patients with tumors of the pancreatic body which have responded to induction therapy [12]. The threshold for considering surgery following induction therapy in patients with locally advanced PC is evolving. However, it is important to note that the expanded use of surgery in very highly selected patients is guided by an objective, reproducible pretreatment and preoperative CT-based staging system (Table 1).

Perineural Invasion in Pancreatic Cancer

Since the pancreas is a retroperitoneal organ which is adjacent to major vascular structures including the SMA and celiac trunk, PCs which abut or encase these vessels often infiltrate. The pancreas is richly innervated by the adjacent celiac and superior mesenteric nerve plexuses, and the close proximity of a PC to both intra- and extrapancreatic nerves allows for the direct infiltration of cancer cells into nerves and the dissociation of cells away from the primary tumor [13]. This process of cancer infiltration into neural tissue is called perineural invasion (PNI) and PNI is a risk factor for local disease recurrence. PNI has been observed in as many as 80–100% of resected PC specimens, making PC one of the most aggressive and neuroinvasive gastrointestinal malignancies [13–18]. In a study of 90 patients with resected PC by Takahashi et al., 88 (98%) patients had intrapancreatic PNI and 47 (52%) had both intra- and extrapancreatic PNI within the retroperitoneal perivascular neural tissues along the SMA, common hepatic artery (CHA), and aorta [16]. Extrapancreatic PNI was identified as a poor prognostic factor associated with decreased overall survival. This finding has been corroborated by a recent meta-analysis, including 121 studies, which identified a 1.68-fold increased risk of death with the presence of PNI (95% CI: 1.47–1.92; $p < 0.00001$) [15]. Importantly, PNI was also associated with a 2.53-fold increased risk of disease progression (95% CI: 1.67–3.83; $p = 0.0001$).

The high incidence of PNI in PC may not be related purely to anatomic considerations, as interestingly, the presence of PNI is independent of tumor size and location, suggesting that additional factors may promote the pathogenesis of PNI [16]. Peripheral nerve Schwann cells are present in precursor lesions of PC in both human PC and genetically engineered mouse models, and the frequency of Schwann cells in the precursor lesions has been correlated with the frequency of neural

invasion in PCs [19]. Furthermore, studies have shown that cancer associated fibroblasts promote the migration of peripheral nerve Schwann cells through Cadherin-2 (neural cadherin) and beta-catenin signaling [20]. In addition, murine models have demonstrated the secretion of glial cell line-derived neurotrophic factor by nerve cells has a direct chemotactic effect on PC cells, resulting in the directional migration of cancer cells towards nerves, and subsequently invasion of nerves by cancer cells [21, 22]. These findings suggest that neural tissue may be recruited by the tumor as an early event in carcinogenesis rather than neural infiltration occurring as a late event of cancer metastases.

Given the ubiquitous presence of PNI and its high association with local recurrence, strategies which enhance local-regional control are likely to be important in the management of PC. Even among patients who successfully undergo pancreatic resection, the local failure rate has been reported to be as high 80% [23]. In more contemporary series of patients who underwent a surgery-first approach, local recurrence rates have been reported to be 24–45% [23, 24]. Although the rationale for neoadjuvant therapy in patients with PC was motivated by a desire to both detect and treat micrometastatic disease prior to surgery, unexpectedly, neoadjuvant therapy, particularly neoadjuvant chemoradiation, has also been associated with superior local-regional disease control. Such improved local control has been associated with lower rates of positive margins, lymph node metastases, and PNI observed in the posttreatment pathologic specimens [25–27]. Neoadjuvant therapy results in decreased rates of PNI as compared to rates observed with a surgery-first approach [18, 26, 28]. For example, in a study by Ferrone et al. evaluating the benefit of neoadjuvant FOLFIRINOX among patients with borderline resectable or locally advanced PC, PNI was identified in 29 (72.5%) of 40 patients treated with neoadjuvant FOLFIRINOX with or without radiation as compared to 83 (95.4%) of 87 treated with a surgery-first approach [18]. Similarly, Chatterjee et al. observed PNI in 123 (58%) of 212 patients treated with neoadjuvant chemoradiation as compared to 48 (80%) of 60 patients who were treated with a surgery-first approach. Among the 212 patients who received neoadjuvant chemoradiation, the presence of PNI was associated with a significant decrease in disease-free survival (11 months with PNI vs. 22 months without) and overall survival (28 months with PNI vs. 56 months without) [17].

Although not completely understood, current data suggests the mechanism by which chemoradiation decreases PNI in pancreatic tumors may be a twofold process. In general, the delivery of radiosensitizing chemotherapy with concurrent radiation is effective at inducing cell death, thereby decreasing the number of cancer cells along the intrapancreatic nerves. However, there is data suggesting that radiation may specifically alter the nerve microenvironment resulting in less PNI [29]. In an in vivo murine model, PC cells were injected into the surgically exposed sciatic nerves of mice. Utilizing both magnetic resonance imaging (MRI) and hematoxylin and eosin (H&E) staining, the investigators observed more extensive PNI in the

sciatic nerves of the nonradiated mice as compared to radiated mice [29]. Further, the delivery of radiation resulted in the suppression of glial cell line-derived neutrophic factor secretion by nerve cells, which is known to have a chemotactic effect on PC cells. The mean concentration of glial-derived neutrophic factor secreted from sciatic nerves was reduced to 65 pg/mL from 130 pg/mL following a single dose of 8 Gy [29].

Are Local Recurrences Preventable with Appropriate Treatment Sequencing?

Local recurrences are a major cause of morbidity and mortality among patients with resected PC, and arguably, they may be preventable. In series of patients treated with surgery first, isolated local recurrence as the first site of recurrence is reported in 20–60% of patients, and as many as 80% will have developed recurrent local disease by the time of death – powerful data in support of the critical need for effective local-regional therapies [24, 30]. A rationale for neoadjuvant chemoradiation is to enhance sterilization of any local-regional micrometastatic disease prior to surgery, thereby reducing the probability of residual microscopic disease which can serve as the nidus for local treatment failure. Neoadjuvant chemoradiation has proven to be effective at achieving local-regional disease control, and this has resulted in a remarkable decrease in the incidence of local recurrences. One of the first trials to demonstrate the benefit of neoadjuvant chemoradiation was a phase II clinical trial performed at M.D. Anderson Center which evaluated the efficacy of neoadjuvant gemcitabine-based chemoradiation among 86 patients with localized PC of which 64 (74%) patients completed all neoadjuvant chemoradiation and surgery. The median time to progression among all 64 resected patients was 28.6 months from diagnosis, and local recurrences developed in 7 (11%) patients [6]. In another cohort of 69 patients with resectable or borderline resectable PC, treated with neoadjuvant intensity modulated radiation therapy (IMRT), the local recurrence rate was 5 (7%) [26]. The significant decrease in local recurrence rates suggests the delivery of chemoradiation prior to surgical intervention may be a highly effective strategy to treat the occult local-regional micrometastatic disease.

Lastly, it is important to note that most local recurrences develop within millimeters of the SMA and celiac artery, as these vessels are immediately adjacent to a surgeon-created margin and PCs frequently extend along the perivascular neural tissues [24]. Although meticulous surgical technique may allow for the dissection of tumor away from the adventitia of the artery, over 40% of patients will have residual tumor cells at the resection margin, which often remain undetected [31]. In a report by Katz et al. involving 194 patients with localized PC of which 147 (76%) received neoadjuvant chemoradiation, the investigators observed the delivery of neoadjuvant chemoradiation was associated with an increased SMA margin distance (>1 mm) and this was associated with a decreased incidence of local recurrence. The median

time to disease recurrence was 19.5 months for all patients, and isolated local-regional recurrence occurred in 14%, isolated distant in 37%, and concurrent local and distant in 9% of patients [32]. This study highlights the importance of neo-adjuvant chemoradiation and meticulous surgical technique, as both may be necessary to achieve local disease control and minimize the rate of local recurrences.

Evolution of Neoadjuvant Chemoradiation for PC

Radiation to the upper abdomen must be delivered with careful planning and great accuracy to adeptly irradiate the defined pancreatic tumor volumes while partially avoiding the many normal organs which live near the pancreas. Significant progress has been made in defining the treatment targets and shaping the dose distribution to securely cover the areas that need radiation and partially avoid the normal adjacent structures. Advanced multi-planar imaging used for radiation planning, including CT, MRI and PET scans, enables excellent target definition, selective dose escalation to key parts of the target volume, and reduction of the irradiated volumes in the sensitive upper abdomen. This leads to better patient tolerance and reduced intraoperative complications if used in the neoadjuvant setting [33]. Use of three dimensional image-based conformal radiotherapy (3DCRT) has been closely followed by development of IMRT.

Intensity Modulated Radiation Therapy (IMRT) for Pancreas Cancer: Neoadjuvant Approaches

IMRT is an advanced version of 3DCRT that entails use of sophisticated computer controlled radiation beam delivery by varying beam intensities within each beam portal to improve the conformity of the dose distribution to the shape of the tumor with associated avoidance of adjacent normal organs. IMRT treatment planning is performed using inverse treatment planning where the planning target volume (PTV) dose is specified as well as the allowable doses/volumes to the adjacent normal organs. The computer program then calculates a customized intensity pattern to best meet the specified dose volume constraints for the PTV and normal organs. In addition to accurate target definition, image guided radiation therapy is the process of positioning the patient on the treatment table and using on board imaging to localize the tumor and adjacent organs at risk before each delivered radiation treatment. This is an essential aspect of IMRT which allows for tighter margins by assessing and correcting for pancreatic motion due to breathing and variable GI filling and motility. IMRT allows for a reduction in morbidity as well as for dose escalation, and is the standard technique for definitive or neoadjuvant irradiation for PC.

The great advantage of IMRT is to produce a greater conformity of the dose distribution than with 3DCRT. This enables dose manipulation to create a sharp dose

fall off near the boundaries of tumor vs. critical normal organs. This may allow for a higher dose to be delivered to the tumor and a lower dose to the organs at risk of radiation injury or both. IMRT has proven to lead to less acute and late toxicity in multiple series [34, 35, 36]. Additionally, this enables excellent target volume coverage, and if needed, dose escalation to critical portions of the tumor near adjacent blood vessels. Neoadjuvant chemoradiation using an IMRT technique can facilitate a margin negative resection with customized treatment of high-risk volumes to maximize local control while at the same time minimizing dose to adjacent organs at risk [26].

Defining Treatment Volumes and Treatment Doses

One of the challenges of using IMRT is accurately defining the tumor or target volume. Appropriate treatment delivery is critically dependent on accurate target identification. IMRT was initially piloted in the postoperative setting and there was concern that use of IMRT could lead to an increase in local failures if the target volume was not accurately defined during planning and accurately treated daily. IMRT, in addition to image guided radiation therapy, has subsequently been used in the EORTC/US Intergroup/RTOG 0848 adjuvant trial after a successful pilot demonstrated no increase in local recurrence [37, 38]. A consensus postoperative atlas was created to help insure consistency in contouring (RTOG Consensus Panel Contouring Atlas for the Delineation of the Clinical Target Volume in the Postoperative Treatment of Pancreatic Cancer (https://www.rtog.org)). A modification of this atlas, based on targeting the most common sites of recurrence, has been published by Dholakia et al. [24] There has been even more debate as to the definition of target volume in the preoperative setting.

At MCW, in the neoadjuvant setting, the entire pancreatic head or body or tail are targeted, rather than just the visible gross tumor volume, along with the celiac axis and superior mesenteric artery and vein [26] (Fig. 1). This targets perineural spread of the tumor as well as microscopic lymph nodes adjacent to the large vessels coming off the aorta. Lesions that are near the portal vein, portal venous confluence, IVC or aorta, or the branches of the celiac artery (common hepatic artery) are also selectively targeted, if close to or involved by the primary lesion. Only suspicious nodes are targeted rather than comprehensively treating all nodal regions at risk. There is even more debate about targeting unresectable disease as this is often the setting where selective dose escalation is needed. CT often underestimates target volume whereas MRI may offer better soft tissue resolution and more accurate target definition. An international consensus document outlining MR-based delineation is now available [39].

Achieving a negative margin resection in the setting of tumor abutment or invasion of adjacent vessels is particularly challenging. Margin negative resection offers the best chance of cure. The presence of positive margins leads to inferior survival and increased local recurrence. Wang et al. used IMRT to not only treat the

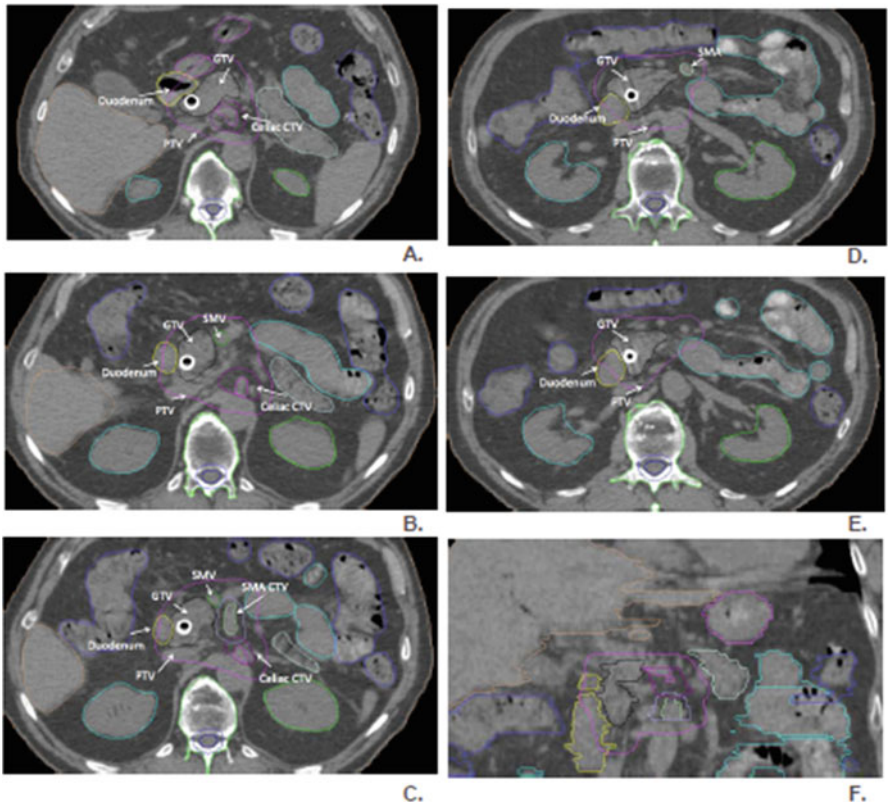

Fig. 1 Representative target volumes for preoperative treatment of resectable adenocarcinoma of the pancreatic head; (**a**–**e**) axial slices from superior to inferior, (**f**) coronal view. *GTV* gross tumor volume, *SMV* superior mesenteric vein, *SMA CTV* superior mesenteric artery clinical target volume, *CTV* celiac artery clinical target volume, *PTV* planning target volume

pancreas and adjacent vessels, but to use a higher dose (56 Gy) near the tumor vessel interface while treating the rest of the irradiated volume with a lower dose per fraction (50.4 Gy). Dose painting or simultaneous integrated boost technique is possible with IMRT, and this has resulted in a statistical trend towards increased resection in patients who received this boost without an increase in toxicity [40]. A similar approach was taken by Huang et al. with delivery of higher doses (56 Gy) to areas of vessel invasion using a combination of PET and CT for tumor definition and lower doses (50.4 Gy) to subclinical disease. In the 23 of 25 patients with borderline resectable disease who went on to resection, 22 (96%) had negative margins (>1 mm) [41]. Dose escalation is challenging as the normal tissues adjacent to the pancreas are very dose sensitive. IMRT along with daily image guidance can allow for delivery of higher doses than 3D conformal plans with better dose sparing of the adjacent

stomach, duodenum, bowel, and kidneys. The dose can be escalated to pivotal portions of the tumor, such as the retroperitoneal margin or tumor further away from the GI tract, while pulling dose away from the adjacent normal organs [42]. Even some patients with locally advanced PC can receive neoadjuvant dose escalated radiation and go on to margin negative resections in this setting [42–44]. IMRT as a definitive therapy has been reported in a number of studies [34, 38, 42, 43].

Altered Fractionation Schemes for Pancreatic Cancer

Historically, radiation therapy for PC, such as IMRT, has typically applied a conventional or "fractionated" treatment course; the radiation therapy is typically broken up over approximately 4–6 weeks of daily treatments. This delivery approach was used for a variety of reasons. First, radiation therapy was given using a two-dimensional treatment technique, which made the ability to visualize normal structures (such as the small bowel, large bowel, or stomach) extremely difficult. Therefore, doses of radiation therapy had to be given in a manner that was within the dose tolerance of these normal structures. Thus, very few options were available to give selectively higher doses to a tumor and spare normal structures, and most patients with PC were treated with low doses of radiation therapy (45–54 Gy) given over 25–28 fractions. This dose selection was largely controlled by the radiation tolerance of the normal tissues near the pancreatic tumor (small bowel and stomach). Technological changes in the ability to deliver radiation therapy over the past 15 years have presented a considerable opportunity to alter the way radiation therapy is delivered and has resulted in the ability to deposit high doses of radiation therapy to a tumor over a shorter treatment time. Considerable investigation has taken place over the past 10 years examining the use of higher doses of radiation therapy with shorter treatment schedules (Fig. 2).

A commonly used modality for the treatment of patients with PC is stereotactic body radiation therapy (SBRT) [45]. SBRT is a rapidly growing radiation therapy technique with applications in numerous malignancies [45]. This is an especially exciting area of radiation therapy delivery that results in a different mechanism of cell kill than conventionally fractionated radiation therapy. Treatments with SBRT are typically given over five or fewer fractions. SBRT has been extensively studied in PC with reports having been published from numerous, single institution series [46–55]. There are several conceptual advantages to the use of SBRT in patients with PC. First, the treatment course with SBRT typically takes less than 2 weeks, which is considerably shorter than conventionally fractionated radiation therapy, which extends over a time of 5–6 weeks. This shorter treatment course may permit an earlier return to systemic therapy. The mechanism of cell kill in SBRT may also hold advantages over conventionally fractionated radiation therapy, particularly for PC. For example, SBRT provides an ablative mechanism of cell kill as compared with conventional therapy [45]. However, SBRT for PC may also carry risks. A

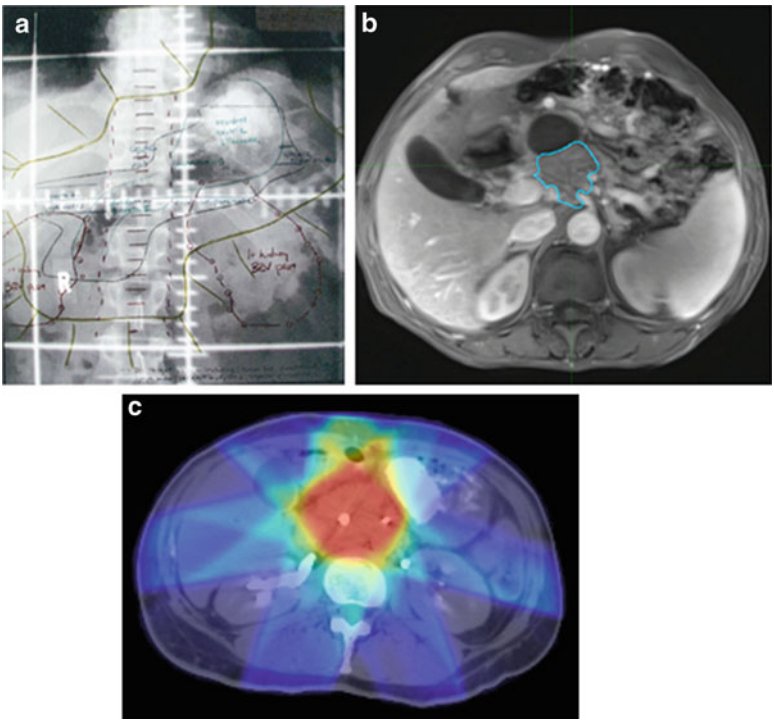

Fig. 2 (**a**) Represents a historic radiation treatment plan using 2D planning techniques, little ability to visualize normal structures or adapt dose accordingly. (**b**) Reflects modern era tumor contouring using MRI. (**c**) Radiation dose deposition (red represents high/prescription dose, blue represents lower radiation dose). Structures such as the small bowel and kidney can be seen clearly and avoided

higher radiation dose per fraction in close vicinity to the small bowel and stomach carries a risk of late toxicity to these organs. In addition, the treatment volumes with SBRT are usually smaller than conventionally fractionated radiation therapy. This may lead to a theoretically higher risk of marginal miss and regional nodal recurrence. While there are numerous theoretical advantages to the use of SBRT, there is a near complete absence of randomized data that has compared SBRT to conventionally fractionated radiation therapy. Table 2 summarizes the current SBRT series that have been published in patients with locally advanced PC. In addition to the multiple series that have described the use of SBRT for PC, recent publications have also examined the use of different fractionation schedules [42]. Krishna et al. present a range of doses and fractionation schedules, most of which are much shorter than fractionated treatment schedules ranging from 5 fractions to 28 fractions. Several patients were treated with fractionation schedules between 10 and 15 fractions. These would not typically be considered SBRT schedules, however these treatment courses do represent a different approach as compared with more conventional and

Table 2 Select series of SBRT in locally advanced pancreatic adenocarcinoma

Author	Year	Dose of radiation	Number of patients	1 Year freedom from local progression	Overall survival months	Acute/late grade 3 or higher toxicity

prolonged treatment courses. Such fractionation approaches may have considerable advantages when compared with more prolonged, fractionated treatment courses. A comparison of these treatment approaches to SBRT approaches may be prudent for future study.

Technological advances in radiation therapy have enabled dramatic changes in dose and fractionation schedule for patients with PC. There is an obvious need for a randomized clinical trial comparing different fractionation schedules in patients with localized PC to determine how such treatments effect pattern of failure and patient survival.

Results from the Medical College of Wisconsin

Between 2009 and 2016, 245 consecutive patients completed neoadjuvant therapy and surgery at MCW for biopsy-proven PC. Of the 245 patients, 126 (51%) had resectable PC and 119 (49%) had borderline resectable PC; the median age at the time of cancer diagnosis was 65 years (interquartile range [IQR]: 12). Neoadjuvant therapy for the 245 patients consisted of chemotherapy alone in 38 (15%), chemoradiation in 83 (34%) or both in 124 (51%) patients. Of the 126 patients with resectable PC, 90 (71%) received chemoradiation, including 11 (9%) patients who were treated with induction chemotherapy prior to chemoradiation. The remaining 36 (29%) patients with resectable tumors were treated with chemotherapy alone. The preferred neoadjuvant treatment regimen for patients with borderline resectable PC consisted of 2 months of induction chemotherapy followed by

chemoradiation, and 113 (95%) of the 116 patients with borderline resectable PC were treated with both therapies. Overall, 207 (85%) of the 245 patients received chemoradiation which was gemcitabine-based chemoradiation in 164 (79%) and capecitabine-based chemoradiation in 43 (21%). Of the 162 patients who received chemotherapy, 77 (48%) patients received FOLFIRINOX, 79 (48%) received combination chemotherapy with either a 5-fluorouracil or a gemcitabine backbone, and 6 (4%) patients received gemcitabine monotherapy.

Of the 245 total patients, 192 (78%) underwent a standard pancreaticoduodenectomy (PD), 30 (12%) underwent a distal pancreatectomy, 17 (7%) underwent a total pancreatectomy and 6 (3%) underwent a pylorus-preserving PD. Vascular reconstructions were performed in 73 (30%) of the 245 patients due to tumor encasement. Margin negative (R0) resections were achieved in 219 (89%) patients and 147 (60%) had lymph node negative (N0) disease. Interestingly, of the 38 patients who did not receive neoadjuvant chemoradiation, only 16 (42%) had N0 disease and 22 (58%) had N1 disease. The majority of tumors were T3 ($n = 154$, 63%) and there was no difference in T stage with or without chemoradiation. However, a complete tumor response (T0) was observed in 6 (2%) patients and all 6 patients had received neoadjuvant chemoradiation. Data regarding PNI was included in the pathology report of 239 patients, and 152 (64%) had PNI and 87 (36%) patients did not. PNI was observed in 31 (82%) of the 38 patients who did not receive neoadjuvant chemoradiation as compared to 121 (58%) of the 207 patients who received neoadjuvant chemoradiation ($p = 0.01$).

Additional adjuvant therapy was administered to 144 (59%) of the 245 patients, and the remaining 101 (41%) patients were observed. Of the 144 patients who received postoperative therapy, adjuvant therapy consisted of chemotherapy in 116 (81%), chemoradiation in 3 (2%), and both in 25 (17%). All 245 patients underwent routine surveillance at 3–4 month intervals with physical examination, laboratory studies, and CT imaging. At a median of 25 months, 136 (55%) of 245 patients developed recurrent disease. Recurrent disease was assessed radiographically and rare cases were confirmed with a tissue biopsy. The site(s) of first disease recurrence were classified as local (peripancreatic or perivascular recurrences; Fig. 3), regional (peritoneal or abdominal wall recurrences; Fig. 4), distant (all other recurrence sites), or multisite.

For all 245 patients, disease recurrence was local in 19 (8%), regional in 17 (7%), distant only in 76 (31%) patients, and multisite in 24 (10%) patients. The median time to recurrence from the date of diagnosis for patients with local, regional, distant, and multisite recurrences was 18.4 months, 11.7 months, 15 months, and 15.1 months, respectively. Of the 100 patients with distant recurrences, the liver was the most common site of recurrence. The median overall survival was 36.5 months for all 245 patients. The median overall survival by first site of recurrence for patients with no recurrence, local, regional, distant, and multisite recurrence was: not reached; 31.5 months; 21.4 months; 24.8 months; and 20.6, respectively.

Note the normal diameter of the SMV (blue *) and the normal tissues surrounding the SMV on immediate postoperative exam. 1-year follow-up exam after surgery demonstrates locoregional tumor recurrence encasing the SMV (blue *) for 360° (yellow arrow)

Conclusion

PC spreads quickly to local-regional perineurium due to the rich innervation of the pancreas by the autonomic nervous system. If patients live long enough, they will be susceptible to local recurrence in the neural tissue enveloping the celiac artery, SMA, or hepatic artery; such local recurrences are anatomically reproducible and a very consistent form of disease recurrence. Isolated local failure is uncommon when median survivals are short – as median survival increases, local recurrences may become more common. Isolated tumor cells in perineural tissue may experience a privileged environment and be less effectively treated with systemic therapy than, for example, microscopic metastatic disease in liver or lung. Such may not be the

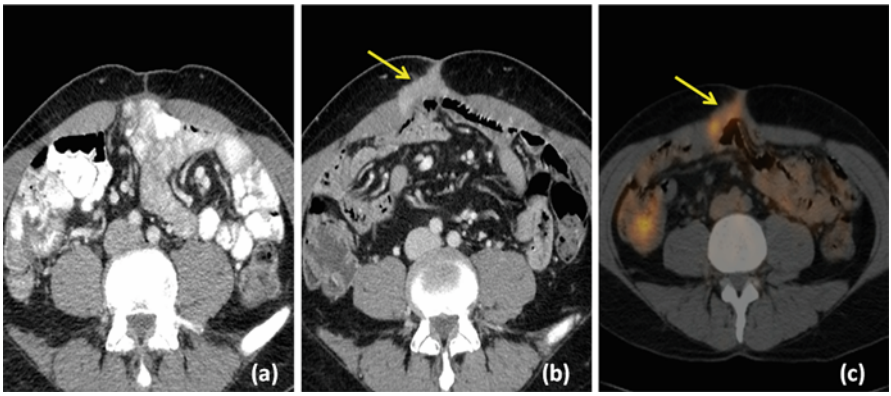

Fig. 4 Regional tumor recurrence in the periumbilical abdominal wall. Short-term postoperative CT exam (**a**) and 2-year follow-up postoperative CT (**b**) and PET/CT (**c**) exams at the same level. Note the new mass (yellow arrow) in the periumbilical abdominal wall region overlying the small bowel loops which is shown to be PET FDG positive (yellow arrow)

case if perineural tumor infiltration is treated with chemoradiation, especially when given preoperatively prior to the immune suppressive effects of surgery and the hypoxic tissue disruption that occurs following pancreatectomy. There is tremendous excitement over the emergence of altered fractionation schemes, techniques for tumor targeting using real-time MRI, and dose/schedule innovations which may make the delivery of neoadjuvant radiation easier and less toxic. In the opinion of the authors, the failure to incorporate modern radiation therapy techniques into the treatment schemas of patients with operable PC could be an error and one that will become noticeable when survival durations increase due to more effective systemic therapies.

Part III

New Directions

Development of Novel Diagnostic Pancreatic Tumor Biomarkers

Lucy Oldfield, Rohith Rao, Lawrence N. Barrera, and Eithne Costello

Contents

Abstract

As the incidence of pancreatic ductal adenocarcinoma cancer (PDAC) increases, the need to improve the outcome for patients with this deadly disease becomes all the more pressing. Earlier detection of PDAC has the potential to improve

survival, and biomarkers that enable earlier diagnosis are sought after. Some of the challenges associated with developing new diagnostic biomarkers for PDAC are reviewed here, including the need for appropriate control groups and the necessity to account for established confounding factors such as obstructive jaundice. High-risk groups, including individuals with new-onset diabetes, are discussed, and the findings of studies utilizing samples from pre-diagnostic cohorts to monitor changes in biomarker levels occurring in the weeks and months prior to diagnosis of PDAC are appraised. Progress toward identification of specific biomarker types is provided, and a variety of sources of biomarkers are examined, including blood, urine, pancreatic juice, gut lavage fluid, and extracellular vesicles. Additionally, a range of biomarker types are reviewed, including protein biomarkers, circulating tumor cells, circulating tumor DNA, and microRNAs. New developments with respect to emerging biomarkers, such as metabolites, are also examined. While progress to date has been slow, clear advances are being made, and the promise of biomarkers with clinical utility is in reach.

Keywords
Pancreatic cancer · Biomarkers · New-onset diabetes · Obstructive jaundice · Early detection

Introduction

The majority of cancers of the pancreas are histologically classified as pancreatic ductal adenocarcinoma (PDAC). For 80% of patients, the diagnosis of PDAC comes after the disease has spread locally or to the liver and other organs. This excludes surgery and severely limits curative treatment options. The overall 5-year survival of 3–5% for pancreatic cancer patients has not improved for many decades and is attributed at least in part to diagnosis occurring at a time when medical intervention does not significantly alter the outcome. PDAC is no longer considered to be a symptomless disease. However, nonspecific symptoms such as backache or lethargy have many possible underlying causes, and pancreatic cancer remains a very challenging disease to detect in the early stages. Overt or alarming symptoms, such as obstructive jaundice, often manifest late in the course of the disease. Almost half of pancreatic cancer patients are diagnosed following an emergency presentation to hospital.

At What Point in PDAC Disease Progression would Biomarker-Facilitated Detection Lead to an Improvement in Patient Outcome?

The World Health Organization (WHO) advocates that for 30% of all cancers, an early diagnosis determines whether the patient can be cured (www.who.int/cancer/en/index.html). Certainly, in the case of pancreatic cancer, patients eligible for

potentially curative surgery have a better prognosis than those with locally advanced or metastatic disease who are not amenable to surgery. Thus, biomarkers that increase the proportion of patients with tumors that are resectable could significantly enhance the overall survival [1].

The term biomarker has been defined as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" [2]. Biomarkers that can facilitate earlier detection of pancreatic cancer are sought after, and much investment has taken place over several decades. However, despite a large number of publications, CA19-9, an epitope of sialylated Lewis blood group antigen, remains the sole biomarker that is in routine use for managing patients with PDAC [3, 4]. A number of factors underpin the failure to translate candidate biomarkers into clinical use for pancreatic cancer diagnosis. PDAC, ranked 11th in terms of incidence, is not as common as other cancers. Moreover, as the vast majority of patients are ineligible for surgery, the availability of pancreatic cancer tissue has in the past been limiting. Until recently, tissue samples were not available at all from PDAC patients who did not undergo surgery. Currently, most patients are diagnosed by fine-needle aspiration (FNA), which yields only small quantities of material for research purposes. PDAC tissue is composed of several cell types, which can potentially complicate biomarker studies using tissue. Moreover, it is now understood that PDAC tumors are characterized by high levels of genomic instability and heterogeneity [5, 6], which may alter the pattern of some biomarkers from patient to patient.

Understanding the nuances of PDAC is critical to the study of diagnostic biomarkers. Nowadays it is uncommon to see a PDAC biomarker study that does not include samples from patients with chronic pancreatitis as controls, alongside healthy controls. However, important additional controls are often sadly lacking. A majority of PDAC patients have tumors involving the pancreatic head, which is associated with obstructive jaundice [7]. Jaundice leads to a buildup of proteins in the circulation and can give rise to false-positive findings in blood-borne biomarker studies [8–10], so should be accounted for. It may also be important to consider other comorbidities, such as diabetes, which are discussed later.

Finally, the aim of diagnostic biomarker studies is to discover biomarkers that will allow disease detection at a time when therapeutic intervention is feasible and will improve prognosis. With current treatments, facilitating the detection of PDAC that is already metastatic is unlikely to provide any benefit to patients, and earlier intervention is necessary. Surgery combined with chemotherapy currently provides the only chance of pancreatic cancer cure. Thus, detecting PDAC when it is still amenable to potentially curative surgical resection or when chemotherapeutic intervention would enable surgery by causing downstaging of locally unresectable disease could improve overall survival. The most recent European Study Group for Pancreatic Cancer trial, ESPAC-4, demonstrated that the adjuvant use of gemcitabine plus capecitabine gave a 5-year survival rate approaching 30%. However, the search for biomarkers that will inform the presence of PDAC that is resectable is hampered by the fact that most patients are diagnosed when the disease is advanced, and the samples provided for research by such patients may not provide

information on the characteristic of early-stage disease. Interrogating samples obtained in months prior to PDAC diagnosis could potentially provide insight into biomarkers that appear earlier in the timeline of PDAC disease progression. The use of cohort studies, such as the European Prospective Investigation into Cancer and Nutrition (EPIC) [11] or UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) [12, 13], has begun to provide insight into markers that are potentially indicative of early disease, as well as markers that are not [14–16]. Recent evidence that preneoplastic lesions are capable of disseminating into the bloodstream [17] begs the question of whether biomarkers of such lesions are required, in order to be sure of detecting early disease. Progress toward such biomarkers is discussed later.

The Current Gold Standard

The best application of CA19-9 is in predicting clinical course during and following treatment, with a rise in CA19-9 levels potentially signifying disease recurrence. CA19-9 has a sensitivity of approximately 80% for PDAC diagnosis [18]. Around 5% of people are Lewis ab negative and as a consequence do not secrete CA19-9 [19]. The specificity of CA19-9 for PDAC diagnosis is also around 80% [18]. This relatively low specificity is due to the fact that CA19-9 is elevated in benign conditions, such as pancreatic inflammation [3], and precludes the use of CA19-9 in large-scale population screening, because of the large number of false positives that would be generated. The values for sensitivity and specificity quoted above were attained by testing CA19-9 in individuals already diagnosed with PDAC. Recent studies have however attempted, using pre-diagnostic cohorts, to evaluate whether CA19-9 levels increase prior to clinical presentation of PDAC. Using case-control samples gathered as part of the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), CA19-9 levels >37 U/mL were found, at a specificity of 95%, to have a sensitivity of 68% up to 12 months prior to diagnosis. At the same specificity, sensitivity decreased to 53% up to 24 months prior to diagnosis. An independent study found CA19-9 to have much lower sensitivity for PDAC detection pre-clinically [20]. In pre-diagnostic sera obtained from cases of pancreatic cancer enrolled in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO), the sensitivity of CA19-9 for PDAC was 17.2% at 95% specificity for patients 1–12 months from diagnosis [20]. Enhancing the performance of CA19-9 for pancreatic cancer diagnosis by adding additional biomarkers or early indications/symptoms of PDAC is clearly desirable [21–23].

Carcinoembryonic antigen (CEA) has been used with some accuracy in the diagnosis of pancreatic cancer and is currently used clinically alongside CA19-9 and imaging. CEA is overexpressed in other tumors, such as colorectal tumors [24], and as such lacks specificity as a stand-alone marker for pancreatic cancer. A recent meta-analysis of CEA as a diagnostic tool found that for identification of pancreatic cancer the mean sensitivity was 44% (95% CI 38.5–50.0%) and the mean specificity was 87% (95% CI 82.5–91.2%) [25]. In comparison to CA19-9, the relatively poor sensitivity indicates that CEA is inferior in identifying PDAC. However, the similar

specificity of CEA when compared to CA19-9 highlights its utility in correctly identifying subjects who do not have PDAC.

Alternatively, using CA19-9 or other biomarkers in combination with early indications/symptoms of PDAC may prove useful. In a study of more than 11 million electronic patient records, from 562 general practitioner practices in the UK, in which 2773 patients with PDAC were diagnosed and compared with over 15,000 controls, it was found that patients with PDAC made a median of 18 visits to their general practitioner in the year prior to diagnosis. Moreover, PDAC was associated with 11 alarm symptoms, including back pain, lethargy, and new-onset diabetes mellitus [26]. Understanding the patterns of early PDAC symptoms will provide the opportunity to combine these with available biomarker tests and lead to earlier PDAC diagnosis.

Considerations Regarding the use of Diagnostic Biomarkers

The sensitivity and the specificity required from a biomarker or biomarker panel depend largely on the intended use of that biomarker. Despite the high morbidity and mortality associated with pancreatic cancer, it is nonetheless a relatively uncommon disease. The current lifetime risk of being diagnosed with pancreatic cancer is 1 in 71, although the incidence of pancreatic cancer is expected to rise significantly in the next decades. This relatively low overall lifetime risk of developing pancreatic cancer argues against population screening, particularly in the absence of highly sensitive and specific biomarkers. Population screening also relies on there being effective treatments, and since surgery is currently the only treatment that guarantees cure, biomarkers would have to enable the detection of resectable disease or disease that could be downstaged to enable resection. Finally, for biomarker tests to be widely used, they should be safe, inexpensive, and acceptable to patients. There are currently no biomarkers that fulfill the criteria for general population screening for pancreatic cancer. Since the incidence of PDAC is higher in groups at high risk of developing the disease, such groups are attractive for the testing of new candidate biomarkers. Moreover, new biomarkers that can further stratify for risk within high-risk groups are greatly sought after.

High-Risk Groups

Individuals with an Inherited Risk of Pancreatic Cancer

Approximately 10% of patients with PDAC have a family history of the disease, and a proportion of these families have a pattern of risk consistent with autosomal dominant predisposition [27]. For this subset of families, screening is justified with a view to earlier disease detection. In this book, the chapter entitled “Secondary Screening for Inherited Pancreatic Cancer” describes both the biomarkers currently available and the approaches taken for screening risk populations. By contrast, the

great majority (over 90%) of PDAC cases cannot be predicted on the basis of family history and are referred to as sporadic. No current screening modality is available for sporadic pancreatic cancer. As such, diagnosing sporadic pancreatic cancer at a curable stage is currently a huge unmet need.

New-Onset Diabetes

The relationship between PDAC and diabetes mellitus (DM) is complex. Long-standing DM increases the risk of PDAC by approximately twofold [28]. However, it is now evident that PDAC causes DM [28]. Approximately 40–80% of PDAC patients have DM or glucose intolerance at the time of diagnosis of cancer [29, 30], although it often goes undiagnosed. By following individuals newly diagnosed with type 2 DM, it became apparent that 1 in 100 patients is diagnosed with PDAC within 3 years of the diagnosis of DM, representing a significantly elevated risk (between five- and eightfold depending on the age of the individual) of PDAC compared to individuals without a new diagnosis of DM [30]. Further analysis suggested that these individuals had early-stage PDAC at the time they are diagnosed with DM. In effect, diabetes was secondary to PDAC and as such is referred to as type 3C diabetes and could be an early warning sign of the presence of cancer. The average time between the diagnosis of DM and the subsequent diagnosis of PDAC is 13 months [28]. This provides a significant window for earlier detection of PDAC and is especially significant because of the high proportion of PDAC patients (>50%) affected by new-onset DM prior to cancer diagnosis. It makes new-onset DM the largest high-risk group for pancreatic cancer.

However, the incidence of diabetes in the general population is rising, and understanding the various subtypes is critical. It is unfeasible, with current modalities, to screen all individuals newly diagnosed with diabetes for PDAC. Undoubtedly, screening this high-risk population would be facilitated if diagnostic biomarkers were available that could enrich for those individuals with new-onset DM who are most likely to have PDAC (making additional screening of this much smaller group feasible), and progress has been made. Plasma levels of adrenomedullin were found to be higher in PDAC patients with diabetes compared to PDAC patients without diabetes and were significantly higher in PDAC patients with diabetes compared to non-cancer subjects with diabetes [31]. The sensitivity and specificity of adrenomedullin (as a single marker) in distinguishing PDAC cases from non-PDAC controls were 69% and 81%, respectively [31]. Pancreatic polypeptide (PP), a hormone secreted by islet cells, has been evaluated for its ability to distinguish pancreatic cancer-associated diabetes from type 2 diabetes [32]. The serum OPG levels of 18 subjects with new-onset diabetes, half of whom had pancreatic cancer- associated diabetes, were evaluated at time intervals following a mixed meal. Serum PP levels were lower in the pancreatic cancer patients at 30 min following a mixed meal. Differences were noted between patients with a tumor in the head compared to the tail of the pancreas [32].

Using gene array analysis, Huang et al. [33] identified vanin-1, a pantetheinase found on the extracellular membrane of epithelial and myeloid cells, as upregulated in peripheral blood samples from patients with PDAC and DM, compared with PDAC patients without DM and control individuals with longstanding DM and healthy controls.

Fully understanding and exploiting the knowledge that individuals with new-onset DM are a high-risk group for PDAC could make a significant impact on the survival of PDAC patients, potentially enabling detection of the disease when it is at a treatable stage.

Biomarkers for Precursor Lesions

Pancreatic intraepithelial neoplasia (PanIN) lesions, intraductal papillary mucinous neoplasms (IPMN), and mucinous cystic neoplasms (MCN) are precursor lesions for sporadic PDAC. These lesions have been well defined in recent years with global consensus guidelines published regarding their management [34, 35]. Cystic precursor lesions are usually discovered as incidental findings on radiological imaging as they are asymptomatic. Given the high mortality associated with pancreatic cancer, diagnosis of these precursor lesion assumes high importance if we are to improve outcomes. Systems capable of accurately predicting malignant transformation of these lesions are hugely sought after.

Technological advances in cross-sectional imaging have improved the ability to detect abnormalities of the pancreas. As a consequence, an increase in the diagnosis of cystic neoplasms of the pancreas has occurred, with an estimated 13% of the population currently diagnosed with incidental cystic pancreatic lesions during cross-sectional imaging [36]. Currently there is no validated serum biomarker accurately able to predict malignant transformation of these lesions, and we are dependent on serial radiological surveillance or invasive endoscopic procedures to characterize them. To compound the problem, PanIN lesions lack specific symptoms for clinical diagnosis and are too small to be easily characterized with current imaging modalities [37]. There has been a global impetus to develop a biomarker panel able to facilitate accurate diagnosis of localized PDAC and neoplastic lesions, which would translate to early diagnosis, curative resection of localized tumors, and ultimately improved survival.

Circulating epithelial cells (CECs) have been reported in preinvasive and early tumorigenesis stages in mouse models [38]. Pancreatic epithelial cells from mice with PanIN lesions, but devoid of tumors, were shown to have acquired invasive properties and were detected in peripheral blood. Interestingly, these circulating cells had undergone epithelial-to-mesenchymal transformation, a process characterized by the loss of epithelial features and the gain of mesenchymal characteristics, such as, invasiveness and resistance to apoptosis.

Detection of circulating epithelial cells via a venous sampling test to diagnose early cancer holds great appeal. Rhim et al. [39] undertook a prospective study aimed at detecting circulating epithelial cells (CEC) of pancreatic origin. Forty-eight

patients were recruited from three groups – healthy subjects, individuals with cystic neoplasms of the pancreas not warranting surgery, and patients with PDAC. High counts of CEC were detected in patients with PDAC (7/9), but interestingly, 40% of individuals with noninvasive pancreatic lesions demonstrated CEC in their circulation. This subgroup of patients had no high-risk stigmata predisposing to development of PDAC. Although it was not known if all patients where CEC were detected went on to develop tumors, understanding the significance of the presence of CEC will be important for their utilization as a biomarker in the future.

There is much current interest in the exploitation of microRNAs (miRNAs) as markers that could potentially predict the malignant transformation of precursor lesions. miRNAs are noncoding RNAs containing 18–24 nucleotides that negatively regulate gene expression. They are described in greater detail in a later section of this chapter; however, their role in the detection of precursor lesions is dealt with here. Habbe et al. [40] undertook profiling of miRNA in the tissue of IPMN lesions that had been surgically resected. The study focused on two miRNAs, miR-21 and miR-155, for their role in identifying IPMN undergoing malignant transformation. Sixty-four samples were analyzed, including low-grade dysplasia (n = 13), moderate dysplasia (n = 31), and high-grade dysplasia (n = 20), with both miRNA-21 and miRNA-155 found to be overexpressed in tissue from IPMN compared to normal pancreatic tissue. Significant upregulation of both miRNAs was observed in patients with IPMN associated with high-grade dysplasia compared to those with low-grade dysplasia. miRNA-155 was overexpressed in patients with intestinal or pancreatobiliary histological subtype of IPMN which have an increased tendency for malignant transformation. Further profiling of these miRNAs in pancreatic juice showed that miRNA-155 was elevated in 60% of IPMN samples while barely detectable in subjects with benign pancreatic conditions such as chronic pancreatitis, indicating that miRNA-155 could serve as a biomarker for IPMN in pancreatic juice analysis.

A subsequent multicenter retrospective study analyzed miR-21, miR-155, and an additional miRNA, miR-101, from laser-microdissected invasive (n = 65) and noninvasive (n = 16) IPMNs, as well as normal pancreatic ductal tissues (n = 5) [41]. miR-21 and miR-155 were significantly overexpressed in invasive IPMN compared to noninvasive IPMN and normal tissues. By contrast, miR-101 was more highly expressed in noninvasive IPMN and normal tissues compared to invasive IPMN. Thus all three miRNAs were altered in expression between invasive and noninvasive IPMN and offer potential discrimination between these states [41].

Genome-wide profiling of miRNA provided additional insight into miRNAs that can distinguish between high- and low-risk IPMNs [42]. In a discovery phase, containing surgically resected IPMNs from 19 high-risk and nine low-risk cases, six miRNAs, miR-100, miR-99b, miR-99a, miR-342-3p, miR-126, and miR-130a, were identified as downregulated in the high-risk IPMNs compared to that low-risk group. The trend was observed also in the validation phase, which contained similar numbers of IPMNs. The above studies show the possible use of miRNAs as aids to clinical management in distinguishing IPMNs with malignant potential, and endoscopic ultrasound has facilitated the accurate sampling of IPMN. Nonetheless, less

invasive tests, ideally using fewer miRNAs, are desirable. Li and colleagues [43] measured 735 miRNAs in blood serum, selecting 18 miRNA for validation. Although a number of miRNAs were identified that could distinguish pancreatic cancer patients from healthy controls, miR-1290 was the best-performing miRNA. It was found to be significantly elevated in pancreatic cancer patients compared to healthy controls and also in patients with IPMN compared to healthy controls. Analysis of cancer tissue indicated higher expression of miR-1290 transcripts in both pancreatic cancer and IPMN tissue compared to normal pancreatic ducts.

Families of Biomarkers

Protein Biomarkers in Biological Fluids

Proteomic profiling of a variety of different biological samples has been undertaken with the aim of identifying sensitive and specific diagnostic biomarkers of PDAC. Each sample type offers unique advantages but also carries distinctive challenges.

Blood as a Source of Protein Biomarkers

By far the most common body fluid used in diagnostic protein biomarker studies for pancreatic cancer is blood in the form of serum or plasma. Although cheap and minimally invasive to obtain, blood contains proteins that are not specific to a particular organ of the body. Furthermore, some proteins in blood are present in very high abundance and may mask others which are present in trace amounts [44]. Nevertheless, a blood test that could enable earlier diagnosis of pancreatic cancer would represent a significant advance. Moreover, given the heterogeneity within the overall population, it is widely considered essential that a biomarker test would consist of a panel of two or more protein biomarkers.

Biomarkers that can demonstrably distinguish pancreatic cancer at an earlier stage than is currently possible are desired. In this respect a significant development has been the use of pre-diagnostic human cohort studies, alongside genetically engineered mouse models of PDAC, to provide vital insight into proteins that are changing in abundance in blood in the weeks and months prior to overt pancreatic cancer. Nolen et al. [20] profiled the levels of 67 proteins in pre-diagnostic sera from PDAC cases and controls registered in the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial. This afforded the opportunity to assess the performance of biomarker panels that had previously performed well in distinguishing PDAC cancer cases from controls when PDAC samples were taken at or post-PDAC diagnosis [22]. Previous analysis of 83 proteins in 333 PDAC patients and 144 patients with benign pancreatic conditions yielded a panel of CA19-9, OPG, and OPN which demonstrated a very promising sensitivity of 82.4% for PDAC detection at a specificity of 95%, yielding an AUC of 0.935. [22]. However, when tested in pre-diagnostic samples [20], the same panel offered poor classification power, demonstrating a sensitivity of 34%, a specificity of 84.7%, and an AUC of 0.547. A number of other candidates, which had shown good discriminating power

when tested in samples taken at the time of diagnosis of PDAC, also fared badly at distinguishing PDAC cases from controls when assessed in pre-diagnostic samples [20]. Jenkinson et al. [45] used the UKCTOCS pre-diagnosis samples to assess the performance of promising candidate diagnostic biomarkers prior to clinical presentation of PDAC. The serum levels of two candidates, intercellular adhesion molecule-1 (ICAM-1) and tissue inhibitor of metalloproteinases-1 (TIMP-1), were evaluated. Despite previous reports that these proteins were elevated in patients diagnosed with PDAC, neither protein was elevated in samples taken 0–12 months prior to PDAC diagnosis compared to non-cancer control samples [45]. Importantly, the study found that both proteins were significantly elevated in patients with obstructive jaundice secondary to either PDAC or gallstones. It was concluded that the failure of previous studies to account for biliary obstruction may have led to false-positive results. The above studies [20, 45] point to the difficulties of extrapolating alterations occurring prior to diagnosis from data acquired at or after the time of diagnosis. Moreover, failure to account for jaundice creates false-positive diagnostic signals in blood samples and continues to lead to the publication of poor-quality studies.

In a separate study, serum samples from the UKCTOCS collection of PDAC cases up to 4 years prior to diagnosis were subjected to proteomic biomarker discovery analysis [15]. Two-dimensional liquid chromatography-tandem mass spectrometry (LC-MS/MS) with isobaric tags for relative and absolute quantification (iTRAQ) of discovery samples ($n = 160$) led to quantification of 225 proteins in serum at 95% confidence. Of these circulating levels of thrombospondin 1 (TSP-1) were found to be reduced prior to diagnosis of PDAC. Multiple reaction monitoring (MRM), an LC-MS/MS technique for accurate protein quantification, along with Western blotting, was then undertaken to validate TSP-1 levels in a total of 472 human samples. Significant decreases in serum TSP-1 levels were observed in PDAC patients compared to controls and in KPC mice when they had cancer. Moreover, circulating TSP-1 levels were found to be reduced in PDAC cases compared to time-matched controls up to 24 months prior to PDAC diagnosis. For samples taken between 0 and 24 months prior to PDAC diagnosis, TSP-1 achieved an AUC of 0.69, while for CA19-9 the discrimination between PDAC cases and controls yielded an AUC of 0.77. Combined, TSP-1 and CA19-9 performed significantly better (AUC of 0.85). Finally, reduced TSP-1 levels were more frequently observed in PDAC patients with diabetes. This work highlighted the potential impact of diabetes on the performance of blood-borne biomarkers for PDAC.

Mirus et al. [46] used an antibody microarray with over 4000 features to profile proteins in plasma samples from the genetically engineered KPC mouse model of PDAC. In order to profile plasma from animals with preinvasive and early invasive PDA, plasma samples were interrogated from mice at 6–8 weeks and midway through the lifespan of animals, respectively. A total of 54 proteins were altered in mice in the preinvasive category with 25 proteins altered in mice in the early invasive category compared to controls. This study was complemented by comparing the proteins present in pre-diagnostic plasma samples from women in the Women's

Health Initiative (WHI) who were subsequently diagnosed with PDAC with control samples from women in the study who did not receive a diagnosis of cancer. In total, 88 proteins were altered in level in pre-diagnostic plasma compared to controls. Based on the mouse and human data, three candidate markers, ERBB2, ESR1, and TNC, were included in a panel which was evaluated for its ability to distinguish pre-diagnostic cancer cases from controls. The panel achieved an AUC of 0.68, and the performance improved slightly when CA19-9 was included in the panel.

Urine as a Source of Protein Biomarkers

Ease of accessing samples is an important consideration, and sample types that are readily obtained in a noninvasive manner, such as urine, are attractive as they would likely be acceptable to patients and cheap to obtain. Radon et al. [47] compared the protein profile of urine samples from healthy controls and patients with chronic pancreatitis and pancreatic cancer using in-gel tryptic digestion followed by liquid chromatography-tandem mass spectrometry (GeLC-MS/MS) analysis. Three markers, LYVE-1, REG1A, and TFF1, were selected for validation using ELISA. As a panel, these three markers performed well in distinguishing pancreatic cancer patients ($n = 192$) from healthy controls ($n = 87$). Areas under the receiver operating characteristic (ROC) curves (AUCs) of 0.89 and 0.92 were achieved in training and validation sets, respectively. Moreover, the panel was able to distinguish early-stage pancreatic cancer patients from healthy controls achieving AUCs of >0.9 when comparing PDAC stage I–II ($n = 71$) with healthy urine specimens. Further work to validate this panel prospectively is ongoing.

Pancreatic Juice/Whole gut Lavage Fluid as a Source of Protein Biomarkers

Pancreatic juice is secreted from the pancreatic ductal system and therefore has close physical contact with the tumor. This makes it an attractive source of biomarkers, as it may contain cancer-specific or cancer-enriched proteins actively secreted from the tumor or released through tumor shedding or necrosis. Indeed, proteomic profiling has revealed pancreatic juice to be rich in potential protein biomarkers [48], and the tumor markers CEA and CA19-9 are present in pancreatic juice [49] but not at higher levels than in serum. Collecting pancreatic juice poses a number of challenges. It is not easy to collect; the process can be invasive and may cause severe pancreatitis. Alternatives to analyzing pancreatic juice are therefore desirable. A new strategy for studying pancreatic juice proteins has been proposed by Rocker et al. [50]. A comparison was made between the protein profiles of whole-gut lavage fluid (WGLF) obtained during routine colonoscopy and pancreatic juice collected during surgery. The application of LC-MS/MS to the analysis of proteins contained within these fluids revealed a considerable overlap, with 90% of 104 proteins in pancreatic juice also present in WGLF samples. Likewise, 67% of proteins present in WGLF were identified in pancreatic juice. The study suggests that WGLF could be a surrogate biofluid for pancreatic juice and would enable an assessment of the pancreas in patients undergoing routine colonoscopies.

Circulating Tumor Cells

Circulating tumor cells (CTCs) are shed by a primary tumor or metastasis into the vasculature or lymphatics that then travel in an individual's circulatory system. Tumor cells may be shed passively by the primary tumor to enter circulation or are subjected to a more active process involving epithelial-to-mesenchymal transition.

Technological advances have created opportunities for the detection of CTCs in liquid biopsies. While there is mounting evidence that CTCs have prognostic value and are useful as surrogate response markers for the management of patients posttreatment, their utility in diagnosis is increasingly explored. Detection of CTCs is challenging due to their low number. In peripheral blood of individuals with metastatic cancer, the number of CTCs is estimated at one per 10^5 to 10^7 mononuclear cells. Individuals with nonmetastatic cancer have fewer CTCs. In addition, viable tumor cells shed into circulation are sequestered by the reticuloendothelial systems of the liver and spleen compounding their detection.

Enrichment techniques have been applied to improve CTC detection in blood (Fig. 1). These techniques target either physical properties of CTCs or biological properties or a combination of both. Centrifugation of cells in an isotonic medium can be used to separate tumor cells from mononuclear cells, as tumor cells have a different buoyant density, and commercial kits such as LymphoPrep™, Ficoll-Hypaque™, and Oncoquick® are available. Filtration techniques take advantage of the fact that tumor cells are comparatively larger than white blood cells; the isolation by size of epithelial tumor (ISET) cells is an example of one such filtration technique. However, both density and size distributions of CTCs are now known to overlap with peripheral blood mononuclear cells, and additional physical properties that could minimize separation of CTCs from blood cells have been explored. Dielectrophoresis is the motion of cells in the direction of increasing electric field intensity and offers opportunities for separating cell types. Enrichment techniques also take advantage of differential expression of cell-surface protein markers. Positive selection of CTCs has involved the use of immunomagnetic separation based on epithelial marker expression, e.g., EpCam or anti-mesenchymal antibodies or both, while negative selection has involved the depletion of mononuclear cells using well-established cell-surface markers for these cells (Fig. 1). Systems enabling cells to be separated using magnetic beads include Dynabeads (Invitrogen) and the system known as CellSearch (Veridex), which depends on expression of the epithelial marker, EpCam. Techniques to detect CTCs in peripheral blood include immunological assays such as immunohistochemistry or immunofluorescence. This enables an evaluation of tumor cell morphology; however, it depends on marker expression, and reliable markers of CTCs remain elusive. Nucleic acid-based tests enable the detection of mutated genes, gene transcripts, or miRNAs. Functional assays allow for detection of secreted proteins or an evaluation of the tumourigenicity of recovered cells in immunocompromised mice.

To date, most of the studies of CTCs involving pancreatic cancer patients have been aimed at understanding which techniques are applicable and have related findings to prognostic data [51]. Of note, in a study of 12 distinct metastatic cancer

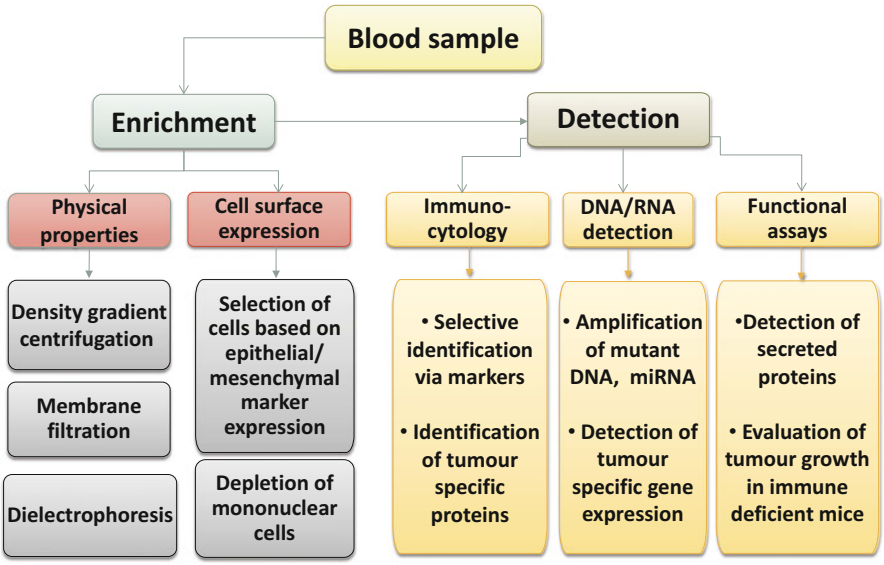

Fig. 1 Techniques employed for the enrichment and detection of circulating tumor cells in blood

types in which CellSearch was used to detect CTC, PDAC patients had the lowest levels of CTC [52]. This may reflect the limitation of using EpCam as a detection marker. When CellSearch was compared with ISET, a technique that relies on cell size, more CTCs were detected with ISET [53].

In terms of diagnosis, Ankeny et al. [54] recruited PDAC patients prior to treatment and employed a microfluidic CTC Chip (NanoVelcro) which targets EpCam. CTCs were detected in 54 of 72 patients with PDAC. In all cases, the KRAS mutations in CTC corresponded to those in the matching primary tumor. Using a cutoff value to >3 CTC in 4 mL of blood, CTC could identify patients with metastasis with sensitivity of 85.2% and specificity of 86.7%. This study demonstrates the potential of CTC as an aid to diagnosis of PDAC, and a larger validation study is in progress which will determine whether the cutoff established here is robust.

In summary CTC can be detected through the targeting of multiple cellular properties and indeed over 30 different techniques have been described. Research to date has provided evidence to support an association between CTC number and prognosis, although considerably more work is required before the potential of CTCs as an adjunct to PDAC diagnosis is exploited.

Circulating Tumor DNA

Circulating cell-free DNA (cfDNA) was reported nearly seven decades ago and continues to generate interest. The majority of circulating free DNA originates from

apoptosis or necrosis of cells, with white blood cells contributing to over 70% of the pool of circulating DNA. Tumor cells with their high mitotic rate undergo rapid apoptosis and release fragments of tumor-derived DNA into the circulation. Known as circulating tumor DNA (ctDNA), this subset of cell-free DNA can arise from apoptosis of primary tumor cells or lysis of CTCs. CfDNA has a low plasma half-life with rapid excretion through hepatic and renal metabolism [55], providing a small window for detection. ctDNA is present at a low level, but it has been identified with confidence using up to 5 mL of plasma [56]. Although ctDNA is readily identifiable in plasma fractions, dilution can occur, and diligence is required during analysis to prevent contamination with cellular DNA. Healthy individuals have an average of 30 ng/mL of cfDNA, but this becomes elevated sixfold in patients with solid tumors [57]. However, inflammatory states and benign tumors can also lead to elevated levels of cfDNA, and hence it lacks the necessary specificity as a stand-alone marker. Analyzing cfDNA for tumor-specific mutations helps to differentiate ctDNA from cfDNA. Combining ctDNA detection with analysis of tumor-specific mutations increases the sensitivity of ctDNA and has been shown to reflect disease stage and predict overall survival [57, 58]. Digital polymerase chain reaction (PCR) has shown the most promise among PCR-based techniques at identifying mutations, and studies have achieved 87–95% sensitivity and 99% specificity in detecting *KRAS* mutations in colorectal cancers [59]. Next-generation sequencing has been utilized in several studies to detect ctDNA and has the advantage of enabling analysis of multiple genes and the detection of novel mutations, making it highly specific.

Bettegowda and colleagues evaluated whether ctDNA was detectable using digital PCR in patients with various cancer types. ctDNA was detected in over 50% of PDAC patients with localized tumors and in over 80% of PDAC patients with metastatic tumors. Further studies including a meta-analysis have noted that the presence of ctDNA was associated with poor survival in PDAC [60]. The prognostic relevance of ctDNA carrying KRAS mutations in patients undergoing resection for PDAC was assessed. KRAS mutations were detectable in 31% of the cohort and were associated with poor survival. This possibly reflects the circulating micrometastatic burden [61].

In summary, ctDNA has been shown to have potential utility to predict survival in pancreatic cancer patients and may highlight patients liable to have early recurrence. However, refinements in detection will be required in order to use ctDNA as an aid for diagnosis.

MicroRNA

MicroRNAs (miRNA or miR) are a class of short, ~ 22 nucleotide, noncoding RNAs that regulate gene expression by binding to specific sites on the mRNA of protein-coding genes to direct their repression. These short single-stranded RNAs have been increasingly studied in recent years with more than 2500 human miRNAs registered to date (www.mirbase.org). miRNAs are now known to be important regulators of a variety of cellular processes, including development, differentiation, cellular

proliferation, and apoptosis. As regulators of multiple protein-coding genes, it is no surprise that dysregulation of miRNA can lead to the disruption of normal cell growth and development, resulting in a variety of disorders including cancer. miRNAs with regulatory roles in cancer have been studied extensively, with two distinct groups clearly categorized: those that are oncogenic and those whose depletion promotes tumorigenesis [62]. Tumor suppressor miRNAs are frequently downregulated in cancer. They inhibit the initiation and progression of pancreatic cancer by negatively regulating cell proliferation (miR-137 (63), miR-615-5p [64]), by facilitating apoptosis (miR-345 (65), miR-506 [66]), or through inhibition of cellular migration and invasion (miR-615-5p (64)). In contrast to tumor suppressor miRNA, oncogenic miRNAs (onco-miRNAs) are often found to be aberrantly overexpressed. Their upregulation has been shown to contribute to proliferation, migration, invasion, and inhibition of apoptosis. Upwards of 100 miRNA have been identified as being differentially expressed in pancreatic cancer [67]. A selection of recently reported miRNAs and their biological function in pancreatic cancer is summarized in Table 1.

Of those onco-miRNAs and tumor suppressor miRNAs found to play important roles in pancreatic cancer tumorigenesis and progression, several key candidates show potential as clinically viable stand-alone biomarkers, including miR-18a [68] miR-34a [69], miR-137 [63], and miR-1290 [70]. For example, miR-34a, a promoter of apoptosis and commonly deleted in human cancer, was recently identified from a number of miRNAs shown to exhibit p53-dependent upregulation upon DNA damage [69]. The significance of miR-34a in PDAC was demonstrated by the reduction or complete loss of expression of this miRNA in 11 pancreatic cancer cell lines. miR-34a has been measured in whole blood and sera, and its ability to distinguish pancreatic cancer from non-cancer controls has been highlighted in independent studies [71, 72], making it a promising candidate for early diagnosis of pancreatic cancer.

While there are an increasing number of studies revealing the potential of stand-alone markers as diagnostic tools, it is worth noting that single-miRNA biomarkers are frequently nonspecific. It is perhaps of greatest utility, therefore, to focus on comprehensive profiling of circulating miRNA and the creation of diagnostic panels. Several recent studies have addressed this need. Using microarray analysis coupled with RT-qPCR, Ganepola et al. [89] identified a panel of three circulating miRNA, miR-642b, miR-885-5p, and miR-22, differentially expressed in plasma from patients with PDAC compared to healthy controls and high-risk individuals. Validation of the combined targets demonstrated a high level of diagnostic accuracy for early-stage PDAC (sensitivity of 91%, specificity of 91%, and AUC of 0.97). Cote and colleagues found a panel of three miRNAs to be differentially expressed in plasma and bile from patients with PDAC compared to controls [67]. miR-10b, miR-155, and miR-106b displayed excellent accuracy in a validation cohort ($n = 120$) for distinguishing PDAC from chronic pancreatitis and normal pancreas (sensitivity and specificity were 95% and 100% in plasma and 96% and 100% in bile). In one of the largest discovery studies to date, 754 different miRNAs were examined in serum ($n = 205$) identifying 24 differentially expressed miRNAs in patients with

Table 1 Selected miRNAs with defined roles in pancreatic cancer, reported from 2014 to 2016

MiRNA	Role	Expression	Function in pancreatic cancer	Reference
miR-29a	Tumor suppressor	Down	Decreases cell proliferation and migration via inhibition of MUC1	[73]
miR-137	Tumor suppressor	Down	Inhibits cell proliferation	[63]
miR-192	Tumor suppressor	Down	Inhibits cell proliferation, viability and EMT via targeting of PAI-1	[74]
miR-200a	Tumor suppressor	Down	Inhibits EMT, cell migration, and invasion	[75]
miR-219-1-3p	Tumor suppressor	Down	Decreases proliferation and migration	[76]
miR-323-3p	Tumor suppressor	Down	Inhibits cell proliferation and EMT via modulation of SMAD2 and SMAD4 expression	[77]
miR-330-5p	Tumor suppressor	Down	Decreases cell proliferation and migration via inhibition of MUC1	[73]
miR-345	Tumor suppressor	Down	Proapoptotic	[65]
miR-506	Tumor suppressor	Down	Proapoptotic	[66]
miR-615-5p	Tumor suppressor	Down	Inhibits cell proliferation, migration, and invasion	[64]
miR-3923	Tumor suppressor	Down	Inhibits cell proliferation and viability via modulation of KRAS expression	[78]
miR-23a	Oncogenic	Up	Inhibits apoptosis and promotes proliferation and migration via inhibition of APAF1	[79]
miR-106a	Oncogenic	Up	Promotes proliferation, EMT, and invasion via targeting TIMPT-2	[80]
miR-181c	Oncogenic	Up	Promotes proliferation and cell survival via inactivation of HIPPO pathway	[81]
miR-191	Oncogenic	Up	Promotes cell proliferation via inhibition of USP10	[82]
miR-203	Oncogenic	Up	Promotes proliferation and migration via targeting of SIK1	[83]
miR-206	Oncogenic	Up	Promotes cell proliferation and invasion via induction of ANAXA2 and KRAS	[84]
miR-212	Oncogenic	Up	Cell proliferation and invasion through targeting of PTCH1	[85]
miR-221/222	Oncogenic	Up	Induces cell invasion via MMP-2 and MMP-9	[86]
miR-301a-3p	Oncogenic	Up	Invasion and migration via inhibition of SMAD4	[87]
miR-371-5p	Oncogenic	Up	Promotes cell proliferation	[88]

PDAC compared with chronic pancreatitis and healthy controls [90]. A training set selected 12 candidates (miR-16, miR-18a, miR-20a, miR-24, miR-25, miR-27a, miR-29c, miR-30a.5p, miR-19, miR-323.3p, miR-345, and miR-483.5p) for validation in four diagnostic panels in 137 subjects. In combination with CA19-9, one panel discriminated stage I and II PDAC from healthy controls (AUC 0.93, sensitivity 77%, specificity 94%). Further validation of this panel in combination with CA19-9 could lead to a clinically useful marker able to distinguish pancreatic cancer from chronic pancreatitis and healthy controls.

The exploitation of miRNA to detect early pancreatic neoplasia may offer the greatest potential to reduce morbidity and mortality. Current imaging features and tissue biomarkers obtained from invasive investigatory procedures are not sensitive enough to asses for malignancy of precursor lesions or to detect pancreatic cancer at an early stage of dysplasia. Recently next-generation sequencing in surgical tissue samples and endoscopic ultrasound-guided fine-needle aspirations (FNA) resulted in the identification of 40 miRNAs capable of discriminating premalignant intraductal papillary mucinous neoplasm (IPMN) and PDAC tissue from normal pancreas [91]. Validation in surgical samples ($n = 52$) and FNA ($n = 95$) showed the capacity of miR-103a, miR-155, miR-181a, miR-181b, and miR-93 to discriminate IPMN from controls with AUCs ranging from 0.68 to 0.92. Genome-wide miRNA profiling has further been employed to evaluate the reliability of miRNA signatures to differentiate low-risk/benign IPMNs from high-risk/malignant IPMNs in plasma in newly diagnosed individuals [92]. Five miRNAs, miR-200a-3p, miR-1185-5p, miR-33a-5p, miR-574-3p, and miR-663b, showed potential to discriminate between malignant and benign IPMNs (AUC 0.73, sensitivity 80.9%, and specificity 52.5%). The relatively small sample size and lack of validation sets limit the conclusions of this study. The findings do, however, support the need for further development of blood-based miRNA assays for IPMN diagnosis and management.

Most studies on miRNAs in pancreatic cancer have thus far been carried out with small patient and control numbers. Validation of promising miRNA candidates in independent, large cohorts will be necessary before being considered for clinical use. However, if data are reproducible when validated in large cohorts with all necessary controls integrated, circulating miRNAs may be a valuable resource for diagnosing pancreatic cancer.

As more diagnostic miRNA panels emerge, it will become increasingly important to ensure that data is reliable and open for meaningful interpretation. This will be achieved through careful optimization and standardization of sampling techniques and analytical methodologies. A great advantage of using miRNA as diagnostic tools is their increased stability compared to protein and mRNA and the feasibility of quantifying very low amounts of material from highly degraded samples [93]. Of additional benefit is their abundance in a variety of biological fluids and hence the potential for noninvasive testing. Measurement of miRNA has been achieved in most biological fluids including blood, urine, saliva, bile, and fine-needle aspirates [67, 91, 94]. To further advance the field, alternate sources of circulating miRNA should be investigated, such as extracellular vesicles and other tumor-derived carriers.

Extracellular Vesicle-Derived Markers

Extracellular vesicles (EVs) are a class of secreted membrane-derived vesicles which include exosomes, microvesicles, and apoptotic bodies. EV subpopulations are shed from numerous, if not all, cell types and have gained attention over the past decade for their role in both local and distant intercellular communication and disease pathogenesis. Exosomes are perhaps the most widely studied EV and will be the focus of this discussion, although it must be noted that other EV subsets, in particular microvesicles, are currently being investigated as sources of biomarkers of disease.

EVs are most often classified according to their size and mode of biogenesis. Exosomes are small EVs ranging in size from ~40 to 150 nm in diameter and originate from the inward budding of endosomal multivesicular bodies (MVB) within cells prior to their secretion. Structurally they are composed of a lipid bilayer which surrounds a cytosol devoid of normal cellular organelles. Exosomes, as with other subsets of EVs, are highly heterogeneous vesicles and can contain all known molecular constituents of a cell, including proteins, lipids, and nucleic acids [95, 96]. The contents reflect their cellular origin and are influenced by the physiological conditions in which they are generated and released. Once released from the surface of the originating cell, exosomal contents can be transferred to a recipient cell via fusion, where they are capable of mediating a phenotypic alteration in the cells which take them up [95]. It is this capacity to modulate the phenotype of recipient cells which makes exosomes key players in disease pathogenesis and which has led to a recent surge in interest for their characterization in a variety of disease states including cancer. Indeed, exosomes have been shown to hold the potential of carrying large arrays of oncogenic material from malignant to nonmalignant cells [97, 98], and studies have highlighted the roles of exosomal proteins and miRNAs in pancreatic cancer tumorigenesis, invasion, metastasis, and recurrence [99, 100].

Due to the close reflection of their cellular origin, exosomes released from cancer cells are a potential source of markers for the detection of cancer. The diagnostic value of exosomes is further evidenced by the variety of noninvasive sources for their collection, including blood, urine, saliva, and bile [101, 102], and the inherent protection they offer their cargo. Indeed, proteins, DNA, and miRNA have all been shown to be stable and abundant in exosomes [103, 104], with exosome-associated miRNA significantly more stable compared to free miRNA due in part to protection from RNase degradation [105]. Significantly higher exosome concentrations have been reported in the systemic circulation of patients with cancer versus controls [106, 107], and markers associated with cancer exosomes may therefore be enriched when harvested from heterogeneous populations of exosomes in biological fluids. The ExoCarta database (http://www.exocarta.org) holds an ever-increasing catalogue of proteins, lipids, RNA, and miRNA that have been identified in EVs from different sources.

Several studies have focused on developing exosome-associated biomarkers for pancreatic cancer detection. Recently, the heparin sulfate proteoglycan, glypican-1 (GPC-1), was reported as a highly specific exosome-associated biomarker for early detection of PDAC [107]. GPC-1 was measured in serum exosomes collected from

patients with PDAC (n = 190), benign pancreatic diseases (BPD) (n = 26), and intraductal papillary mucinous neoplasms (IPMN) (n = 5) and healthy volunteers (n = 100). The levels of GPC-1-positive (GPC-1^+) exosomes were found to be significantly higher in all 190 PDAC and 5 IPMN cases compared to BPD and healthy controls. Furthermore, GPC-1^+ exosomes revealed a sensitivity and specificity of 100% in distinguishing PDAC from healthy controls. These observations were consistent in a smaller validation study. Despite initial enthusiasm in GPC-1 as a breakthrough biomarker for early PDAC, it has also been shown to be associated with breast and colorectal cancer [107, 108], putting into question the test specificity. The diagnostic utility of GPC-1 was further questioned in a study by Lai et al. [109], where liquid chromatography-tandem mass spectrometry was employed to quantify GPC-1 levels in plasma exosomes. In a small cohort of PDAC, CP, and healthy control samples, no significant differences in GPC-1 levels were observed between the three groups. With further validation, GPC-1 may still hold value in the isolation of cancer-specific exosomes; however, current problems with the availability of specific GPC-1 antibodies will, at present, limit the utility of GPC-1.

Plasma levels of adrenomedullin (AM) have previously been reported in PDAC patients with diabetes compared to PDAC patients without diabetes and non-cancer subjects with diabetes [31]. Aggarwal et al. also established that pancreatic cancer (PCC)-derived AM inhibits insulin secretion by β-cells and AM was presented as a potential maker for type 3c (PDAC-associated) diabetes [31]. An independent study later demonstrated the release of exosomes by PCCs and their subsequent internalization by β-cells [110]. Western blot analysis confirmed the presence of AM in cancer-associated exosomes isolated from PCCs, and PCC-derived exosomes were further shown to inhibit insulin secretion in human islets, an effect abrogated by AM receptor blockade. These studies are important as they provide the first demonstration of a potential exosome-associated protein biomarker along with an associated function. Further validation will be required to establish whether exosome-associated AM provides an enriched source of AM for detection of type 3c diabetes among high-risk individuals.

As described above, in addition to exosomal protein biomarkers, exosome-associated miRNA may serve as diagnostic tools. The exosome provides a stable environment for miRNA and is a significantly enriched source compared to free-circulating miRNA [105, 109]. As such, it may be particularly advantageous when using miRNA for diagnostic purposes, to focus studies on the identification of cancer-associated miRNA located within exosomes. The miRNA content of human exosomes isolated from pancreatic cancer patients and control individuals has been studied by several groups. Que. et al. [111] found levels of miRNA-17-5p (miR-17-5p) and miR-21 to be heightened in serum exosomes from pancreatic cancer patients (n = 22) compared to healthy controls (n = 8), with good sensitivity and specificity for the diagnosis of PDAC (AUC 0.887, 95% CI: 0.796 to 0.978 and 0.897, 95% CI: 0.803 to 0.991, respectively). miR-21 was also shown to be expressed at higher levels in serum-derived exosomes from individuals with pancreatic cancer compared to those with chronic pancreatitis. Using a novel localized surface plasmon resonance (LSPR)-based sensor for specific and targeted miRNA

detection, Joshi et al. demonstrated the quantitative measurement (limit of detection ~10^{-9} M) of miR-10b in human plasma exosomes, pancreatic cancer cell lines, media, and human plasma [112]. Using their highly sensitive and specific sensing technique, the level of miR-10b was shown to be significantly elevated in plasma-derived exosomes from pancreatic cancer patients (n = 3) compared to chronic pancreatitis (n = 3) and normal controls (n = 3) (four- to tenfold increase and 50- to 60-fold increase, respectively). While this is a relatively small study in terms of sample size, Joshi and colleagues highlight the potential use of LSPR-based sensors, and other on-chip devices, in the label-free quantitative measurement of defined miRNA signatures within exosomes.

More recently, an enrichment of several previously reported cancer-associated miRNA was demonstrated within exosomes compared to whole plasma [109]. Using RT-qPCR, exosomal miR-10b, miR-21, miR-30c, miR-181a, and miR-let7a were shown to readily differentiate pre-resection pancreatic cancer samples (n = 29) from chronic pancreatitis and healthy control samples (n = 11 and 6, respectively). Interestingly, post-resection levels of miR-10b, miR-21, miR-30c, and miR-let7a showed a return to normal values, with a partial decrease in miR-181a observed. ROC analysis revealed that this group of five miRNA had 100% sensitivity and specificity in distinguishing pancreatic cancer from healthy controls.

The diagnostic complementarity of exosomal proteins and miRNA has been investigated in pancreatic cancer [113]. This research generated a pancreatic cancer-initiating cell (PaCIC)-specific marker panel selected via the analysis of exosomes isolated from PaClC culture supernatants compared with serum-derived exosomes from healthy controls. Candidate miRNA were selected via microarray analysis of exosomes isolated from PaCIC culture supernatant and serum-derived exosomes from pancreatic cancer patients and healthy controls. ROC analysis of both panels independently and in combination revealed their diagnostic complementarity. In a validation set comprising patients with pancreatic cancer, chronic pancreatitis, benign pancreatic tumors, non-pancreatic cancer malignancies, and healthy controls (n = 140 total), the combination of CD44v6, CD104, Tspan8, and EpCAM with miR-1246, miR-3976, miR-4306, and miR-4644 in serum-derived exosomes showed excellent sensitivity (100%, 95% CI: 0.95 to 1) with a specificity of 80% (95% CI: 0.67 to 0.90) for PDAC versus all other control groups. Excluding other malignancies, specificity reached 93% (95% CI: 0.81 to 0.99). Interestingly, miR-1246 and miR-4644 have also been shown to discriminate PDAC from healthy controls in salivary exosomes (AUC 0.83) [114], opening up the potential future validation of miRNA, either alone or in combination with protein markers, in a variety of biological fluids.

The noninvasive methods of sample collection, sample stability, and diverse cargo which reflects their cellular origin make exosomes, and EVs in general, an attractive source of biomarkers. However, to date, a highly specific pancreatic cancer diagnostic marker has not been fully validated in EVs. It is expected that the number of studies identifying EV-associated biomarkers will continue to rise. As such it is important to address the current shortfalls in EV analysis which will limit the meaningful interpretation of validation studies. Any EV study must address the

heterogeneity of the EV population analyzed and must demonstrate the association of the function or feature attributed to the EV of interest by specific co-isolation. Where other vesicles have the same functions, the whole component of EVs must be analyzed, not just a specific subset (e.g., exosomal) fraction. Where a biomarker is associated with a specific EV subset, strict standards must be applied to correctly evidence the isolation methodology (e.g., via surface markers or size distribution).

The present lack of standardized methods for the isolation and characterization of EVs significantly hinders their potential as routine clinical markers. However, in response to the rapid increase in interest of EV, there are an increasing number of commercial kits for isolation and purifications, and a number of analytical tools, such as lab on a chip, are being investigated [115, 116]. Coupled with the efforts of EV working groups to standardize workflows and the distribution of guidelines such as the minimal information for studies on EVs (MISEV) [117], it is likely that EV-associated markers will in the future become clinically viable diagnostic tools.

Imaging

Multiple detector computed tomography (MDCT) has proven to be the optimal modality for staging of pancreatic masses, with magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) complementing it. MDCT has high sensitivity and specificity to predict resectability of pancreatic tumors and detects focal metastasis. MRI has superior sensitivity to identify small lesions, characterize parenchyma, and delineate the relationship of lesions to the ductal system. Certainly when monitoring of cystic lesions is required, MRI is preferred due to lack of repeated exposure to radiation. EUS is being increasingly used as it can detect small focal lesions and allows sampling for cyto-molecular analysis [118]. Fludeoxyglucose F-18 positron emission tomography (FDGPET) detects the increased metabolic activity of tumor cells and can identify small metastasis and differentiate cancer from benign cystic lesions [119]. It can identify sub-centimeter lymph node metastases, but reports suggest its sensitivity is affected when lymph nodes are in close proximity to the pancreas, and a high false-positive rate in hyperglycemic patients must be addressed [120]. Nevertheless, it is used to identify occult metastasis and also assess response of tumors to adjuvant therapies.

Novel technologies are being utilized to identify early pancreatic cancer and predict malignant transformation of IPMN. Early recognition of malignant lesions is thought to increase the chances of curative resection and hence improve overall survival. Magnetic resonance imaging (MRI), magnetic resonance cholangiopancreatography (MRCP), and EUS can quantify IPMN lesions, but they are not able to identify PanINs nor can they grade IPMNs. Dual-energy computed tomography (CT) has been shown to have increased sensitivity in detecting lesions of less than 2 cm and also iso-attenuating tumors, which make up some 10% of pancreatic tumors. Hybrid PET/MRI is being trialed for staging response to adjuvant/neo-adjuvant therapy. Fluorothymidine positron emission tomography (18F–FLT PET) is a new molecular imaging modality targeting the proliferative activity of tumor

cells and was shown to have increased specificity compared to other imaging modalities [121]. EUS is being increasingly utilized to assess pancreatic parenchyma and cystic lesions and allows relatively easy access to the collection of tissue biopsies or cystic fluid for analysis of protein markers and genomic studies. The rapid advancement of imaging techniques has led to improvements in earlier diagnosis of pancreatic cancer. With new technologies currently in development, there is great potential for diagnosis of high-risk pancreatic lesions and PDAC at earlier stages, leading to improved patient outcome.

Emerging Technologies

Metabolomics

Metabolomics is the most recently established "omics" strategy employed in systems biology. It describes the study of metabolites in biological systems and most often involves the quantitative determination of low molecular weight metabolite concentrations, both at a system-wide and at a cellular level. The human metabolome is the ultimate product of a process originating with the genome. Compared with other omics strategies, such as genomics and proteomics, metabolomics offers the greatest potential to observe the phenotype of the system. The metabolome is extremely responsive to varying physiological conditions and, as such, can provide a snapshot of the biological state at specific time points. Research has shown that metabolic reprogramming is one of the hallmarks of cancerous cells and many of the genes and proteins found to play important roles in cancer are known to be involved in metabolic processes. Metabolic profiling holds great potential as a powerful tool for the discovery and development of clinically viable biomarkers.

Metabolomics strategies chiefly employ either targeted (hypothesis-driven) or untargeted (hypothesis-generating) approaches. Targeted strategies involve the assessment of a defined number of metabolites, or a specific metabolic pathway, and benefit from maximum analytical sensitivity and specificity. Untargeted strategies aim to capture all metabolic pathways and the maximum number of metabolites under a given set of experimental conditions. This untargeted workflow comes at the cost of lower analytical sensitivity and specificity. A variety of analytical techniques are utilized to facilitate these approaches, including proton nuclear magnetic resonance (^{1}H–NMR) spectroscopy, gas chromatography-mass spectrometry (GC-MS), liquid chromatography-mass spectrometry (LC-MS), and Fourier transform-ion cyclotron resonance-mass spectrometry (FT-ICR-MS). Increased capabilities of state-of-the-art techniques offer the benefit of both targeted and untargeted analyses in the same analytical run. As with other omics workflows, sophisticated bioinformatics tools are required to process the vast data sets generated and to explore biologically significant findings. Multivariate analyses, such as principal component analysis, partial least squares analysis, cluster analysis, and random forest, are most commonly employed for visualization and interpretation of global data sets, essential in biomarker discovery workflows. By contrast, univariate analysis has utility in the

discrimination of individual metabolites, which is particularly useful in secondary biomarker analyses.

Despite the firm standardization now routinely implemented in other omics fields, such as proteomics and genomics, metabolomics studies often fail to reach necessary analytical standards. Importantly, metabolomics studies frequently fail to include relevant control groups and the validation of findings in at least one independent cohort of samples. The use of matched pre- and post-diagnostic samples is also critical if biomarkers capable of distinguishing pancreatic cancer at an early stage are to be discovered. Finally, appropriate sample collection and storage are critical for the meaningful interpretation of metabolomics data. The influence of circadian rhythm, diet, xenobiotic exposure, and underlying physiological conditions must be considered along with efforts to quench ongoing metabolism post-collection.

An overview of findings from recent comprehensive metabolomics-based biomarker research in pancreatic cancer is presented below.

A targeted UHPLC-MS/MS method employing a commercial 206 metabolite data set utilized sparse partial least squares discriminant analysis and greedy stepwise and GeneticSearch algorithm to select four metabolites with high discriminating potential [122]. Of these, palmitic acid and oleanolic acid exhibited excellent diagnostic accuracy (AUC 1.0) when subjected to ROC analysis in the cohort of PDAC (n = 40) and HC (n = 40) serum samples. At a cutoff value of 134.3 μM, palmitic acid outperformed CA19-9, achieving 100% sensitivity and specificity. Future validation in large cohorts with relevant controls would be required to further investigate the clinical utility of palmitic acid in pancreatic cancer. However, this discovery study clearly demonstrates the potential of multivariate methods and classification trees in the interrogation of MS-based metabolomics data.

Richie et al. [123] generated comprehensive metabolic profiles of sera from pancreatic cancer patients and healthy controls using a nontargeted approach on a FT-ICR-MS platform. A significant alteration in the metabolome of pancreatic cancer patients was shown with alterations in a number of metabolites including long-chain fatty acids, cholines, and sphingomyelins. The ultra-long-chain fatty acid PC-594 was subjected to further validation, along with CA19-9, in an independent cohort (n = 188) [124]. ROC analysis revealed the superior performance of P-592 compared to CA19-9 in distinguishing pancreatic cancer from normal controls (AUC of 0.93, 95% CI: 0.91 to 0.95 and 0.85, 95% CI: 0.82 to 0.88, respectively). A PC-594 threshold of 1.25 μmol/L produced a relative risk (RR) of 9.4 ($P < 0.0001$, 95% CI: 5.0 to 17.7), sensitivity was 90%, and specificity was 87%.

Accurately distinguishing pancreatic cancer from chronic pancreatitis remains a significant challenge in terms of correctly diagnosing pancreatic cancer. Recently, a metabolite-based biomarker signature was identified that can discriminate pancreatic cancer from chronic pancreatitis with much greater accuracy than is currently observed with CA19-9 alone [125]. In a study involving more than 900 subjects, 477 blood-based metabolites were identified with 29 of those significantly altered in level between pancreatic cancer and chronic pancreatitis patients. A nine metabolite signature was derived and when used with CA19-9 showed very high accuracy for the discriminating pancreatic cancer and chronic pancreatitis [125].

A large proportion of metabolomics studies in pancreatic cancer have focused on glucose and glutamine metabolic pathways; however, there is increasing interest in the diagnostic potential of altered amino acid metabolism. A large study conducted in Japan [126] employed targeted LC-MS/MS to the analysis of 19 plasma-free amino acids (PFAA) in 360 pancreatic cancer patients, 28 chronic pancreatitis patients, and 8372 healthy controls. In fasting plasma samples, 14 PFAA were shown to be differentially expressed in pancreatic cancer ($p < 0.05$). A multivariate model using six specific PFAA (serine, asparagine, isoleucine, alanine, histidine, and tryptophan) was developed and applied to training (PDAC n = 120, HC n = 600) and validation (PDAC n = 240, CP n = 28, HC n = 7772) sets. ROC analysis of the PFAA index showed good sensitivity and specificity for the diagnosis of pancreatic cancer in the training set (AUC 0.89, 95% CI: 0.86 to 0.93). Validation of the PFAA index continued to demonstrate good sensitivity and specificity in the distinction of pancreatic cancer patients from healthy controls and patients with chronic pancreatitis (AUC 0.86, 95% CI: 0.84 to 0.89 and 0.87, 95% CI: 0.80 to 0.93).

Most biomarker studies employ a cross-sectional design, comparing samples collected at a single time point after diagnosis. This approach limits the observation of molecular changes that occur early in disease progression and hence the identification of markers for early diagnosis. To investigate whether global metabolic changes could be detected in circulating metabolite levels in the years preceding pancreatic cancer diagnosis, Meyers et al. [127] profiled metabolites in pre-diagnostic plasma from individuals with pancreatic cancer and matched controls. Levels of three branched-chain amino acids (BCAAs), leucine, isoleucine, and valine, were strongly associated with future PDAC development ($p \leq 0.0006$). Individuals with the highest BCAA levels had at least a twofold increased risk of developing pancreatic cancer, with the risk greatest 2–5 years prior to diagnosis. Interestingly, while elevated BCAA levels are also associated with diabetes [128], a risk factor for PDAC, the correlation between BCAA levels and PDAC risk was found to be independent of diabetes.

A number of metabolomics-based biomarker signatures have been proposed for the diagnosis of pancreatic cancer; however, none have moved beyond the discovery phase. With the increasing application of high-resolution MS-based methodologies, there is the promise of more comprehensive coverage of the metabolome and ultimately the creation of robust biomarker panels with clinically viable sensitivity and specificity.

Conclusion

While a number of biomarkers for PDAC have now been reported in the literature, significant efforts are still required to fully validate their clinical utility in the early detection of PDAC. Both biomarker discovery and validation programs require large numbers of samples. Increasingly, it is recognized that collaboration between specialist centers is required to achieve the samples necessary for robust studies. Sampling from different centers also rules out local bias in collection method.

In addition, longitudinal patient sampling is not frequently undertaken. Thus, although samples are taken at the time of diagnosis, enormous value could be derived if biomarker levels were measured again following surgery and chemotherapy. The use of high-risk registries will provide both the samples required for discovering biomarkers and the individuals in which to test good candidate markers. Understanding the relationship between type 3c diabetes and PDAC may contribute to the early detection of PDAC. However, this will require the collection of samples from individuals newly diagnosed with diabetes and the recognition of the importance of this high-risk group in research groups in Europe as it is currently in the United States.

Good practice, such as the use of training and test sets that are independent; the careful choice of samples, with variables such as age and gender matched across comparator groups; and the avoidance of known confounding factors and of overfitting of data [129] should all contribute to higher-quality studies. Careful review of manuscripts and judicious editorial decisions should prevent biomarkers that have already been discounted from being published yet again as promising candidates.

Finally, significant improvement in the survival of pancreatic cancer patients will only come about if progress in early detection is concurrent with advances in treatments.

Development of Novel Therapeutic Response Biomarkers

Nils Elander, Karen Aughton, and William Greenhalf

Contents

Abstract

Biomarkers that can indicate the best treatment option for each patient could greatly improve pancreatic cancer survival. Markers need to be practical to use in a timely fashion in order to change the choice of therapy. In vitro or ex vivo studies are useful in identifying potential markers, but these may not have relevance to marker profiles of in situ tumors, and adequate quality of tumor tissue may not be routinely available in patients with advanced disease, and so

blood-based markers of systemic determinants of response may be more attractive. Any marker, tissue- or blood-borne, needs to be tested in clinical studies involving multiple populations before entering routine use. These studies cannot rely just on prognosis as one individual's survival may be improved by therapy but still be significantly shorter than another whose survival was independent of therapy. Ideally an objective measure of response that links to survival benefit should be used to evaluate a biomarker. However, this may not be possible for adjuvant therapy where the tumor is removed before treatment begins and the link between survival and response in an advanced setting is not always reliable. Survival on its own is a poor surrogate for response, and its use may lead to confusion of prognostic and response markers unless used within large clinical trials. Adverse responses to treatment such as rash linked to survival may be an alternative measure. Difficulties in defining the level of beneficial response make empirical identification of response biomarkers difficult. Theory-based studies have more power to identify and validate markers, but the determinants of drug response are complex, and popular (but potentially misguided) beliefs about specific proteins may lead to multiple testing and hence type 1 errors. Grouping biomolecules (proteins, RNA, metabolites, or DNA sequences) into marker panels linked to function, for example, grouping proteins that determine mesenchymal transition of cancer cells or which define the nature of stroma, may offer a way forward. Alternatively, functional analysis alone, including level of immune response, may allow the most beneficial therapy to be directed to each patient.

The Promise of Personalized Medicine

It is not as easy to be defeatist when discussing pancreatic ductal adenocarcinoma (PDAC) as it once was. Clinical trial after clinical trial has shown that long-term survivors do exist [1, 2] and that the proportion of these survivors will depend on the specific treatment regimen chosen. Most patients will not respond or will only have a transient benefit, but in the last few years, it has become apparent that populations can be identified who will benefit from one treatment but not another [3]. It may even be true that one individual's cure may be another's poison, making their individual prognosis worse than it would have been with no treatment at all. New treatment modalities are being developed, in particular immunotherapy and targeted therapy [4], and although the benefits have yet to live up to the initial expectations for these agents, they join a well-established range of chemotherapeutics with ever-improving regimens that are achieving iterative (albeit small) improvements in survival. What we lack are the tools to identify which therapy to give to which patient and when to change the therapy as the cancer evolves.

Requirements of a Therapeutic Biomarker

Diagnostic biomarkers help clinicians to diagnose the presence and origin of the disease or the relapse of a previously treated disease that was in remission. Prognostic biomarkers discriminate between patients with the same cancer diagnosis who will do better or worse. Whereas therapeutic biomarkers indicate the benefit of a certain treatment, this can be predictive of the cancer's response or the patient's tolerance to a certain therapy.

In some cases, a biomarker can be classified in more than one of these categories, e.g., prostate-specific antigen (PSA) may be used in diagnosis, in early detection of relapsing disease, and as a prognostic marker in assessment/follow-up of given therapies [5]. Another example is the amplification status of HER2 in breast cancer; this is of general prognostic value (HER2-positive patients have worse prognosis than HER2-negative ones) [6], but beyond this, it is also predictive of treatment response (i.e., HER2-targeting treatments will only benefit HER2-positive patients) [7]. In some cases, the relationship between a biomarker and prognosis can be the inverse of its relationship to response, for example, high levels of the protein HuR (which will be discussed later in this review) are in general associated with poor survival but also good response to the drug gemcitabine [8].

Therapeutic response can be measured in a number of ways. For neoadjuvant therapy and in advanced cancer, it can be measured by reduction of tumor volume assessed by imaging techniques, reduction in tumor biomarkers, or increased time to progression. With adjuvant therapy, the target is micrometastatic disease which is not measurable by any standard means, so it is not possible to measure any reduction in tumor volume, and (to add a further complication) the tumor, which is the most likely source of therapeutic biomarkers, is removed before chemotherapy begins. For all therapy, overall survival is the most important measure, although it is difficult to separate prognosis and response on this basis.

In order to enter clinical practice, a therapeutic biomarker has to pass a series of hurdles as illustrated in Fig. 1. A marker must be selected where a biomarker-positive patient gains more benefit from a given treatment than patients who are negative for that marker. This is not the same as marker-positive patients having a survival advantage over marker-negative patients; in fact marker-negative patients could have better overall survival than patients who are marker positive but still be getting less benefit from the therapeutic: it is necessary to show that the survival benefit is treatment specific. Even if a biomarker indicates greatest benefit from one drug, it will not necessarily be of any practical use, knowing that the benefit patient A gets from, for example, gemcitabine is less than the benefit patient B will receive is of little comfort to patient A if gemcitabine is the only option for treatment. It is self-evident that to be of greatest use, a therapeutic marker should allow a choice of therapeutic, so a negative result for one therapy should indicate that a patient would get more benefit from an alternative therapy. In the absence of an alternative treatment, the only utility the biomarker can have is to indicate the absence of any benefit, thereby allowing a toxic drug to be avoided. This is a very real advantage, but depressingly in the case of pancreatic cancer, this advantage may be associated with the loss of the last hope a patient has.

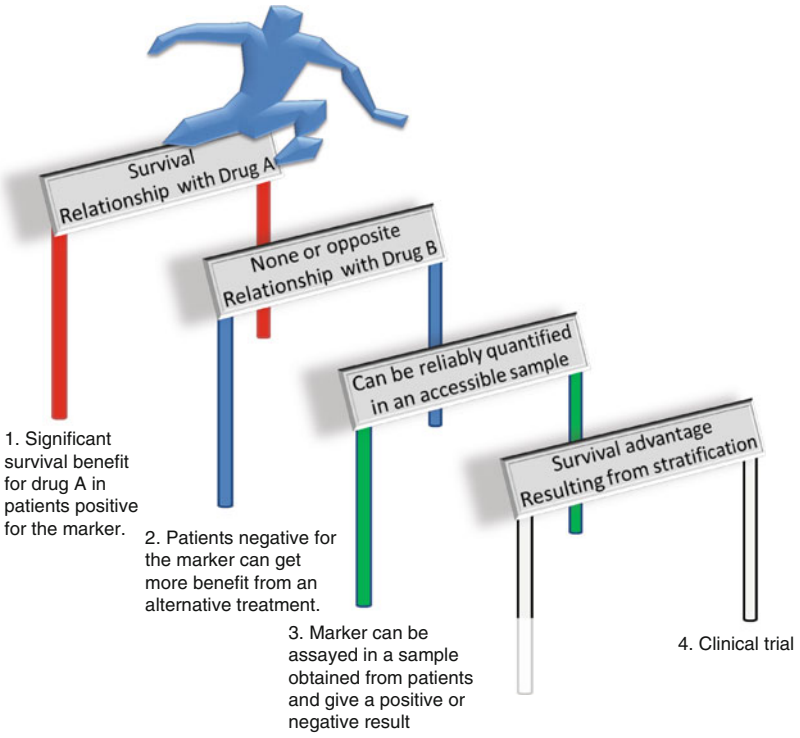

Fig. 1 Hurdles that must be overcome to get a therapeutic biomarker to the clinic. In order for a therapeutic marker to be useful, it must not only indicate individuals who benefit from a therapy but also indicate that they would benefit less from an alternative. It must also be practical to adequately quantify the marker. Only then is it suitable for clinical trial

In order to reach the clinic, the biomarker should be validated in a clinical trial, but before this can happen, it must be possible to apply the biomarker in a clinical setting. There is surprisingly little guidance on what is required in identifying and utilizing a biomarker for therapeutic response. The problems associated with testing a biomarker in a clinical trial are somewhat different from testing a drug. A fundamental difference to pharmacokinetic analysis is that the test substance is indigenous. The Crystal City VI meeting in 2015 addressed this issue [9], concluding, among other things, that spiking as a method to measure linearity of measurements and limits of quantification is generally unsafe. To overcome this, clinical samples with high levels of biomarkers should be diluted in an appropriate matrix (e.g., serum or an artificial equivalent). Analysis of parallelism (measured concentration change related to theoretical concentration change) can be used to define adequacy of an artificial matrix, and if an artificial matrix can be validated, it could potentially be used to assess a measure of assay accuracy; otherwise, thresholds for biomarkers will have to be admitted to be pragmatically defined.

Even when a marker can be validated in a research project, it may be impractical in the clinic due to availability of adequate clinical samples. Germline DNA is

unlikely to be a problem as blood, saliva, or buccal swabs can be obtained from any patient, and thanks to the polymerase chain reaction, tiny amounts are adequate for even the most complex analysis (even whole-genome sequencing). However, germline differences are very unlikely to explain the majority of variation in drug response given the far greater genetic variation in different tumors compared to different germlines. Identifying tumor-specific differences in blood samples is very attractive, but distinguishing differences due to the cancer from background variation may be a challenge and require relatively large volumes of blood that may be difficult to obtain from very sick patients, for example, obtaining sufficient numbers of circulating tumor cells for intracellular protein or RNA analysis may be feasible in some but not all patients. Even for patients undergoing curative intent surgery, heterogeneity of the sample may be a significant practical problem, convenient approaches such as the use of tissue microarrays may work where it is possible to reconstruct a 3D model of the original tumor, allowing the relevant cancer or stromal regions to be identified, and this may be possible within a research study, but in routine care, the clinician may have to rely on data from one or two cores per patient. For patients presenting with inoperable and/or metastatic disease, large volumes of tumor tissue are rarely available. In the best case, representative biopsies can be taken, but in current practice, fine-needle aspirates are more common (in many cases, diagnosis relies exclusively on radiology and clinical signs), so a biomarker validated in biopsy samples may not be applicable without a very dramatic change in clinical practice.

Identification of Biomarkers

There are a variety of ways by which candidate biomarkers are identified, but in essence, these can be divided into two classes: empirical and theoretical. The theoretical approach has the disadvantage of being much more sensitive to publication bias. Each analysis will be based on a restricted number of hypotheses (e.g., the hypothesis that marker A is associated with response); therefore, the statistical barrier to demonstrating an association will be relatively low (e.g., $P<0.05$). However, if a theoretical relevance is clear, then it is likely that many groups will look for an association, and failure to show an association will be difficult to publish, but if this is tested enough times, sooner or later significance will be suggested and will be relatively easy to publish. In this respect, empirical analysis is safer, but the barrier to establishing a relationship with response is obviously much greater.

Empirical Analysis

Intuitively the best way to identify a biomarker of response is simply to detect something that is present in those patients who respond to the therapy and is absent in those who do not (or vice versa). Of course, if enough potential markers are

examined, positive results will be found, but this problem can be overcome by rigorously testing independent populations after the initial discovery process: so all that is needed is multiple populations of responders and nonresponders. However, in the case of pancreatic cancer, identifying a responder is not as simple as it sounds. In an adjuvant setting, there should not be any visible tumor after resection so imaging cannot be used to measure response to a drug. Theoretically, biomarkers produced or induced by metastases could be used instead, but this depends on the marker being stably detectable after resection (if a marker such as CA19-9 declines to extinction after resection, regardless of treatment, its decline cannot be taken as an indication of response in a given individual). Survival is a poor surrogate as a long-term survivor might have done even better without the drug and poor survivors may contribute to an overall clinical benefit by surviving longer than they would have done otherwise.

Responders

In an advanced setting, there is a tumor mass to follow, but reduction in tumor mass does not necessarily equate to a survival benefit. Changes in volume of primary tumors may, for example, not reflect changes in more critical but difficult to measure metastases. Also clinically important responses such as necrosis or metabolic changes may be missed, while reduction in tumor volume due to reduced stroma may be difficult to distinguish from a genuine reduction in cancer cells within the primary. With immunotherapy in metastatic malignant melanoma and other solid cancer, the caveat of "pseudoprogression" has been highlighted [10]; this means that the tumors grow in volume on radiology scans and are mistakenly interpreted as progressive disease, whereas the true reason is not growth of tumor cells per se but recruitment of immune cells doing their job attacking the cancer. In a Japanese study using Response Evaluation Criteria in Solid Tumors (RECIST), it has been shown that progressive disease does correlate with worse survival in advanced pancreatic cancer, but no significant survival difference was seen between stable disease and partial response using the same criteria in patients receiving chemotherapy [11]. This seems inconsistent with data from other solid tumors where an almost linear correlation exists between reduction in tumor size following chemotherapy and survival [12]. Whether this indicates a difference in tumor biology or study design is difficult to know.

Conceptually, a reduction in CA19-9 would seem an attractive measure of response (assuming this is a specific measure of metastatic and primary cancer burden). However, a drop in serum CA19-9 levels in patients with advanced pancreatic cancer after treatment has been shown to be a poor indicator of prognosis following chemotherapy [13].

Neoadjuvant therapy offers a much clearer association between objective measures of response and survival, with the added advantage that such patients provide tissue samples that can be used to identify and test potential biomarkers. Measures such as tumor regression grade (TRG) [14] and reduction in CA19-9 levels [15] indicate better survival. To an extent this association with survival is implicit, as neoadjuvant therapy has as yet been confined to patients who are borderline

resectable, so measures of response define the patients who will go on to receive surgery and who, for that reason, will be likely to survive better.

Ex Vivo Analysis

As an alternative to survival as a measure of response, tumor cells can be removed from a patient and treated with therapeutics outside of the body. Clearly, this removes many potential factors that determine response in the actual patient: the immune system, tolerance of the patient for the agent, the tumor microenvironment, 3D interactions of tumor cells with stromal cells and with themselves, etc. To address some of these issues, patient-derived xenografts (PDX) [16] and organoids [17] have been employed to test response. Treating such models with drug and measuring growth inhibition and cell death could in theory be used in itself as a marker for response in the patient, unfortunately the time required to get a result means that this would be difficult to apply clinically. The approach is more easily applied in identifying potential biomarkers expressed in the isolated cancer cells.

Survivors

Many studies have identified prognostic markers that have then been associated with response to chemotherapy based on multivariable analysis. It can be questioned whether these are truly empirical studies (i.e., was the choice of variables to include influenced by theoretical considerations of drug action) but where the data was collected as part of normal clinical practice, this can at least be defined as semiempirical. Some studies have simply used the observation of a biomarker's association with improved overall or progression-free survival in a cohort of patients treated with chemotherapy as evidence that the biomarker relates to response. In this way, markers such as derived neutrophil-lymphocyte ratio have been claimed to be linked to the effectiveness of chemotherapy regimens including gemcitabine [18]; supporting studies will be described later that make the same conclusion based on very clear theoretical considerations.

Genome-wide association studies suggested that the single-nucleotide polymorphism (SNP) rs11644322 is associated with gemcitabine-specific outcome [19]. This SNP is within the gene for WWOX, which inhibits Wnt signaling upstream of β-Catenin. The A allele of rs11644322 binds SP family members more tightly than the more frequently occurring G allele (allele frequency approximately 75%) resulting in lower expression of WWOX, which has been associated with poorer survival in PDAC patients treated with gemcitabine [19]. Knockdown of WWOX gives greater gemcitabine sensitivity in lymphoblastoid and pancreatic cancer cell lines but did not alter sensitivity to 5-FU significantly. Lymphoblastoid cell lines with GG have lower gemcitabine EC50 levels than the AA and GA versions.

Low levels of the E3 ligase CBL relates to poor survival [20]. CBL also seems to relate to chemoresistance in cell lines, and it is proposed that it helps regulate ERB2 such that its impact on chemoresistance may be modified by the use of erlotinib [21].

High level of cancerous inhibitor of protein phosphatase 2A (CIP2A) has been related to poor survival (although no data was given on chemotherapy), and knockdown of CIP2A in cell lines was claimed to increase sensitivity to gemcitabine [22].

A biomarker that predicts survival benefit with a treatment yet indicates no survival benefit without the said treatment is indicative of a relationship with response. This can even indicate a subpopulation of patients who will benefit from a treatment that overall gives no benefit. For example, bevacizumab did not offer any survival advantage when used in combination with gemcitabine over gemcitabine alone, while abnormal pretreatment serum albumin levels were associated with poor survival in patients treated with bevacizumab but had no benefit in patients treated just with gemcitabine (the implication being that patients with normal b-albumin should receive bevacizumab) [23].

Omic Categorization of Tumors

Tumors can be categorized on the basis of their genome, transcriptome, or metabolome. Response measures can then be compared across the groups.

Whole-genome sequencing of 100 PDAC samples combined with analysis of copy number variation indicated four subtypes of cancer: stable, locally rearranged, scattered, and unstable [16]. Of the five patients who were either in the unstable group or who had otherwise been defined as "on-genotype" due to association with BRCA pathway mutations, four had at least partial response to platinum-based therapy, compared with none of three in the "off-genotype" group. This was supported by two of three "on-genotype" PDXs responding to cisplatin, compared with none of four "off-genotype" PDXs.

Collisson et al. used transcriptional profiling to divide PDAC tumors into three subtypes: classical, quasi-mesenchymal (QM), and exocrine-like [24]. Subtype-dependent in vitro responses to gemcitabine and erlotinib (an EGFR-targeting tyrosine kinase inhibitor) were revealed, with QM being more sensitive to gemcitabine and the classical subtype being more sensitive to erlotinib. It remains to be proven whether the multigene profile is predictive in patients.

To date there has been limited progress in categorizing PDAC based on different metabolomes, but it has been possible to identify a metabolic profile that distinguishes PDAC from pancreatic parenchyma, and within this profile, high cancer ethanolamine was associated with worse survival [25]. In liposarcomas, metabolic profiling of cell lines derived from PDXs distinguished cell lines that responded to gemcitabine from those that did not. The basis of this metabolic difference appears to be high expression of deoxycytidine kinase which increased nucleoside uptake by cells in culture. This could be measured in vivo using positron emission tomography with 1-(2′-deoxy-2′-[18F]fluoroarabinofuranosyl) cytosine (FAC).

Adverse Response to Treatment

An adverse response may limit effectiveness of a given agent; the side effects themselves may be a cause for discontinuation of treatment or dose reductions to the point where any potential benefit is lost. On the other hand, an "adverse response" can be evidence of activity and so could be linked to a survival benefit. For example, some chemotherapeutic and immunotherapy agents cause a rash as an adverse event [26, 27]. In some cases, it has been observed that patients with

a rash have better survival than patients without: this was shown in response to combined gemcitabine or capecitabine with erlotinib [28], and it was also shown with a combination of cetuximab, gemcitabine, and oxaliplatin (followed by chemoradiation with cetuximab) [29]. On the other hand, no relationship was seen between rash and survival with a combination treatment of erlotinib and capecitabine in gemcitabine refractory patients [30].

Rash as a marker of response has a significant disadvantage in that it can only be assessed after the drug has been administered. Furthermore, it takes time to develop, and so a potential window for using an alternative therapy could be lost. There have been attempts to link the development of rash to genetic factors and other biomarkers. Overexpression of EGFR was found not to be linked to rash [31]. On the other hand, adverse events (including rash) associated with gemcitabine have been suggested to be linked to a deleterious cytosine deaminase polymorphism [32], and adverse events associated with capecitabine (including one case of rash) have been reported to be more prevalent in patients with variants in the thymidylate synthase gene enhancer [33].

Resistant Cell Lines

The question of multiple drug resistance and specific drug resistance can also be addressed by generating resistant cell lines. Empirical comparison of expression, mutations, or epigenetic changes between resistant and nonresistant lines can then be addressed, the problem being that this cannot easily identify determinants of response that require interaction between cancer cells and stroma or which are systemic in nature.

A study of acquired gemcitabine resistance in ten derivatives of the cell line BxPC3 concluded that there was little cross resistance because only one cell line had acquired resistance to all the other agents they tested (5-FU, CDDP, CPT-11, and DTX). However, there was evidence of cross resistance to at least one agent in nine out of ten of the lines, so depending on the perspective of the reader, this could be viewed as either proof for or against acquired multidrug resistance. The authors explain gemcitabine resistance in at least four of the cell lines on elevated transcript levels of one of the components of the gemcitabine target ribonucleotide reductase, RRM1. This empirical discovery was perhaps strongly influenced by theory, but other genes involved in gemcitabine transport (human equilibrative nucleoside transporter 1, hENT1) and activation (deoxycytidine kinase, dCK) were excluded as their mRNA was not increased. This assumes transcript level equates to protein level, and the authors provide support for this in relation to RRM1 [34].

Cell lines have also been used in an attempt to identify intrinsic drug resistance, for example, Kim et al. applied elegant proteomic analysis of the cell lines BxPC3 and Panc1 on the basis that the latter cell line is more resistant to gemcitabine and therefore markers that distinguish the cell lines could be markers for resistance [35]. The approach used cannot truly be described as empirical as the differences highlighted were selected on the basis of a theoretical relationship with resistance. Specifically, upregulation of genes associated with epithelial mesenchymal transitions (EMT) was taken to relate to drug resistance because of previously described association between EMT and gemcitabine response [36].

Regulatory Factors as Response Markers

Before discussing methodologies based on known pathways of drug metabolism and action, it is worth considering studies that have focused on regulatory factors selected on observed measures of response rather than on the assumed target of regulation, the most obvious example being microRNA (miRNA) analysis. miRNA arrays or next-generation sequencing techniques have been used to identify individual species or panels of miRNA from resected tissue which correlate with prognosis; these have then been mapped back to the mRNA they regulate in order to propose mechanisms for survival advantage [20]. miRNA species can also be analyzed in a similar way from plasma or serum; comparison between profiles from cancer and noncancer patients can be used to indicate cancer-specific species [37]. On the basis of such profiles, associated with prognosis and/or tumorigenesis, specific miRNA species have been selected and examined for a role in treatment-specific response (using specific PCR or sequencing methods to quantify individual species). In particular, miR-21 has been proposed as a response marker on the basis of low expression being associated with benefit from adjuvant therapy (including gemcitabine) [38]. Association of other miRNAs with drug response has been heavily influenced by assumed mechanisms, for example, the assumed role of ribonucleotide reductase in determining gemcitabine resistance extends to an assumed role of miRNA 101-3p which has been shown to reduce the levels of RRM1 and to restore chemosensitivity to pancreatic cancer cell lines that have acquired chemoresistance due to RRM1 overexpression [39].

If analysis of miRNA is an attractive area for investigation of drug response due to their pleiotropic destabilization of RNA species, factors that stabilize mRNA must similarly be of interest. The protein HuR binds to the 3′ untranslated regions of specific mRNA in response to stress, stabilizing these transcripts. The protein has been shown to be upregulated in various forms of cancer [40], and cytoplasmic localization is associated with poor prognosis [41]. However, low (not high) expression of HuR was found to associate with poor survival in pancreatic cancer patients treated with gemcitabine [8]. HuR was shown to increase levels of dCK and increase sensitivity to gemcitabine in cell lines, which could explain why it increases the sensitivity to gemcitabine (increasing the level of the active metabolite trapped in cancer cells). It could also partly explain why cancer aggression increases in the absence of gemcitabine by potentially increasing the level of nucleotides available for rapidly dividing cells [8]. However, in the RTOG trial, 9704 dCK levels were found to be associated with good survival in patients treated with 5-FU, and, although cytoplasmic HuR did correlate with dCK, no survival advantage was seen with HuR itself [42]. The authors of this study explained the lack of association between survival and HuR on radiation interfering with HuR's regulatory effects [42].This confusing story is perhaps instructive and reflects the difficulty of assessing the impact of proteins which have multiple effects and are affected by multiple factors. Chemotherapeutics including gemcitabine, but also including mitomycin C, oxaliplatin, cisplatin, carboplatin, and a PARP inhibitor, cause HuR to migrate from the nucleus to the cytoplasm, and so measurement of HuR posttreatment will give a very different impression than pretreatment measurement [43]. It is also perhaps a little too easy to

choose the HuR effect that best fits with our assumptions, dCK is regulated by HuR, and dCK is related to gemcitabine response; the easy conclusion is that HuR is related to gemcitabine response. However, a lot of other proteins (e.g., Wee1) are also effected by HuR and may impact tumor aggression and patient survival [43]. It cannot be ruled out that the impact of gemcitabine on HuR is a greater determinant of patient survival than the impact of HuR on the activity of gemcitabine.

Nonempirical Studies of Drug Response Markers

Determinants of Drug Resistance

Response to chemotherapeutics depends on (i) the cancer cell susceptibility to the agent, (ii) the toleration of the agent by the patient's other cells, (iii) the ability of the patient's immune system to respond positively to the action of the chemotherapeutic, and (iv) the availability of the drug at the location of the cancer cells (see Fig. 2).

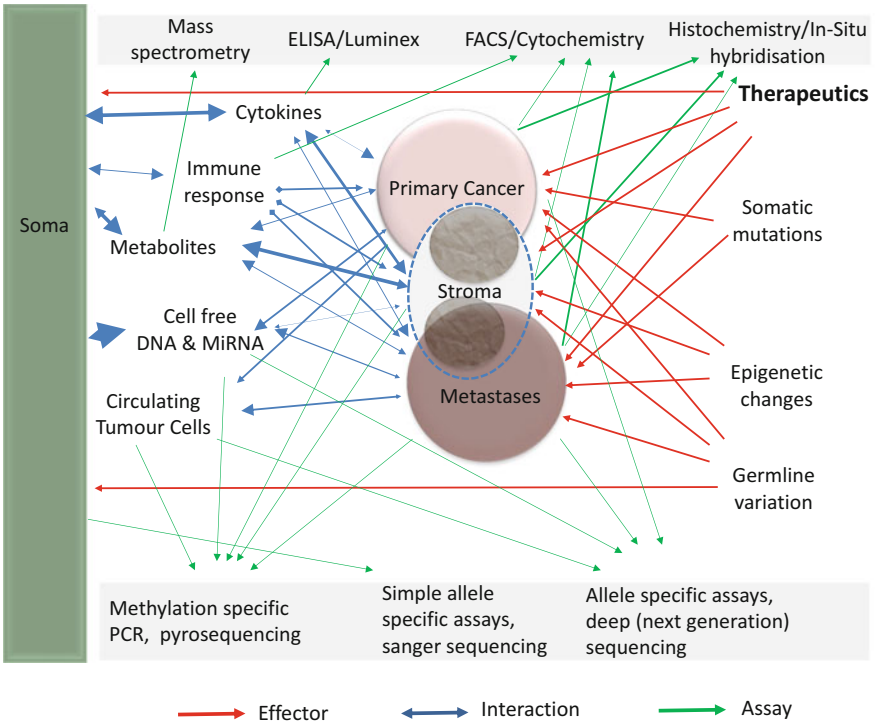

Fig. 2 Sources of biomarkers. The nature of the body (soma), cancer, and stroma is defined by their genetics and epigenetics and also by the actions of external factors such as therapeutics. As a result, the different forms of tissue will release material (cells, exosomes, DNA/miRNA, metabolites, and cytokines) which in turn may act on the tissues to change them further. A picture of how a patient is likely to benefit from a given therapeutic can be obtained by sampling the cancer and stroma or by assay of the substances released by, and corporeal response to, the cancer

Knowledge of how a drug works allows prediction of how response might differ between individual patients dependent on the nature of their particular tumor or germline genetic background.

Pyrimidine-based chemotherapeutics act in a variety of ways: inhibiting various aspects of nucleotide biosynthesis, incorporating into RNA (preventing cell growth and division) or, via incorporation into DNA, stalling replication forks, thus causing DNA breaks and cell death. These modes of action require processing of the drugs along nucleotide biosynthetic pathways which are represented schematically in Fig. 3. The simplest forms of pyrimidine-based chemotherapeutics are nucleobases, the best known example being 5-FU. Nucleobases can be converted to nucleosides by the addition of a sugar moiety or they can be directly converted to nucleotides by the addition of a phosphorylated sugar[44]. 5-FU is converted to a deoxy-nucleoside (5-fluoro deoxy-uridine, 5FdUrd) by the enzyme thymidylate phosphorylase (TP; otherwise known as platelet derived-endothelial cell growth factor) or to a ribonucleoside (5-fluoro uridine, 5-FUrd) by uridine phosphorylase (UP). Conversion of uracil directly to a nucleotide is catalyzed by orotate phosphoribosyltransferase (OPRT) which occurs in the gastrointestinal tract, and inhibition of OPRT by potassium oxonate reduces the toxicity of 5-FU in the gastrointestinal mucosa [45]. Alternatively, the orotate ring of 5-FU can be reduced by the enzyme dihydropyrimidine dehydrogenase (DPD) to the less toxic nonaromatic compound 5-fluorodihydrouracil, which in turn is converted by dihydropyrimidinase and β-ureidopropionase to the effectively nontoxic compound α-fluoro-β-alanine [46].

Nucleosides are phosphorylated in cells to first give nucleoside monophosphates. For gemcitabine, this is carried out by cytidine kinase, for dFdUrd by thymidine kinase, and for 5-FUrd by uridine kinase. Monophosphate deoxynucleotides derived from gemcitabine and 5-FU both inhibit the enzyme thymidylate synthetase (TS) which catalyzes the transfer of a methyl group from folate to uracil to produce thymidine monophosphate. Inhibition of TS will therefore reduce the nucleotide pool and arrest the cell cycle. This explains the sensitivity of therapies (in particular 5-FU) to folate levels. For this reason, the reduced folate analogue leucovorin is usually added to 5-FU, both in traditional 5FU monotherapy and in novel combination regimens such as FOLFIRINOX. Leucovorin not only has the advantage of not requiring dihydrofolate reductase (DHFR) but also appears to induce increased DHFR activity [47]. The ribonucleotide produced from 5-FUrd by uridine kinase or by OPRT is converted to the diphosphate nucleotide by uridylate kinase. Both the ribonucleotide and deoxyribonucleotide diphosphates are converted to triphosphate nucleotides by nucleoside diphosphate kinases such as NME1 (NM23-H1); this would allow incorporation of 5-FU derivatives into RNA inhibiting transcription and translation or causing DNA breaks. Knockdown of NME1 increases sensitivity to 5-FU [48] but increases resistance to other agents such as cisplatin [49], suggesting the inhibition of TS by the diphospho-deoxynucleotide is the critical element of 5-FU toxicity, at least in cell lines.

Nucleoside monophosphate kinase (NMK) catalyzes the conversion of monophosphate to diphosphate nucleotides; on the gemcitabine pathway, this will give difluorodeoxy cytidine diphosphate (dFdCDP), a potent inhibitor of the enzyme

ribonucleotide reductase, which is comprised of the subunit RRM1 and either RRM2 or its stress protein homologue p53R2. Ribonucleotide reductase converts ribonucleotides to the deoxynucleotides necessary for DNA synthesis, so inhibiting its activity will prevent cell division.

Capecitabine (Xeloda) is often described simply as an orally available 5-FU prodrug. Processing of capecitabine almost certainly begins in the liver, where an aliphatic chain is cleaved from the amine group on the orotate ring by the enzyme carboxylesterase to give 5-deoxy-5-fluorocytidine (DFCR). DFCR then needs to be converted into 5-deoxy-5-fluorouridine (DFUR) by cytidine deaminase (CDD) before being converted into 5-FU by thymidine phosphorylase (TP). It is not so clear where these latter two steps occur; it is quite possible that liver CDD and TP carry out these processes, but it is equally possible that this occurs within cancer cells and stromal cells or even extracellularly. Certainly overexpression of CDD in cancer cells increases sensitivity of these cells to DFCR [50]. In contrast, gemcitabine deamination by CDD reduces its toxicity.

As shown in Fig. 3, there are a large number of intermediates lying between prodrugs and their effectors, and the intermediates will interact in a complex way. For example, inhibition of TS by monophosphate nucleotides or ribonucleotide reductase by diphosphate nucleotides will reduce DNA synthesis and so reduce the toxicity of triphosphate nucleotides. It is not only the absolute concentration of these intermediates in a cancer cell that determines the effectiveness of the drug but also the relative concentrations. Concentration will be effected by rate of metabolism inside and outside of cancer cells and also by rate of cellular import and export. Nucleosides and to a lesser extent nucleobases are transported into cells by concentrative (cNTs) and equilibrative (eNTs) nucleoside transporters and are transported out by eNTs. Nucleotides are not transported by nucleoside transporters, and so the phosphorylation of nucleosides will trap metabolites in cells (or prevent their entry), while adding a ribose sugar to a nucleobase will increase import (or export).

Genetic variation in a cancer cell can clearly alter that cell ability to metabolize cytotoxic agents, and it has been demonstrated that genetic heterogeneity does indeed correlate with the variability of pancreatic cancer cell lines to chemotherapeutics [51]. Cancer is a disease characterized by somatic mutations. The genomes of cancer cells are therefore different to the patient's germline. As the objective of chemotherapy is to kill the cancer and not the patient, this offers an opportunity if the chemotherapeutic can be targeted so as to exploit this genetic difference; the genetic difference would then be the most obvious response marker. However, most chemotherapeutics are aimed more generically at the functional differences between cancer cells and their hosts (such as increased cell division). Furthermore, detecting the specific somatic mutations that define sensitivity may be difficult if the tumor load is at a low (treatable) level. For example, following resection of a primary tumor, it is to be hoped that the bulk of the cancer cells have been removed; the remaining cells are now the problem, and these may be genetically very different from the tumor sent to the pathology department.

Germline variants will be carried by cancer and noncancer cells, potentially defining the rate of activation or clearance of chemotherapeutics as well as the

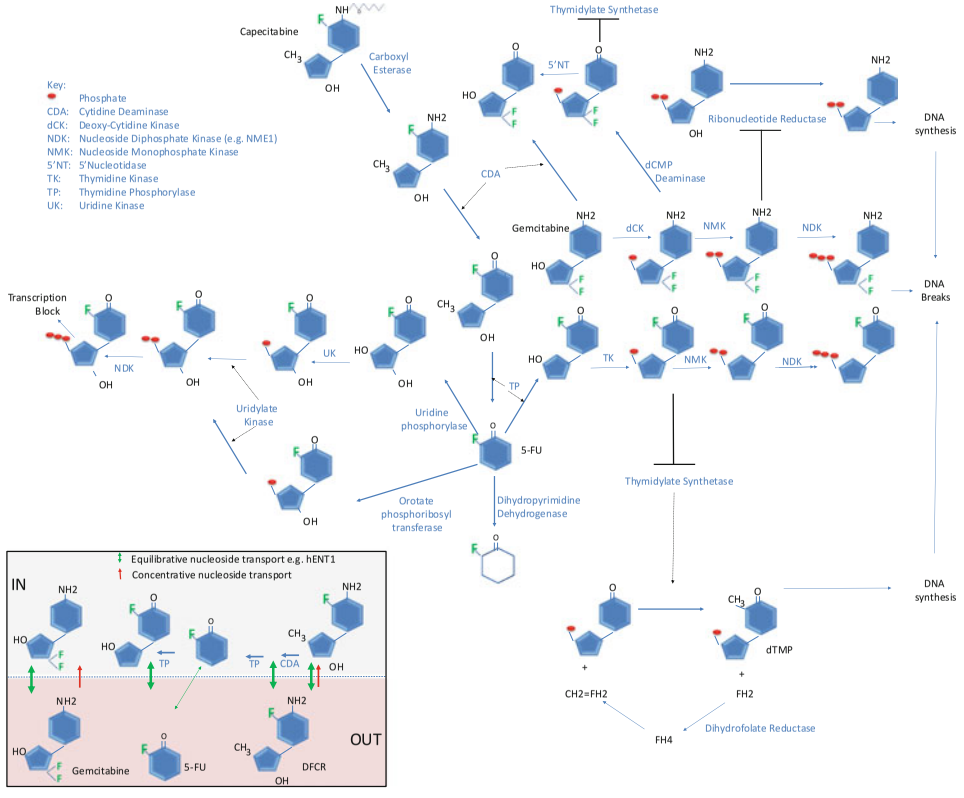

Fig. 3 Schematic of pyrimidine metabolism showing 5-FU, gemcitabine, and capecitabine. Structural features are only shown where they differentiate one form of ribose or base from another (e.g., 3′ hydroxyl groups and orotate ring nitrogens are not shown as they are uniformly present). Gemcitabine would be as for cytidine (an amino-substituted nucleoside) with two fluoro residues on the 2′ carbon of the ribose. 5-FU is uracil with a fluoro residue on the fifth carbon of the

toxicity of the drug and effecting tolerance of the agent and effectiveness against the cancer cells.

Germline Determinants of Benefit: Pharmacogenomics

Dissection of the pathways involved in drug metabolism seems a good place to start when looking for a biomarker. An individual's enhanced ability to clear a drug may reduce toxicity of the compound. On the other hand, too efficient clearance may cause low concentrations of the active compound and result in no antitumoral effects.

Germline polymorphisms of the genes encoding OPRT, DPD, cytosine deaminase (CDA), 5′-nucleotidase (5'NT), uridine monophosphate kinase (UMPK), TS, and methylene tetrahydrofolate reductase (MTHFR) have all been associated with response to pyrimidine-based chemotherapeutics [44, 52, 53]. Neutropenia following treatment with gemcitabine occurs more frequently in patients with a particular haplotype of SNPs within CDA [54]. On the other hand, the same SNPs have been reported to give better survival in patients with acute myeloid leukemia treated with AraC [55], perhaps reflecting the balance between increased sensitivity of tumor cells and reduced tolerance of the rest of the soma. The c.A79C polymorphism of CDA translates into p.K27Q. Individuals with the A/A genotype have a lower CDA activity [56], and in a meta-analysis of seven independent studies the polymorphism did associate with gemcitabine-related severe anemia. However, there was no significant relation with response rates (at least in patients with non-small cell lung cancer) [57].

Systemic 5-FU is mostly detoxified by DPD activity in the liver. Severe and occasionally life-threatening toxicity following administration of 5-FU is commonly associated with DPD deficiency which in turn is associated with the genotype of the DPD gene (*DPYD*) [58]. Two individual polymorphisms – *DPYD**2A (IVS14 +1G>A, c.1905+1G>A, or rs3918290) and c.2846A>T (p.D949V or rs67376798) have consistently shown connection with DPD deficiency [59], and screening for the DPYD*2A variant has been be used for prospective dose adjustment in the clinical routine setting [60]. A meta-analysis examining the relevance of the c.1679T>G, c.1236G>A/HapB3 and c.1601G>A polymorphisms showed that the first two were associated with severe toxicity to 5-FU [61].

Individual SNPs in nucleoside transporters have yet to be shown to have any effect on sensitivity to pyrimidine-based drugs, but a haplotype based on three SNPs

Fig. 3 (continued) ring. Capecitabine is a nucleoside lacking a hydroxyl at the 5′ carbon of the ribose and having an aliphatic chain on the amine group of the base. Like 5-FU, capecitabine has a fluoro residue on the 5′ carbon. Tegafur (the 5-FU prodrug in S1) is not shown in the diagram, but like capecitabine it has a reduced ribose moiety that needs to be cleaved off (giving 5-FU) in order for the drug to become active. Inset is potential transport mechanisms in the tumor: In and out of the cells (stromal or cancer cells). In this figure it is assumed that 5-deoxy-5-fluorocytidine (DFCR) is produced in the liver from capecitabine and converted to 5-deoxy-5-fluorouridine in cancer or stromal cells

in the promoter region of hENT1 (SLC29A11345C4G, 1050-G4A, and 706G4C) has been shown to associate with higher median expression of hENT1 in a Cos-1 cell luciferase reporter assay [62]. This reporter assay does not mean that hENT1 transcription levels will be higher in patients, nor does it mean that this will specifically relate to cancer cell transcription, nor that transcription rate will equate to protein levels in the tumor, it does give one mechanism for heterogeneity in patients. Similarly, common variants in the dCK promoter region have been shown to give up to fourfold differences in transcription level [63]. Again this may not lead to any difference in a given tumor cell's sensitivity to gemcitabine, but it does indicate one way in which patient heterogeneity can be defined that is relevant to drug metabolism.

The principle enzymatic target of gemcitabine is ribonucleotide reductase, which is a protein complex of the RRM1 and RRM2/p53R2 proteins. In non-small cell lung cancer, a haplotype of SNPs in RRM1 was found to associate with survival, although no correlation with protein level was observed [64].

Gemcitabine also causes replication fork stalling and hence DNA damage as an alternative mechanism of toxicity, associating it with the broad range of other DNA damaging chemotherapeutics. The capacity to repair DNA is obviously influential in determining response to an agent that causes DNA damage. Polymorphisms in *ATM* and *CHK1* genes have been associated with overall survival in patients treated with gemcitabine [65]. ATM is involved in detecting DNA breaks and CHK1 acts downstream of ATM to arrest the cell cycle and promote DNA repair.

Cyclin D1

The minor allele of the c.G870A SNP (A) in Cyclin D1 gives an increase in a splice variant form of Cyclin D1 (Cyclin D1b) which results in a truncated protein with gain and loss of function characteristics. The minor allele frequency is approximately 40% in Caucasian populations, and in a mixed population of 300 German patients undergoing resection for PDAC, the 50 patients homozygous for the minor allele had poorer survival (quoted as 15.1 months) than heterozygotes (quoted as 21.5 months) or homozygote major allele (quoted as 29.4 months). The authors also state that in multivariate Cox regression analysis, "a moderate/strong expression of the Cyclin D1 protein was identified as [an] independent prognostic factor for poor outcome with a relative risk of 1.82 (95%CI [1.28–2.67]; $P = 0.003$)" [66].

This is clearly an evidence for a prognostic significance (albeit weak evidence), but lack of chemotherapy data makes this of little value in relation to treatment. However, there is increasing evidence for a relationship between Cyclin D1b and response/prognosis in other cancers, including greater risk of recurrence of breast cancer in patients with D1b. In some studies, this is reported to be independent of D1a protein isoform [67], while in others it is in combination with D1a [68]. Most patients in these analyses had combined doxorubicin and cyclophosphamide treatment, and mouse model data suggests D1b is associated with PARP1 activation (and so DNA damage response) [69]. It is possible that increased D1b at once makes cells more susceptible to spontaneous mutation and more able to survive and proliferate with DNA damage: hence more resistant to DNA damaging agents. D1b is also

associated with anchorage-independent cell growth [70] and is a potential target in its own right for novel forms of therapy.

However, all of the above interpretation has to be treated with caution given findings with prostate cancer. In benign prostate, c.A870 appears to be associated with the level of D1b (as would be expected), but there is no such association in prostate cancer. This seems to be due to the upregulation of the splicing factor ASF/SF2 in prostate cancer and the preferential binding of this protein to the c.G870 transcript [71].

Immune Response

Pancreatic cancer is by nature immunosuppressive, but the level of this suppression is tumor and patient specific with patients showing better immune reactions having the best survival [72, 73]. Measurement of immune response could be a marker of how much a patient will benefit from therapies that co-opt the immune system to fight the cancer. Neutrophil-to-lymphocyte ratio (NLR) is a general prognostic marker; the level of change after gemcitabine-based chemotherapy may also relate to response to the therapy [73].

In an adoptive immunotherapy study where effector cells were selected and expanded using zoledronate, it was observed that the response was better in patients with a high baseline level of lymphocytes [74]. This is of course a special case in terms of a therapeutic biomarker, given that each individual patient was both the source and beneficiary of their treatment.

Evaluation of an immune response to peptide or protein cancer vaccines has largely been disappointing to date; although it has proved possible to engender a specific immune response with the vaccines, this has not resulted in a clear survival benefit [75]. However, whole-cell vaccine approaches, although far from a panacea for PDAC, have been reported to engender an immune response that relates to survival, for example, GVAX (tumor cells engineered to secrete GM-CSF) increases thyroglobulin antibodies, and the level of induction has been claimed to relate to survival [76]. More generally whole-cell vaccines including algenpantucel (allogeneic pancreatic cancer cells engineered to express murine galactosyl transferase) give variable elevation of anti-mesothelin and/or anti-calreticulin antibodies which also correlate with survival [77].

Calreticulin surface exposure will cause macrophage phagocytosis of cancer cells and is a potent inducer of immunogenic cell death (ICD). Its exposure is therefore defined as a key damage-associated molecular pattern (DAMP) quantifying ICD [78]. The ability to cause ICD may be a crucial determinant of whether chemotherapy will be effective or not. CD47 is believed to inhibit exposure of calreticulin [79], and CD47 upregulation causes resistance to agents such as sorafenib [80]. Conversely, loss of CD47 can cause increased immune clearance, at least in human papillomavirus (HPV) carrying oropharyngeal squamous cell carcinoma.

ER stress-induced autophagy (which can be induced by some forms of chemotherapy) reduces exposure of calreticulin [81]. On the other hand, chemotherapy-induced autophagy can also facilitate ATP secretion, which stimulates ICD [82], and

it has been shown that cells lacking the autophagy protein LAMP2A do not expose calreticulin in response to the chemotherapeutic mitoxantrone [83].

Selected Proteins Associated with Drug Metabolism, Transport, or Repair in Tumors

Examination of Figs. 2 and 3 gives an idea of how complex and tangled the pathways are that determine response. Nevertheless, picking the level of a specific protein to measure on the assumption that it might be the key element is by far the most popular approach to assess potential response. Typically, proteins are quantified in a resected tumor sample, despite the fact that the cancer cells resected from a patient are not themselves the target for subsequent therapy and that protein levels are determined at least in part by the tumor microenvironment, which is likely to be very different in metastatic deposits than in the primary.

Enzymes Involved in Drug Metabolism

The levels and activities of proteins involved in drug metabolism are modulated by many factors other than the primary sequence of the genes encoding them. Analysis of epigenetic changes to the genes is one approach, but direct quantification of the proteins in drug pathways is a more direct method to investigate a link to response or even better measure the protein's activity. The challenge is to identify a relevant and accessible clinical sample to analyze. A germline genetic change may only have an impact in one cell type (e.g., cancer, stromal, or liver) but can be measured in any sample from the patient. A somatic mutation is likely to be specific for the cancer cell but can be identified wherever cancer DNA is found (e.g., biopsy, circulating tumor cells or cell-free DNA). High protein levels of a drug-metabolizing enzyme may link to improved response (e.g., increased cancer cell death) when identified in a cancer cell or poor response (e.g., reduced tolerance) when seen in a hepatocyte, and so context is all important.

The plasma levels of a metabolite following the administration of a standard "test dose," enzymatic activity in peripheral white blood cells, or analysis of enzyme expression and/or activity in liver biopsies can all be used as measures but will not necessarily inform about critical features of drug metabolism in the tumor. An individual may be a "slow metabolizer" systemically, whereas the tumor itself may express high levels of the metabolizing enzyme and so clear the tumor microenvironment. As seen in Fig. 3, gemcitabine is metabolized away from its toxicity pathway by CDA, while capecitabine is pushed through its toxicity pathway by the same enzyme. The effect of CDA on 5FU is somewhat more complex; clearly it will change the flux of 5-FU metabolism, but depending on cellular environment, this could increase toxicity (removing non-fluorinated orotate moieties so increasing flux in the direction of toxic nucleotide metabolites) or decrease toxicity (removing fluorinated nucleosides).

Ciccolini et al. measured serum CDA activity in cancer patients treated with gemcitabine, 64 given monotherapy (of whom 40 had pancreatic cancer) and 66 given combination therapy (of whom 12 had pancreatic cancer): patients with higher CDA activity had less treatment-related toxicity [84], consistent with

previous case studies linking low CDA activity to hematologic toxicity [85]. The same group later reported data on serum CDA from 40 patients with advanced pancreatic cancer; 23 had received gemcitabine monotherapy and the rest combination therapy. Response was measured using RECIST, and the authors claimed significantly higher CDA activity in the 11 patients with progressive disease compared to patients with stable disease or a partial response [86]. In direct contrast, the group reported that an adrenocortical carcinoma patient with severe capecitabine-associated toxicities had high CDA, consistent with the contrasting roles of CDA in gemcitabine and capecitabine metabolism (Fig. 3).

Some studies indicate that the intratumoral expression of DPD, as measured by immunohistochemistry (protein level) or in situ hybridization (RNA level), may be inversely linked to survival in patients treated with 5-FU [87] and its associated prodrugs (capecitabine [88] or tegafur [89]) as would be expected as DPD in the tumor will detoxify the drug. More difficult to explain, DPD has also been associated with improved survival in patients treated with gemcitabine [90], raising issues as to whether low DPD in the tumor is a prognostic or predictive biomarker. To add further complexity to this somewhat confused story, although a high ratio of TP to DPD has been reported to be associated with good response to capecitabine in rectal cancer [91] and in a pancreatic cancer study [92] (potentially due to high TP rather than low DPD), another study in pancreatic cancer showed the absolute opposite, i.e., improved survival with lower TP/DPD ratio [93]. This illustrates the problem of assuming a mechanism to explain response. Nevertheless, the concept of DPD inhibition as an adjunct to treatment with 5-FU-based prodrugs has been taken forward with apparent success. The DPD inhibitor gimeracil is used along with tegafur in the combination therapy S1, giving higher concentration of 5-fluorouracil in blood and tumor tissue [2], with a reported increased therapeutic benefit.

As shown in Fig. 3, the effect on drug response of the level of nucleoside transporters is difficult to predict. Concentrative nucleoside transporters would be predicted to increase the concentration of potentially toxic metabolites in cancer cells but will also pump unsubstituted nucleosides into cells changing the flux of metabolites after entry into the cell and determining the consequence of treatment with prodrugs. Equilibrative nucleoside transporters will pump gemcitabine, 5-FU, and other toxic compounds into cancer cells but also out of cells. Numerous cell line studies have examined the effect of different levels of nucleoside transporters on response to gemcitabine and 5-FU with contradictory results [94]. In contrast, studies in patients have fairly consistently shown that high levels of hENT1 are associated with better prognosis in PDAC patients treated with adjuvant gemcitabine [95]. Of importance this does not seem to be true in patients treated with 5-FU [3]. One study indicated that hENT1 levels were not prognostic in patients with advanced pancreatic cancer treated with gemcitabine [96], although this is possibly because of the choice of antibody used to analyze the hENT1 levels [97].

Drug Targets

The discussion above indicates how difficult it is to predict how the levels of enzymes controlling the flux of toxic metabolites will impact on response.

Superficially, it would seem to be much easier to predict the effect of an increased level of a drug target. Obviously, this will only apply assuming no other factor is limiting: the level of a target is immaterial if the drug cannot reach it in an active form. However, considering the target in isolation, it is very tempting to assume that the greater the amount of target in the tumor, the greater the amount of drug required and so the lower the expected level of response. A problem with this is that cancers may become more resistant by losing dependence on a drug target, in which case a tumor might have very low levels of a redundant target protein and be more resistant than a tumor which has very high levels of an essential target protein. Another problem is the potential for multiple targets for a single drug, or the use of drugs with different targets in combination, for example, inhibition of target A may reduce an effect on target B, and so low levels of target A may result in resistance because target B is protected.

It can be seen in Fig. 3 that pyrimidine-based chemotherapeutics have multiple targets. A number of groups have looked at tumor levels of ribonucleotide reductase subunits and TS as possible response markers. Increasing resistance during treatment of cell lines with gemcitabine seems to be associated with increasing levels of RRM1 and RRM2 [98], and reducing the level of RRM1 restores sensitivity to resistant cell lines [39]. Consistent with this, some groups have shown that low RRM1 measured in tumors at the protein level [99] or at the RNA level [100] is related to good prognosis in patients treated with gemcitabine. However, other groups have dismissed this association, again at both the protein [101] and transcript level [102–104]. It is also telling that particular p53 mutations which increase gemcitabine sensitivity, apparently by increasing dCK, also increase RRM1 and RRM2 [105], so higher (rather than lower) levels of ribonucleotide reductase would be a passenger of this particular genetic mechanism for defining sensitivity.

It has proved harder to demonstrate that high TS is associated with poor response to 5-FU, partly because cell lines tend to be sensitive to modulation of TS level regardless of 5-FU treatment and partly because 5-FU effectively induces TS expression in most cell lines. However, by expressing TS using a Tet-OFF system in a colorectal cell line, it has been possible to confirm (at least in this system) that there was a linear relationship between TS and 5-FU sensitivity [106]. In patients (as in cell lines), TS is induced by 5-FU and, at least in lung cancer, this increase is associated with acquired resistance to 5-FU [107].

In patients, the relationship between TS and survival is even more confusing than that seen between ribonucleotide reductase and survival. In some studies with pancreatic cancer, low TS is associated with good response [108]; in others high TS is associated with good response to 5-FU [109] and gemcitabine [110] even though this is otherwise associated with poor prognosis. In still further studies, low TS is linked to good prognosis in pancreatic cancer patients without treatment [111]. This contrasts with studies suggesting high TS is associated with good survival, but this is not related to 5-FU [112]. This confusion is not unique to pancreatic cancer; in colorectal cancer, high [113] and low [114] TS have also both been associated with good response to 5-FU.

It is of course very possible that the differences seen between studies looking at TS and ribonucleotide reductase are due to differences in patient groups and/or analytical methods (the antibody used or method to measure transcripts). Alternatively, this could be explained by a statistical anomaly. It is so manifestly obvious that the level of the drug target in a cancer cell should be relevant to response (confirmed by manipulation of their levels in cell lines) that anyone interested in this area is likely to test this out. Failure to show a relationship will of course be quickly forgotten, while chance demonstration of an association will be published.

This is not to say that drug targets are not excellent candidates as response biomarkers; the problem is that with traditional chemotherapeutics, there are usually multiple potential targets. The current progress in targeted therapy (see Table 1) provides a safer basis for use of targets as biomarkers. Certainly absence of targets within cancers is likely to mean the patient will not respond to the therapy.

Secreted Protein Acidic and Rich in Cysteine (SPARC) Stroma and Nab-Paclitaxel

To improve solubility of taxanes, paclitaxel was bound onto albumin nanoparticles to form nab-paclitaxel (abraxane). SPARC (osteonectin) is an albumin-binding protein which plays a key role is deposition of extracellular matrix. It is expressed on cancer cells and was confirmed to increase intracellular accumulation of nab-paclitaxel [116]. Although initial data seemed to support high SPARC as a marker for response to nab-paclitaxel in various forms of cancer [117], data from the MPACT trial cast doubt on this [118]. This negative finding is consistent with observations in breast cancer where no relationship with survival has been reported with tissue or serum SPARC in patients treated with abraxane [119].

Table 1 Targeted therapy

Target	Drugs in development
EGFR	Erlotinib/SKLB261
IGF-1R	AMG479
JAK/STAT	Ruxolitinib
AKT	RX-0201
MEK	Trametinib/AZD6244
PI3K	BKM120
Wnt	OMP-54F28/LGK974/vantictumab omp-18RS
mTOR	Everolimus/metformin
VEGFR	Sorafenib/axitinib/foretinib/nintedanib
VEGF	Bevacizumab
PARP	Veliparib/olaparib
NOTCH	OMP-59R5
SMO	Vismodegib
TGFβR1	LY2157299

Adapted from Karanikas et al. [115]

Proteins Involved in DNA Repair

PARP compensates for loss of BRCA2; therefore, PARP inhibitors, such as olaparib, are more effective in patients with BRCA2 mutations [120]. BRCA2 itself is relatively rarely mutated in pancreatic cancer, but a much larger group of patients have a pattern of mutation that gives a deficiency in recombination repair analogous to loss of BRCA2 (so called BRCAness), and these patients may benefit from drugs like olaparib which inhibits PARP [16].

As described above, ATM is involved in the cell's response to DNA double-strand breaks, and elevated levels of ATM have been identified in premalignant and invasive pancreatic tumors [121]. Low ATM (with normal Tp53) was found to be associated with poor prognosis in pancreatic cancer [122]. Of the 396 patients in this study, the majority had some form of chemotherapy, but critically 21 had neo-adjuvant therapy only one of whom had loss of ATM, and this patient showed no objective sign of response.

Tp53

Because p53 is mutated in approximately half of all PDAC and is such a crucial gene in the response to DNA damage and other forms of stress caused by chemotherapeutics, mutations in Tp53 are an obvious place to look in regard to drug response. Indeed agents that restore wild-type p53 function do seem to sensitize cancer cell lines to chemotherapeutics such as adriamycin and gemcitabine [123]. It may well be that specific forms of Tp53 mutation do relate to response, but to date attempts to associate the histological p53 levels (mutant p53 being more stable than wild type) or mutant p53 sequences to response have proved unsatisfactory.

Combinations of Protein Markers

It may not be the absolute level of a protein but rather its level relative to other proteins that affects response. For example, 5-FU is processed toward its toxic metabolites by TP and is cleared by DPD, so it is reasonable to assume that a high TP-DPD ratio would relate to efficacy of 5-FU and there is some evidence for this [92]. Interestingly, hENT1-DPD ratio relates to efficacy of capecitabine [92], whereas gemcitabine is affected by hENT1 levels but 5-FU is not, so this suggests that the agent does not enter cancer cells in the form of 5-FU.

Proteins Indicating Epithelial to Mesenchymal Transition (EMT)

The intrinsic capability of cancer cells to transition from an epithelial phenotype, with cobblestone appearance, to a mesenchymal phenotype, with a fibroblastic, spindle-like appearance, has been linked to drug resistance [124]. Exposure of pancreatic cell lines to cytostatic drugs, such as gemcitabine, results in activation of the EMT pathway [125], and cells with high levels of the epithelial marker, E-cadherin, combined with low expression of its transcriptional repressor, Zeb-1, have been shown to be sensitive to three commonly used chemotherapy drugs gemcitabine, 5-FU, and cisplatin[126]. A phase II clinical trial combining MEK1/2 inhibitor, selumetinib, with the EGFR

inhibitor, erlotinib, in patients with advanced PDAC showed that patients with tumors expressing higher levels of E-cadherin, i.e., epithelial phenotypic cells, were significantly associated with treatment sensitivity [26]. Several molecular pathways have been linked with EMT. Embryonic signaling pathways involved in cell differentiation, Hedgehog, Wnt, and Notch can be reactivated in response to gemcitabine treatment [127], and increased expression of these molecules may result in inactivation of the apoptotic pathway or increased expression of drug efflux pumps thereby resulting in the lack of cell sensitivity to cytostatic agents. Additionally, some epithelial cell types are known to be addicted to K-Ras mutations; however, upon transition to mesenchymal cell type, dependency is overcome. This loss of the K-Ras dependency gene signature has been shown to result in a loss of sensitivity to EGFR kinase inhibitors [128]. Therefore, analysis of combinations of markers that indicate the level of mesenchymal or epithelial cancer cells may prove effective in predicting drug response.

Stroma

There is little doubt that stroma is a major determinant of response, but the nature of this involvement is far from clear. Early work with transgenic animal models strongly suggested that stroma prevents chemotherapeutics such as gemcitabine reaching cancer cells, therefore determining level of response [129]. Hedgehog pathway inhibition improved delivery of gemcitabine in a mouse model (presumably by reducing stroma), but the smoothened inhibitor vismodegib did not improve response to gemcitabine in early phase trials [130]. Subsequent work indicated that far from promoting cancer development and spread, stroma could restrain the cancer: depletion of stroma with sonic hedgehog inhibitor was shown to accelerate PDAC progression [131], furthermore eliminating fibroblasts from a transgenic mouse model increased immunosuppression and again accelerated progression [132]. It appears that it is not the level of stroma so much as the type of stroma that matters, for example (again in a mouse model), small metastatic lesions with little stroma seem as resistant (or sensitive) as larger metastatic lesions with high levels of stroma to a combination of gemcitabine and abraxane [133]. At least part of the explanation may lie with stromal remodeling by tumor expressed focal adhesion kinase (FAK); the FAK1 protein seems to reduce CD8 lymphocyte invasion of the tumor microenvironment and increase the number of immunosuppressive cells [134], as a consequence making cancers more resistant to immuno- and chemotherapy [134]. FAK1 may therefore prove to be an important response marker, even if FAK1 inhibition is not successful as an adjunct to other therapies.

Another possibility is that high interstitial pressure may prevent drugs reaching their target because of reduced perfusion and compression of intratumoral vessels. A factor in this is the glycosaminoglycan polymer hyaluronan (HA) that accumulates in stroma. Drugs targeting HA (such as PEGPH20) could therefore increase efficacy of chemotherapeutics. There are early indications that this can be effective if there is high levels of HA [135]

Conclusion

The complexity and interrelatedness of the factors determining drug response means that complex and multifactorial biomarker approaches are needed. The real challenge is to get markers into the clinic; failure of oversimplistic single markers or over-fitted panels of markers is to be expected and should not discourage continued work on rigorously validating new leads. That validation will require careful choice and application of endpoints; in this respect, expectations probably need to be managed, biomarkers predicting cure will certainly be easy to validate, but biomarkers predicting small incremental improvements are at once more probable and less easy to test.

Abstract

Metabolomics, one of the latest omics' technologies, focuses on the global, quantitative, and simultaneous measurement of endogenous metabolites in a biological sample. Investigation of either individual metabolites, a panel of metabolites, or a broad metabolite profile (metabolome) can be carried out in cells, tissues, or body fluids. Recent publications indicate that there is an enormous, constantly growing multitude of metabolomics applications in oncology. As a translational research tool, metabolomics provides a link between basic *in vitro* laboratory data to *in vivo* preclinical results and clinical oncology and enables systems biology insights. In the present chapter, the current and potential future applications of metabolomics in PDAC research are focused on the clinical aspects of diagnostics.

Keywords

Metabolomics · Metabolite profiling · Mass spectrometry · Nuclear magnetic resonance · Metabolism · Biomarker · Systems biology approach · Stable isotope-labeled metabolites · Metabolite flux · MS-based metabolite imaging

Introduction

Metabolomics, also referred to as metabolite profiling, metabonomics, metabolic fingerprinting, or metabolic phenotyping, is defined as a comprehensive, simultaneous, and (semi)quantitative measurement of endogenous metabolites within a biological system [1–3]. It represents a modern omics' technology applying automated analytical instrumentations to facilitate the assessment of many different metabolites within the context of alterations in gene regulation or altered kinetic activity of enzymes, and thus changes in metabolic reactions [2]. Therefore, metabolomics complements upstream biochemical information obtained from genes, transcripts, and proteins, thus widening the current understanding of cell biology, physiology, and medicine by linking cellular pathways to biological mechanisms.

Cellular processes and the physiological status are most closely reflected by the patterns of metabolites (metabolome or metabolite profile), the small molecular weight (<1.5 kDa) endogenous and exogenous molecules such as nucleotides, carbohydrates, amino acids, lipids, hormones, cofactors, and vitamins whose levels are highly responsive to both genetic and environmental factors. Many of these metabolites represent building blocks of the genome, transcriptome, proteome, and cellular membranes or are used as signaling molecules or energy sources. The precise number of human metabolites (the size of the human metabolome) is unknown, with estimates ranging from thousands to tens of thousands.

Compared to other omics' technologies, metabolomics reflects the endpoint of the omics' cascades [4] and the closest snapshot of the cellular phenotype (Fig. 1). In contrast to regulated genes or enzymes, metabolites represent the functional status of the organism. This deep insight into the actual phenotype of any biological system is

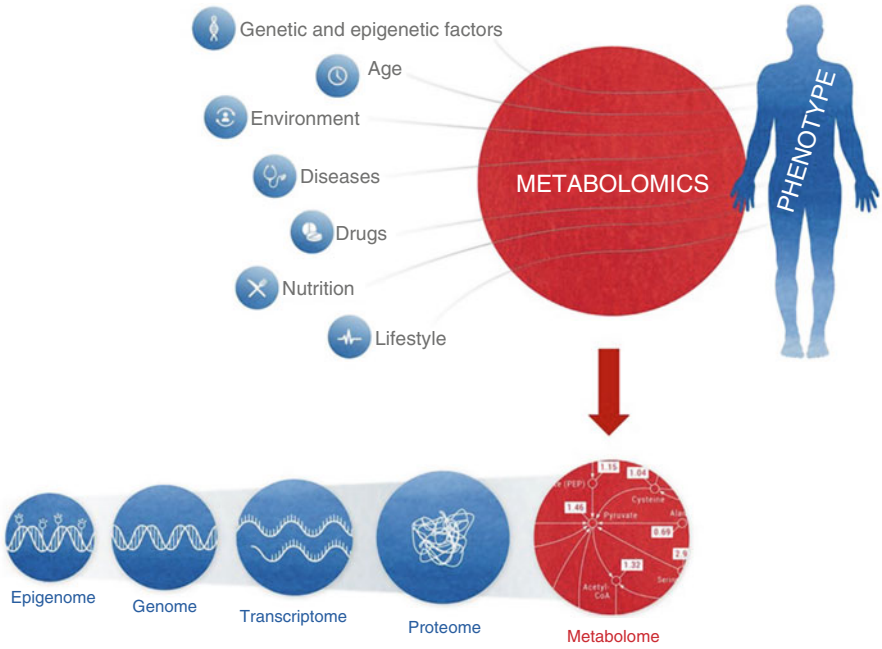

Fig. 1 Metabolomics provides a direct, integrated characterization most closely related to the phenotype

metabolomics' advantage over other omics' technologies. Although, other features of metabolomics are similar to those of genomics, transcriptomics, or proteomics, including the ability to measure both *in vitro* and *in vivo* samples such as cells, tissues, and body fluids. Up-to-date metabolomics represents the ideal approach to understand the current status of a cell or organism of interest and how it is affected by disease, drug treatment, nutritional status, lifestyle, or environment. The resulting characteristic fingerprints can serve as metabolic biomarkers. Metabolic biomarkers are translational across species based on highly conserved biochemical processes and molecular structures, while sequence-based biomarkers (e.g., genes or transcripts) vary between biological classes. This makes them especially useful in the transition from preclinical to clinical studies.

Together with the application of sophisticated statistical approaches, the vast amount of metabolomics data generated from instrumentation can be analyzed and mined, thereby aiding biological and biochemical interpretation (Fig. 2). The success of metabolomics studies is highly influenced by the quality of the investigated sample, innovative instrumentations, sophisticated bioinformatics, as well as biological data interpretation to extract the most relevant findings [5]. Consequently, metabolomics data can be used to build databases that can be integrated with pathway maps, or it can be integrated with other omics' data such as genomics and proteomics providing an enhanced holistic understanding of the biological system.

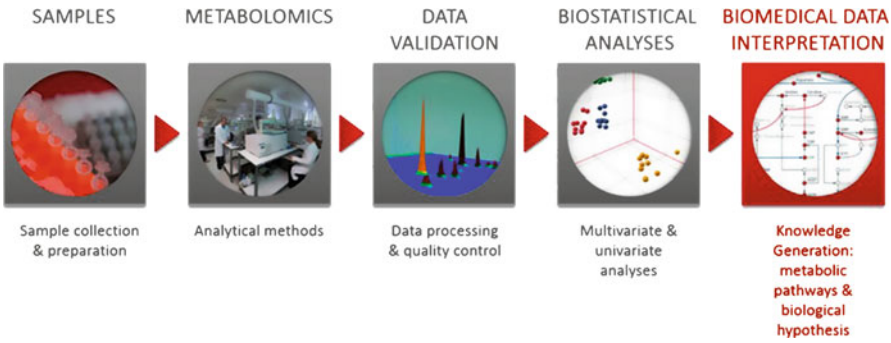

Fig. 2 Experimental setup for metabolomics approach analysis

In this review, general concepts and technical approaches to metabolomics methodology will be highlighted and discussed how it is being applied in the field of pancreatic ductal adenocarcinoma (PDAC) with particular attention to its clinical applications.

Metabolomics: Basic Concept and Insight into Technology

The measurement of single metabolites as a source of information related to health and disease has a long history that precedes the introduction of metabolomics. The Ancient Chinese used ants for the evaluation of urine of patients to detect whether the urine contained high levels of glucose, indicative for a disease now known as diabetes [6]. In the Middle Ages, "urine charts" were used to link the colors, tastes, and smells of urine to various medical conditions, which are metabolic in origin [7]. Over the last decades, metabolomics has developed at an accelerating speed as indicated by the increasing number of metabolomics publications in scientific journals of any biological research field. This development is mainly achieved by increasingly robust, sensitive, and rapid analytical instrumentations allowing the analysis and quantification of hundreds to thousands of metabolites from any biological system.

Metabolites are characterized by a broad repertoire of physiobiochemical properties such as polarity, concentration, structure, mass, and volatility making it challenging to analyze in parallel many different metabolites and/or metabolite classes in a biological sample. Currently, no single technology provides all of the desired properties at once. So far, the main analytical techniques used for the analysis of the metabolome are nuclear magnetic resonance (NMR) spectroscopy and hyphenated techniques (coupling of a separation technique and an online detection technology) such as gas chromatography (GC), liquid chromatography (LC), capillary electrophoresis (CE) coupled to mass spectrometry (MS), flow injection analysis (FIA), and ion mobility spectrometry (IMS). These platforms are complementary in parts so that comprehensive insights can be obtained by combining them.

NMR-Based Metabonomics

NMR spectroscopy can provide measurements for different types and sizes of both polar and non-polar metabolites through analysis of different spectral windows. This technique is based on the energy absorption and re-emission of the atom nuclei due to variations in an external magnetic field [8]. NMR instruments are highly versatile, and with only minor adaptations, users can achieve spectral information for different nuclei (^{1}H, ^{13}C, ^{15}N, and ^{32}P, among others) in solvent or solid samples and even *in vivo* [9]. The major advantages of NMR include its nonbiased metabolite detection and quantitative nature of the data. Furthermore, NMR represents a rapid high-throughput technology, it is non-invasive, non-destructive, and highly discriminatory which can analyze rather crude samples without extensive sample preprocessing and separation. On the other hand, the major problem of NMR technology is its low sensitivity, which limits the majority of currently available instruments to the measurement of approximately 100 metabolites in a single experiment [10]. Mass spectrometry-based technology is preferred in metabolomics and currently has a number of publications exceeding the number of NMR-based publications.

MS-Based Metabolomics

Mass spectrometry is a powerful analytical technology used to quantify known metabolites and identify unknown metabolites (analytes) in a sample. Its high sensitivity and resolution achieved with separation techniques such as capillary electrophoresis, liquid, or gas chromatography allows for the detection of hundreds to thousands of molecules in a single measurement. The complete process involves the conversion of the extracted metabolites into gaseous ions, with or without fragmentation, which are then resolved through the manipulation of electric or electromagnetic fields by their mass-to-charge ratios (m/z) and relative abundances (intensities of detected ions).

Recent technological advances in separation science, ion sources, and mass analyzers have considerably increased the sensitivity, selectivity, specificity, and speed of metabolite detection by MS. The most common ionization techniques in metabolomics encompass, e.g., electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), electron impact (EI), or matrix-assisted laser desorption/ionization (MALDI). Mass analyzers with different resolving powers have also been used in metabolomics. A broad range of mass analyzers can be used such as quadrupole, ion trap, time of flight (TOF), orbitrap, Fourier transform ion cyclotron resonance (FT-ICR), and sector field spectrometers. Sensitivity as well as specificity of the measurement can be increased, and further fragmentation information can be acquired through various combinations of mass analyzers to isolate and fragment target ions and to analyze/detect the resulting fragments. Some of the most commonly used tandem mass spectrometers include combinations of TOF, quadrupole, orbitrap, ion trap, and Fourier transform ion cyclotron resonance (FT-ICR), e.g., quadrupole time of flight (Q-TOF) and triple quadrupole (QQQ). Selection of a

specific MS platform for metabolomics depends on the goal of the metabolomics projects, throughput, and instrumental costs.

Coupling a separation technique to MS provides an excellent solution for complex mixture analyses and has been extensively used in metabolomics. Hereby, analytical separation of metabolites prior to MS analyses offers several advantages: (1) reduced matrix effects and ionization suppression, (2) separation of isomers, (3) availability of orthogonal data (i.e., retention time) valuable for metabolite annotation, and (4) enhanced accuracy in quantification of individual metabolites. Currently, three predominant separation techniques have been incorporated in MS-based metabolomics, i.e., GC, LC, and CE.

GC-MS-Based Metabolomics

GC-MS investigates volatile, energetically and thermally stable metabolites. Due to their poor volatility, GC-MS is less amenable to large, highly polar metabolites. Chromatographic analyses of these metabolites rely on other chromatographic techniques such as LC and CE. GC-MS is limited to volatile compounds. However, relatively few metabolites meet this requirement in their native state, but the number of analyzed metabolites by GC-MS can be further increased by including a prior derivatization step. However, this derivatization step might introduce variability and produce derivatization artifacts. Nevertheless, the high resolution and reproducibility of the chromatographic separation makes GC-MS an excellent tool for complex metabolite extract analyses especially with respect to the differentiation of stereoisomers with a large linear range, e.g., glucose and galactose or oleic acid and elaidic acid.

LC-MS-Based Metabolomics

LC-MS is highly sensitive, typically at the picogram level, and allows simultaneous analyses of multiple metabolites specifically multiple metabolite identification at low concentrations [4]. The coupling of liquid chromatography (LC) to MS (LC-MS) increases specificity and facilitates metabolite quantitation by reducing sample complexity. LC-MS typically involves comparison of the relative abundances of metabolites in multiple samples without prior identification. After selecting interesting features according to statistical criteria, these features can be characterized based on their mass spectral information (accurate mass, isotopic pattern, and fragmentation pattern) and retention time.

CE-MS-Based Metabolomics

CE-MS offers an alternative approach for analyzing anions, cations, and neutral particles in a single run. CE separates metabolites based on charge and size, and it is particularly suitable for the analysis of highly polar and ionic metabolites which can be analyzed with high resolution and sensitivity. A potential limitation of CE-MS might be the poor reproducibility. Recently, the performances of GC-MS, LC-MS, and CE-MS were compared in quantitative metabolomics, and it was concluded that CE lacked the necessary robustness and was the least suitable platform for analyzing complex biological samples [11]. Overall, CE is less frequently used for metabolomics analyses.

Nontargeted and Targeted MS-Based Metabolomics

Metabolomics approaches are often divided into targeted and untargeted applications. As the name suggests, targeted methods [12] are designed to detect and often quantify rather few but specific metabolites of interest within a sample. This approach has the advantage of maximizing the specificity and the sensitivity of MS methods. Furthermore, targeted approaches usually report absolute concentrations based on calibration with authentic standards. In contrast, untargeted global metabolite profiling aims to maximize coverage of many different metabolites, metabolite classes, and metabolic pathways, often compromising the sensitivity and specificity for any particular metabolite. These metabolomics approaches involve less up-front method development compared to quantitative targeted approaches, but require much more data analysis. Interpretation of the hundreds or thousands of resulting ions can be challenging due to a large number of unknown metabolites (analytes with missing structural identification and, therefore, without the exact metabolite name). Identifying and characterizing the structure of metabolites has become one of the major drawbacks for converting raw spectrometric data into biological knowledge, preventing metabolomics from evolving as fast as the other omics' sciences. Furthermore, expertise to integrate metabolomics data and other systems-wide data is still in its infancy.

Metabolomics Applied to PDAC Research

The Pancreas and Its Role in Metabolism

The pancreas has central key roles in the regulation of macronutrient digestion and hence metabolism and energy homeostasis by releasing various digestive enzymes and pancreatic hormones. Hereby, the pancreas acts as an exocrine and endocrine secretory organ. The vast majority of the pancreas consist of exocrine cells knowing to secrete the pancreatic juice containing digestive enzymes, such as amylase, pancreatic lipase, phospholipase A2, lysophospholipase, cholesterol esterase, and proteases (e.g., trypsin and chymotrypsin), into the ducts. These enzymes support digestion and metabolism of carbohydrates, complex lipids, fatty acids, and proteins. In contrast, pancreatic hormones such as glucagon, insulin, ghrelin, somatostatin, amylin, and C-peptide are released in an endocrine manner into the bloodstream. These hormones act as messengers, affecting cells and tissues in distant parts of the human body, and regulate glucose homeostasis. Due to these two main functions of the pancreas (digestion and metabolism of nutrients) and the nature of the involved molecules, metabolomics provides an extremely valuable tool to study the activities of this organ in more detail. Furthermore, metabolomics offers great potential to evaluate metabolite changes connected to abnormal, dysregulated phenotypic characteristics of PDAC cells. A comprehensive overview of the metabolic deregulations in PDAC is discussed in the chapter "New Directions - Metabolism and Pancreatic Cancer" of the present book and was recently reviewed [13, 14]. Briefly, PDAC cells

are characterized by increased glucose uptake and glycolytic activity, addiction to glutamine metabolism [15], increased protein catabolism via enhanced autophagy, as well as upregulated lipid and cholesterol metabolism.

Challenges in PDAC Research

Metabolomics' advancements rely on robust and reproducible measurements as well as low coefficients of variation, crucial for successful metabolomics approaches. Validated protocols including information on sample requirements and handling for metabolomics analysis have been published previously, with emphasis on proper sample collection [16, 17]. Recently, the first validated assay for a holistic human plasma quality control was developed to ensure reliability of the results and secure the investment of a large-scale metabolomics study [18]. Nevertheless, major clinical advances have not yet materialized even though significant scientific progress has been made in the last decade in understanding the biology and natural history of PDAC. Although PDAC shares some of the characteristics of other solid malignancies (e.g., mutations affecting common signaling pathways, tumor heterogeneity, development of invasive malignancy from precursor lesions, and environmental risk factors), there are also unique obstacles that have made progress against PDAC difficult. These include: (i) diagnosis at a late disease stage because of a lack of specific symptoms or biomarkers to facilitate early diagnosis, (ii) dynamic interaction of the tumor with stromal cells creating dense fibrous tissue around the tumor (desmoplasia) that contributes to therapeutic resistance, and (iii) the low number of patients for whom curative surgery is a feasible option. There has been a tremendous initiative to discover novel biomarkers that may aid in detecting the disease earlier, improving prognosis, and predicting response to available chemotherapy. The number of implicated biomarkers in PDAC is staggering.

Explorative Discovery Approaches of Metabolomics in PDAC R&D

Metabolite profiling has been used for various study questions in the field of PDAC encompassing explorative *in vitro* cell culture applications, as well as preclinical and preliminary clinical aspects including samples from humans and animal model systems. Clinical investigation will be addressed later on in this book chapter. Regarding explorative studies, scientists have used metabolomics in a multitude of applications including investigation of PDAC cell autophagy or drug response/resistance. Daemen et al. stratified human pancreatic ductal adenocarcinoma cell lines into subtypes with distinct sensitivities to metabolic inhibitors [19]. Mass spectrometry-based metabolomics was applied to profile the metabolic differences between gemcitabine-sensitive and gemcitabine-resistant PDAC cells [20]. Grüner et al. utilized an established genetically engineered mouse model of spontaneous PDAC to examine the distribution of the small-molecule inhibitor erlotinib, a tyrosine kinase inhibitor acting on the epidermal growth factor receptor (EGFR) in

the healthy pancreas and PDAC by matrix-assisted laser desorption/ionization imaging mass spectrometry (MALDI-IMS) technology [21]. In a humanized genetically modified mouse model of PDAC, it has been shown that autophagy's role in tumor development is intrinsically connected to the status of the tumor suppressor p53, highlighting important considerations for the treatment of this malignant disease [22]. Cachexia is reported in the majority of advanced PDAC patients and has been shown to worsen prognosis. While substantial research is currently focused on determining the mechanism behind cachexia development, no precise understanding has yet been described. Thus, an initial metabolomics experiment was performed to investigate the difference in serum metabolite levels in PDAC patients with and without cachexia and to analyze the pattern and intraday variation in metabolite levels [23].

Overview of Clinical Metabolomics Biomarkers of PDAC

In order to highlight the current advances in metabolomics biomarker discovery for PDAC, a comprehensive literature survey of metabolomics biomarker studies was done and is summarized in Table 1. Human PDAC metabolomics studies were compiled based on the following criterion: only human studies with equal to or greater than five subjects, only studies using MS or NMR technology, and only studies including additional univariate statistics instead of multivariate analysis (principal component analysis, orthogonal projection to latent structure-discriminant analysis) only. Upregulated or downregulated metabolites from cancer patients versus controls are listed according to the studies' biomarker selection criteria. If a study did not indicate the directional change in metabolite levels, then N/A was inserted. In addition to the literature survey, a patent database was screened to identify patent applications referring to either NMR or mass spectrometry-based metabolomics technology to identify PDAC-related human biomarker candidates (Table 2).

The majority of PDAC clinical biomarker studies that employed MS- or NMR-based metabolome analysis reported significant alterations in glucose, amino acid, and protein metabolism as well as lipid metabolism. These dysregulated pathways represent the key metabolic features of PDAC, although different types of diseases and external stimuli (i.e., diet) can cause variations in the same metabolites, making it difficult to connect metabolomics data to specific metabolic pathways. For example, increased glucose concentrations in the urine of PDAC patients, as reported in several studies [27, 32], can be due to the fact that diabetes mellitus (DM) and PDAC are associated diseases that have a complex and not completely understood relationship with each other [43]. On the one hand, long-standing DM is a low to moderate risk factor for PDAC [44]. Conversely, new onset of DM, especially over the age of 50, can be of paraneoplastic character and the first symptom of PDAC preceding other symptoms [45].

Increased levels of circulating branched-chain amino acids (BCAAs) are an early sign of PDAC onset, precede clinically evident cachexia, and are also elevated in

Table 1 PDAC biomarker publications that employed MS- or NMR-based metabolome analysis

[a]Diagnosis and management of pancreatic cysts is clinically important because approximately half may have the potential for malignant transformation to pancreatic adenocarcinoma [42]

individuals with obesity, impaired fasting glucose, and type 2 diabetes which are common PDAC risk factors and/or comorbidities. It has been demonstrated that increased protein breakdown and a subsequent increase in plasma levels of BCAAs are early events in PDAC progression [24], suggesting muscle protein loss and/or paraneoplastic diabetes. These BCAAs and the breakdown products of muscle and adipose tissue may also serve as fuel sources for tumor growth [13].

Reprogramming of lipid metabolism represents another important metabolic feature of PDAC, as reported in several studies [25, 36], but this is also evident in individuals with the some of the most common risk factors and/or comorbidities of PDAC such as obesity. PDAC cells can use alternative lipogenesis routes to obtain fatty acids, whether through the uptake of extracellular lipids derived from diet, liver synthesis, or release from adipose tissue [46]. Additionally, the elevated requirement of cholesterol by PDAC cells can be supplied by *de novo* synthesis, receptor-mediated uptake of cholesterol (low-density lipoprotein receptor (LDLR)), or by

hydrolysis of cholesteryl ethers [47]. This emphasizes the role of high dietary intake and obesity as a risk factor of PDAC.

Further metabolomics studies in PDAC in combination with the integration of genetic information, such as that performed by Zhang et al. [36], are likely to improve disease management and may provide new insights and pave the way to new therapeutic strategies, urgently needed for this disease.

Potential Clinical Applications of Metabolomics in PDAC Management

Clinical metabolomics is expected to be a promising technology for precision medicine (also known as stratified or personalized medicine); however, cutting-edge metabolomics platforms are mainly found in specialized laboratories. Measurement of metabolites is well accepted in clinical routine use, and modern diagnostics rely heavily on the evaluation of pathologically altered metabolites, and the installed base for respective diagnostic platforms is high (i.e., urine test strips, clinical chemistry analyzer). The studies reviewed in this book chapter have identified potentially useful biomarker candidates that may be used in the future for the diagnosis of early PDAC either by improving the sensitivity and specificity of current tests or by substituting them.

Early Diagnosis

Developing a metabolomics-based biomarker for diagnosing a rare disease like PDAC is of special challenge. The benefit is clearly in early diagnosis when the disease is still in its resectable stage allowing for curative treatment. However, sample collections of early-stage patients are even more time-consuming. Access to large-sized and well-balanced case-control studies and prospective cohorts needs more time and resources compared to high-prevalence diseases. Statistical challenges need to be met for an excellent diagnostic performance in order to achieve sufficient positive and negative predictive values and develop a multivariate classification algorithm for a multi-panel biomarker. For example, Kobayashi et al. [28] constructed a GC-MS serum-based diagnostic model and then validated it via the stepwise variable selection method and subsequent multiple logistic regression analysis. The sensitivity of the new model was 77.8% compared to CA19-9 = 55.6% and CEA = 44.4%, in resectable PDAC (stages 0 to IIB). Another recent study [48] showed that a lipid called phosphatidylcholine-594 distinguishes PDAC from control with a sensitivity of 85% at a fixed specificity of 90% and is on the market as a PDAC risk assessment test (PanaSee™, Phenomenome Discoveries Inc.). Since these diagnostic models had a higher sensitivity than CA19-9, applying them in a clinical setting could reduce the incidence of missed malignant changes, reduce unnecessary and expensive follow-up diagnosis or surgery due to a false-positive diagnosis, and lower the psychological burden of being falsely diagnosed with a deadly disease.

Differential Diagnosis

Patients with chronic pancreatitis have a much higher risk for the development of PDAC than the general population. Established diagnostic methods such as CA19-9 (tumor surface marker Sialyl-Lewis A) suffer from insufficient clinical performance, and both diseases present with similar symptoms. Therefore, the differentiation between both diseases remains a clinical challenge. In a multicenter discovery case-control study, subjects were prospectively recruited with either PDAC, chronic pancreatitis, or non-pancreatic control patients (preoperative patients admitted for thyroid resection or hernia repair), and plasma samples were investigated by metabolomics [33, 49]. A biomarker signature of nine metabolites and CA19-9 was identified and validated in independent cohorts for the differential diagnosis between PDAC and chronic pancreatitis [33]. From these results, a targeted quantitative assay (MxP® PancreasScore) was developed that simultaneously quantifies polar and lipid metabolites after extraction and dansylation of samples by LC-MS/MS analysis (personal communication). Applying a fixed diagnostic cutoff value of $\geq$0.608 for the pancreatic biomarker score, an 81% sensitivity for PDAC was achieved in combination with a specificity of 94% for chronic pancreatitis and 91% for non-pancreatic controls, respectively (Fig. 3). Routinely utilizing this biomarker assay and the underlying biomarker signature can, inter alia, help to more accurately distinguish PDAC from chronic pancreatitis and thus support physicians in choosing optimized therapeutic options.

Conclusion

Metabolomics, a high-throughput global metabolite analysis, is a developing field, and substantial evidence has demonstrated its emerging role in PDAC management. Advances in metabolomics along with the novel strategies to analyze, understand, and construct the metabolic pathways open a window of opportunity in a very effective manner. The systems biology approach in biomarker investigation may allow for a deeper understanding of the metabolic path mechanisms of PDAC [50]. Such an approach does not focus on identifying a single target or mechanism of an observed phenotype, but rather seeks to identify the biological networks or pathways that connect the differing elements of a system [51]. Thus, the systems biology approach in combination with metabolomics may lead to the discovery of panels of metabolites that more accurately capture the disease status and help acquire information valuable for individualized clinical care [52].

So far, the different applications of metabolomics have resulted in promising findings but are not sufficient to change current clinical practice. More studies are needed in the future. Clinical trials are ongoing, testing different combinations of drugs that target specific metabolic pathways associated with PDAC. Metformin combined with PDAC chemotherapy (i.e., gemcitabine) is currently being tested in several clinical trials on metastatic PDAC patients. The direct targets of metformin

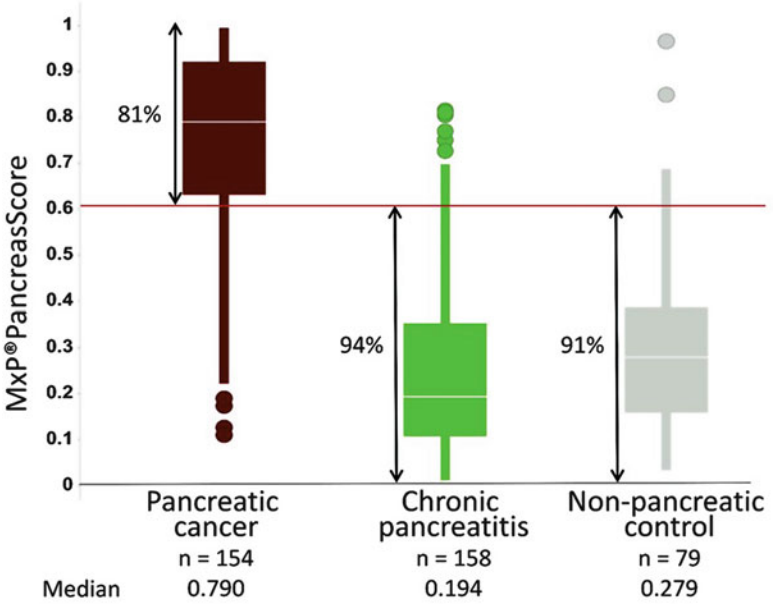

Fig. 3 MxP® PancreasScore generated with metabolites and CA19-9. Box plots give median, upper quartile and lower quartile by the box, and the upper adjacent and lower adjacent values by the whiskers. The upper adjacent value is the largest observation that is less than or equal to the upper inner fence, which is the third quartile plus 1.5-fold interquartile range. The lower adjacent value gives the corresponding value for downregulation. The diagnostic cutoff of the pancreatic biomarker score was set to $\geq$0.608. This translates in a sensitivity for PDAC of 81% and a specificity for CP of 94%, respectively, non-pancreatic controls of 91%.

are not well understood. It does, however, target key metabolic pathways of PDAC cells, giving it potential therapeutic value [13].

Future research frontiers in cancer metabolomics offer great promise. For example, the surgical iKnife (intelligent knife) could help surgeons distinguish between tumor and healthy tissue in the operating room. The iKnife couples existing electrosurgical equipment with a technique known as rapid evaporative ionization mass spectrometry to provide analyses in near real-time by *in vivo* analysis of the aerosol ("smoke") released during electrosurgical dissection [53]. Since tumors have different chemical signatures than healthy tissue, analysis of these signatures via mass spectrometry could help cancer surgeons remove tumors but leave suitable margins of healthy tissue intact, providing a faster, more data-rich alternative to sending samples to a pathologist during surgery.

Stable isotope-labeled metabolites could represent a suitable approach to increase the current basic understanding of the metabolic dependencies of PDAC cells. Isotope labeling is often used to trace pathways within metabolic networks [54, 55]. Another beneficial experimental method for cell culture metabolomics analysis involves stable isotope labeling followed by either MS or NMR measurement. This approach enables pathway tracing, easier metabolite assignment, and

metabolic flux measurements. Isotopic labeling has previously enabled detailed determination of pathways leading to the production of specific metabolites and the development of highly accurate mathematical models of these pathways [56].

MS-based metabolite imaging uses radioactively labeled metabolites or their precursors for *in vivo* imaging that can be used to confirm, in intact living systems, preclinical and *in vitro* assessments. A limitation of LC-MS, CE-MS, or GC-MS methods is the loss of spatial information that results upon metabolite extraction from homogenized samples. Metabolomics imaging technologies can be, therefore, an important alternative and provide information on the spatial distribution of metabolites within tissues. MALDI imaging is the most widely used MS-based tissue imaging approach [57]. MALDI matrix is typically applied to the sample (i.e., tissue) either by spotting or spraying, and images are generated by raster scanning the laser over the sample. Composite images are constructed by mapping the distribution and abundance of ions within the sample.

Although, direct translation of metabolite findings toward management of PDAC medicine is still in its infancy, the advance of analytical metabolite profiling technologies will enable new diagnostic assays with improved sensitivity and specificity over the current conventional biomarkers to be implemented in routine laboratories.

Abstract

Analysis of cellular and molecular components of tumor origin detectable in the bloodstream, so-called liquid biopsies, is demonstrating potential to support management of cancer patients. Development of sensitive technologies enables detection, isolation, and downstream analysis of both circulating tumor cells (CTCs) and circulating tumor DNA (ctDNA) from the blood of patients with various malignancies, in a minimally invasive way, allowing temporal and spatial monitoring of the clinical course of the disease. This is particularly significant in cancers such as pancreas cancer, a particularly aggressive disease with limited treatment options and poor outcomes, where serial biopsy is challenging. CTC enumeration; genomic, transcriptomic, and proteomic analysis; as well as in-depth sequencing of ctDNA may define a comprehensive molecular and genetic landscape of pancreatic cancer and provide a set of novel biomarkers for screening, diagnosis, prognosis, and response assessment. A number of pilot studies have been conducted to assess the role of liquid biopsies in the setting of pancreatic cancer. Although results so far seem promising, more extensive studies are required to establish the clinical utility of CTCs and ctDNA in developing a personalized approach for the management of this malignancy.

Keywords

Circulating tumor cells · Circulating tumor DNA · Liquid biopsy · Pancreatic cancer · Biomarkers

Introduction

A major challenge in managing patients with pancreatic cancer is the need for rapid assessment of disease stage to design an optimal treatment plan. Liquid biopsies, including circulating tumor cells (CTCs) and circulating tumor DNA (ctDNA) to

diagnose cancers, stratify cancer patients for personalized therapies, and monitor tumor evolution and response to treatment are increasingly being studied and are beginning to be clinically implemented. Notably, the first ctDNA test for lung cancer treatment with an epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor was approved by the Food and Drugs Administration (FDA) and European Medicines Agency (EMA) in June 2016 and January 2015, respectively. The potential for liquid biopsies to assist the management of pancreatic cancer, a disease where tumor biopsy is particularly challenging, is reviewed throughout the following sections.

Management of pancreatic cancer, and in particular pancreatic ductal adenocarcinoma (PDA), presents an urgent medical need. PDA is the 10th most common solid cancer in the United States and ninth in Europe, and the second most common gastrointestinal malignancy. However, due to late diagnosis, aggressive disease progression, and limited treatment options, PDA is currently the fifth leading cause of cancer-related death in Europe and the fourth in the United States [1], [2].

Premalignant stages of PDA are classified as pancreatic intraepithelial neoplasia (PanIN). Common genetic aberrations such as activating mutations in the oncogene KRAS and loss of function in the tumor suppressor genes CDKN2A, SMAD4, and TP53 have been identified early during PDA development. Genomic analysis in fully developed PDA and metastatic lesions has further identified ~200 less frequently occurring genetic aberrations. When grouped according to the pathways affected by these mutations, new therapeutic opportunities may emerge [3], [4].

Most patients with PDA are diagnosed at advanced stages and only one in five patients is eligible for surgery with or without adjuvant chemotherapy, which is the only curative treatment strategy available at the moment. Unfortunately, 66% of these patients will experience local recurrence, distant metastasis, or both, leading to a median overall survival in the range of 28 months [5]. The remaining 80% of patients present at the metastatic stage with a dismal 5 year overall survival (OS) of only 2% [2] and are offered standard of care chemotherapy (either gemcitabine monotherapy or combination chemotherapy regimens: gemcitabine and *nab*-paclitaxel or FOLFIRINOX [5-fluorouracil, oxaliplatin, and irinotecan]) with modest impact on overall survival. Although new treatment modalities have been introduced recently, these still only improve OS by weeks to months.

The Metastatic Cascade and Timing of Metastatic Events in Pancreatic Cancer

Development of metastatic disease accounts for 90% of cancer-related deaths in solid tumors and is a common phenomenon during the natural course of PDA. The most common site of metastasis is the liver followed by the peritoneum, lung, and abdominal lymph nodes. Less commonly PDA metastasizes to the adrenal glands, bones, and thoracic lymph nodes. Metastasis is driven by accumulation of genetic and/or epigenetic aberrations, which provide cells with enhanced capabilities for migration, tissue invasion, survival in new microenvironments, and the ability to

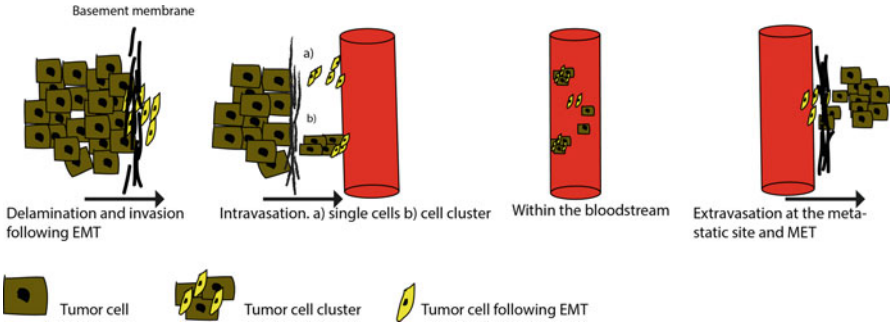

Fig. 1 The metastatic cascade. *Arrows* indicate direction of move. EMT: epithelial to mesenchymal transition. MET: mesenchymal to epithelial transition

seed distant organs and form secondary tumors [6]. Key events underpinning tumor cell metastasis include the delamination and intravasation of tumor cells into the vascular system. Provided they survive in the circulation, tumor cells then extravasate and invade distant organs to form secondary tumors. Together this is also known as "the metastatic cascade" (Fig. 1).

Circulating tumor cells (CTG), the likely harbingers of metastasis, are identifiable in the circulation of genetically engineered murine models (GEMMs) of PDA, even at early stages of disease development (PanIN). This suggests that the metastatic cascade may be initiated early and that the primary and secondary tumors evolve separately in different microenvironments [7]. Clinically this is translated into the synchronous presence of primary and metastatic tumors at diagnosis. Genetic analysis of matched primary and metastatic human tumors provided insight into intratumoral heterogeneity and the acquisition of mutations during the metastatic cascade.

The estimated timeline for PDA metastasis [6] combined with the poor median OS of 3–6 months from time of diagnosis suggests that most patients are only diagnosed after the dissemination of the first metastatic cell. Consequently, newly diagnosed patients likely already harbor occult micro-metastases undetectable by current imaging methodologies. Furthermore, the genetic and epigenetic changes accumulated by cells during and after this period cause remarkable heterogeneity. Firstly, the population of cells that form metastatic deposits is significantly altered compared to the original tumor-initiating cell (TIC) due to clonal evolution in the primary site giving rise to distinct subclones [6]. Further epigenetic changes are accumulated after the formation of metastatic deposits [8], even though metastases share common driver mutations with subclones within the primary tumor [9]. The heterogeneity of metastasis-initiating cells is also evident by their ability to seed various organs with different capillary bed structures and adjacent microenvironment. Moreover, there is ongoing clonal evolution after overt metastases formation and evidence that secondary metastases also harbor TICs, which in turn might enter the circulation to seed further sites [10].

This overall heterogeneous tumor burden has direct implications for the management of metastatic pancreatic cancer. Firstly, certain cell subpopulations such as TICs and those cells undergoing EMT are thought to be relatively chemoresistant [11], [12]. Furthermore, due to inter- and intra-patient tumor heterogeneity, patients respond differently to standard treatments and also after initial response, rapid progression occurs. In addition, the aforementioned diversity makes selection of patients for clinical trials highly inefficient and is likely to result in erroneous assessment of the efficacy of potentially useful agents.

There is a compelling argument that tumor heterogeneity within a patient with metastatic disease might be best reflected in the bloodstream where the cells that have completed the first steps in the metastatic cascade (migration, tissue invasion, and intravasation) can be sampled and assessed. Although it is not clear at the time of sampling which of the sampled CTCs will successfully complete the latter stages of the metastatic cascade and initiate secondary tumors, studying CTCs and the biology of metastatic dissemination will lead to better understanding of the complex biology that underpins pancreatic cancer metastasis. CTCs also have potential as prognostic tools and a source of biomarkers to support the development and selection of therapy.

Circulating Tumor Cells

The history of CTC research began in 1869 by Thomas Ashworth, an Australian physician who observed "...cells identical with those of the cancer itself..." in the blood of a patient with metastatic breast cancer at autopsy [13]. He compared the morphology of the cells in the blood to those from different lesions and concluded that "One thing is certain, that if they [CTCs] came from an existing cancer structure, they must have passed through the greater part of the circulatory system to have arrived at the internal saphena vein of the sound leg."

Eighty-six years later, the interest in CTC detection was revived when Engell published a report describing "the occurrence of cancer cells in the peripheral blood and in venous blood draining the tumor area at operation" [14]. During the following decade, 40 groups described CTC detection using cytological methods; reports that were notable for high CTC numbers. However, there were false-positive counts, as CTCs were often confused with hematopoietic cells, particularly megakaryocytes. Improvements in CTC detection came in 1980s with the emergence of immunocytochemistry. Despite advances in methodology for the detection and characterization of CTCs, their clinical utility was not demonstrated until 2004, when Cristofanilli and colleagues showed that in metastatic breast cancer, increased number of CTCs at baseline and after initiation of treatment is associated with worse progression free and overall survival [15].

The first attempt to detect CTCs in pancreatic cancer was reported in 1996, when Funaki et al. used reverse transcription-polymerase chain reaction (RT-PCR) to detect carcinoembryonic antigen (CEA) mRNA as an indicator of the presence of

adenocarcinoma cells in the blood of patients diagnosed with pancreatic cancer [16]. To date, multiple studies using a variety of methods have been reported trying to establish the optimal method to isolate and characterize pancreatic cancer CTCs and to determine their clinical significance.

The natural history of CTCs can be partitioned into four steps that overlap with key events of the metastatic cascade. Each of these steps is associated with specific changes at the molecular and phenotypic level.

Step 1: Delamination and Intravasation

The first step involves detachment of tumor cells from the primary site and entry into the blood circulation. Acquisition of a migratory phenotype, possibly through epithelial to mesenchymal transition (EMT), allows individual tumor cells to separate from the bulk of the primary tumor. Key to this process is the loss of cell-cell adhesions, for example, through downregulation of E-cadherin expression, a protein critically involved in the establishment of adherens junctions between epithelial cells. In parallel, expression of mesenchymal markers, such as α-SMA, FSP1, vimentin, and desmin, are typically increased. Moreover, during EMT epithelial cells change their shape, lose their apical-basal orientation, and acquire the more mobile mesenchymal phenotype [17]. These changes are accompanied by production of metalloproteinases, which disintegrate the basement membrane and the extracellular matrix, together with tumor neovascularization that facilitates tumor cell invasion into the circulation [17].

An alternative, but nonexclusive, theory supports the "collective migration" of tumor cells, where malignant cells that maintain their epithelial phenotype and cell-cell contacts migrate in cohorts "led" by mesenchymal cells. In co-cultures of squamous cell carcinoma (SCC) cells and fibroblasts, fibroblasts in contact with and at the leading edge of SCC cell clusters paved the way by remodeling the matrix through both physically generated forces and MMP-mediated degradation. The epithelial cells then follow, keeping together via regulated cytoskeletal forces between them [18]. Consistent with this mechanism, the role of EMT in pancreatic cancer cell invasion has been questioned after data showing that deletion of the EMT-inducing transcription factors Twist or Snail in mouse models of PDA failed to abrogate the migratory and invasive potential of the cancer cells [19]. In contrast to the above active form of migration, cell clusters may also passively separate from the primary and enter into the bloodstream [20].

Step 2: Within the Bloodstream

Once in the circulation, cancer cells travel to distant organs along with billions of normal blood cells. The half-life of CTCs in the blood is estimated in the range of 1–2.4 h [21]. CTC survival in the bloodstream is limited by apoptosis, induced by deprivation of stroma-derived growth and survival signals, shear stress in the

circulation, capture and apoptosis within the lungs [20], and clearance by liver Kuppfer cells [22]. CTCs may undergo immune attack by both the innate and possibly the adaptive immune system, orchestrated by natural killer cells (NK cells) and T-lymphocytes, respectively [23].

The assumption is that a fraction of CTCs must survive in the circulation in patients with metastatic cancer, but whether all surviving CTCs are able to form secondary tumors is highly questionable. In an experimental mouse model, where xenografts were developed by injection of CTCs isolated from patients with metastatic breast cancer, immunohistochemistry shows that TICs are likely $CD44^+$ $CD47^+MET^+$ [24] indicating that subsets of cells with higher tumor-initiating capability exist within this population. Such TICs with migratory capabilities have been identified in PDA as $CD133^+/CXCR4^+$ cells [12].

Step 3: Seeding Distant Organs and Metastatic Tumor Formation

Upon arrival at distant organs CTCs extravasate through the capillary walls. As demonstrated in mouse models, cells with a permanent mesenchymal phenotype do not cause development of metastatic tumors. Instead cells undergo the reverse process of mesenchymal to epithelial transition (MET), which transforms mesenchymal circulating cells to epithelial disseminated cells. This is achieved by down-regulation of transcription factors that promote EMT, and potentially explains why metastatic deposits from epithelial primaries demonstrate epithelial histology [25].

CTCs face a new microenvironment at the secondary site. Direct visualization by in vivo videomicroscopy of intraportally injected melanoma cells in an experimental mouse model revealed that only a small fraction of extravasated cells will actively proliferate to form micro-metastases and even fewer micro-metastases result in overt tumor colonies. Another subset of cells remain in the host microenvironment as single cells in dormancy showing neither proliferation nor apoptosis as assessed by Ki67 staining and TUNEL assay, respectively [26]. Apart from these quiescent cells, dormancy can also be observed in dividing cells that are unable to expand as the rate of proliferation is counteracted by equal rate of cell death. Mechanisms responsible for this process include inefficient angiogenesis and control by the immune system [27].

Critical to cancer cell survival in the metastatic host organ is the generation of promoting signals by a “metastatic niche,” a term referring to the outcome of the interaction of stromal cells, extracellular matrix components, and cell signals that enhance survival and self-renewal of extravasated cancer cells [25]. In a mouse model of pancreatic cancer liver metastasis, it has been proposed that this niche is induced by exosomes derived from the primary tumor. Exosomes are membrane vesicles of endocytic origin containing proteins, DNA, mRNA, and microRNA that are taken up by the liver and induce changes in the microenvironment, such as fibronectin production and recruitment and deposition of bone marrow-derived macrophages and granulocytes, ultimately resulting in enhanced liver metastatic seeding. Importantly, the above described changes and initiation of the metastatic

niche are thought to commence before primary tumorigenesis, at the stage of preneoplastic pancreatic lesions [28].

Having secured their survival and also self-renewal capacity via interaction with the metastatic niche, disseminated tumor cells (DTCs) with tumor-initiating capacity activate adaptive programs that provide them with phenotypic characteristics enabling host organ colonization. For example, potential metabolic adaptations may be required for DTCs to overcome the increased oxidative stress at visceral organs [29]. Once DTCs acquire the new traits, they can exploit the interaction with host stromal cells, to destroy the host organ's extracellular matrix, leading to creation of space for the cancer cells to grow.

Step 4: Self-Seeding

CTCs may not originate solely from the primary tumor. In breast cancer models, tumor cells escape metastatic sites to reenter the circulation and reinfiltrate the primary tumor site responding to chemoattractants, a process known as "tumor self-seeding," where in contrast to distant sites, there is little additional adaptation required for further expansion. This process recruits aggressive CTC populations, such as CTC that were shed from metastatic sites after accumulation of additional genetic aberrations, with the result that the primary is now reseeded with more aggressive and heterogeneous tumor cells. These recently recruited cells can interact with the tumor stroma leading to release of growth signals that promote angiogenesis and invasion with an ultimate outcome of local-regional progression and enhanced heterogeneity [30].

Methods for CTC Detection

Overview

CTCs are rare cells with an average of one CTC per 10^6–10^8 blood cells in the circulation. This rarity makes the detection and isolation of CTCs technically challenging. CTC detection, enrichment, and isolation assays exploit various defining characteristics of tumor cells to discriminate and isolate them from the overwhelming number of blood cells in the sample. Most CTC workflows start with enrichment of CTCs followed by CTC detection and enumeration and then a second step to isolate and analyze single CTC molecular profiles. However, not all steps are incorporated within every platform, depending on the purpose of the study and the complexity of the method used. More recent approaches dispense with the enrichment step (where CTC losses can occur) and detect, enumerate, and characterize CTCs within the entire blood sample. This "no cells are lost" approach may be critical for minimal residual disease monitoring and for early detection. Also central to the utility of a CTC assay is the portability of the blood sample, that is, the time from blood draw to CTC enrichment and analysis before the sample has degraded.

This is especially important for multisite studies and the CellSave® preservative tube that allows 4 days from blood draw to analysis at room temperature was a significant step forward in the field.

The worth of a CTC platform is commonly measured by means of CTC recovery rate, enrichment, purity, and throughput. Recovery rate is the fraction of the tumor cells present in the sample often derived using a "spike-in" of a known number of cultured tumor cells. Purity refers to the ratio of bona fide CTCs to other cell types recovered by the platform, and enrichment is the factor by which output purity has increased compared to the input purity. Finally, throughput refers to the volume of blood or number of cells that are processed by the platform within a given time. A high performance platform therefore is considered one which combines high enrichment, purity, recovery rate, and throughput [31]. Another attractive feature is the ability of the platform to enrich and or isolate viable, intact CTCs suitable for culture in vitro or in vivo.

The technologies that have been employed in pancreatic cancer CTC studies are discussed followed by the clinical information they generated.

CTC Enrichment

Methods for enriching CTCs can be broadly divided into marker-dependent and marker-independent approaches. Marker-dependent CTC enrichment is based on expression of cell surface molecules that distinguish CTCs from white blood cells, while marker-independent methods exploit the different physical properties of CTCs compared to blood cells, such as size, inertia, dielectric charge, and density.

Marker-Dependent CTC Platforms

Typically multiparameter immunofluorescence is used for positive and negative cell selection using epithelial cell adhesion molecule (EpCAM), a transmembrane glycoprotein widely and exclusively expressed by epithelial cells and carcinomas [17], and/or alternative tumor associated surface markers, and CD45, a glycoprotein expressed by nucleated hematopoietic cells, to exclude white blood cells (WBC), respectively [17]. Vital to the appropriate assignment of mesenchymal CTCs that may have downregulated epithelial markers via EMT is the inclusion of a marker to exclude circulating endothelial cells (that usually outnumber CTCs in a blood sample). Specifically, increasing the staining assay complexity to assess CD31 or CD105 and vimentin expression allows identification of CD31/CD105-negative, vimentin-positive, epithelial marker-negative cells to be assigned as likely mesenchymal tumor cells. Even then isolation and genomic evaluation of putative CTCs is warranted to confirm tumor origin.

The CellSearch CTC platform (recently acquired by Menarini-Silicon Biosystems) led the CTC research field and is considered the "gold standard" for other platforms to benchmark against in terms of robustness. It has been extensively used in the setting of various malignancies and is FDA-approved for the prognosis and monitoring of metastatic breast, colorectal, and prostate cancers. Patient blood

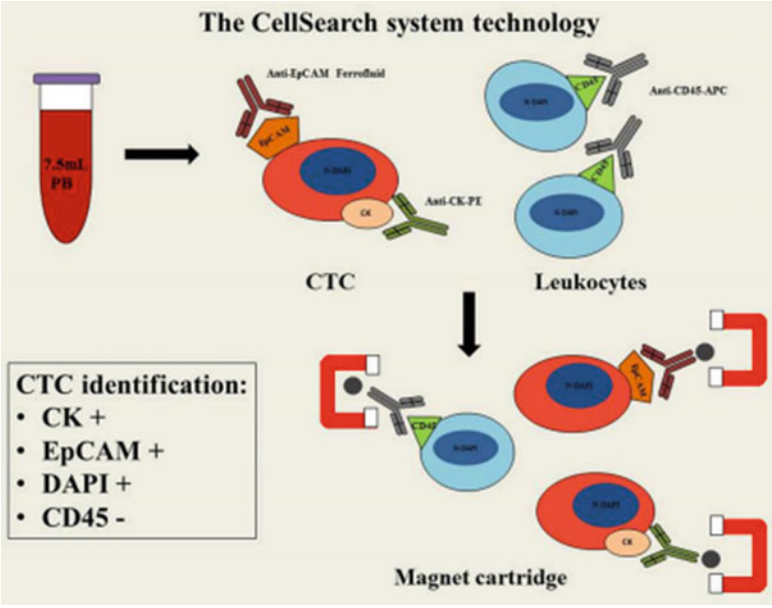

Fig. 2 The CellSearch workflow. *PB* peripheral blood. (Figure as originally published in Ref. [122])

(7.5 ml) is mixed with ferrofluid particles covered with anti-EpCAM antibodies that bind to epithelial CTCs. These ferrofluid particle-CTC complexes are then separated from other cellular components by application of a magnetic field. The sample containing the enriched CTCs is then stained with immunofluorescent monoclonal antibodies against pan-cytokeratin (CK-8, CK-18, and CK-19), CD45 to exclude white blood cells, and a nuclear stain, 4,6-diaminidino-2-phenulindole (DAPI) in order to identify nucleated cells. Samples are then imaged and CTCs are detected as CK+/CD45−/DAPI+ cells (Fig. 2).

In patients with metastatic pancreatic cancer, CTCs were detected less frequently and in smaller numbers compared to other malignancies [31]. CellSearch was also used in the locally advanced pancreatic cancer, to assess the prognostic role of CTCs [32]. However, despite its widespread use, CellSearch has a significant disadvantage, as CTCs that have undergone EMT may have lost epithelial surface markers and remain undetected. As outlined above, these mesenchymal CTCs are likely to hold greater potential to initiate metastasis.

In an attempt to maximize yield and capture pancreatic CTCs that may not express EpCAM, another immunoaffinity approach used immunomagnetic Dynabeads coupled with both anti-EpCAM and anti-MUC-1 antibodies, as MUC-1 is a marker with high sensitivity and specificity for PDA [33]. This method is similar in concept to CellSearch, but following application of magnetic field, in addition to EpCAM expressing cells, it also captures EpCAM negative cells that express the surface marker MUC-1 [34].

Negative Enrichment Approaches

Negative selection via immunoaffinity-based depletion of nontarget cells from a blood sample results in the capture of intact, viable, unmodified CTCs for further downstream analysis. This approach could potentially enrich multiple CTC subpopulations, addressing CTC heterogeneity, but confirmation of tumor origin of the unlabeled cells would be mandatory.

A study using antibodies against multiple markers expressed in nontumor cells resulted in high CTC enrichment efficiency and a mean recovery rate of 82 ± 10%, in "spike-in" experiments which included pancreatic cancer cells. The antibody cocktail used targeted multiple categories of blood cells, specifically, anti-CD45 to target leukocytes, anti-CD16 to target natural killer cells and neutrophils, anti-CD19 to target B-cells, anti-CD163 to target monocytes and macrophages, and anti-CD235a to target red blood cells [35]. Other studies used anti-CD45-only coated magnetic beads to capture and remove WBCs in order to enrich for CTCs independently of EpCAM expression [36], [37].

Marker-Independent CTC Platforms

Size-Based Methods

The majority, but not all, CTCs are larger than WBCs, a difference that has been exploited by many platforms that capture CTCs on microfilters. This approach offers the advantage of isolating cells without modifying their morphology as long as the pressure placed upon them during filtration is optimized. However, contamination by trapping nontumor cells on the filters reduces purity. Two similar filtration methods have been applied to pancreatic cancer: isolation by size of epithelial tumor cells (ISET) [38] and ScreenCell [39], [40].

The ISET platform consists of a 10-well plastic reservoir above a polycarbonate membrane perforated with 8 μm cylindrical pores. After red blood cell lysis, blood is loaded on each of the wells and undergoes filtration by applying regulated suction. CTCs are fixed onto the membrane and are then stained, enumerated, and further analyzed. In a study directly comparing CellSearch with ISET, CTCs were detected in more pancreas cancer patients and in greater numbers per patient by ISET. There was no correlation between the two platforms regarding the number of detected CTCs, suggesting that the two different methods may capture separate subpopulations of CTCs [41]. In the ScreenCell device, blood flows through a microporous filtration membrane and CTCs are captured via low-pressure vacuum-filtration on small metal-rimmed filters.

Density Gradient–Based Methods

Here, blood samples are layered over a resolving medium (Nycoprep [42], Monopoly [43], Ficoll-Isopaque [44]), followed by centrifugation, which separates the CTC-containing peripheral blood mononuclear cell (PBMC) layer, based on density properties. The presence of CTCs in this cell layer can then be detected either by mRNA extraction and RT-PCR for cancer-specific genes or assigned via immunocytochemistry.

Dielectrophoresis Enrichment (DEP)

Due to their unique phenotype and cellular constituents cells of different origins have different electric properties, and this property can be utilized by application of an electric field, resulting in controlled movement of individual cells. The dielectrophoresis method exploits this property to separate and enrich CTCs from normal blood cells. In pancreatic cancer, a study has combined DEP with immunocapture in a Hele-Shaw flow cell to enhance the purity of the captured cells. Application of an electric field near the antibody-coated immunocapture surface in the device achieved isolation of cells from various pancreatic cell lines with high purity, by attracting tumor cells and repelling noncancerous blood cells in spike in experiments [45].

Microfluidic Methods

So-called Lab-on-a-chip devices are designed to encompass several laboratory functions on a microchip. Microfluidic "lab-on-a-chip" devices can process blood down to microliter amounts and by utilizing high throughput arrays are useful for rapid CTC enrichment from patient blood samples. The internal surface of such devices can be functionalized using coatings of antibodies against cell surface markers for positive selection of CTCs.

The CTC-CHIP consists of an array of micropillars conjugated with anti-EpCAM antibodies, where capture of CTCs on the surface of micropillars is achieved, as shown in a study where CTCs were isolated from >99% of patient samples with sensitivity of 99.1% and specificity of 100% and high reproducibility [46]. In an attempt to further increase efficiency a staggered herringbone design (geometrically enhanced mixing Chip, GEM-CHIP) was adopted, which by inducing micro-vortices leads to increased rate of cell-chip surface interaction and greater capture efficiency [47].

CTC-iCHIP

The CTC-iCHIP, the most advanced microfluidic device, can be utilized to enrich CTCs both from epithelial and nonepithelial malignancies, as it can operate either in a surface marker dependent or independent marker (positive and negative selection). It combines several functions exploiting different cell properties, incorporated in three sequential steps on the device. During the first step, whole blood containing either immunomagnetically labeled CTCs (positive selection) or WBCs (negative selection) flows through a set of micropillars along with buffer, where based on their size, red blood cells, platelets, and other blood components are separated and discarded. The remaining CTCs and WBCs enter the second step where they are aligned in single file using inertial focusing. Finally by application of a magnetic field, CTCs are separated and collected for further analysis. The CTC-iCHIP was assessed in spike-in experiments and in a study with blood from patients with

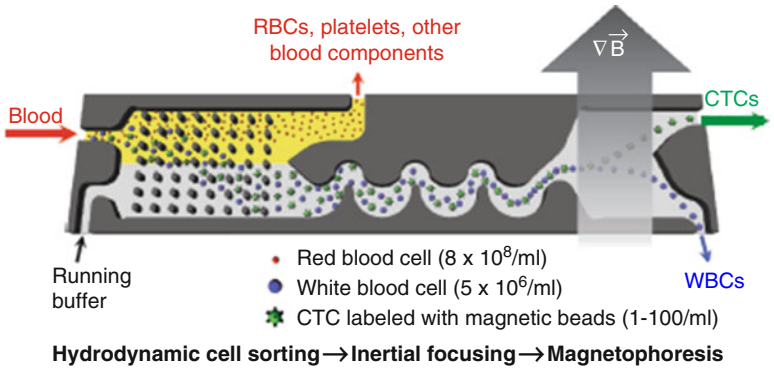

Fig. 3 The CTC-iCHIP workflow (positive selection mode). Following immunomagnetic bead labeling, whole blood flows through a set of micropillars along with buffer. In the first step nucleated cells are separated from other blood components and enter a nonsymmetric, serpentine-shaped microchannel where they are aligned in single file by inertial focusing. In the final step, labeled cells are deflected and collected following application of magnetic field [48]

prostate, pancreatic, breast, lung, and colorectal cancer and yielded CTCs in suspension with high efficiency and purity, suitable for further analysis (Fig. 3) [48].

Functional Assays

Functional assays for CTC enrichment exploit the ability of cancer cells to adhere to a tissue or tumor microenvironment mimic, referred to as cell adhesion matrix (CAM). The Vita-Assay enriches CTCs, including TICs, regardless of primary tumor origin, cell size, morphology, or surface markers, based only on their capacity to invade CAM. Therefore, theoretically it captures the most aggressive cells that hold the greatest metastatic potential. Captured cells are viable cells that can undergo further downstream analysis. Importantly, CAM-captured cells can also ingest CAM. Fluorescently labeled CAM allows for direct visualization of CAM+ cells. This method has been used to enrich CTCs form patient blood including patients with pancreatic cancer [49]. Combination of this platform with fluorescence activated cell sorting (FACS) resulted in increased capture purity in another study of patients with metastatic PDA among other metastatic cancers [50].

CTC Detection

CTC detection, the process by which enriched cells are assigned as CTCs, is achieved based on protein expression profiles or genomic analysis. Protein markers can either be generic, showing the epithelial or mesenchymal origin of a cell, or more specific to tumor tissue of origin suggesting the assigned cell is a CTC candidate. A combination of phenotyping and genotyping is preferable to confirm the identity as a CTC.

Immunocytochemistry

CellSearch utilizes fluorescently tagged antibodies to pan-cytokeratin (CK-8, CK-18, CK-19) as an epithelial marker and to CD45 as WBC marker in order to detect EpCAM-based enriched CTCs, as outlined above. AE1/AE3 is an additional pan-cytokeratin marker which has been used to detect epithelial cells in the blood and bone marrow from patients with pancreatic cancer [42]. CTCs with tumor-initiating capacity were detected by staining with antibodies CD133, CD44, and ALDH to detect "cancer stem cells" [38]. CTCs undergoing EMT were also detected, after staining with antibodies against the EMT marker zinc finger E-box binding homebox 1 (ZEB1) [40]. Immunofluorescent staining was also used to detect MUC1 [51] and MUC4 (another marker present only in pancreatic malignant and premalignant tissues and not in healthy pancreas) expressing pancreatic CTCs [52]. Finally the combination of carbohydrate antigen (CA) 19–9 and CK 8/18 was used to detect apoptotic pancreatic CTCs following fluoropyrimidine treatment, as coexpression of these markers on cells was found to correlate with morphological changes and apoptosis-indicating staining markers [53].

Genomic Confirmation of CTC Assignment

Genomic analysis can be used to confirm CTC identities based on genetic alterations that they share with the primary tumor and are absent in normal somatic cells. This method was used to detect CTCs in a Patient -denied explant (PDX) mouse model of PDA, where single cell genomic analysis of CTCs revealed that they had the same KRAS G12 V mutation as the primary tumor [54]. KRAS mutation is a particularly useful marker in detecting pancreatic CTCs, as it is present in >90% of pancreatic adenocarcinoma. As a consequence, isolated cells positive for this mutation can be reliably identified as pancreatic cancer cells.

An alternative approach is to detect the presence of pancreatic tumor-specific mRNA by RT-PCR after RNA extraction from cells that are present, for example, in the PBMC cell layer following centrifugation in the enrichment step. This approach, even though does not allow for direct cell visualization, provides indirect evidence of the existence of cancerous among nonmalignant cells, like blood cells. mRNA markers that have been used in studies of pancreatic cancer include carcinoembryonic antigen (CEA) [43], CK20 [44], EpCAM [55], and CK19 [56].

Single-marker approaches do not address tumor heterogeneity. A multimarker approach employing RT-PCR analysis of multiple genes, namely KRT19, MUC1, EpCAM, CEACAM5, and BIRC5, resulted in higher detection rates compared to when each of the markers was used separately. In contrast to extracting mRNA from the PBMC pellet following centrifugation, as in previous studies, the multimarker detection was applied to cells isolated by immunomagnetic enrichment with anti-EpCAM and anti-MUC1 [34]. A similar approach was adopted by another group using a different gene panel consisting of human telomerase reverse transcriptase (h-TERT), CK20, CEA, and c-MET [57].

Genomic methods have also been combined with immunocytochemistry in order to increase the power of CTC detection and characterization. Immune staining with

CK, CD45, and DAPI was performed in addition to fluorescence in situ hybridization (FISH) with the centromere of chromosome 8 (CEP8) probe, following negative depletion enrichment for CTCs from blood of patients with benign and malignant pancreatic lesions. This approach utilized ploidy as marker of malignancy and showed that CTCs can be either CK positive diploid or hyperdiploid cells or CK negative hyperdiploid cells [37].

Alternative Detection Methods

Flow cytometry has been used to detect CTCs following density gradient centrifugation and staining of the isolated PBMC layer with antibodies against α5β4-Integrin, MUC-1, EpCAM, CD45, and also Hoechst and Propidium Iodide (PI) for nuclei and dead cell staining, respectively. Tumor cells were identified as α5β4-Integrin^{+}/EpCAM^{+}/Hoechst^{+}/CD45^{-}/PI^{-} cells by applying the relevant gating parameters [58]. Aptamers have also been used as probes for CTC detection. Aptamers are single stranded nucleic acid fragments, which specifically bind to a given molecule, even if the exact composition of that molecule is not known. In a method known as systematic evolution of ligands by exponential enrichment (SELEX), these fragments are developed by repeated exposure of the target molecule to a random nucleic acid library and selecting the sequence that binds to the target with the highest affinity. SELEX Aptamers that specifically bind to tumor cell constituents have been identified and have been used to detect pancreatic CTCs in patients' blood, showing similar efficacy to immunocytochemistry [59]. Another detection method has been developed to exploit the telomerase activity of cancer cells. In this case a recombinant telomerase-specific adenovirus, with a telomerase promoter at the 5-end of the viral genome and green fluorescent protein (GFP) at the 3-end, specifically infected CTCs and allowed their detection by GFP monitoring. This method was successful in detecting CTCs in a study where patients with various malignancies, including pancreatic cancer, were enrolled [60].

Finally, pancreatic CTCs can be detected by classic cytopathology using Giemsa or toluidine blue staining, following microfluidic filtration enrichment [39], or immunohistochemistry with EpCAM and CK following staining with hematoxylin and eosin [41].

Downstream Analysis Beyond Confirmation of Tumor Origin

Once cells have been detected, isolated, and confirmed as CTCs, they are released from the device and are ready for further downstream analysis.

Downstream analysis of pancreas cancer CTCs has been performed in a number of studies. Firstly, mutational analysis of the KRAS gene for codon 12 [40] and codon 13 [40] mutations from single CTCs has been successful with PCR followed by gel electrophoresis and Sanger sequencing. Another group performed whole genome amplification followed by copy number analysis with array comparative genomic hybridization and next-generation sequencing for the genes KRAS, TP53,

and NOTCH1, on CTCs isolated from spike in experiments with a PDA cell line [50]. mRNA microarray analysis has been used in a study trying to identify genetic signatures predictive of response [61]. Furthermore, by subjecting CTCs to single molecule RNA sequencing, a digital gene expression profile was derived which showed that the WNT gene family members were enriched in CTCs with increased metastatic potential, implicating WNT signaling in the metastatic process [62]. Whole genome microarray analysis on RNA extracted from CTCs has also been reported in a study which identified a gene panel consisting of nine genes involved in cell migration, motility, and invasion. The expression of this "cell motility gene signature" was enriched in CTCs [63].

Apart from genomic analysis, pancreatic CTCs were also subjected to molecular characterization with immunocytochemistry. A study used a panel of five markers, namely EpCAM, panCK, Vimentin, CK 7, and E-Cadherin, to characterize CTCs captured by ISET [41]. Finally, viable CTCs isolated by microfluidic approaches were successfully cultured in vitro [47].

Clinical Utility of CTCs in Pancreatic Cancer

Assessment of a suspicious pancreatic mass begins with a pancreatic protocol computed tomography (CT) scan. CT has a sensitivity of 90% and specificity of 99% in diagnosis of pancreatic cancer and the images correlate well with operative findings. Magnetic resonance imaging (MRI) and positron-emission tomography (PET) scans can also be utilized to assist with the assessment of difficult lesions and tumor resectability. However, imaging is not efficient in detecting early postoperative relapse. One confounding element is the associated profuse desmoplasia which, along with the postoperative inflammatory reaction, poses difficulty in identification of small recurring tumors. Moreover, despite the high sensitivity and specificity of imaging modalities, definitive diagnosis is obtained only by endoscopic ultrasound-guided fine needle aspiration (EUS-FNA). On average four passes are required to obtain adequate tissue for subsequent diagnosis. This method is characterized by high sensitivity and specificity, but the presence of chronic pancreatitis, which often accompanies pancreatic adenocarcinoma, can reduce sensitivity. In this case more passes are required [64], increasing the risk of complications. Unfortunately, this technique only provides a small piece of the primary tumor for histological examination and may not accommodate spatial tumor heterogeneity. Furthermore, EUS-FNA is very rarely performed for metastatic lesions, and moreover, serial biopsy is impractical precluding analysis of tumor evolution and dynamic changes before, during, and after treatment that could give insight into the development of drug resistance and provide targets for new therapeutic approaches.

With regards to less invasive biomarkers, there is a relative paucity in the field of pancreatic cancer. CA 19-9 is the most widely used serum biomarker in clinic. However, there are several factors limiting its clinical use. Firstly, 5–10% of the

population are Lewis blood group negative and therefore do not express CA 19-9 even in the presence of advanced pancreatic cancer. Furthermore, CA 19-9 levels are elevated in nonmalignant pancreatic and extrapancreatic diseases, giving false positive results on the one hand, and also being unable to differentiate between benign and malignant pancreatic disease on the other. CA 19-9 is also characterized by an extremely low positive predictive value of only 0.5–0.9%, being ineffective as a screening tool even in symptomatic patients [65].

It is therefore undeniable that better, additional biomarkers are required in many aspects of pancreatic cancer management, from screening, diagnosis, and staging to prediction of relapse and identification of resistance to treatment. Predictive biomarkers are required to stratify patients for personalized therapy and pharmacodynamics biomarkers are vital to support drug development. CTCs in which DNA, RNA, and proteins can be assessed have the potential to provide useful tools in the management of pancreatic cancer and CTC cultures for real-time therapy testing would be a step change for drug development and therapy selection. Table 1 summarizes studies where CTC-based analyses have been used to potentially aid clinical decision making such as for prognosis or response monitoring.

The Potential for CTC-Based Screening

No screening method is currently available for the early diagnosis of pancreatic adenocarcinoma, even for high-risk groups such as individuals with family history of this disease. Screening could lead to earlier diagnosis and consequently increase the number of cases for which surgery and adjuvant chemotherapy with curative intent is possible. A screening method should ideally be minimally invasive and of low cost in order to be suitable for large-scale application. A high positive predictive value for pancreatic malignancy is also necessary. So far, the combination of imaging with serum markers and genetic tests has not proven an effective screening method in familial pancreatic cancer [66].

CTCs have several characteristics that may prove useful in designing a screening tool. Firstly, circulating epithelial cells of pancreatic origin were detected in patients with precancerous pancreatic conditions such as intraductal papillary neoplasm or mucinous cystic neoplasm [67]. This finding supports the theory that epithelial cells circulate in the bloodstream before overt cancer development, providing evidence that findings from genetically engineered mice may also apply to humans. Secondly, circulating cells in patients with precancerous conditions are morphologically similar to those found in the circulation of patients with pancreatic adenocarcinoma and to cells from the primary tumor [39]. Finally, in a study, CTCs and/or CA 19-9 were positive in all patients with confirmed PDA, as CTCs were detected even in patients with normal CA 19-9 levels [36].

No large-scale clinical trial has been designed so far to specifically assess the robustness and cost efficiency of CTCs as a screening tool for pancreatic cancer. The evidence, however, suggests that this minimally invasive method may be useful in

Table 1 Potential clinical utility of circulating tumor cells in pancreatic Cancer

Clinical utility	Method	Patient number	Stage	CTC number	CTC cutoff	CTM	Ref.
Prognosis	ISET	60	Resectable	Mean: 2–4/ml depending on markers used	≥1	N/A	Poruk et al.
	CellSearch	79	Locally advanced	Median: 1/7.5 ml	≥1	N/A	Bidard et al.
	Density gradient centrifugation/ immunocytochemistry with panCK (AE1/AE3)	171	Stage I–IV	Median: $0.4/10^6$ cells	N/A	No	Z'graggen et al.

	Anti-EpCAM-conjugated supported lipid bilayer-coated microfluidic chip	63	Stage I–IV	Mean: 70.2/2 ml	≥70/2 ml	Mean: 29.5/ 2 ml Cutoff: ≥30/ 2 ml	Chang et al.
	ScreenCell	105 (PDA)	Stage I–IV	Not stated	≥1	N/A	Cauley et al.
	CellSearch and ISET	54	Metastatic-inoperable	Median: 0 (CellSearch) 9 (ISET)	≥1 CellSearch N/A ISET	Not detected (CellSearch) Detected (ISET)	Khoja et al.
Prediction of response	CAM-cell invasion assay	50	Locally advanced/ metastatic	Not stated	N/A	N/A	Yu et al.
Response monitoring	CTC-chip	15 (pancreatic)	Metastatic	Mean: 196 ± 228/ ml	N/A	N/A	Nagrath et al.
	GEM-chip	Not stated	Stage IV	Mean: 3/ml	N/A	N/A	Sheng et al.
	Immunomagnetic depletion of $CD45^+$ cells followed by immunofluorescence	41	Stage III–IV	Mean: 16.8 ± 16/ 7.5 ml	N/A	N/A	Ren et al.

this setting, especially for high-risk groups and for patients already diagnosed with preneoplastic conditions, though confirmation at the gene level that the circulating cells are confirmed as tumor cells is required to reduce false positive data.

CTCs for Pancreatic Cancer Prognosis

Identification of prognostic biomarkers is critical in both resectable and locally advanced/metastatic pancreatic cancer. Robust prognostic biomarkers would inform treatment decisions and guide management. In the case of resectable tumors, decisions regarding use of neoadjuvant or adjuvant chemotherapy could be based on prognostic biomarkers indicating worse prognosis. Thus only patients in the worst prognostic group will receive multimodality treatment, saving patients in the favorable prognostic groups from the side effects of chemotherapy. Prognostic biomarkers could also inform more intense follow-up of patients at high risk of relapse, to ensure earlier detection. In the locally advanced/metastatic setting, treatment strategies could be improved by selecting more aggressive chemotherapy regimens for patients with worse prognostic features. The use of CTC count as prognostic biomarker has been proven beneficial in metastatic breast, colorectal, and prostate cancer where the CellSearch assay ($EpCAM^+$/$Cytokeratin^+$ CTCs) is FDA approved. However, the data on CTC count in PDA are contradictory both in resectable and nonresectable metastatic tumors.

CTCs in Localized Disease

Initial evidence in localized disease using density gradient centrifugation to separate the mononuclear cell layer and immunocytochemistry to assign AE1/AE3 positive cells as CTCs showed that CTC number at baseline was not predictive of overall survival (OS). Interestingly, more advanced stage was significantly associated both with the presence of CTCs and worse survival, but this was not translated to a similar effect of CTCs on survival [42]. Also, in a study of 48 patients with PDA (40 resectable, 8 unresectable) where RT-PCR was used for the detection of EpCAM mRNA as a surrogate for CTC presence, there was no impact of the presence of CTCs pre- or postoperatively on disease-free survival (DFS) in the group of patients with resectable disease ($p = 0.28$). Of note, there is significant increase in EpCAM mRNA counts immediately after tumor resection ($p = 0.001$), indicating that surgical maneuvers may result in dissemination of cancer cells from the primary site. However, this phenomenon does not influence DFS [55]. A third study using the ScreenCell platform to filter blood from patients with pancreatic lesions demonstrated no significant difference in OS ($p = 0.69$) or time to recurrence ($p = 0.51$) between CTC-positive and CTC-negative patients in the PDA cohort ($n = 105$ of which 77 had resectable PDA). In this study, the presence or absence of CTCs did not correlate with disease resectability [39].

On the other hand, there are clinical studies to support CTC utility. Firstly, in a study of 67 patients with resectable biliary-pancreatic cancer (of which 34 had pancreatic cancer), the presence of CTCs as indicated by CEA mRNA positivity in

the nucleated cell layer following density gradient centrifugation of blood samples obtained during surgical resection predicted the risk of developing liver metastases with significantly higher risk ($p = 0.01$) in CTC-positive patients. This was translated into significantly worse OS ($p = 0.03$) in earlier stages (stage I–III). CTC detection rate was increased in blood obtained after tumor resection compared to blood obtained at the beginning of the operation, further supporting the phenomenon of cancer cell dissemination during surgery [43]. Furthermore, baseline CTC presence prior to operation was found to be a negative prognostic factor for OS ($p = 0.05$) in a large cohort of 172 patients undergoing surgery. In this study CTC presence was evaluated by RT-PCR for cytokeratin 20 mRNA again in the mononuclear cell layer of patient blood following density gradient centrifugation. Poor tumor differentiation was also associated with worse survival. However, this study showed that based on CTC presence, well and moderately differentiated (grade I and II) tumors could be subdivided in groups of better versus less favorable prognosis, potentially informing different management of these tumors [44].

More recent studies have gone beyond simple detection of CTCs, to CTC enumeration. Negative enrichment by CD45+ cell depletion followed by a combination of immunostaining with CK, CD45, and FISH with the centromere of chromosome 8 (CEP8) probe for CTC identification was used in one of such studies, where 61 patients with pancreatic lesions including 22 pancreatic cancer patients were analyzed. CTC-positive patients demonstrated worse survival rate ($p = 0.0458$) [37]. Also, another study using the same method in 25 patients with PDA (stages I–IV) showed that by using a cutoff count of 3 CTCs/7.5 mls of blood, patients with <3CTC/7.5 ml had significantly increased OS compared to those with >3 CTCs/7.5 ml (15.2 vs 10.2 months, $p = 0.023$) [36].

CTCs are not phenotypically homogeneous. In one study of 60 patients with PDA utilizing the ISET platform, a subset of CTCs with tumor-initiating capacity was significantly correlated with worse DFS ($p \leq 0.03$) and OS ($p \leq 0.01$). These CTCs express at least one of the tumor-initiating cell markers, namely CD133, CD44, and ALDH. In the same study, cytokeratin-only expressing CTC positivity was not significantly associated with survival outcomes [38]. Also in another study of 21 patients with PDA exploiting the ScreenCell platform, while the presence or absence of CTCs was not prognostic for survival, patients with CTCs harboring the KRAS mutation demonstrated better median OS ($p = 0.015$) [40]. These results stress the likelihood that the presence of specific CTC subpopulations may serve as better prognostic biomarkers compared to the whole CTC population.

Differences in CTC detection methods and insufficient statistical power are likely culprits in the discrepant data on CTC number and prognosis so far, along with a lack of consistency in patient selection and inadequate patient numbers for a statistically powered analysis. CTC heterogeneity is possibly another reason for the lack of clarity on CTC number for prognosis. A standardization of CTC enumeration with CTC molecular characterization in future adequately powered studies would lead towards better understanding of the prognostic role of CTCs and eventually may establish this parameter as a useful prognostic biomarker.

CTCs in Locally Advanced/Metastatic Disease

Studies that included patient groups with both localized, resectable and advanced, unresectable pancreatic cancer have reported a trend that CTCs are detected more frequently and in larger numbers in the latter group [41], [55], and [68], although this difference did not reach statistical significance. CTCs expressing mesenchymal markers (ZEB1) are more frequently detected in the metastatic setting ($p = 0.05$), possibly implicating this subgroup of cells to the development of metastatic disease [40]. However, the evidence so far has failed to demonstrate consistent results regarding the prognostic role of CTCs.

In the ancillary CircCe 07 study of the locally advanced pancreas cancer (LAP)-07 trial in 79 patients with locally advanced PDA, the presence of CTCs as assessed by the CellSearch platform at baseline and following 2 months of treatment did not correlate with PFS. However, CTC-positive patients at any time point had a significantly worse OS compared to CTC-negative patients ($p = 0.01$) [32]. Another study using a multimarker assay (RT-PCR for KRT19, MUC1, EPCAM, CEACAM5, and BIRC5 genes) for the detection of baseline CTCs following immunomagnetic enrichment in a cohort of 34 patients showed that the presence of CTCs was significantly associated with worse PFS ($p = 0.01$) [34]. Based on these results, it could be speculated that by increasing the efficiency of detection of CTC subpopulations using multiple markers, the latter study better captured tumor heterogeneity and derived a more accurate assessment of the prognostic role of CTCs. Interestingly, both of the above studies reported significant correlation between the presence of CTCs and tumor grade, with increased CTC positivity rate in poorly differentiated tumors. Finally, a study using two different methods for the detection and isolation of CTCs (CellSearch vs ISET) in 54 patients reported no significant difference both in PFS and OS between CTC-positive and CTC-negative patients, by either method [41].

The negative prognostic role of CTCs on survival was shown by three additional studies using different enrichment and detection approaches, that is, CellSearch [68], [69] and combination of CK, CD45 immunostaining with FISH for CEP8 following negative enrichment [37]. The presence of CTCs at baseline resulted in worse OS [37], [68], and [69]. Of note, CTC-positive patients also had increased serum levels of CA 19-9, but CTC positivity could predict worse survival outcomes even in CA19-9-negative patients, suggesting that combination of these two markers may have some value for prognosis [37]. Lastly, the importance of separation of the whole population of CTCs into subgroups and assessment of the prognostic role of these was demonstrated by a recent trial in 50 patients using the CellSearch platform, where even though CTC number per se was not significantly correlated with survival, patients with CTCs expressing MUC-1 had worse OS ($p = 0.044$) [51].

The prognostic role of CTCs in pancreatic cancer was more comprehensively evaluated by a meta-analyses that included nine studies and a total of 623 patients. This review found that CTC-positive patients had worse PFS ($p < 0.001$) and OS ($p < 0.001$) compared to patients with no detectable CTCs, establishing the presence of CTCs as a useful prognostic biomarker in pancreatic cancer [70].

CTCs as a Monitoring Tool for Response to Treatment

Accurate treatment response monitoring is of great importance for the optimal management of pancreatic cancer as development of resistance and clinical progression is common and happens early in the clinical course of this disease. Precisely identifying the time point of treatment failure would inform timely changes in the management plan. Furthermore, obtaining information regarding the mechanism (s) of treatment resistance would provide the basis for development of new and more effective treatment regimens. The challenge of serial biopsies, the rapid clinical deterioration that patients usually experience, and the unrealistic goal of routinely obtaining tissue from metastatic sites at times of disease progression all point to the urgent need for minimally invasive monitoring approaches.

Liquid biopsies that can be repeated over time may hold the key to improved treatment response monitoring. CTC burden may have potential as a surrogate of tumor burden and/or to predict treatment failure. Molecular profiling of CTCs would provide information about mutations associated with development of resistance. At the same time, liquid biopsies could provide insight into tumor heterogeneity, as both the primary and metastatic sites are represented in the pool of CTCs.

There are some emergent and promising preclinical data that support this view. In a PDX mouse model of PDA, CTC counts effectively mirrored treatment responses. In this study, CTCs were isolated using an anti-EpCAM antibody coated microfluidic device and enumerated based on their electric impedance signatures. Mice were randomized to receive either placebo or a phosphatidylinositol-3 kinase (PI3K) inhibitor, BKM120, which inhibits one of the main RAS-mediated PI3K downstream pathways. The two cohorts demonstrated no significant difference in CTC counts at baseline ($p = 0.8081$). CTCs were significantly decreased in the mice receiving BKM120 ($p = 0.0207$), whereas there was no change in the control group. While there was no statistically significant correlation between CTC number and tumor size ($p = 0.0547$), the fold change in CTC count and fold change in tumor volume were significantly correlated ($p = 0.004$), indicating that CTCs may be an effective biomarker of response [54]. The positive association ($p = 0.03$) between percentage change in CTC number, as measured by the CTC-Chip, and percentage change in tumor burden was confirmed by a clinical study in a cohort of patients with various malignancies, including three patients with pancreatic cancer receiving chemotherapy. This study again failed to demonstrate any association between absolute CTC number and tumor size [46]. However, this association was shown in a third trial which assessed CTCs as response monitoring biomarker in a small cohort of three patients with metastatic pancreatic cancer using the geometrically enhanced mixing chip microfluidic device (GEM-Chip). Here, CTC number decreased in parallel to CT scan-based tumor volume decrease and was associated with tumor size [47]. Finally, in another study that included 41 patients with advanced pancreatic cancer, following one cycle of 5-fluorouracil (5-FU) chemotherapy, CTCs were found in fewer patients and in decreased numbers compared to pretreatment. In this study CTCs were identified by negative enrichment with $CD45^+$ cell depletion followed by immunofluorescent staining with anti-CK8/18 and

anti-CA19-9. Of note, 20% of the post-chemotherapy CTCs displayed apoptotic changes [53].

Despite the positive results outlined above, a more recent study using the CellSearch platform in a cohort of 40 patients with unresectable pancreatic cancer undergoing chemotherapy or chemoradiotherapy showed no correlation between change in CTC number and treatment response based on CT scan [71]. This study leads to two important conclusions: firstly that standardization of the methods used for the detection and quantification of CTCs is absolutely necessary to draw conclusions with cross-site independent validation; secondly, once the most appropriate method is identified, further clinical trials with larger patient numbers are required in order to obtain reliable results regarding the efficacy of CTCs for monitoring of treatment responses.

CTCs as a Source of Predictive Biomarkers

CTC analysis was a useful approach to develop predictive biomarkers in a study of 50 patients with advanced PDA, where genomic profiling of pancreatic CTCs categorized patients into three groups (sensitive, intermediate, resistant) with regards to chemotherapy response. CTCs were captured in a cell adhesion matrix (CAM) using a cell invasion assay and subsequently were subjected to mRNA microarray analyses. Median PFS was significantly prolonged in the sensitive group compared to the resistant group, while PFS in the intermediate group was between the two extremes ($p = 0.0001$). Also median OS was significantly better in the sensitive group compared to the resistant one ($p = 0.0249$). This study showed that treatment responses could be predicted based on genomic analysis of isolated CTCs [61]. These exciting data could provide the basis for a personalized approach in the treatment of pancreatic cancer.

CTCs in Portal Venous Blood

A number of studies have examined CTCs in blood obtained from the portal vein of pancreatic cancer patients. The portal vein is the major draining blood vessel of the pancreas, providing a link to the liver. Liver capillaries serve as a filter through which blood containing CTCs need to travel before reaching systemic circulation. However, CTCs could be trapped in the liver, which may explain why liver is the most common site of pancreatic metastases and also why CTCs are detected in peripheral blood of pancreatic cancer patients less frequently and in fewer numbers compared to patients with other malignancies [15], [32], [41]. The first attempt to detect CTCs in portal venous blood in the setting of pancreatic cancer was in 20 patients with resectable PDA, where blood was obtained from the systemic and portal circulation simultaneously at operation and analyzed by CellSearch. CTCs were detected in the portal venous (PV) blood of patients that had no detectable CTCs in the circulation (five patients) and one patient had CTCs only in the systemic circulation. Also in

patients with CTCs in both PV and peripheral blood, more CTCs were detected in the PV compared to peripheral blood. Despite that no correlation with OS or disease free survival (DFS) was identified, CTC positivity in PV blood was associated with significantly increased frequency of liver recurrences ($p = 0.038$) [72]. These findings were also confirmed by another group, which by comparing PV and peripheral vein blood obtained at operation and analyzed by a microfluidic chip in a cohort of 60 patients with peri-ampullary or pancreatic adenocarcinoma showed that portal venous blood transports CTCs more frequently ($p = 0.0098$) and in higher numbers ($p = 0.0002$). PV CTC count was once again significantly correlated with higher rate of liver metastases within 6 months after surgery ($p < 0.001$) [73]. Importantly, PV blood can be safely obtained not only at operation but also by EUS-FNA, as shown in a study, where no immediate or delayed complications were observed following acquisition of PV blood. CTCs were present in PV blood in sufficient numbers (mean = 111.8 cells/7.5 ml, SEM ±35.3) to allow downstream applications [74].

Interestingly, more recent evidence suggests that the portal vein represents an immune tolerant environment, which promotes the presence and activation of CTCs. In a study of 41 patients with resectable pancreatic lesions including 21 with PDA, myeloid-derived immunosuppressor cells (MDSC) counts were significantly correlated with CTC counts and KRAS mutant mRNA expression, indicating that CTCs were actively transcribing mutant genes ($p < 0.0001$) [75]. MDSC exist in the portal vein and induce immune tolerance, so that normal flora or food particles that are absorbed from the bowel do not cause allergy or autoimmune reactions. Therefore, increased MDSC numbers may facilitate immune evasion and contribute to viability of transcriptionally active tumor cells in the portal vein, which in turn may explain both the higher rate of detectable CTCs in PV blood and the higher incidence of liver metastasis in patients with pancreatic cancer.

Circulating Tumor Microemboli

Apart from traveling as single cells, tumor cells can be found in the bloodstream in association with other cancer cells or noncancerous cells. These groups of cells are termed CTC clusters or circulating tumor microemboli (CTM). Evidence from an experimental mouse model of breast cancer has shown that CTC clusters are detached from the primary tumor as oligoclonal cell groups and are neither formed in the circulation by cell aggregation nor are derived from proliferation of a single CTC. CTC clusters demonstrate greater ability to form metastasis and have shorter half-life in the circulation compared to single CTCs [76]. The above properties lead to the hypothesis that CTC clusters are possibly entrapped within the capillaries where they extravasate and initiate formation of metastatic deposits. Therefore, their presence in the circulation may signify worse patient outcomes. Indeed, in small cell lung cancer, it has been demonstrated that the presence of CTM at baseline is significantly associated with worse PFS (HR = 2.07, 95% CI: 1.21–3.54, $p = 0.008$) and OS (HR = 2.94, 95% CI: 1.67–5.19, $p < 0.001$) [77].

The presence and clinical significance of CTM were also investigated in pancreatic cancer. CTM were detectable by ISET but not CellSearch in a study were both platforms were compared. Cells within CTM were heterogeneous with regards to expression of epithelial and mesenchymal markers, as both cytokeratin (epithelial marker) positive and negative cells were detected and also there was heterogeneity of the expression of E-cadherin (epithelial) and Vimentin (mesenchymal) markers [41]. In a more recent study, the detection of CTM by an EpCAM coated microfluidic device was used to categorize patients of both early and advanced stage to favorable versus unfavorable groups, using a cutoff of >30 CTMs/2 mls of blood. Patients in the unfavorable group demonstrated significantly worse PFS (2.7 vs 12.1 months, $p < 0.0001$) and OS (6.4 vs 19.8 months, $p < 0.0001$). Importantly, when a cutoff of >70 CTCs/2 mls blood was used, no statistically significant difference in PFS and OS was seen between the favorable and unfavorable groups, showing that CTM probably are a better prognostic biomarker compared to single CTCs [78].

Circulating Tumor Cell Derived Explants (CDX)

As already outlined, the population of tumor cells that circulate in the bloodstream contain the subgroup of cells with tumor-initiating capacity that is responsible for the generation of metastasis. It is therefore implied that transplantation of CTCs in immunocompromised mice would lead to tumor formation and development of in vivo models that could potentially recapitulate the biology of the most aggressive tumor compartment. CTCs enriched from the blood of patients with small cell lung cancer were injected into the flanks of immunodeficient mice and formed tumors. These patient CTC-derived explant models (CDX) demonstrated similar morphological characteristics to the primary tumors when assessed by histopathology and immunohistochemistry. Genomic analysis by next-generation sequencing and copy number aberration (CNA) analysis of matched CDX and patient tumors showed that CDX preserved the genomic signature of the tumor of origin. Finally, when the in vivo models were treated with cisplatin-etoposide chemotherapy, responses were similar to those of the donor patients [79]. More recently, CDX were also developed from melanoma patient CTCs with a success rate of 13% (6 out of 47 attempts). Again, CDX shared common morphology and immunophenotype with the original tumor and also demonstrated common genetic characteristics as assessed by whole exome sequencing (WES), CNA and RNA sequencing, and similar response to treatment, providing a potentially useful clinical decision making tool [80].

However, CDX models were first developed from hematopoietic cell depleted blood from patients with metastatic breast cancer, following transplantation into the femoral medullar cavity of immunodeficient mice. In this case, metastatic bone, lung, and liver deposits of human breast tissue origin were reported in six mice out of 118 attempts. Only samples containing at least 1109 CTCs, as measured by CellSearch, led to mouse tumor development, and these samples were drawn from three different patients from a cohort of 110. By surface marker analysis with fluorescence activation cell sorting (FACS), it was shown that $CD44^{+}CD47^{+}MET^{+}$ CTCs possess metastasis-initiating

capacity and that the number of these cells correlates better with disease progression and OS compared to the number of the whole CTC population [24].

To date CDX models have not been reported for pancreatic cancer. The rarity of CTCs in pancreatic cancer patient blood may pose a barrier to the development of such models. It is clear, however, that CDX could serve as a platform to study the complex biology and test novel treatments that will aid at tackling this particularly aggressive disease.

ctDNA in Pancreatic Cancer

Cell-Free DNA (cfDNA) and Circulating Tumor DNA (ctDNA)

Cell-free DNA (cfDNA), was first described in 1948 [81] and, more recently, has been the subject of intense study and is now being used in a number of clinical settings. Most studies and this review focus on cfDNA released into the bloodstream and assessed in plasma or serum; however, cfDNA can be examined from other body fluids, including urine, cerebrospinal fluid, stool, saliva, uterine lavage, and pleural fluid. Although the origin and any potential function of cfDNA remains unknown, it is thought to be released by dying cells and, based on observations that most cfDNA fragments appear to be 170–200 base pairs (bp) inter-nucleosomal fragments, it is inferred that cfDNA is derived primarily from apoptotic cells [82]. The half-life of cfDNA has been estimated to range from 16 min to 2.6 h [83], [84], with removal of cfDNA from circulation mediated by the kidneys, liver, spleen, and/or circulating nucleases [85]. Healthy individuals have detectable cfDNA; however, a number of physiological and/or pathological conditions can alter cfDNA size and concentration [86].

For patients with cancer, some of their cfDNA is released by tumor cells to generate circulating tumor DNA (ctDNA) and can provide a snapshot of genetic changes in the tumor itself. The tumor component of cfDNA in cancer patients was firmly established through cfDNA genomic analysis which identified canonical oncogene mutations in TP53 in patients with bladder cancer [87] and KRAS in patients with colorectal [88] and pancreatic cancer [89]. In a study of pancreatic cancer patients, matched tumor and cfDNA sequencing established that in each patient there was a precise match between the sequences observed in plasma cfDNA and tumor [90]. Based on the observation that tumor DNA is often detectable in the cfDNA obtained from cancer patient blood, the term ctDNA is now often used for all oncology cfDNA studies even though some samples may not contain any detectable tumor DNA.

Cancer patients can have higher overall levels of cfDNA compared to healthy individuals, although the levels can overlap [91]. Correlations have been made between cfDNA levels and tumor size [92] as well as staging [93] and ctDNA is shorter than cfDNA from healthy tissue [94]. However, although increased cfDNA

concentration and differential size can indicate the presence of cancer, this is not widely accepted as sufficient for a definitive diagnosis.

The low levels of ctDNA present in cancer patient blood samples represent a major technological challenge which has been met by the development and application of highly sensitive PCR methods and the application of next-generation sequencing (NGS). Targeted, PCR-based mutation analyses yield high sensitivity and the ability to pick-up single mutant DNA molecules. Allele-specific PCR techniques, for detecting hot-spot mutations in ctDNA, have been used for more than a decade [95]. Technologies, such as the amplified refractory mutation system (ARMS) and competitive allele-specific TaqMan PCR (castPCR), report sensitivities as low as 0.01% in clinical samples [96], with one study reporting mutation detection of one tumor-derived copy of DNA in a background of 200,000 wild-type DNA molecules [97]. Digital PCR methods are now matching the older PCR/qPCR technologies for analytical sensitivities and can provide additional advantages. The basis for digital PCR is to separate and amplify single DNA molecules and provide a digital readout for each molecule amplified. The approaches to digital PCR are differentiated largely by the method of partitioning the DNA, either by microfluidic chambers (Fluidigm and OpenArray) or generation of microdroplets using water-in-oil emulsions (ddPCR using Bio-Rad and RainDance Technologies). These highly sensitive and quantitative methods are now used extensively to quantify ctDNA levels [98]. However, these PCR-based approaches are limited in their multiplexing capacity that is, they typically address a single locus or nucleotide and require prior knowledge of the molecular genetics of the tumor type or individual tumor.

Two main approaches are used for NGS analysis of clinical samples: (1) amplicon-based approach which involves PCR amplification of defined regions and subsequent NGS of the amplified product and (2) pull-down or hybrid capture where genome-wide NGS libraries are prepared and the targeted regions selected by hybridization pull-down [99], [100].

With amplicon-based NGS analysis, it is possible to target many kilobases, using dozens to hundreds of amplicons [101], [102]. While amplicon-based NGS has high sensitivity, it is limited by numbers of primers and inability to multiplex across multiple genes as well as their inability to detect complex alterations, such as chromosomal rearrangements. Hybrid capture-based approaches can target dozens to hundreds of kilobases and thus increase the genomic regions studied [99]. Until recently, the analytical sensitivity of NGS was limited by error rates generated while generating NGS libraries which typically has a background error rate of ~1%. This is particularly important for cfDNA analysis since the tumor fraction may be low, meaning tumor-specific mutations may be obscured by background error rate. Recently, a number of methodologies (lab-based and bioinformatics approaches) have been developed to lower the limit of detection in the NGS approaches. Using molecular barcoding, running multiple replicates, error suppression using bioinformatics, or a combination of all, it has been possible to reliably detect ctDNA allele fractions below 0.1% [101], [103].

Comprehensive, Untargeted Analysis of ctDNA

With the introduction of NGS, it is now possible to interrogate the ctDNA in a more comprehensive genome or exome-wide approach, although it typically requires higher ctDNA concentrations (typically a minimum of 5–10%). The advantage of more comprehensive analysis is that there is no requirement for prior knowledge of the genetic landscape of the tumor and can find de novo mutations, as well as scrutinize complex genome rearrangements. While this comprehensive approach is powerful, it is still time-consuming, more expensive, and requires much higher depth sequencing, but with the aid of improved bioinformatics approaches, reductions in the cost per genome advances are being made in this field. Whole exome sequencing (WES) was reported for ctDNA in longitudinal blood samples in 2013, identifying mutations associated with acquired drug resistance [100]. However, due to the limited analytical sensitivity and high costs, it is not used commonly. Whole genome sequencing (WGS) is especially informative, as it is not limited to known changes/mutations and can follow tumor evolution and heterogeneity during disease progression and selective pressures from cancer treatments. Genome-wide studies revealed a dynamic and complex mutational landscape in cancer, but also the utility of ctDNA and liquid biopsies in general in the field of personalized medicine and beyond [104], [105]. As well as analyzing chromosomal aberrations, focal amplifications, and gene rearrangements using high depth WGS, it is possible to analyze plasma ctDNA copy number changes using low depth WGS [106]. This approach reliably detects somatic copy number changes in plasma ctDNA, down to 5% in a fast and cost-effective way [106], [107].

Clinical Utility of ctDNA and ctDNA in Pancreatic Cancer

A number of studies have shown that patients with detectable ctDNA have worse survival outcomes than those without [108]. It has also been reported that ctDNA is a significantly better prognostic predictor than commonly used markers, such as CA 15-3 and CA-125 levels in breast and ovarian cancer, respectively [109], [110]. Schwaederle et al. analyzed ctDNA in patients with multiple cancer types using a 54-gene panel and found 58% of the cohort had detectable ctDNA, with 71% patients carrying at least one actionable mutation linked to a specific therapy [111]. In a study across a range of cancers including pancreatic cancer, Bettegowda et al. found that ctDNA was detected in 82% of patients with stage IV disease and 47% with stage I disease, showing its potential for noninvasive early diagnosis [93].

Although relatively few clinical studies have looked at ctDNA in pancreatic cancer, the initial data looks promising and indicate that ctDNA may be a valuable addition to the current pancreatic cancer blood-based biomarkers such as CA19-9 [112]. In a relatively small study of 14 patients with advanced pancreatic cancer, pretherapy ctDNA levels correlated with both PFS and OS, and longitudinal

changes in ctDNA levels corresponded both with radiological follow-up data and CA19-9 levels [113]. Since mutations in *KRAS* occur in 90% of primary pancreatic cancer tumors [114], *KRAS* has been widely examined in ctDNA from pancreatic cancer patients and the results show that detection of mutant *KRAS* indicates worse OS [68], [115]. Sausen et al. showed an overall detection rate for *KRAS* mutations in cfDNA of 43% and that detection of ctDNA after resection was able to predict clinical relapse and poor outcome (with recurrence) 6.5 months earlier than with traditional CT scans [116]. Droplet digital PCR, a highly sensitive methodology which can detect single molecules, was used to identify the presence of *KRAS* mutations in cfDNA from 105 patients enrolled for pancreatoduodenectomy and showed mutations were detectable in 31% of cases and associated with significantly poorer OS [117]. A similar chip-based digital PCR study of 50 patients with pancreatic cancer reported an overall detection rate for *KRAS* mutations in cfDNA of 35% [118]. More recently both NGS and digital PCR have been used to study cfDNA from patients with metastatic pancreatic cancer with digital PCR used to examine additional genes found to be frequently mutated in pancreatic cancer (BRCA2, EGFR, KDR, ERBB2) [119]. In addition to confirming the value of ctDNA for prognosis, this study also reported the use of ctDNA for measuring tumor response [119].

Given the difficulty in obtaining tumor biopsies from pancreatic cancer patients, the development of ctDNA based assays are highly likely to be beneficial by providing an alternative source for molecular analysis. As an anecdotal example, in a patient with PDA, an *EGFR* deletion was detected in ctDNA, 7 months prior to confirmation using a matched tissue biopsy [120].

A recent large-scale study has found that selecting therapies based on genomic analysis could improve outcomes for patients with cancer, although given the limits of drug accessibility and availability, the study found only 7% of patients benefitted from the screening. The authors did state that further randomized trials were needed and by expanding the access to drugs, more patients could have benefitted in their trial [121]. Personalized therapies, selected based on molecular tumor data, are not currently conducted as part of routine clinical management of pancreatic cancer. Here, ctDNA clearly holds promise as a predictive and monitoring biomarker, but with limited current utility while there remains a paucity of effective treatments. ctDNA could, however, be usefully employed in future early clinical trials of targeted therapeutics for stratification and therapy response monitoring.

Conclusion

The poor outcomes achieved in pancreatic cancer, where conventional chemotherapy remains the basis for treatment, highlight the need for improved understanding of this disease. Easily accessible circulating biomarkers are a promising means of expanding our basic knowledge of pancreatic cancer with the goal that this

knowledge will translate into improved patient outcomes. The examination of both CTCs and ctDNA in pancreatic cancer has fallen behind their use in other cancer types such as breast, lung, prostate, and colorectal cancer. This most likely reflects the complex biology of pancreatic cancer as well as the technical and biological limitations of identifying CTCs and ctDNA in a small blood sample. For pancreatic cancer CTC analysis there is the promise of platform optimization incorporating pancreatic cancer-specific or EMT markers alongside improvements in isolation and analysis of CTM as well as the development of CDX models that can provide informative biological models. Furthermore, the analysis of CTCs present in the portal vein blood may provide greater understanding of metastatic dissemination to the liver, the most common metastatic site in this disease.

Similarly, the ability to detect and quantify ctDNA as well as define the presence of disease-specific and/or targetable mutations holds great promise for the treatment of pancreatic cancer. The correlation between ctDNA concentration and tumor size, staging, and survival outcomes combined with the fact that *KRAS* mutation is detected in >90% of PDA provides a target for allele-specific mutational analysis that could indicate the pancreatic tumor origin of ctDNA. Furthermore, temporal evaluation of ctDNA has the potential to monitor dynamic changes in both tumor burden and clinical course of the disease, earlier and more frequently than conventional imaging allows. In addition, improved interrogation of ctDNA by untargeted analysis can identify complex genomic aberrations and assist in defining the genomic landscape of PDA more comprehensively, ultimately providing novel targeted agents or improved patient management.

Ultimately, the clinical utility of blood borne biomarkers will be established through incorporation of the appropriate biomarkers into relevant clinical trials. For this to be successful and benefit pancreatic cancer patients, it is essential that the continued advances in CTC and ctDNA research are incorporated alongside any improved therapies in pancreatic cancer.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is a treatment-recalcitrant and highly metastatic cancer. Recent studies have demonstrated that PDAC is associated with an increased release of small vesicles called exosomes that are ~40 to 130 nanometers in diameter. These exosomes may derive from pancreatic cancer cells, cancer-associated fibroblasts, and infiltrating immune and inflammatory cells. They carry a cargo rich in proteins, lipids, DNA, and microRNAs. Exosomes can modulate the tumor microenvironment, promote pancreatic cancer cell proliferation, invasion, and metastasis, and prime the pre-metastatic niche to facilitate formation of distant metastatic lesions. Components of the exosomal cargo may also serve as diagnostic biomarkers and guide the design of precision medicine strategies. Finally, exosomes have been proposed to act as biological nanoparticles that can be loaded with drugs for therapeutic use.

Exosomes

Unique Origin of Exosomes

Exosomes are ~40 to 130 nanometer (nM) particles of endosomal origin that derive from multivesicular bodies (MVBs) from which they are released following MVB fusion with the cell membrane [1, 2], as shown in Fig. 1. Consequently, they express

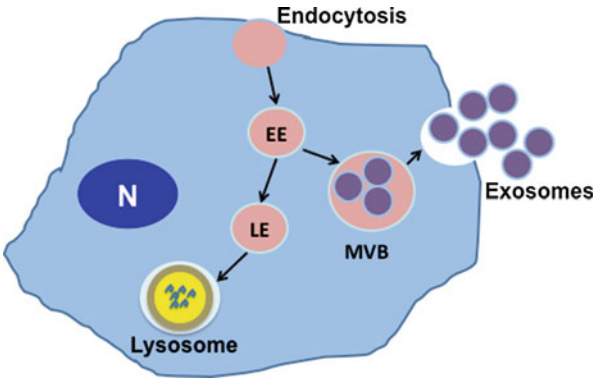

Fig. 1 Schematic representation of exosome formation. A cancer cell is shown exhibiting endocytosis followed by formation of an early endosome (EE) that can progress to become a late endosome (LE) or end up in a multivesicular body (MVB). Fusion of the MVB with the cell membrane leads to the release of exosomes. Most late endosomes end up in lysosomes where they undergo degradation. N: nucleus

endosomal proteins, including tumor susceptibility gene 101 (Tsg101) and Alix [1, 2], as well as many other proteins. By contrast to exosomes, microvesicles are shed directly from the cell membrane and are ~50 to 1000 nM in diameter, whereas apoptotic bodies are generated by the release of membrane blebs from cells undergoing apoptosis, and their diameter ranges in size form ~800 to 5000 nm [3–5].

It has been known for several decades that cells have the capacity to internalize fluids, large molecules, plasma membrane fragments, extracellular ligands, and cell-surface receptors through a process called endocytosis [6]. The internalized material ends up in multiple endocytic vesicles that undergo fusion to form the early endosome compartment. Some of this internalized material, including signaling receptors, can recycle from the early endosome to the cell surface, whereas other components are transported to the late endosomal pathway and subsequently to lysosomes where they undergo degradation [6].

Receptor-mediated endocytosis may occur through clathrin-coated pits on the cell membrane, and through clathrin-independent mechanisms, and is under complex regulatory control [7, 8]. Importantly, ligand-receptor dissociation occurs in the late endosome, whereas these complexes often remain intact in the early endosome and can continue to signal [9]. Since exosomes derive from MVBs that had formed from endosomes, exosomes also have the capacity to carry and deliver the internalized receptors to target cells where, in theory, they may participate in signaling events [9–11]. Conversely, growth factor receptor signaling can act to promote late endosome formation [12], suggesting that this compartmentalization mechanism serves to fine tune receptor-mediated signaling output.

Exosome Isolation Methods

Exosomes can be isolated from all bodily fluids, including blood, urine, and saliva. When seeking to study exosomes in the circulation, serum or plasma can be prepared by using red top or lavender top collection tubes, respectively. Lavender top collection tubes are coated with EDTA, which does not interfere with microRNA (miRNA) analysis.

Specimens should be promptly placed on ice or in a refrigerator (4 °C), taken to the lab within less than 60 min, and rapidly centrifuged (1000 x *g* for 10 min) at 4 °C. Supernatants can then be collected and stored at −80 °C until it is time to prepare the exosomes [13, 14], or subjected to a second optional centrifugation (10,000 x *g* for 10 min) at 4 °C to ensure the removal of any residual coarse debris prior to storage at −80 °C. To prepare exosomes, samples should be thawed on ice, centrifuged at 10,000 x *g* for 30 min (4 °C), and filtered through a 0.22 μm filter to remove remaining debris. Appropriate aliquots (for example, 250 μl/sample) can then be centrifuged at 110,000 x *g* for 2 h (4 °C). The resulting pellets should be washed with phosphate-buffered saline (PBS) to remove debris, and then resuspended in PBS prior to undergoing a second 110,000 x *g* centrifugation for 2 h (4 °C).

There are a variety of alternate methods for isolating exosomes [15–17]. A few examples include sucrose gradient fractionation, size-exclusion chromatography,

affinity chromatography, affinity immunoprecipitation, polymer-based precipitation as described in System Bioscience's protocol (https://www.systembio.com/downloads/Manual_ExoTC_WEB.pdf), and immunoaffinity capture [14, 15]. An example of the latter method is based on the observation that exosome extraction from solutions can be accomplished through their binding to bead-immobilized Tim4 via their surface phosphatidylserine (PS) [16]. Given that Tim4 binding to PS is Ca^{2+}-dependent, the captured exosomes can be released from the magnetic beads by Ca^{2+} chelation [16].

When studying exosomes released by cells during cell culture, it is important to remember that serum, including fetal bovine serum (FBS), contains exosomes and that these exosomes should be removed prior to use in cell culture studies. Alternatively, exosome-free FBS is commercially available.

Exosome Characteristics

Exosomes are vesicles consisting of a single membrane phospholipid bilayer with both surface and embedded proteins (Fig. 2). In addition to expressing endosomal proteins, exosomes are enriched for proteins deriving from cell membrane domains that tend to undergo internalization to form endosomes, such as tetraspanins, lipid-protein raft components, and adhesion molecules [17, 18]. Tetraspanins have four transmembrane domains and may be highly abundant in certain exosomes, depending on their cell of origin [3]. Exosomes are also rich in flotillins, which are involved in endocytosis [15], and annexins, which are phospholipid-binding proteins

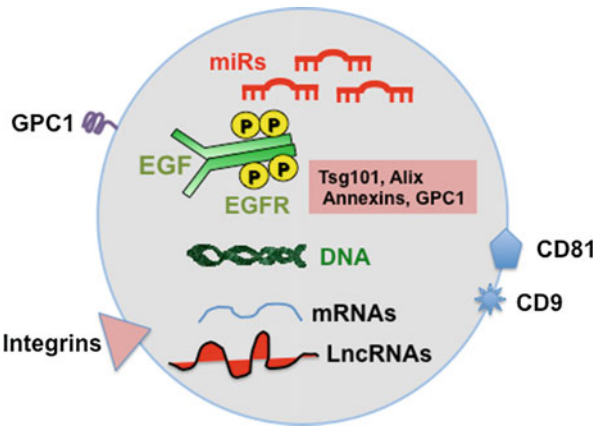

Fig. 2 Schematic representation of an exosome. The cholesterol-rich membrane of an exosome is shown decorated with the glycophosphatidylinositol-anchored glypican-1 (GPC1), the tetraspanins CD9 and CD81, and integrins. The cargo within the lipid bilayer of the exosome includes microRNAs (miRs), DNA, mRNAs, and long noncoding RNAs (LncRNAs). Cargo proteins include the EGF receptor (EGFR), TSG101, Alix, and GPC1, among many others

that are regulated by calcium and that have been implicated in the modulation of numerous cell processes including exocytosis [19].

Exosomes also tend to be enriched for proteins that are anchored to the cell membrane via a glycosylphosphatidylinositol (GPI) motif [20]. For example, the heparin sulfate proteoglycan (HSPG) glypican-1 (GPC1) is overexpressed in PDAC and is a GPI anchored protein [21] that contributes to PDAC angiogenesis and pancreatic cancer cell proliferation [22–24]. HSPGs are ubiquitous cell surface molecules consisting of core proteins covalently linked to glycosaminoglycans (GAGs) polysaccharide chains that are characterized by disaccharide repeats such as L-iduronic or D-glucuronic acid and either N-acetylgalactosamine or N-acetylglucosamine [25, 26]. GAGs may consist of heparin and heparan sulfate (HS), chondroitin or dermatan sulfates, as well as hyaluronan or keratan [26, 27]. Importantly HSPGs act as receptors that internalize exosomes [28] and HSPGs are also taken up by exosomes [28]. Therefore, it is not surprising that GPC1 was recently shown to be present in exosomes from patients with PDAC, normal control subjects, and patients with chronic pancreatitis [29]. The manifold components of the cargo of exosomes can be found in the ExoCarta database (http://www.exocarta.org).

Pancreatic Cancer and Exosomes and Diagnostic Potential

Size Distribution of Pancreatic Cancer Exosomes

Several techniques are generally used to assess the quality and size of the exosome preparation. Visualization by electron microscopy provides strong confirmatory evidence for the purity of the exosome preparation. However, alterations caused by sample fixation or dessication, or by exosome adherence to the template surface can alter the shape and apparent diameter of the exosomes [30]. Moreover, electron microscopy is both expensive and time consuming. Alternate techniques for assessing exosome size and number are generally used by many laboratories [31]. For example, the size distribution and concentration of exosomes in a biological fluid can be determined with readily available instruments. Thus, nanoparticle tracking analysis (NTA) allows for the measurement of particle size by determining the angular variation in intensity of scattered light following laser illumination [32]. NTA is readily performed in a reproducible manner by instruments manufactured by Nanosight [33]. By contrast, the qNano system uses a nanopore and tunable resistive pulse sensing to quantitate particle size and concentration [33].

Using the qNano system, a recent study evaluated the size of exosomes from normal controls, patients with PDAC, and patients with chronic pancreatitis [28]. The diameter of the majority of normal control exosomes ranged from 60 to 100 nm. By contrast, the diameter of CP and PDAC exosomes ranged from 70 to 120 nm [28]. However, only the PDAC-derived exosomes had numerous exosomes that ranged in size from 85 to 115 nm (Fig. 3a). Importantly, within 24 h following PDAC resection the diameter of the PDAC-derived exosomes in the circulation

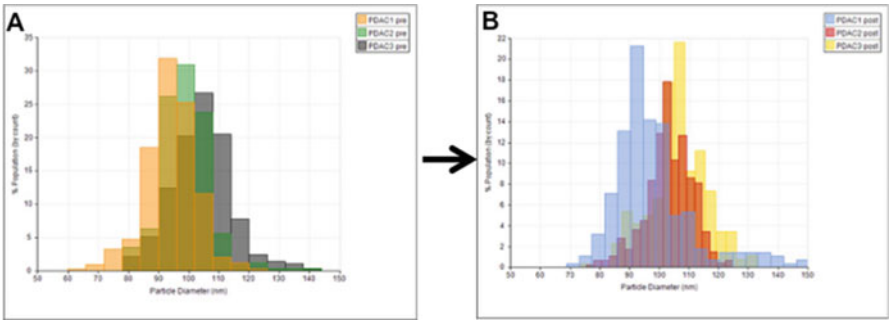

Fig. 3 Exosome distribution pre- and post-resection. Exosome diameter was determined using the qNano system. (**a**) Size distribution of exosomes prior to pancreatic cancer resection, when exosomes were mostly in the 85–115 nm range. (**b**) Size distribution of exosomes 24 h following PDAC resection was similar to that observed in control samples and in chronic pancreatitis samples. Data are from reference 28

reverted to the diameter in control samples (Fig. 3b). These observations suggest that high levels of 85–115 nm range exosomes point to the presence of an underlying PDAC and that these exosomes contain an altered, cancer-associated cargo.

Content of Pancreatic Cancer Exosomes and Diagnostic Utility

Studies with exosomes in pancreatic cancer patients have mostly relied on exosome isolation from serum or plasma, but PDAC-derived exosomes can also be found in saliva [34] and potentially other bodily fluids such as ascites, bile juice, and pancreatic juice. In the case of urinary exosomes, it has been demonstrated that following immunocapture on magnetic beads, it is possible to rapidly trypsinize the outer exosome proteins on the beads and identify them by liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis [35].

Irrespective of their source, exosomes are stable in the circulation. However, in addition to their elimination into the urine, exosomes are also removed from the circulation due to their uptake by different cell types in various organs, as demonstrated in studies with miRNA-155-loaded exosomes that were injected into miRNA-155 knockout mice [36] and with fusion protein engineered for intra-exosomal expression and that had been labeled with radioactive iodine [37]. It is therefore likely that a steady state exists between exosome release into the circulation and exosome uptake in peripheral tissues and clearance by other means, which dictates the number and source of exosomes present in the blood. Nonetheless, the cargo within the exosome is protected from degradation, and this characteristic feature of exosomes enhances their diagnostic utility in disease states.

In addition to a complex intra-exosomal cargo that consists of proteins, miRNAs, long non-coding RNAs, mRNAs, transfer RNAs, lipids, and double-stranded DNAs that

have been shown to derive from all human chromosomes [5, 19, 35], PDAC-derived exosomes can carry mutated *KRAS* and *TP53* DNA, reflecting the mutation profile in the specific PDACs from which the exosomes were released [38]. In theory, therefore, it should be possible to establish signatures based on a mix of these biomarkers to confirm PDAC diagnosis and to monitor response to therapy, and ultimately to diagnose the disease at an early and resectable stage. For example, the combination of the levels of proteins, such as CD104, EpCAM, and Tspan8, together with the levels of miRNAs such as miRNA-1246, miRNA-4644, miRNA-3976, and miRNA-4306 has been reported to constitute a sensitive and specific signature for PDAC [39]. However, sensitivity and specificity issues remain to be addressed for many PDAC biomarker studies, even in relation to DNA mutation analysis [40].

Importantly, to date, early PDAC detection has remained an elusive goal [41]. Yet, it is widely accepted that noninvasive, informative biomarkers for early PDAC diagnosis are a major unmet need that have the potential to aid considerably in prolonging survival in this patient population. Although a well-executed recent study using an anti-GPC1 antibody reported that exosomal GPC1 may be diagnostic for early PDAC with high sensitivity and specificity [42], another study, using LC-MS/MS, revealed the presence of GPC1 in exosomes from normal controls and from patients with chronic pancreatitis, with overlap in exosomal GPC1 levels between the three groups [28]. The differences between the two studies could be due to the different methods used to detect this HSPG. Thus, one study used an anti-GPC1 antibody [42] and such an antibody could be directed against an aberrant glycan epitope that in theory could be cancer-specific. By contrast, the LC-MS/MS method used in the second study [28] measured the core protein and is not influenced by the glycanantion status of GPC1.

Exosomes from patients with PDAC carry high levels of miRNA-10b, miRNA-21, miRNA-30c, whereas the exosomal levels of all three miRNAs are low in normal control subjects or in patients with chronic pancreatitis [28]. Moreover, the elevated levels of all three miRNAs are greatly decreased at 24 h following PDAC resection, underscoring their PDAC origin [28]. It remains to be determined, however, whether a combined exosome and plasma signature could yield sensitive and specific biomarkers for early PDAC diagnosis and for monitoring PDAC recurrence following resection.

Given the clinical implications and potential benefits of early PDAC diagnosis, there has been a great deal of effort to devise advanced technologies to facilitate exosome analysis. For example, to enrich for PCC-derived microvesicles circulating in the plasma, Liang et al. designed a sensor chip that was coated with an antibody that targets the tetraspanin CD81, leading to the highly efficient capture and immobilization of microvesicles directly from plasma [43]. PCCs are believed to preferentially release exosomes (50–100 nm) over other microvesicles [44], so presumably, when using plasma from PDAC patients, this chip would mostly retain exosomes.

The captured vesicles were hybridized with gold nanospheres and nanorods that have been conjugated with antibodies against membrane-bound erythropoietin-producing hepatocellular receptor tyrosine kinase class A2 (EphA2), and anti-CD9,

respectively [43]. The use of gold nanoparticles provided two key advantages. First, the inertness of gold nanoparticles prevented spurious interactions. Second, gold nanoparticles are known to exhibit robust localized surface plasmon resonance, and the use of two different types of antibody-conjugated nanoparticles (nanospheres and nanorods) enhanced both the sensitivity and specificity of the assay due an increased intensity of the plasmon resonance and a readily detectable wavelength shift [43]. Using this nanoplasmon enhanced scattering (nPES) assay, Liang et al. showed that they can differentiate the high EphA2 vesicle signal from PDAC patients by comparison with corresponding signal from normal controls and chronic pancreatitis patients.

It will be important to confirm that specificity and sensitivity of the nPES assay will remain high as more samples are examined. It is also not clear whether this approach could be used to diagnose microscopic PDAC or early Stage IA disease. Finally, it should be noted that PDAC is rich in cancer-associated fibroblasts (CAFs), and these CAFs also release exosomes. It would therefore be interesting to determine whether the anti-CD81-coated sensor chip is also able to capture CAF-derived exosomes.

Pathological Actions of Exosomes in Pancreatic Cancer

Exosome Actions in the Tumor Microenvironment (TME)

Lung cancer cells release exosomes that carry miRNA-21 and miRNA-29a, and these exosomes bind Toll-like receptor 7 (TLR7) and TLR8 in immune cells, thereby eliciting an inflammatory response that enhances cancer cell proliferation and metastasis, revealing a novel role for exosomes in the TME [45]. Inasmuch as miRNA-21 is abundant in PDAC-derived exosomes [28], it is possible that a similar phenomenon may occur in the TME in PDAC. Additional potential actions in the TME include the modulation of oxidative phosphorylation or glycolysis by both cancer cell-derived and CAF-derived exosomes due, in part, to the inhibition mitochondrial oxidative phosphorylation and providing an energy supply to the cancer cells through the exosomal cargo of amino acids and lipids [46, 47].

It is possible that exosomes within the TME may also transfer to noncancerous cells mutant Kras protein and tyrosine kinase receptors such as the epidermal growth factor (EGF) receptor (EGFR) and ligands that bind to EGFR, such as amphiregulin, thereby creating a field effect that nurtures tumor growth [48–50]. In addition, through their stimulatory effects on the conversion of pancreatic stellate cells (PSCs) into CAFs, exosomes can act to enhance PDAC desmosplasia, and through their ability to induce EMT and inhibit cancer-directed immune pathways, exosomes can promote PDAC metastasis [51, 52]. Exosomes also contain proteases and can therefore degrade components of the extracellular matrix such as collagens, fibronectin, and laminins [53]. In turn, ECM degradation liberates growth factors and

matrix metalloproteases that combine to exert mitogenic, motogenic, and invasion promoting effects on the PCCs while also activating pro-survival pathways and apoptosis resistance in the PCCs.

PDAC-Associated Exosomopathies

PDAC may be associated with systemic prodromal manifestations that appear prior to the cancer diagnosis. Such prodromal syndromes include pancreatogenic diabetes, which is also known as type 3c diabetes mellitus or T3cDM diabetes [43, 54], unexplained weight loss, which could be viewed as a pre-cachexia state, and thromboembolic events that have also been described as Trousseau syndrome.

The mechanisms underlying T3cDM have not been completely delineated but include resistance to insulin actions. In addition, a recent study [43] reported that one mechanism for T3cDM is the release by the PCCs in PDAC of exosomes that carry adrenomedullin (AM). Following release into the systemic circulation these exosomes return to the pancreas, enter the islets, and interact with the β-cells where AM delivery induces an unfolded protein response that interferes with β-cell function and may even lead to β-cell death [43]. Consequently, these patients cannot mount a robust insulin response to their insulin-resistant state, and therefore exhibit rising blood glucose levels. Thus, T3cDM can be viewed as an exosomopathy [55].

In spite of a great deal of progress in understanding the multiple pathways that contribute to cancer cachexia [56], the potential role of exosomes in PDAC-associated cachexia is yet to be fully explored. Nonetheless, it is now recognized that microvesicles from PC1, Panc-2, and MIA PaCa 2 PCCs carrying miRNA-21 can signal through TLR7 in Pax7-positive murine myoblasts to activate c-Jun N-terminal kinase and promote muscle cell apoptosis [57]. By contrast, similar myoblasts prepared from $TLR7^{-/-}$ mice were resistant to apoptosis when exposed to either conditioned medium samples from Lewis lung carcinoma cells that induce cachexia in mice, or to serum samples from 5 of 7 pancreatic cancer patients who were diagnosed as having cancer cachexia [57]. Of note, Pax7 is a transcription factor expressed in the nuclei of muscle stem cells that controls their self-renewal. Previously, it was shown that its persistent expression in muscle stem cells during cachexia prevents them from differentiating into adult muscle cells and/or from fusing to damaged myofibers and thus impedes myofiber repair and promotes muscle atrophy [58]. It remains to be determined whether such a mechanism is active in relatively early stages of PDAC, whether TLR8 in humans mediates the same pathways as TLR7 to induce muscle stem cell apoptosis, and what ultimately dictates the fate of these Pax7-positive satellite cells between failure to differentiate vs. apoptosis.

With respect to the third type of exosomopathy, while the underlying etiologies in venous thromboembolic events in PDAC are not well understood, they have been correlated with elevated plasma Tissue Factor (TF) levels [59]. This correlation has

also been observed in a mouse xenograft model of PDAC [60]. TF is carried by microparticles [61], and therefore may also be carried by exosomes. However, in the case of melanoma cells, it was shown that most of the TF is found in microvesicles and apoptotic bodies [62]. Nonetheless, monocyte-derived exosomes have been shown to exert pro-thrombotic actions [63]. Given that thromboembolic events are an important cause of death in cancer patients receiving chemotherapy as outpatients [64], this aspect of PDAC pathobiology needs further exploration.

Exosomes and the Metastatic Niche

The metastatic process consists of a complex sequence of events that includes different types of cancer cell migration, EMT, invasion, immune alterations within the TME, and, systemically, extracellular matrix degradation, breaching of barriers in a manner that enables the cancer cells to enter into blood vessels and lymphatics, survival of these cells in the circulation, and successful colonization of distant organs within a receptive microenvironment called the metastatic niche [65–67]. Recent studies have highlighted the important role of miRNAs in cancer progression and metastasis due to their ability to regulate cell proliferation, migration, invasion, and metastasis [68–73].

Exosomes can promote cancer metastasis by carrying deleterious miRNA and proteases to distal sites where they prime the normal microenvironment to be receptive to circulating cancer cells [53, 74]. In addition, exosomes can target immune pathways in a manner that promotes the metastatic process. For example, exosomes have been reported to exert effects on the distant "soil" by priming the pre-metastatic niche to be receptive to metastatic cells. Exosomes were also suggested to increase the number of myeloid derived suppressor cells (MDSCs) in the TME which leads to the release of inflammatory cytokines that in turn prime the pre-metastatic niche [75].

Costa-Silva et al. performed a crucial study that definitively demonstrated an important role for PDAC-derived exosomes in priming the pre-metastatic niche in the liver [76]. They showed that purified exosomes from different murine models of PDAC (5 μg exosomes per injection) every other day for 3 weeks prime the hepatic pre-metastatic niche to be receptive to intrasplenic injections of PCCs, yielding macro-metastatic lesions 3 weeks later. Mechanistically, they demonstrated that the exosomes are taken up by the Kupffer cells and induce transforming growth factor β (TGF-β) expression that in turn upregulates fibronectin production by hepatic stellate cells [76]. The abundant fibronectin leads to the recruitment and retention of bone marrow–derived macrophages. Importantly, exosomal macrophage migration inhibitory factor (MIF) was required for TGF-β upregulation, and in the absence of MIF or following macrophage ablation, the exosomes no longer exerted a pro-metastatic effect. Clinically, exosomal MIF levels were higher in stage I PDAC patients that eventually developed hepatic metastases by comparison to stage I patients who did not develop such lesions. As pointed out in an accompanying commentary [77],

other exosomal components may also be important for the metastatic process both in terms of metastatic sites and in terms of PCC proliferation, which may also include unrecognized intrinsic characteristics of the PCCs. These findings are also in agreement with a long-standing observation that high levels of TGF-β isoforms in PDAC patients who had resectable disease and who did not receive any post-operative therapies were associated with earlier disease recurrence and shorter overall survival by comparison with patients whose PDAC expressed low levels of these isoforms [78]. It may therefore be timely to reconsider the reluctance to target TGF-β in clinical trials in patients with PDAC.

Therapeutic Implications

Exosomes for Drug Delivery

Initial efforts at using exosomes as drug delivery "nanoparticles" began in the past several years. For example, Alvarez-Erviti et al. reported that it is possible to deliver short interfering RNAs (siRNAs) to the mouse brain by systemic injection of targeted exosomes, based on the fact that exosomes cross the blood-brain barrier [79]. The exosomes were self-derived from dendritic cells, thereby avoiding any possible immune reactions against foreign exosomes, and were targeted to the central nervous system by engineering a fusion of lamp2b to neuron-specific RVG peptide [79].

In a subsequent study, it was shown that exosomes can be targeted to breast cancer cells expressing high EGFR levels by engineering the cells to express the GE11 peptide that is known to bind to EGFR, and making sure that expression is directed to the cell membrane by using a vector expressing the transmembrane domain of the platelet-derived growth factor receptor [80]. The authors then showed that the intravenous injection of exosomes from the engineered cells can deliver miRNA let-7a to breast cancer xenografts [80]. A variety of other strategies have been proposed to improve exosomes as drug delivery vehicles [81], and a more recent study demonstrated that it is possible to engineer exosomes to express a single domain antibody (nanobody) against EGFR using a GPI-based anchoring strategy, thereby greatly enhancing exosome delivery to EGFR overexpressing cells [82].

A novel therapeutic approach for PDAC was recently proposed based on the fact that oncogenic *KRAS* is the major truncal mutation in this malignancy and that the mutant Kras protein has been resistant to targeting. Using exosomes derived from normal fibroblast-like mesenchymal cells that were engineered to express either the siRNA or the hairpin RNA (shRNA) that specifically downregulate $Kras^{G12D}$, the most common type of mutated *KRAS* in PDAC, Kamerkar et al. demonstrated dramatic efficacy in several mouse models of PDAC [83]. It seems likely that this strategy will also be successful with other forms of mutant Kras, but this remains to be demonstrated.

Conclusion

It is likely that following up on the advances of recent years, it will be possible to develop novel strategies for early PDAC diagnosis that are based on the analysis of exosome cargo and that this approach will also yield novel prognostic markers. Moreover, advances in DNA mutational analysis of exosomal DNA could guide novel precision medicine approaches and the rapid monitoring of therapeutic responses. Exosomes will also be increasingly useful as drug delivery vehicles and as positive modulators for activating cancer-directed immune mechanisms. The combination of these new tools will likely dramatically improve the survival of patients with PDAC.

Key Research Points

- Exosomes are important intracellular regulatory vesicles within their cells of origin.
- Exosomes are released into their microenvironment and biological fluids, where they regulate numerous cellular processes.
- In PDAC, exosomes may exert effects on the tumor microenvironment to enhance PDAC growth and metastasis and to prime the pre-metastatic niche.

Future Scientific Directions

- There is a need for improved and highly reproducible assays of exosome content.
- There is a need for strategies to promote beneficial effects of exosomes and to block their deleterious effects.
- There is a need to understand how to modify endogenous exosomes for therapeutic purposes.
- There is a need to gain a better understanding of the therapeutic applications of exogenous exosomes.

Clinical Implications

- Exosome cargo can be analyzed to establish diagnostic and/or prognostic signatures in PDAC.
- Exosomes can be used as therapeutic vehicles.

Specific medical conditions associated with PDAC such T3cDM, cachexia, and venous thromboembolic event may be aggravate by exosomes and targeting these exosomes could lead to improved survival and improved quality of life in patients with PDAC.

Metabolism in Pancreatic Cancer

Ioannis Poursaitidis and Richard F. Lamb

Contents

Abstract

Despite knowledge of an increasing number of genetic changes present in pancreatic ductal adenocarcinoma (PDAC), the most common form of pancreatic cancer, it remains one of the cancers with the poorest prognosis, and the development of novel therapies that target its unusual biology and metabolic features is imminently required. Pancreatic tumor cells are thought to evolve under the conditions of limited oxygen and nutrient supply due to high levels of stromally produced extracellular matrix and associated poor blood supply. The prevalence of oncogenic KRAS mutations in PDAC, together with inactivation of TP53,

CDKN2A, and SMAD4, predicates the engagement of distinct adaptive metabolic features that maximize the uptake and utilization of limiting oxygen and nutrients. Rewiring of the metabolism of glucose, amino acids, and lipids provides biosynthetic/metabolic intermediates required to maintain proliferation and survival, while the induction of autophagy and macropinocytosis permits repurposing of nutrients by PDAC tumor cells. Finally, PDAC tumor cells affect their neighboring cells, activating pancreatic stellate cells to produce a dense fibrotic stroma and provide nutrients in a paracrine manner, while inhibiting an effective antitumor immune response by restriction of nutrients from immune effector cells. It is hoped that by targeting such aberrant metabolism and nutrient utilization additional therapeutic options might soon be available in PDAC.

Introduction

PDAC is among the cancer types with the poorest prognosis, with around roughly 367,000 new cases diagnosed and 359,000 deaths in 2015. Overall PDAC has an extremely poor 5-year survival rate of around 6–8% that has not satisfactorily improved over the last four decades, and thus PDAC is expected to become the second most common cause of cancer-associated death before 2030 [1].

PDAC is thought to initiate and progress from a population of microscopic premalignant lesions termed PanINs (Pancreatic Intraepithelial Neoplasias) through multiple stages in a process that may take over two decades, while remaining asymptomatic to the patient [2]. Currently, there are neither diagnostic symptoms nor robust tumor biomarkers that might easily reveal the development of PDAC over this timeframe [3]. Thus, PDAC tumor cells can disseminate, resulting in metastasis to distant sites prior to overt diagnosis [4]. The main oncogenic event in PDAC, identified in the late 1980s, is mutations in the protooncogene KRAS [5], which occur in more than 90% of PanIN and PDAC [2, 6]. In later stages of PDAC progression, mutations and deletions of tumor-suppressor genes such as TP53, CDKN2A, and SMAD4 also occur with variable frequency [7].

Despite mutations in the proto-oncogene KRAS being identified as the key PDAC tumor-driving oncogene and the most common genetic change, and evidence that it plays distinct roles in mouse models both in tumor initiation and tumor maintenance (reviewed in [8]), the development of direct inhibitors of mutant KRAS has been problematic. Other indirect approaches that act to prevent the translocation of KRAS to the plasma membrane, its activation by exchange factors, or act in a synthetic lethal manner, may be more promising [9]. Current treatments in PDAC however utilize instead relatively nonselective cytotoxic agents, often in combination, but unfortunately with limited efficacy [1]. Moreover, such treatments can be difficult to tolerate without robust responses in many cases [1]. Therefore, there is a clear clinical need

both to understand in more depth the mechanisms of PDAC tumor evolution and heterogeneity, and to understand mechanisms of tumor maintenance in the face of limiting nutrients in order to develop new therapeutic strategies.

Recent studies have unveiled many metabolic adaptations activated downstream of KRAS signaling, which play important roles in determining the unique biology characteristic of PDAC, and which may ultimately lead to novel therapeutic regimens that target metabolic addictions found in PDAC (reviewed in [10–12]). These adaptations are found associated with several unique features of the biology of PDAC. In particular, the pancreatic tumor microenvironment contains a dense fibrotic stroma termed desmoplasia and a relatively low cancer cell cellularity in which intratumor interstitial pressure is high relative to normal pancreas [13]. Aside from PDAC tumor cells themselves, PDAC tumors contain a large population of activated fibroblasts (termed pancreatic stellate cells, PaSCs, or PSCs), which normally reside in exocrine areas of the pancreas, and various immune cells within the tumor microenvironment [14]. The high interstitial pressure found in advanced PDAC is thought to result at least in part from extensive deposition of ECM proteins from PSCs, including the glycosaminoglycan hyaluronan which is a CD44 ligand involved in cell-ECM adhesion [13]. As a result, the vascular capillaries collapse, limiting perfusion of oxygen and nutrients to the tumor and generating a hypoxic tumor microenvironment [14, 15] that acts to impair drug delivery to tumor cells [13]. Despite these harsh environmental conditions however, PDAC cells are capable of surviving, proliferating, and metastasizing due to various metabolic adaptations.

Nutrient Sensing

In normal cells, the utilization of extracellular nutrients depends both on the metabolic needs of the cell and their detection by a variety of nutrient-sensing mechanisms that prepare the cell to utilize nutrients for anabolic or maintenance functions. These mechanisms are normally tightly regulated to recognize changes in nutrient availability and elicit differential responses [16]. Critical responses that have been well studied include the activation of Adenosine MonoPhosphate–activated protein Kinase (AMPK) upon glucose restriction, and inhibition of the mechanistic Target of Rapamycin Complex 1 (mTORC1) upon amino acid restriction.

AMPK is generally activated physiologically upon detection of decreased cellular ATP levels, resulting in AMP accumulation, and phosphorylates an increasing variety of substrates [17]. Overall the result of AMPK activation in most cells is a cessation of energy-consuming anabolic processes such as protein and lipid synthesis, an enhancement of glucose and lipid catabolism to regenerate ATP, or induction of autophagy [17]. mTORC1, on the other hand, is activated by the presence of both growth factors and amino acid nutrients, promoting various aspects of cell growth including ribosome biogenesis and inhibiting autophagy, and in normal cells is inhibited by energy stress or by overall or specific amino acid restriction [16].

AMPK can itself repress mTORC1 activation, either by phosphorylation and activation of the mTORC1 pathway inhibitor, tumor sclerosis complex 2 (TSC2, [18]) or by phosphorylation of Raptor [19], a regulatory and structural component of the mTORC1 complex. The activation of mTORC1 inhibits autophagy [20] and therefore AMPK can induce autophagy either directly or indirectly through negative regulation of mTORC1. Additionally, AMPK can itself directly activate both bulk autophagy and mitophagy (breakdown of mitochondria) independently of its regulation of mTORC1 through phosphorylation and activation of ULK1 (Unc-51 Like Autophagy Activating Kinase 1) the mammalian ortholog of Atg1, a key initiator of the autophagic process in yeast [21]. AMPK can further promote mitophagy directly by facilitating mitochondrial fission through phosphorylation of a fission-promoting protein present on the outer mitochondrial membrane, MFF (Mitochondrial Fission Factor [22]).

During tumor progression, tumor cells are now appreciated to undergo metabolic reprogramming which enables them to utilize anabolic and catabolic pathways in a manner that promotes their survival and unrestricted proliferation. PDAC tumor cells exhibit many such adaptations and are capable of surviving in hypoxic microenvironments as well as in metastatic niches by activating both nutrient scavenging and nutrient acquisition pathways [10]. These strategies endow PDAC tumor cells with a selective advantage over normal pancreatic cells and are thought to be critical to promote their sustained viability and proliferation under harsh environmental conditions [11]. However, these aspects of deregulated PDAC cell function may themselves represent tumor-specific vulnerabilities and be sensitive to targeted therapies [10, 12].

Autophagy

The PDAC tumor microenvironment is characterized by local hypoxia [23] and limited accessibility to nutrients [15]. Therefore, PDAC tumor cells utilize a number of scavenging mechanisms to exploit the limited nutrients available through the vasculature. One of these mechanisms, leading to nutrient recycling, is autophagy (also termed macroautophagy), a process that normally results in the regulated degradation and recycling of cellular components for biosynthesis [24]. However autophagy also performs an important function in normal cells in cellular quality control by acting to eliminate potentially toxic protein aggregates and/or damaged organelles [25].

Through autophagy, macromolecules are first sequestered within double-membrane microtubule-associated protein 1A/1B-light chain 3 (LC3)-positive vesicles, the autophagosomes. Through a regulated series of events, autophagosomes ultimately fuse with lysosomes forming autolysosomes that mediate the digestion of the internalized cytoplasmic components. The autolysosome digestion products, namely amino acids, nucleotides, fatty acids, sugars, and ATP, are then transported back from the lysosome to the cytoplasm where they serve as biosynthetic precursors, cofactors or as an energy source for cells undergoing nutrient

starvation [26]. One of the key mechanisms used by nutrient-deprived cells for autophagy initiation is via the activation and suppression of the protein kinases AMPK and mTORC1, which regulate autophagic capacity through ULK1/2 and ATG13 proteins [24]. An alternative mechanism of autophagic stimulus (that is independent of ULK1 activation) occurs through the accumulation of ammonia produced by amino acid catabolism during glucose restriction [27].

Previous studies have indicated critical, but contrasting, roles for autophagy in cancer, and the same appears true in PDAC [28]. On the one hand, autophagy is thought to constitute a barrier to tumor formation through mitigation of oxidative stress/ROS and subsequent effects upon genomic integrity within premalignant PanINs [29]. In contrast, autophagy can also promote tumor formation in a number of cancer model systems (reviewed in [28]). In the progression of PDAC, autophagy appears also to play opposing tumor suppressive and tumor promoting roles [30]. Evidence for tumor suppressive function(s) of autophagy comes from pancreas-specific knockouts of autophagy regulators Atg5 or Atg7 that show an augmented emergence of KRASG12D-driven premalignant pancreatic lesions following autophagy inhibition [31]. Thus, it appears that in the early stages of PDAC progression autophagy acts in a tumor suppressive manner to prevent the initiation of premalignant lesions that act as a precursor to PDAC.

However, it is also clear that elevated basal autophagy (in the absence of starvation of nutrients) is a major feature of PDAC tumor cells, even when such cells are grown ex vivo under cell culture conditions in which nutrients are unlikely to be limiting, and is itself required for tumor progression in vivo [31]. Induction of autophagy however appears to be a relatively late event in PDAC development [31] and increased autophagy, as determined by LC3 immunocytochemistry, correlates with poorer clinical outcome in PDAC patients [32]. At least in part this is likely to be due to autophagy inhibition leading to a reduced degree of tumor cell proliferation rather than survival and is known to be dependent in some contexts upon intact TP53, but not in others [10]. Using an inducible mouse model of mutated KRAS in a p53Lox/WT background, thought to be analogous to that occurring in advanced PDAC, has shed further light on the role autophagy performs in advanced PDAC development. Ablation of KRAS in this model results in pancreatic tumor regression within 2–3 weeks followed by relapse after a few months. Transcriptome analysis of tumor cells surviving KRAS ablation revealed a significant enrichment of genes involved in lysosomal activity, mitochondrial electron transport chain, and autophagy, indicating that induction of increased autophagy and lysosomal activity was critical for tumor relapse [33].

Major questions that have arisen following these observations are what mechanisms lead to increased basal autophagy, and how they are related to the specific genetic changes found in PDAC? The increased number of autophagosomes and lysosomes frequently identified in PDAC tumor cells [34] suggests that some deregulation of the regulatory mechanisms controlling the abundance of these vesicular organelles occurs in PDAC. Indeed some human PDAC cells have been shown to exhibit both increased expression, and loss of cytoplasmic retention, of members of the microphthalmia/transcription factor E (MiT/TFE) family of

transcription factors [34] that are known to induce a transcriptional program that acts to increase lysosome biogenesis and therefore lysosomal catabolism [35].

In normal cells cultured under nutrient replete conditions, MiT/TFE factors are thought to be negatively regulated via phosphorylation by mTORC1 present on lysosomal membranes, leading to their interaction with cytosolic 14-3-3 proteins and nuclear exclusion [35, 36]. However, in PDAC cells, and despite elevated mTORC1 activity, MiT/TFE factors appear to be preferentially nuclear [34], indicating that additional regulatory events active in PDAC cells act to override mTORC1-mediated regulation, thereby promoting nuclear localization of MiT/TFE factors. Although the nature of these mechanisms, and how they operate preferentially in PDAC tumor cells, remain to be elucidated, they may impact on the function of importins such as IPO8/7 that direct nuclear import of specific cargo [37]. Thus, knockdown of these two importins in PDAC cells has been shown to prevent MiT/TFE nuclear localization [34].

Autophagy as a tumor promoting process might also represents a therapeutic target in PDAC. The antimalarial drug chloroquine (or its analog hydroxychloroquine, HCQ) is thought to block autophagic flux by increasing the normally low pH typical of lysosomes, thereby blocking the final stage of autophagy [38]. In preclinical studies, HCQ treatment has shown promise in inhibiting tumor growth in patient-derived xenograft (PDX) and human PDAC cell line xenograft mouse models [39]. Currently HCQ is in fact under evaluation in several clinical trials for PDAC treatment in the US, including as a single agent in metastatic cancer (trial designation: NCT01273805), in combination with gemcitabine (NCT01128296, [40]), in combination with gemcitabine/nab-paclitaxel (NCT01506973), or in combination with capecitabine with either radiation or proton therapy (NCT01494155). However, a key shortcoming of HCQ treatment is its poor drug pharmacodynamics whereby relatively long periods of drug administration are required to reach therapeutic levels [41]. However, when HCQ has been used under conditions where evidence of autophagy inhibition has been clearly established as a biomarker of drug efficacy [40], improved disease-free and overall survival in PDAC patients has been demonstrated. As an alternative to HCQ, Lys05, a novel dimeric derivative of chloroquine, has been shown to have significant in vivo activity, both as a single agent [42] and in combination with a BRAF inhibitor [43]. Interestingly, the inhibition of autophagy in PDAC is known to incur additional effects on metabolism that may have therapeutic implications. Thus, upon autophagy inhibition PDAC cells have been found to utilize less oxygen during oxidative phosphorylation in mitochondria, and instead switch to increased dependence upon glycolysis as a source of ATP [28, 31].

Macropinocytosis

In addition to autophagy and the recycling of intracellular material for biosynthesis, PDAC cells also have the ability to internalize extracellular macromolecules such as proteins and lipids through an endocytic process called macropinocytosis. After being internalized, the macromolecules are carried through large vesicles, the

macropinosomes, which ultimately fuse, as with autophagosomes during autophagy, with lysosomes [44], where the degradation of their components occurs. Degradation products are eventually transported from lysosomes and used to fuel other biosynthetic processes. Several studies have demonstrated that KRAS oncogenic mutations, including KRAS mutations found in human PDAC tumor cells, can strongly upregulate the process of macropinocytosis [45].

Macropinocytosis of serum proteins such as albumin has been shown to be a vital source of amino acid supplementation in PDAC cells undergoing glutamine starvation, and PDAC cell treatment with inhibitors that block macropinocytosis, as for example the endocytosis of albumin, can suppress tumor cell proliferation in vitro and tumor development in vivo [15, 45]. In addition, macropinocytosis can be used to internalize both extracellular material and membrane receptors. Thus, oncogenic KRAS-transformed primary pancreatic ductal cells have been shown to also internalize extracellular lipids to promote their proliferation [46, 47], while other cancer cells have also been shown to internalize extracellular ATP to support ATP-consuming biosynthetic processes [48]. In addition to accumulating soluble nutrients such as proteins and ATP, cancer cells are known to internalize a class of secreted vesicles, called exosomes or microvesicles, through macropinocytosis [49]. For PDAC tumor cells, internalizing exosomes requires KRAS and EGFR-dependent macropinocytosis [49], while other cell types, such as cancer-associated fibroblasts (CAFs), do not apparently require oncogenic KRAS signaling to internalize exosomes [50]. Interestingly, PDAC tumor cells can also release exosomes that may induce dysfunction in normal cells, although the consequences of this for disease progression are currently less clear. Thus, PDAC tumor cells have been shown to release exosomes that can be internalized by normal cells such as pancreatic β-cells, or subcutaneous adipose tissues, to negatively impact insulin secretion or stimulate lipid breakdown, respectively [51].

As cancer cells frequently employ macropinocytosis to aid in receptor regulation and internalize essential metabolites, extensive efforts have been underway in utilizing macropinocytosis therapeutically to deliver cytotoxic drugs specifically into PDAC and other cancers. Some anticancer agents innately undergo macropinocytosis, such as AS1411, which internalizes into various cancer cells through cell-surface nucleolin-dependent mechanisms that activate macropinocytosis only in malignant cells [52]. Other therapeutics specifically target cell surface receptors that may trigger macropinocytosis. For example, therapeutic drugs conjugated with peptides that target a combination of proteoglycans and keratinocyte growth factor receptors (KGFR) can selectively internalize into and kill KGFR-expressing lung cancer cells via macropinocytosis [53].

Another intriguing therapeutic front includes conjugating cytotoxic drugs onto albumin not only to enhance drug pharmacokinetics, but also because albumin has long been observed to accumulate within solid tumors through macropinocytosis [54]. An example includes the FDA-approved nanoparticle albumin-bound form of paclitaxel (nab-paclitaxel or Abraxane®) for treating multiple cancers, including PDAC [1]. However, cancers are still able to overcome these drugs through acquired resistance, likely via differential regulation of proteins that regulate macropinocytosis,

including cytoskeletal and lipid metabolism proteins [55], or through increased expression of drug exporters such as P-glycoprotein [56]. Other albumin-based conjugates targeting folate receptors have also demonstrated efficient delivery of cytotoxic compounds specifically into cancer cells [57]. Finally, as both the autophagic and macropinocytotic pathway converge into lysosomal uptake and digestion of macromolecules, the lysosome can be considered as a therapeutic target for both processes [11].

Redox Balance and Reactive Oxygen Species

Reactive Oxygen species (ROS) are damaging metabolic byproducts generated upon cellular metabolic processes, including oxidative phosphorylation in mitochondria and the action of cytosolic or membrane-associated nicotinamide adenine dinucleotide phosphate (NADPH) oxidases. They are responsible for damage via oxidation of proteins, DNA, and lipids, and when left unmanaged can lead to cell death. Furthermore, the oxidation of DNA is one of the leading causative factors of mutations through generation of 8-hydroxy-2′-deoxyguanosine [58]. However, ROS should no longer considered as simply a damaging byproduct of metabolism as they are now known to also play a significant role in regulating multiple cellular signaling processes, including immune responses, inflammation, adhesion, and cell migration [59].

The generation of ROS has been demonstrated to be crucial for both KRAS transformation and KRAS-driven PDAC tumor expansion [60, 61]. As mentioned earlier, PDAC is characterized by a predominant desmoplastic response, and the activation of PSCs appears to be mainly responsible for the desmoplasia typical of PDAC [14]. ROS may here be an important mediator in the activation of PSCs in this process. During hypoxia, ROS can activate PSCs by stabilization of the transcription factor hypoxia-inducible factor 1α (HIF-1α) and upregulation of the zinc finger transcription factor GLI1 (also known as glioma-associated oncogene) and promote release of other cytokines and growth factors such as IL-6, SDF-1, and VEGF-A to promote pancreatic cancer cell invasion [62]. ROS can also act as an adaptive strategy to inhibit autophagic cell death and its antiautophagic effect may be mediated by upregulating AKT/mTOR signaling in PDAC [63]. In PDAC, the presence of oncogenic KRAS might increase cytoplasmic ROS production through activating NADPH oxidase 4 (Nox4), which is regulated by mitogen-activated protein kinase (MAPK) signaling [64, 65]. As part of the desmoplastic reaction, extracellular components such as fibronectin and laminin may also positively promote Nox4 expression in a 5-lipoxygenase-dependent manner [66]. Oncogenic KRAS is also known to favor the generation of one type of ROS species, superoxide anion, by upregulating the levels of NADPH oxidase 2 (Nox2), an enzyme responsible for electron transfer from NADPH to oxygen molecules. Nox2 activity may critical for PDAC devolvement as Nox2 inhibition in PDAC cell lines can hamper clonal expansion [61]. Relatively similar results have been generated after Nox4 inhibition, indicating that Nox4 (which directly generates an alternative ROS

species, hydrogen peroxide) is also important for PDAC survival [67]. Reduced NADPH enables the preservation of the pool of reduced glutathione, which is essential for subsequent glutathione oxidation, a crucial event for the down-regulation of intracellular ROS levels. The redox capacity of the cells is maintained through the NADP+/NADPH balance that controls recycling of oxidized glutathione [68]. Elevated levels of intracellular ROS within PDAC tumor cells likely promote the progression of pancreatic cancer in the following ways: (1) supporting cell proliferation and survival [64, 66]; (2) promoting angiogenesis via increasing expression of IL-8 [69]; and (3) inducing invasion and metastasis through promoting EMT [70], and increasing the expression of matrix metalloproteases (MMPs) [71].

Cellular control of ROS levels occurs principally through the nuclear factor (erythroid-derived 2)-like 2 (Nrf2) transcription factor that promotes the transcription of various genes essential for ROS detoxification. Such genes include glutathione reductase, NADPH:quinone oxidoreductase 1 (NQO1), thioredoxin, as well as enzymes related to NADPH production such as malic enzyme ME1 [72]. Indeed, Nrf2 has been shown to be overexpressed and activated in PDAC and enables the tumor cells to elicit a sustained ROS detoxification response critical for KRAS-induced tumorigenesis in PDAC models [73]. Therefore, PDAC tumor cells utilize a number of different mechanisms in order to utilize, but carefully control, increased ROS levels to promote tumor survival and proliferation.

Glucose Metabolism

Glucose is the principal growth-supporting substrate in cancer cells and can act as a major provider of carbon for biosynthesis of various macromolecules. Cancer cells are now appreciated to exhibit an aberrant metabolic profile that differs from that of their differentiated counterparts [74]. A major manifestation of this profile is that the presence of oxygen does not restrict glycolysis. This phenomenon, termed aerobic glycolysis and described first by Otto Warburg, is the capacity of cancer cells to metabolize glucose even in the presence of sufficient oxygen, producing lactate [75, 76]. Many human tumors have now been shown to exhibit augmented glucose acquisition coupled to increased flux through downstream glycolytic metabolic pathways. Thus, it is not surprising that mutations in KRAS found in PDAC (as well as other oncogenes and tumor suppressors) reprogram cellular metabolism by acting upon both acquisition and metabolic flux of glucose [60]. Perhaps surprisingly however, in the vascular-poor PDAC microenvironment, overall levels of glucose, and glucose uptake, are thought to be modest compared with other tumor types, and steady-state glucose concentrations have been found not to be significantly elevated compared with normal pancreatic tissue [15]. However despite this, higher levels of glucose uptake (determined by 18F-fluoro-2-deoxyglucose positron emission tomography, FDG-PET) and expression of the glucose transporter GLUT1 have been shown to correlate with poor prognosis in PDAC [77]. Moreover, KRAS-driven alterations in glucose uptake and utilization have been shown to be required,

at least in part, for PDA tumorigenesis [78]. This increased glucose uptake might be facilitated further in PDAC lacking TP53 function, as expression of wild-type TP53 negatively regulates the expression of two different glucose transporters, GLUT1 and GLUT3 [79]. As might be anticipated, in an inducible transgenic GEM model, KRAS silencing strongly reduces glucose uptake and is associated with down-regulation of GLUT1 and multiple enzymes involved in subsequent stages of glycolysis [11, 78]. Indeed, although mutant KRAS can clearly activate the expression of several glycolytic enzymes and alter the glycolytic pathway flux [78], other mechanisms, including hypoxia, have similarly been shown to activate glycolytic enzyme gene expression in PDAC [80]. In contrast, mitochondrial metabolism/ATP generation is likely to be contributed to mainly by glutamine carbon in PDAC cell lines [78, 81].

With more glucose entering PDAC tumor cells, six-carbon units can be diverted into parallel biosynthetic routes, particularly via recruitment of glucose-6-phosphate and other glucose derivatives into both the nonoxidative pentose phosphate pathway (PPP) and hexosamine biosynthesis pathway (HBP) [78]. These twin alterations appear to be KRAS dependent in PDAC and occur via increased expression of two PPP enzymes (ribose-5-phosphate isomerase A and ribulose-5-phosphate-3-epimerase) that promote increased flux of ribulose-5-phosphate (R5P) through the nonoxidative PPP, as well as upregulation of the first enzyme in the HBP pathway, glutamine fructose-6-phosphate amidotransferase (GFPT1) [78]. Additionally however, hypoxia-driven HIF-1α stabilization can also enhance the nonoxidative arm of the PPP by increasing the expression of transketolase genes [82]. This unusual reliance upon the nonoxidative PPP may itself represent a therapeutic target in PDAC, as normal pancreatic cells are thought to generate R5P mainly via the oxidative phase of the PPP [83].

For HBP, the metabolic products are uridine diphosphate-*N*-acetylglucosamine and other nucleotide hexosamines which are major substrates for protein and lipid glycosylation [84]. Indeed, following suppression of KRAS in PDAC, the overall O-glycosylation and tumorigenicity has been found to be reduced dramatically [78]. Excessive O-glycosylation has been previously described in PDAC cells as eliciting an antiapoptotic effect by modulation of nuclear factor-kappa-B (NF-κB) [85]. It should also be noted that in hypoxic conditions, the levels of O-glycosylation in proteins are also thought to be elevated, possibly as an adaptive response to stabilize proteins important for the survival of cells under conditions of low nutrients and oxygen [86]. Thus both KRAS and a hypoxic microenvironment may synergize to elevate O-glycosylation, thereby contributing to PDAC tumor cell survival.

Although such metabolic diversions permit biosynthetic intermediates to be synthesized, the major fate of glucose in PDAC remains lactate [86], converted from pyruvate via lactate dehydrogenase (LDH). PDAC cells are known to alter the flux of this conversion of glucose to lactate in two ways: first, via a KRAS-driven increase in LDHA transcription [78]; and second, by deacetylation of lysine 5 in the LDHA protein, which acts to promote enzymatic activity [87]. To combat the increased accumulation of lactate, PDAC tumor cells also enhance the mechanisms of lactate efflux to the extracellular environment. This occurs in at least three ways.

Firstly, via a combined upregulation of the monocarboxylate transporters for lactate, MCT1 and MCT4, the latter particularly in hypoxic tumor regions [86]. Secondly, by upregulation of a specific G-protein-coupled receptor for lactate, GPR81, which can increase the expression of lactate transporters, and thirdly via increased expression of CD147 that acts as a chaperone for newly synthesized MCT transporters [10, 80].

Given the large production and efflux of lactate, other consequences might be anticipated. Indeed, the use of lactate as an alternative fuel for biosynthesis in some PDAC has been suggested, with lactate produced by PDAC tumor cells in hypoxic areas of the tumor feeding PDAC tumor cells in normoxic areas [86]. Lactate secretion also has been shown to have unexpected effects upon epithelial-stromal interactions. Thus lactate secreted from PDAC cells has been shown to contribute to polarization of a population of immunosuppressive macrophages [88]. Although the full consequences of excess lactate in the PDAC microenvironment remain to be established, in other cancers increased levels of lactate efflux have various other tumor-promoting effects. These include promoting the emergence of an immune-permissive microenvironment by attenuating monocyte migration [89] and dendritic [90] and T cell activation [91]. Furthermore, lactate accumulation is important to promote angiogenesis. Thus, lactate can induce secretion of the proangiogenic factor VEGF from tumor-associated stromal cells [92], while increased levels of lactate can stimulate hyaluronic acid production by fibroblasts, which may contribute to subsequent tumor invasiveness [93]. The final step of glycolysis, the conversion of pyruvate to lactate by LDH, is required to regenerate NAD+ and thus to facilitate continued cycles of glycolysis in PDAC. Thus, LDH represents a potentially attractive drug target in PDAC, as blocking lactate production would be expected to inhibit glycolysis. Indeed, FX11, an inhibitor of LDH [94] has been shown to reduce growth and induce apoptosis in PDAC PDXs in a preclinical study [95].

Glutamine Metabolism

The unexpected finding that the generation of pentoses is uncoupled from NADPH generation in PDAC, with a reliance instead upon the nonoxidative arm of the PPP [81], led to the issue of understanding how PDAC tumor cells can then generate enough NADPH to maintain redox homeostasis. An apparently PDAC-specific glutamine-consuming pathway generating NADPH identified in PDAC [78] has provided a potential explanation for this issue of NADPH deficit. Perhaps unsurprisingly, given its relative abundance in blood plasma [96], the amino acid glutamine plays critical metabolic roles in PDAC, particularly in maintenance of redox homeostasis [11].

In addition to its role in protein biosynthesis, glutamine acts as a major source of carbon and nitrogen for biosynthesis in proliferating cells [96]. PDAC cells grown in culture are known to require glutamine for both proliferation and redox balance [81]. Redox balance is thought to be achieved by two means: by increased generation of the antioxidant glutathione from glutamine-derived glutamate; by utilization of an unusual method of production of NADPH [81], which is itself involved in recycling

of oxidized glutathione and in other reducing reactions. In regard to glutamine-derived glutathione, glutathione abundance has been found to be increased in PDAC in comparison to normal pancreatic tissue, with inhibition of glutathione synthesis in vitro inducing growth inhibition and promoting apoptosis [97]. This latter pathway appears to be driven by oncogenic KRAS and converts glutamine-derived carbon into aspartate. This occurs within mitochondria via a series of reactions that firstly utilize the mitochondrial Asp aminotransferase (GOT2) [81]. Glutamine-derived aspartate is then transported into the cytosol and acted upon by a second enzyme, aspartate aminotransferase (GOT1), generating oxaloacetic acid (OAA). OAA is then converted to pyruvate by the cytoplasmic form of malic enzyme 1 (ME1), yielding NADPH [81]. This pathway of glutamine metabolism may also represent a specific metabolic vulnerability in PDAC as is has not been found to be used in normal pancreatic cells [81].

In addition to activation of the above mitochondrial/cytosolic pathway, as discussed previously mutant KRAS also initiates a nuclear Nrf2 transcription factor-dependent ROS detoxification program [72, 98]. The Nrf2 transcriptional response is normally activated in most cells by redox stress [99]; however, mutant KRAS constitutively activates this transcriptional program to suppress ROS and promote PDAC tumorigenesis and proliferation [100]. The Nrf2-directed transcriptional response has also been shown to redirect glucose and glutamine into anabolic and antioxidant pathways [72, 98]. Nrf2 also increases ME1 expression, thereby linking mutant KRAS with increased flux through ME1, generating increased NADPH to assist redox homeostasis [81]. Interestingly, the expression of malic enzymes ME1 and ME2 are transcriptionally repressed by wild-type TP53 [79], indicating again that the loss of TP53 function in advanced PDAC might synergize with KRAS to further increase metabolic flux to generate increased NADPH levels. Underscoring the importance of this antioxidant pathway, inhibition of these enzymes involved in NADPH generation in PDAC impairs viability both in vitro and in vivo [81]. Since Nrf2 also activates glutathione biosynthesis [98], mutant KRAS appears to enhance antioxidant defense in PDAC both via enhanced NADPH-dependent recycling of oxidized glutathione, and by an Nrf-2-dependent increase in glutathione synthesis.

In addition to contributing to redox homeostasis, glutamine plays a key role in providing substrates for biosynthesis via glutaminolysis by generating α-ketoglutarate (α-KG). α-KG is produced via the action of glutamate dehydrogenase (GLUD1) upon glutamate, with glutamate produced via breakdown of glutamine by glutaminases (GLSs) in mitochondria. Ultimately, this leads to the generation of α-KG–derived intermediates from the TCA cycle that are subsequently utilized in fatty acid (FA) synthesis [96], or in generating nonessential amino acids with glutamine acting as the nitrogen donor [96]. In PDAC tumor cells, KRAS acts to increase GOT1 while suppressing GLUD1 expression [81], suggesting that PDAC tumor cells preferentially utilize glutamine to counteract redox homeostasis and promote ROS detoxification, rather than to promote biosynthesis. Since ROS, generated by the action of NADPH oxidases Nox2 and Nox4, is increased by KRAS and is itself required for clonogenic growth [61, 67] and EMT [101] in

PDAC, it appears that the benefits of ROS for PDAC tumor cells are counteracted by glutamine-derived NADPH, thereby preventing excessive ROS inducing deleterious effects upon viability.

Alterations in Lipid Metabolism in PDAC

Metabolomic studies in the lipid metabolism mechanisms of PDAC cancers have surprisingly shown that they bear a lower fatty acid (FA) content when compared to normal surrounding tissue [43, 102]. However, when a study assessed the effects of dietary fat on a GEMM model of PDAC development, it was demonstrated that the high levels of lipids obtained from the diet led to a KRAS-COX2-dependent increase in the formation of PanINs and PDACs [103]. Indeed, high-fat diets and obesity are strongly linked with PDAC incidence [104], suggestive of a role of lipids in PDAC initiation or progression. Interestingly, PDAC tumor lines cultured with oleic (a monounsaturated omega-9 fatty acid) or linoleic acid (a polyunsaturated omega-6 fatty acid) have increased the rates of proliferation [105], suggesting that some FAs may be limiting for tumor growth, and rapidly metabolized. Consistent with this notion, KRAS transformation of normal immortalized pancreatic ductal epithelial cells (HPNE) is also known to increase scavenging of extracellular lysophospholipids as an alternative source of FAs [46], while PDAC cells exhibit increased acquisition of cholesterol [47]. Fatty acid synthase has also been reported to be upregulated in PDAC, likely downstream of KRAS via MAPK signaling, with increased expression correlating with poor prognosis [106].

Metabolic Crosstalk in the PDAC Tumor Microenvironment

One of the most prominent characteristics of PDA is an intense desmoplastic reaction around the tumor. Surrounding stroma occupies the largest volume of the tumor and it is developed from noncancerous cells including pancreatic stellate cells, immune cells, and endothelial cells surrounded by a dense extracellular matrix rich in collagen and hyaluronic acid [107]. As previously discussed, the formation of this unusual stroma induces a poorly vascularised microenvironment that limits the diffusion of oxygen and nutrients alike in PDAC [15, 108]. As a result of the limited vasculature, carcinomas are hypoxic and require adaptation to sustain their growth [11]. PSCs are the most abundant resident fibroblast-like cells present in lesions of the pancreas and a variety of evidence indicates are responsible for the desmoplastic reaction [14]. In healthy exocrine pancreas, PSCs are thought to maintain normal tissue architecture via regulation of the synthesis and degradation of extracellular matrix (ECM) proteins [109]. Following injury or inflammation, PSCs transform from their quiescent phase into an activated, myofibroblast-like phenotype, secreting excessive amounts of ECM proteins leading to the fibrosis typical of chronic pancreatitis and PDAC [109]. Furthermore, PSCs can also regulate the turnover of the tumor stroma through the expression of matrix metalloproteinases

such as MMP1 and MMP2 [110]. Targeting the stroma through enzymatic modulation of hyaluronic acid enhances the delivery of chemotherapeutic agents and therefore increases the cytotoxic potential of those drugs [13].

PDAC cells can initiate a reciprocal signaling network between the tumor cells and the neighboring PSCs [111]. In the face of poor nutrient supply from the vasculature, metabolites are accessed by PDAC tumor cells from surrounding stromal cells [112]. PSCs have for example been found to release nonessential amino acids (NEAAs) in response to culture with PDAC tumor cells [112]. PDAC cells in particular consume PSC-derived alanine and use it to fuel additional metabolic processes including mitochondrial metabolism, fatty acid synthesis, and synthesis of other amino acids [112]. The mechanism involved in such nutrient accessing by PDAC tumor cells appears to be via autophagy that is induced within PSCs. Indeed, the blockage of autophagy prevents alanine release from PSCs, although the specific mechanism of alanine release remains to be established [112].

Another component of the tumor microenvironment is infiltrating leucocytes. The T-lymphocytes account for the most abundant cell type in adaptive immunity and are responsible for the identification of foreign antigens which have been previously processed and presented by antigen-presenting cells (APCs), such as dendritic cells and macrophages. Antigen recognition mediated through T-cell-APC interaction leads to T-cell activation, clonal expansion, and migration toward the antigens where the T-cells exert various effects according to their subtype.

The T-cells are divided into CD4+ T-helper cells which are further subdivided into Th1, Th2, and Th17 populations; CD8+ cytotoxic cells; and regulatory T-cells (Tregs). Each of the T-cell subtypes has distinct functions; the polarization of the CD4+ cell populations is triggered by different cytokine combinations, and therefore Th1, Th2, and Th17 cells display differential cytokine production patterns with opposing effects. The CD8+ cells are responsible for cell-mediated cytotoxicity whereas the Tregs exhibit immunosuppressive properties [115].

CD8+ cells are capable of infiltrating tumor sites and killing cancer cells and have therefore been associated with better prognosis in numerous cancer types, among them melanoma, head and neck cancer, lung, breast, and colon cancer. However, human PDAC is characterized by poor CD8+ T-cell infiltration to the tumor site. This could be attributed to the low mutation rate observed in PDAC in contrast to other KRAS-induced cancers (e.g., lung cancer), which leads to the limited formation of neoantigens that could be recognized by the T-cells [113]. Furthermore, the formation of a tumor microenvironment with a predominant presence of Th2 cells, Tregs, MDSCs, and immunosuppressive cytokines further impedes the CD8+ T-cell activation, favoring tumor sustainability and progression.

CD4+ T-cells play a pivotal role in the regulation of CD8+ T-cell function and therefore the predominance of the Th2 cells in the PDAC tumor milieu are thought to significantly hamper the activation of the CD8+ T-cells through the production of immunosuppressive cytokines such as IL-4, IL-5, and IL-10 [114]. On the other hand, the Th1 cells can suppress tumor proliferation by producing IL-2 and IFN-g which have a proinflammatory effects and are essential for CD8+ T-cell activation and proliferation [115]. Therefore, the Th1/Th2 ratio is crucial in order to determine

whether the elicited immune response at the tumor site will either suppress or promote tumour growth [115].

Aside from the large amounts of Th2 cells, the PDAC tumor microenvironment is also preoccupied with another Tregs, which have a prominent immunosuppressive role [116]. The Tregs can inhibit the function of several immune cell types such as natural killer cells (NK), B-cells, and dendritic cells through granzyme B production but can also secrete several cytokines such as TGF-β1, IL-6, TNFa, and the receptor activator of NF-κB, which strongly enhance further tumor development [117].

The metabolic landscape of pancreatic cancer microenvironment further enhances tumor progression by dampening the immune response. Infiltration of immune cells can be observed early in the development of pancreatic cancer. PanINs initiate the accumulation of leukocytes that consist mostly of macrophages, $CD4^+$ T regulatory cells (Tregs), and myeloid-derived suppressor cells (MDSC) that all act in an immunosuppressive manner [118]. Effector $CD8^+$ T cells that could suppress tumor growth have only been found in low numbers and with no indication of activity [118].

One of the underlying causes for the lack of significant effector immunity could be the nutrient competition between immune cells and cancer cells. T cells are also known to utilize aerobic glycolysis to support their high needs of energy upon clonal expansion and secretion of various cytokines [119]. Glucose deprivation of T cells leads to "exhaustion," a phenomenon that blocks effector function of T cells and leads to low levels of IFN-γ production [120]. Such an effect has been observed in the studies of sarcoma and melanoma models where the existing pool of glucose in the tumor microenvironment is diminished due to excessive glycolytic metabolism of cancer cells, leading to glucose restriction of nonregulatory CD4+ T helper cells (TH1) [120]. TH1 cells subsequently fail to mount a prominent presentation of the antigen or recruit effector cells.

Conclusion

Altered metabolism is now recognized as an important hallmark of cancer [121], and efforts are ongoing to therapeutically exploit some of these metabolic differences between normal and cancer cells [12]. In the case of pancreatic cancer, metabolism is known now to be significantly impacted upon by mutation of the KRAS proto-oncogene, presenting exciting potential opportunities for selective targeting of metabolism in PDAC. Together with KRAS mutations, the hypoxic microenvironment generated by stromal deposition similarly forces PDAC tumor cells to rely on alternative sources of nutrients, and to utilize unique methods to obtain them. Unfortunately however, there are currently no clinical useful mutant KRAS inhibitors, and only a few clinically viable Ras-effector treatments that might be the most direct way to combat altered metabolism in PDAC deriving from mutant KRAS.

Of other mechanisms that might be therapeutically viable in PDAC, recent work indicates that constitutive autophagy – a major feature of PDAC tumor cells – and glutamine utilization, fuelling NADPH reserve to maintain redox homeostasis,

would appear to be two of the most promising avenues for therapeutic intervention. Inhibitors of autophagy, such as HCQ, are currently being assessed in PDAC clinical trials, although HCQ pharmacostability is likely to be an issue, as is penetrance of any small molecule inhibitor through the dense stroma and hypoxic PDAC microenvironment. In the case of therapeutic targeting glutamine utilization, the use of an apparently PDAC-specific breakdown of glutamine is particularly attractive, although whether there are other normal tissues that might use such a strategy would need to be more completely explored.

Confounding such approaches however will likely be the presence within PDAC of distinct metabolic subtypes and significant intratumoral heterogeneity. These might allow significant tumor evolution during the course of any therapy aimed at targeting one specific metabolic feature [122]. In addition, unlike specific fixed genetic alterations such as mutant KRAS, metabolic networks are now known to exhibit inherent plasticity and are therefore likely to be rewired in the face of targeted therapies unless cell death is rapidly obtained [123]. Finally, although there is great interest in dissecting immune responses in the PDAC microenvironment and evolving immunotherapies that attack PDAC cancer cells [124], glycolysis inhibitors targeting PDAC tumor cells may further interfere, in unknown ways, with antitumor immune responses by blocking metabolic alterations also critical for immune cell activation.

Abstract

The prevalence of pancreatic cancer is too low, and the accuracy of current screening methods is not high enough to permit general population screening. Secondary screening in high-risk groups may be possible for the disease or its precursors. Pilot screening studies have been initiated and are generating data on the nature of inherited predisposition and the early stages of cancer development. It is already apparent that the specificity and sensitivity of secondary screening tests need to be improved. In this chapter, the preliminary evidence from the pioneering screening studies will be considered in order to discuss which participants should be recruited into future pilot studies and how biomarkers may in future be combined with imaging to reduce the number of missed cancers and premature surgical interventions.

Keywords

Pancreatic cancer · Inherited diseases · Risk · Screening

Introduction

Pancreatic ductal adenocarcinoma (PDAC) remains one of the most lethal cancers, with a 5-year survival of about 6% [1]. In the USA, it is estimated that in 2016, there are roughly 53,070 cases of pancreatic cancer diagnosed with 41,780 deaths [1]. The incidence of PDAC has been rising, and it is predicted to be the second leading cause of cancer deaths by 2030 [2]. Despite significant improvements in cancer treatment, prognosis remains poor as the majority of patients with PDAC (80–90%) [3, 4] have unresectable disease at diagnosis, due to late presentation.

Surgery remains the only potentially curative treatment, but even after resection, 5-year survival rates are less than 10% [5]. Adjuvant chemotherapy with gemcitabine and capecitabine following resection has recently been shown to convey a significant improvement in 5-year survival 29% over the previous standard treatment with gemcitabine monotherapy of 16% [6].

The cohort series of partial pancreato-duodenectomy (with variable neoadjuvant and adjuvant therapies) from Johns Hopkins Medical, showed that the median survival rate for cancers <3 cm was 21 months, and the 1-, 2-, and 5-year survival

rates were 73%, 45%, and 23%, respectively [7]. Smaller pancreas cancers without perineural or lympho-vascular invasion had a better prognosis. For cancers >3 cm, the median survival was 15 months, and the 1-, 2-, and 5-year survival rates were 59%, 31%, and 4%, respectively. PDAC with the best chance of a cure are small <1 cm, well-differentiated stage 1 cancers, with postresection 5-year survival rate of up to 75%. To improve survival early detection is necessary but small pancreatic cancers are generally asymptomatic and so patients with such tumors do not present for clinical investigation. Imaging techniques are sensitive, but do not approach the level of 100% specificity, which is required to avoid an excess number of false positives given the relatively low prevalence of the disease [8].

Pancreatic cancer represents only 3% of estimated new cancers each year [9], but is the fourth most common cause of cancer mortality. By 2030, it is estimated to be the second leading cause of cancer death [2]. Approximately, 5–10% of PDAC cases have an inherited genetic component. With an ever aging population, the incidence and frequency of PDAC will increase. There is a need for focused affordable screening in high-risk populations based on reliable biomarkers and efficient imaging modalities. The nature of genetic susceptibility was discussed in a previous chapter of this handbook. In this chapter, the discussion will be expanded to address the question of how great the risk needs to be in order to justify secondary screening.

Who to Screen

Primary Versus Secondary Screening

To be effective any test should provide a True Positive:False Positive ratio of >1.0. The True Positive:False Positive ratio is affected by the sensitivity and specificity of the test and the prevalence of the disease in the population being screened. The age adjusted incidence of pancreatic cancer is up to 10 per 100^5 overall and even for those over 75 years of age (the highest risk age group), it is less than 120 per 100^5 [10]. This means that in a screened population of 10^3 participants it would be reasonable to expect just one true positive individual. Unless the screening test was better than 99.9% specific there would be many more false positives than true positives. For example, assuming a test with sensitivity and specificity both of 85% and a partially enriched screening population with a prevalence of 20 per 100^5, screening 10^5 individuals would produce 17 True Positives, 84,983 False Negatives, 14,997 False Positives, and three False Negatives with a True Positive: False Positive ratio of 0.001. So, primary screening of the general population is not an option. The positive predictive value of a test can be improved by selecting a population with an increased prevalence of the disease being tested for, such as age, smoking history and a potential or actual genetic predisposition to pancreatic cancer. Secondary screening requires a highly enriched population with as high a prevalence as possible and a highly sensitive test. As any potentially curative treatment will require surgical resection of the pancreas, which has considerable morbidity and a small mortality rate [11], the specificity must approach 100%.

Screening Consensus

Consensus recommendations for secondary screening of high-risk groups were initially proposed at the Fourth International Symposium on Inherited Diseases of the Pancreas in 2003 [12]. It was concluded that secondary screening should only be carried out in patients with a strong genetic susceptibility. Hereditary pancreatitis (HP, with PRSS1 mutations) was included as was Peutz-Jeghers' syndrome (PJS, with STK11/LKB1 mutations). The International Cancer of the Pancreas Screening Consortium (CAPS) was formed in 2010 with the specific objective of developing statements on screening in individuals at risk (IAR) with an inherited disposition to PDAC. From the 2011 CAPS meeting, the group recommended screening should be undertaken in IARs to detect relevant lesions, in participants who would be suitable for potential surgical resection. Ideally, this should be at a tertiary center as part of a recognized research program [13]. IARs included familial pancreatic cancer (FPC), PJS, familial atypical multiple mole melanoma (FAMMM) syndrome with *CDKN2A* mutations, breast-ovarian syndrome with *BRCA2* mutations, and hereditary non-polyposis colorectal cancer (HNPCC) mutation carriers with >1 affected first-degree relatives (FDR). No consensus was reached on the ages for initiating and stopping screening, on the imaging modality of choice (although endoscopic ultrasound (EUS) and MRI were recommended), or on screening intervals. Defining a strong genetic predisposition is not straightforward and involves a complex assessment of polygenic and environmental factors. In the end, the experts at the CAPS meeting reached a compromise on a select few conditions and what constituted an individual at risk.

Individuals at Risk (IAR)

There are numerous factors that increase the risk of developing PDAC, including age, tobacco consumption, non-O blood groups, chronic pancreatitis, late-onset diabetes mellitus, hereditary pancreatitis, cystic fibrosis, certain cancer family syndromes, and a family history of PDAC. The lifetime risk of PDAC in the general population is around 1%. Individuals with an at least 5–10-fold increased risk for PDAC are deemed IAR and are considered to be good candidates for screening.

An FPC family is defined as having at least two FDRs, or three or more second-degree relatives, with pancreatic cancer. Despite pancreatic cancer being relatively uncommon, clusters of cases will occur by chance. If the cluster is random then prospective incidence of pancreatic cancer would be equivalent to the general population. A family history will make it more likely that an individual is carrying some high-risk allele of a gene, but the majority of people with a family history will not have any particular genetic predisposition and instead family members may share some environmental risk factor. Stratification of risk is based on a family history, the greater the chance that a family has autosomal dominant genetic predisposition, the greater the risk estimate. Klein et al. have shown that the risk of PDAC in an individual with two FDRs affected is 6.4-fold greater than someone with no

affected FDRs (8–12% lifetime risk), whereas an individual with three FDRs can be estimated to have a 32-fold increased PDAC risk (40% lifetime risk) [14].

Risk can be further refined if an individual has undergone specific genetic testing to identify mutations in known pancreatic cancer susceptibility genes. Several germline gene mutations have been identified as increasing PDAC risk [12]. The relative risk of PDAC associated with each gene mutation is summarized in Table 1.

Hereditary pancreatitis (HP) is characterized by recurrent attacks of acute pancreatitis, progressing to chronic pancreatitis with a family history of pancreatitis consistent with an autosomal dominant inheritance pattern and/or the presence of a proven known genetic mutation [15]. HP confers an approximate 25–40% lifetime risk of PDAC to the age of 70 years [15]. Sporadic chronic pancreatitis also increases the risk of pancreatic cancer fivefold [16], but the risk is too low to enable effective secondary screening in this group of patients.

Peutz-Jeghers' syndrome (PJS) is an autosomal dominant disorder with increased risk of multiple cancers. The phenotype comprises hamartomatous gastrointestinal polyps, and oro-buccal mucosal pigmented macules most of whom have an STK11 gene mutation with a very high pancreatic with cancer risk [17]. A meta-analysis of 210 patients found the relative risk (95% confidence interval, CI) for all cancers was 15.2 (2, 19) % with an average age of onset of malignancy of 41 years, compared with over 60 years for the general population [18]. The cumulative risk for all cancer was 93% from age 15 to 64 years old. A statistically significant increased relative risk (95% CI) was found for esophagus (57; 2.5, 557%), stomach (213; 96, 368%), small intestine (520; 220, 1306%), colon (84; 47, 137%), pancreas (132; 44, 261%), lung (17.0;5.4, 39%), breast (15.2;7.6, 27%), uterus (16.0; 1.9, 56%), ovary (27; 7.3, 68%), but not testicular or cervical malignancies.

BRCA2 mutation carriers constitute the largest group of mutation carriers at risk for PDAC [19]. The PDAC risk in this group is between 3.5% and 10%, depending on number of affected family members [20]. The PDAC risk would appear to be context specific as not all carriers in a BRCA2 family will develop PDAC. Pandharipande et al. used MRI based simulation screening model for PDAC in BRCA2 families and demonstrated a small life expectancy gain with screening, which was eliminated with a slight increase in surgical mortality rate (>2.3%) [21]. The recommendation was to restrict screening to BRCA2 mutation carriers with at least two FDRs with PDAC.

Familial atypical multiple mole and melanoma (FAMMM) is an autosomal dominant syndrome with a subset of patients with this syndrome harboring mutations in *CDKN2A* (the gene encoding p16 protein), which are frequently found in sporadic pancreatic cancer [22]. The estimated cumulative risk of developing PDAC in CDKN2A is 17% [23].The association between inherited gene mutations and pancreatic cancer in the other syndromes mentioned in Table 1 is small including the risk in hereditary breast-ovarian cancer caused by *BRCA1* mutations [24].

Whole genome sequencing has defined considerable genetic heterogeneity of FPC [25]. Although familial aggregation of pancreatic cancer has been established, the cause of this aggregation in most families is unknown. Roberts et al. sequenced

Table 1 Inherited gene mutations associated with PDAC

Hereditary tumor predisposition syndromes	Gene mutations	% of presumed FPC families	Relative risk	Risk at 70 years of age (%)
None	**None**	–	1	0.5
Peutz–Jeghers syndrome	***STK11/LKB1***	<1	132	30–60
Hereditary pancreatitis	***PRSS1***	0	50–80	25–40
FAMMM	***p16/CDKN2A***	1	20–34	10–17
Hereditary nonpolyposis colon cancer (HNPCC)	**MSH2, MLH1, MSH6, etc.**	<1	8	3.7
Hereditary breast-ovarian cancer	***BRCA1***	<1	Unknown	Unknown
Hereditary breast-ovarian cancer	***BRCA2***	5	3.5–10	3.5
Li–Fraumeni syndrome	**TP53**	<1	<5	<5
Familial adenomatous polyposis	**APC**	<1	<5	<5
Cystic fibrosis	**CFTR**	0	<5	<5
Ataxia telangiectasia	***ATM***	<1	Unknown	Unknown
Possible FPC	***PALB2***	<1	Unknown	Unknown

the germline genomes of 638 patients with FPC and the tumor exomes of 39 familial pancreatic adenocarcinomas. Previously identified FPC susceptibility genes such as BRCA2, CDKN2A, and ATM, were confirmed but novel candidate genes harboring rare, deleterious germline variants were also identified requiring further characterization. The genetic underpinning of inherited pancreatic cancer is highly heterogeneous which has significant implications for the management of patients with FPC. In particular, for screening the implication is that the focus must be heavily reliant on the phenotype of family clusters.

Quantified Risk of Incident Pancreatic Cancer Among First-Degree Relatives of Patients with Familial Pancreatic Cancer

The Johns Hopkins group prospectively quantified the risk of PDAC among first-degree relatives of incident cases in both sporadic forms and those with FPC, defined as kindreds with at least two first-degree relatives with PDAC in families enrolled in the National Familial Pancreas Tumor Registry (NFPTR) [26]. There were 191 families with sporadic pancreatic cancer (without a pair of affected first-degree relatives) and 150 families with FPC including 52 kindreds containing three or more affected members at the time of enrolment. Risk was estimated by comparing observed new cases of PDAC during the observation period with expected numbers based on data in the USA population-based Surveillance, Epidemiology, and End Results (SEER) program. Incidence was estimated using person-years risk analyses. During the

observational period, six incident cases developed in the first-degree relatives, two in the sporadic families, and four in the FPC kindreds.

The PDAC risk in the sporadic kindreds was not significantly greater than expected [observed: expected (O:E) = 6.5 (95% CI = 0.78–23.3)] with an incidence rate of 24.5 per 10^5 per year. The expected incidence of PDAC from the SEER data was 8.8 per 10^5 per year. There was a significant increased risk in first-degree relatives in FPC kindreds (O:E = 18.3; 4.74–44.5), with an incidence of 76.0 per 10^5 per year. In the subset of FPC kindreds with three or more affected family members there was a 57 (12.4–175)-fold increased risk with an incidence of 301.4 per 10^5 per year. In the FPC kindreds, the increased risk appeared to be largely confined to relatives 60 years of age and older.

In an Italian study of 570 index cases of pancreatic cancer, there were 54 who reported of a family history of pancreatic cancer [27]. Pancreatic cancer was significantly increased in first-degree relatives (relative risk at age 85 years = 2.7). Nearly all the risks were explained by just seven families with little increase in remaining 47 families.

These data support the notion of secondary screening, but would not be appropriate for most families with a family history. Identification of the most efficient screening systems is still in development [28].

The more cases there are in a family the more likely it is to be consistent with FPC, but this is balanced by a reduced probability that the family is FPC if there are nonpenetrant members of the kindred.

It is difficult to define nonpenetrant, partly because most FPC kindreds have no identified disease mutation. This problem can be partially resolved by using obligate carriers, for example anyone who has both antecedents and descendants with pancreatic cancer, but at what age can they be described as having past the point at which they should have developed cancer. There is some evidence for anticipation in FPC, with progressively earlier age of cancer with successive generations [29]. Therefore, if an obligate carrier exceeds the age of an affected parent, or exceeds the age of an affected child by at least 10 years, then they can reasonably be defined as nonpenetrant. Figure 1 shows four hypothetical families, each with two members who are affected with pancreatic cancer. Families A and D have the least nonpenetrants and so are the most likely to be FPC kindreds. The seven out of 570 Italian families described by Del Chiaro et al. as being high risk had just one nonpenetrant individual between them [27], limiting screening to apparently fully penetrant families in the Del Chiaro series would therefore have risked missing one genuine family, but would have meant that the majority of false families would not be screened. The probands from families A and D but not B or C would be recruited for screening. Further refinement of selection is possible, for example, the single family with a nonpenetrant had three affected individuals, a criteria of three or more affected per nonpenetrant would mean that none of the high-risk families in the Del Chiaro study would be missed, but a large proportion of false families would be eliminated.

The risk of cancer is not solely determined by the nature of the family. The probability an individual within that family is a carrier must always be taken into

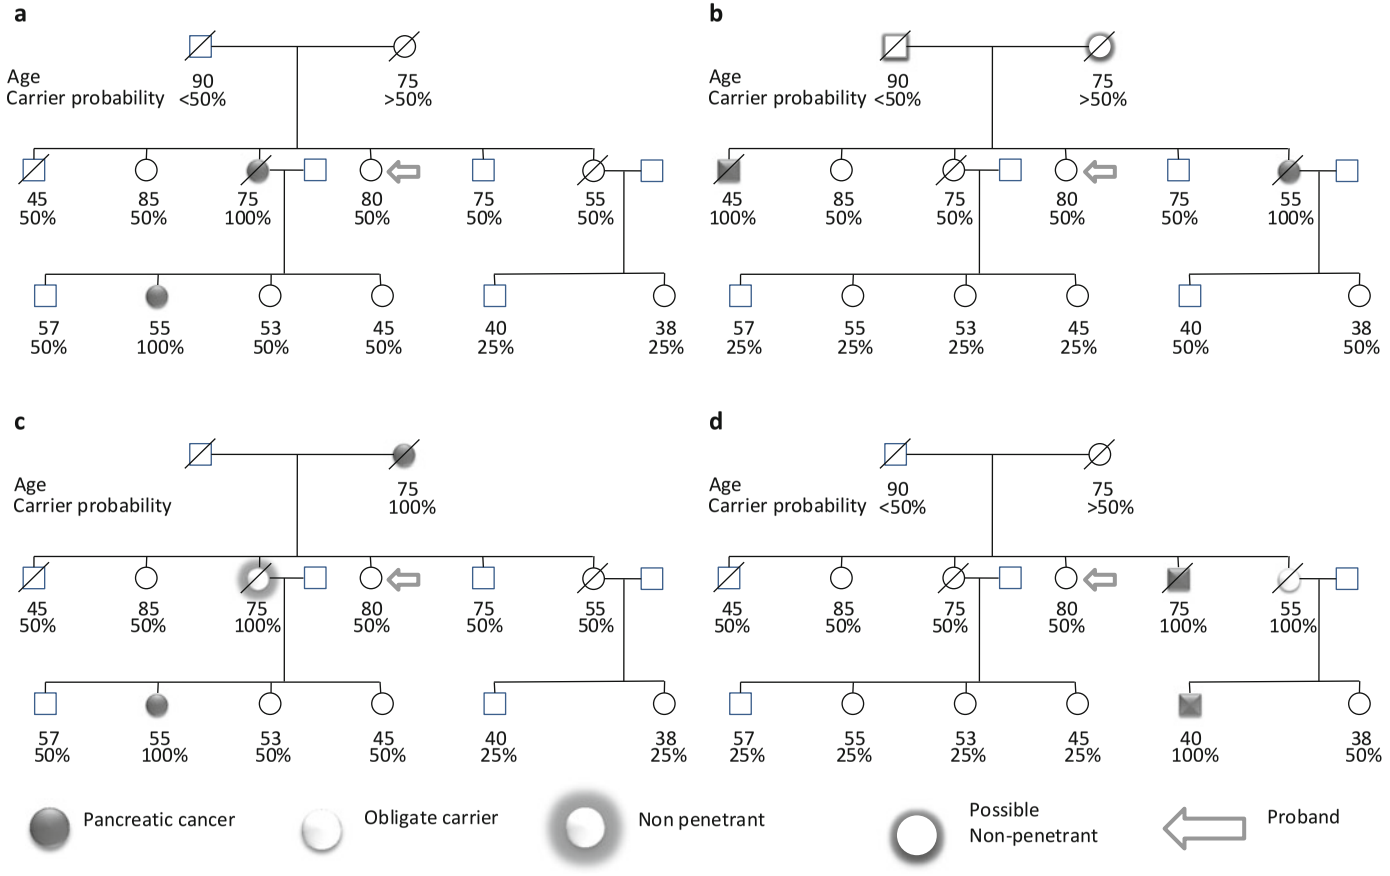

Fig. 1 (continued)

account, the 57-year-old nephew of the proband in family A from Fig. 1 is therefore at more risk than the equivalent nephew in family D. In addition, the age of the individual must be considered.

When to Screen and Risk Stratification

Age Dependent Risk

Age is the greatest risk factor for sporadic pancreatic cancer, below the age of 60 years age adjusted incidence of pancreatic cancer is less than 1 in 10^5, between 60 and 75 years it is close to 40 in 10^5, and over 75 years the incidence approaches 100 per 10^5, [10]. Genetic predisposition could increase cancer risk at specific ages. For example, an affect linked to puberty could increase risk a fixed number of years afterwards, cancer risk before or after this point would be unchanged but overall risk would increase. Alternatively, a risk later in life might be increased but risk at younger ages could be unchanged, thus only late-onset disease would be increased. Comparison of data for pancreatic cancer incidence from the SEER program of the National Cancer Institute in the USA with data for FPC kindreds from the European Registry of Hereditary Pancreatitis and Familial Pancreatic Cancer (EUROPAC) suggests that high risk in FPC can best be modeled by a 120- fold constant factorial increase in risk at each age, rather than a greatly increased risk at particular ages and smaller increases at others [28].

The figure of a 120-fold increase represents an average, some families will have greater factorial increases and some less; equally some individuals will have a greater increased age dependent risk than other at risk members of the family. This is evident from anticipation, which can only be explained if parents have a lower age specific risk than their offspring [29]. Other variables that may affect age specific risk are gender, smoking, and secondary genetic factors.

Men have a slightly increased risk of pancreatic cancer compared to women in the general population [10], but gender makes no significant difference to age of cancer in FPC [29]. Similarly in HP cancer risk does not seem to be significantly affected by

Fig. 1 Consistency with autosomal dominance. All family trees have two affected members with pancreatic cancer, but only family (**a**) and (**d**) have no requirement for anyone to be defined as nonpenetrant. Thus, (**a**) and (**d**) are more likely to be carrying a monogenic predisposition for pancreatic cancer. In family (**a**), one of the proband's parents must be a carrier if the family has FPC, the mother was just 75 (the same age as the proband's affected sister), which means that this parent could have been a carrier who never reached the age of penetrance. In contrast, both parents of the proband in family (**b**) are more than 10 years older than the oldest affected individual. One of the parents must therefore be nonpenetrant. In family (**c**), the 75-year-old sister of the proband must either be nonpentrant or the family does not suffer from FPC. In family (**d**), the 55-year-old sister of the proband must be a carrier if this family does genuinely suffer from FPC, but this individual died 20 years before her affected sister, so again this carrier could have not reached the age of penetrance. Family (**d**) is more likely to be FPC than (**b**) or (**c**), but less likely than family (**a**)

gender [15]. Tobacco smoking is the most important environmental risk factor associated with PDAC and increases the risk of sporadic pancreatic cancer by twofold compared to nonsmokers [30], and accounts for 25% of all PDACs [31], with a strong dose-response relationship [32], so some smokers may be at even greater risk. It seems that smoking is synergistic with family history in predisposing to cancer [33]. In the EUROPAC cohort of FPC families, it is less clear that smoking has a significant impact [29], but there are reports of earlier age of pancreatic cancer even in the context of autosomal dominant predisposition [34]. In HP, smoking is a clear risk factor for pancreatic cancer [35]. Polymorphisms in cell cycle genes are associated with earlier age of onset in sporadic pancreatic cancer [36]. It is possible that these and other polymorphisms will also influence age of onset in FPC.

The age at which to start and stop screening for PDAC is uncertain, and more evidence is required. There was disagreement on this topic at the CAPS summit, where the slight majority of experts (51%) voted to initiate screening at 50 years of age; however, most of the active research programs, and thus support data, start screening around the age of 40–45 years, or at 10 years younger than the youngest case of PDAC diagnosis in the family.

Risk Stratification

The relative lack of success of pilot screening programs for pancreatic cancer can be explained by inclusion of too many low-risk individuals in the screening cohorts. Risk stratification models could be used to optimize screening and surveillance programs, to increase the likelihood of detecting a PDAC and mitigating the unavoidable risks associated with false positive screening results. Risk-prediction models such as Panc-PRO, a Mendelian risk prediction tool for pancreatic cancer and have been developed to help identify individuals in families with HP and FPC who have the highest risk of developing PDAC [37]. Work continues to model risk and it is hoped that these mathematical models will be able to provide age specific risk stratification. They may also have a role in reassuring members of the public who have no elevation in PDAC risk. This would be particularly useful in FPC in the absence of a genetic test. Meanwhile, simple stratification is relied upon, such as above or below 40 years, or a certain number of years before the age of cancer diagnosis in other members of the family.

Alarm Symptoms and Screening for Pancreatic Cancer

Risk stratification could be combined with symptoms [38]. Early alarm symptoms such as dyspepsia, vague upper abdominal pain, anorexia, weight loss, and late-onset diabetes mellitus are easily dismissed in the general population as too unspecific to trigger investigations [39], but as part of a primary screen they could be used to trigger secondary screening. Evidence that diabetes mellitus is a very early symptom of pancreatic cancer is provided by the observation that pancreatic cancer patients

were more likely than controls to have developed hyperglycemia within a 4 year period [40] and such recent onset diabetes often resolved following pancreatic cancer resection indicating that it was the cancer causing the diabetes rather than the diabetes predisposing to cancer [40, 41].

Risk Assessment for Screening

Risk assessment to estimate whether benefits of the entire screening process outweighs any drawbacks should be made before first approaching potential participants. Risks to the participant start with raised anxiety and extend through to a chance of unnecessary pancreatic resection. The principal benefits include reassurance and possible lifesaving early treatment. Unfortunately, in the case of pancreatic cancer there are great gaps in our knowledge which makes risk assessment more an art than a science.

Any risk assessment must start with an estimation of cancer incidence and the maximum number of people screening could possibly benefit. Age adjusted incidence of pancreatic cancer was approximately 10 in 10^5 [10] with 53,070 cases in 2016 [1]. As shown in Fig. 2 a primary screening program with 95% test sensitivity and 99% test specificity aimed at the entire USA population (320 million) would give a gross excess of false positives over true positives. Approximately 10% of pancreatic cancer cases [34] and 1% of the general population [42] report a family history of pancreatic cancer. This shows that for the screening test to have a True Positive:False Positive ratio >1 then a family history with an autosomal dominant pattern of inheritance is required. In the absence of a known mutation, this would need to be at least three first-degree relatives in two or more generations (Fig. 3).

Increasing the stringency of the definition of a family history will further increase the incident population. From the Del Chiaro study of Italian index cases, approximately seven of 54 (13%) of pancreatic cancer patients who report a family history have at least two other cases in the family [27]. By definition, the risk of pancreatic cancer for any individual in a family without any predisposition is independent of family history. Based on the probability of 1% of control families having a single family member with pancreatic cancer [42], the chance of any family having two cases is 0.01%. EUROPAC recruits participants on the familial pancreatic cancer register as families with two or more affected individuals not fulfilling criteria for any other familial cancer syndrome. [29]. In October 2016, 746 of 980 families (76%) were consistent with autosomal dominance. It is unclear how much of this is due to random clustering and how much is due to genuine predisposition. Only 69% of families with just two affected members are consistent with autosomal dominance compared to 88% for families with more than two members. It can therefore be conservatively assumed that 88% of genuine families and 69% of random clusters will be consistent with autosomal dominance; screening 9,288 individuals would give just 90 false positives and still give 273 true positives.

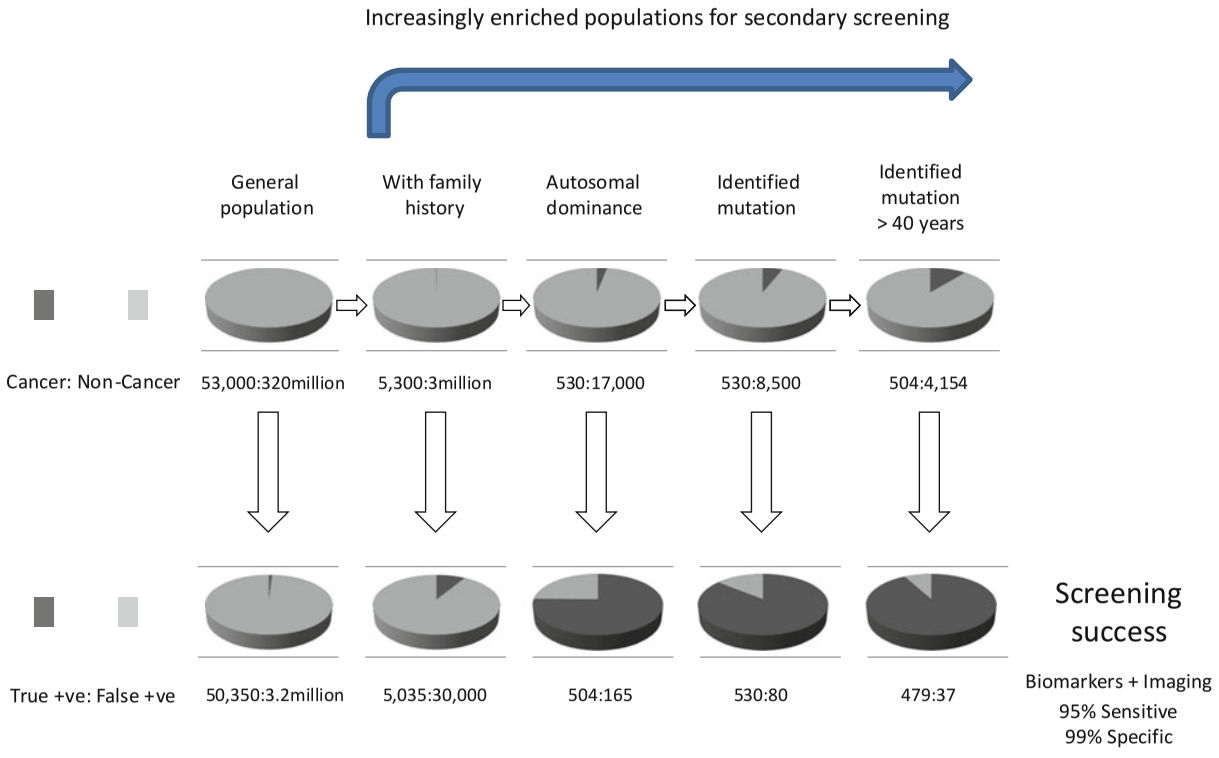

Fig. 2 Evaluation of primary and secondary screening. The upper set of pie chart shows how the proportion of pancreatic cancer cases in a population changes with primary screening. The rationale explaining these numbers is given in the main text. If a secondary screening program with 95% sensitivity and 99% specificity was applied at each point in this primary screening process, the proportion of true positives and false positives would be as shown in the second row of pie charts. The numbers underneath the pie charts are based on an initial population of 350 million individuals and 35,000 cases of pancreatic cancer (roughly equivalent to the population of the USA)

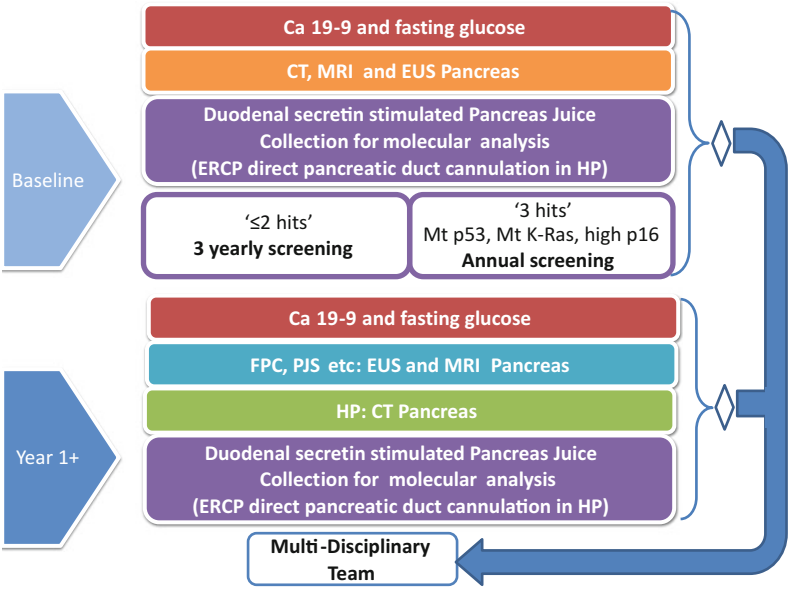

Fig. 3 The EUROPAC secondary screening protocol in FPC. Following identification of high-risk individuals by primary screening, members of FPC kindreds undergo baseline testing. If there is evidence of malignancy, the patient is referred to the clinical multidisciplinary team meeting (*MDT*). Otherwise, pancreatic juice is obtained by ERCP, and this juice is analyzed for molecular markers of cancer. If this analysis raises concerns, the patient is referred to the MDT. The MDT may suggest close surveillance which involves annual EUS and possibly ERCP, or they might recommend that the option of surgery is discussed with the participant. For those not under close surveillance, screening continues with a three yearly imaging cycle and ERCP for molecular analysis in the year following EUS. ◊ = clinical input)

First-degree relatives of a case of pancreatic cancer in a family with autosomal dominance would have a 50% chance of carrying the disease mutation; if this mutation could be identified, then the proportion of genuine at-risk individuals would be doubled.

Pancreatic cancer risk is heavily age dependent. If age is taken into account, then the proportion of individuals with cancer in the screened population can be greatly increased. Simply by limiting screening to people over the age of 40 years, the population without cancer will be roughly halved (median age in the USA is projected to be 40 years by 2025) with only a modest reduction in the number of cancer cases (<5%) [10].

The risk analysis will also have to take into account costs and morbidity associated with the secondary screening modalities. The question is therefore whether there are modalities available which offer adequate sensitivity and specificity at a reasonable cost.

Screening Modalities

Two main approaches have been employed to detect early pancreatic neoplasms and precursor lesions. The first is imaging predominantly with EUS, and the second relying on molecular analysis. Secondary screening requires higher specificity and sensitivity than is currently possible with any single modality, but combinations of imaging and biomarkers might be sufficient.

Imaging

Current imaging tests used in normal clinical practice for the investigation and management of pancreatic disease include; EUS, abdominal ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), endoscopic retrograde cholangiopancreatography (ERCP), and ^{18}F-Fluorodeoxyglucose positron emission tomography (18FDG-PET).

CT, MRI, and EUS have all been employed in various combinations for the detection of early pancreatic neoplasms. A study in 2012 by Canto et al. undertook a prospective comparison of all three modalities in 225 asymptomatic IARs [43]. EUS detected a pancreatic abnormality in 43% of patients, in contrast with MRI and CT, which identified lesions in 33% and 11%, respectively. Five EUS detected lesions underwent surgical resection, of which three where intraductal papillary mucinous neoplasms (IPMN) with high-grade dysplasia.

EUS

A study from the CAPS Consortium showed that EUS had the highest detection rate of pancreatic abnormalities among high-risk patients (42.6%), compared to CT (11%) and MRI or magnetic resonance cholangiopancreatography (MRCP) (33.3%). EUS has also been shown to have a greater sensitivity and specificity than CT (>90% sensitivity [44]), particularly for small tumors [43]. Hanada et al. showed that for PDAC <10 mm, EUS was the most valuable imaging modality for tumor detection [45].

EUS is also particularly sensitive in detecting precursor cystic lesions of the pancreas such as IPMNs [46]. Other smaller pancreatic precursor lesions such as pancreatic intraepithelial neoplasia (PanIN) [47] are not directly visualized at EUS, but their presence might be inferred by pancreatic parenchymal heterogeneity and lobulocentric atrophy.

The accuracy and interobserver agreement of EUS is influenced by user experience, completion of advanced training, and the type of echoscope used. Radial echoendoscopes may miss some early lesions in patients with high risk for pancreatic cancer while linear scopes allow the operator the ability to perform fine needle aspiration (FNA) during the same procedure if an area of interest is identified making it more cost and time effective. The results of two large meta-analyses suggest that combining EUS and FNA to diagnose PDAC gives a high sensitivity (89–92%) and specificity (96%) [48, 50].

EUS however, is not very specific in patients with benign inflammatory diseases of the pancreas. Positive predictive value was only 60% in a study of 85 patients aimed at distinguishing between chronic pancreatitis and pancreatic cancer [50]. Combining EUS with FNA or "Tru-cut" biopsy does not fully resolve this problem as it is still very easy to miss small tumors in a patient with cancer in a background of chronic pancreatitis [51].

Overall, it would appear that EUS has several advantages over other screening modalities. If suspicious lesions are identified during the EUS, they can be sampled during the procedure, unlike with the other imaging methods and unlike CT, EUS does not expose patients to radiation or intravenous contrast. The procedural risk profile of EUS is like other endoscopic procedures and includes infection, bleeding, and perforation.

Computed Tomography (CT)

CT must use a pancreas specific protocol and requires a specialist radiologist to interpret the images. A retrospective analysis of CT scans showed that it was possible to pick up abnormalities up to 18 months before formal diagnosis with pancreatic cancer [52]. In practice tumors below 1 cm are almost impossible to detect [53]. Sensitivity is further reduced in the presence of chronic pancreatitis. CT has the added disadvantage that it involves exposing the participant to a dose of up to 10 millisieverts (mSv) of radiation for each scan [54]. Although it may be possible to reduce the dose depending on the size of the participant, the use of radiation in a screened population that could well include individuals with inherited DNA repair defects is a matter of concern.

Magnetic Resonance Imaging (MRI)

MRI is an alternative that does not involve the use of ionizing radiation. It has also been reported that use of high tesla magnets and T1 weighted spin-echo can give images of small lesions that are significantly better than those seen with spiral CT [44, 55]. MRI is more sensitive for identifying cystic lesions, and that MRI and EUS appear to be complementary rather than interchangeable [56–58].

Positron Emission Tomography (PET)

^{18}Fluorodeoxyglucose (18FDG) is not metabolized so will accumulate in all cells where there is high glucose uptake such as in primary tumors and metastases [44]. 18 FDG-PET is not very helpful in detecting early stage PDAC, which in one study identified only 50% of stage 0 and 1 tumors [59] and two of seven IPMNs [60], with care being taken to ensure normal blood glucose levels.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

While ERCP is claimed to produce images that are characteristic of PanIN lesions, irregular or ectatic ducts with possible sacculations [47], this should not be used for imaging because of the unacceptable risk of complications [47]. ERCP can also be used to collect pancreatic juice for molecular analysis via direct cannulation of the pancreatic duct [61], but while the complications are very low in hereditary

pancreatitis they are unacceptably high in suspected familial pancreatic cancer with a normal parenchyma and main pancreatic duct [62]. The main complication is post-ERCP acute pancreatitis even with the use prophylaxis with nonsteroidal anti-inflammatories or self-expelled pancreatic stents [62]. The preferred method is pancreas juice obtained by secretin stimulation of the pancreas and duodenal aspiration at endoscopy [63]. More recently, pancreatic juice collected directly from the ampulla using an endoscopic distal cap yielded higher concentrations of pancreatic fluid mutations than form duodenal aspiration [64].

Defining Imaging Screening Success

Consensus agreement from the CAPS consortium was that for a screening program to be deemed successful, it should lead to the identification and treatment of T1 N0 M0 margin negative PDAC, and high-grade dysplastic precursor lesions such as PanIN Grade 3, main duct intraductal papillary mucinous neoplasm (MD-IPMN), or a branch duct IPMN (BD-IPMN) with high-grade dysplasia [13]. Potentially relevant lesions might also include multifocal PanIN2 (>10) lesions, BD-IPMNs with low- or moderate-grade dysplasia and/or atypical flat lesions, and pancreatic neuroendocrine tumors (pNETs) (>G0) [58].

Screening outcomes were reported on 411 asymptomatic high-risk individuals using annual MRI and or EUS from three European centers [65]. There were 214 individuals from FPC families, 178 CDKN2A mutation carriers, and 19 BRCA1/2 or PALB2 mutation carriers. PDAC was detected in 13 (7.3%) of 178 CDKN2A mutation carriers with a 75% resection rate and a 24% 5-year survival rate. Two CDKN2A mutation carriers (1%) underwent surgical resection for low-risk precursor lesions. Two individuals (0.9%) in the FPC cohort had a pancreatic tumor, including one advanced PDAC and one early grade 2 neuroendocrine tumor. Thirteen (6.1%) individuals with FPC underwent surgical resection for a suspected precursor lesions, but only four (1.9%) had high-risk lesions (high-grade IPMNs or grade 3 PanINs). One BRCA2 mutation carrier was found to have PDAC, and another BRCA2 mutation carrier and a PALB2 mutation carrier underwent surgery and were found to have low-risk precursor lesions. Surveillance of CDNK2A mutation carriers was relatively successful but the benefit of surveillance in families with FPC was less evident.

Biomarkers

Diabetes Mellitus (DM)

Long-standing DM increases the risk of PDAC by approximately twofold [66]. DM diagnosed shortly before diagnosis with PDAC is most likely caused by pancreatic cancer itself. Pancreatic cancer cells can produce prodiabetic substances such as adrenomedullin [67]. Approximately, 1% of patients diagnosed with type 2 DM will have newly diagnosed PDAC. New-onset DM in those over 50 years confers up to

an eightfold risk of having PDAC compared with the general population. Chari et al. have shown that the average time between the diagnosis of DM and the subsequent diagnosis of PDAC is 13 months [68]. Boursi et al. developed a clinical prediction model to assess risk for pancreatic cancer among patients with new-onset DM [69]. Data were analyzed from 109,385 patients with new-onset DM of whom 390 (0.4%) were diagnosed with PDAC within 3 years. The final model (area under the curve, 0.82; 95% CI, 0.75–0.89) included age, body mass index, change in body mass index, smoking, use of proton pump inhibitors, and antidiabetic medications, and levels of hemoglobin A1C, cholesterol, hemoglobin, creatinine, and alkaline phosphatase. If the predicted risk threshold for PDAC screening was set at 1% over 3 years, only 6.19% of the new-onset DM population would undergo screening, which would identify patients with PDAC with 44.7% sensitivity, 94.0% specificity, and a positive predictive value of 2.6%. New-onset DM in an FPC kindred would therefore be an early warning symptom of PDAC. Pilot screening studies have employed fasting glucose serum samples and serial HbA1c measurements.

Serum Antigens

CA19-9 is the only biomarker in routine use for the management and follow-up of PDAC with a sensitivity and specificity of ~85% [70, 71]. There is lack of expression in ~5% of the population (Lewis Le(a-b-) phenotype) and is elevated in chronic pancreatitis and obstructive jaundice [70, 72]. It may also be effective in the detection of early tumors and in asymptomatic individuals but with reduced sensitivity [73]. Other serum tumor markers such as carcinoembryonic antigen (CEA) and CA125 have a similar lack of sensitivity with small tumors but may be efficiently combined with novel biomarkers [74].

Circulating Tumor Cells (CTCs)

CTCs may be defined as cells isolated from blood with an intact nucleus, which stain positive for epithelial cell adhesion molecule (EpCAM) an epithelial cell marker, cytokeratin (CK) a marker of epithelial-derived cells and are negative for CD45 a universal marker of leukocytes. Detectable cancer cells have been found in the circulation of patients with advanced pancreatic cancer [75]. Despite these earlier promising reports, the detection rate CTCs and reproducibility in pancreatic cancer has remained challenging. Using the CellSearch (Veridex) system that exploits immunomagnetic capture with EpCAM, Kurihari et al. detected CTCs in seven of 24 patients with stage 4 pancreatic cancer with no false positives in 11 patients with chronic pancreatitis patients and 10 healthy controls [76].

Epithelial mesenchymal transition (EMT) is a central tenet involved in allowing for cancer cells to invade, disseminate, and metastasize [77]. Gorges et al. showed in murine breast cancer xenograft models that there was downregulation of EpCAM in CTCs (and hence not detected by Ep-CAM based methods), whereas mesenchymal markers like Twist and EGFR were upregulated on CTCs [78]. Khoja et al. compared CTC detection using CellSearch with isolation by size of epithelial tumor cells (ISET) that is a marker independent, blood filtration device in samples from

54 patients with pancreatic cancer [79]. ISET appeared to detect CTCs in more patients than CellSearch (93% vs. 40%) and in higher numbers with a median (range) 9 (0–240) versus 0 (0–144) CTCs per 7.5 ml. There was considerable CTC heterogeneity of expression for EpCAM, pan-CK, E-cadherin, vimentin, and CK7. While CTC concentration correlated with survival in the study by Kurihari et al. [78], there was no association in the latter study [79]. CTCs were not characterized by molecular analysis so the true numbers of actual CTCs isolated is not known.

Rhim et al. showed that EMT and dissemination preceded pancreatic tumor formation in a mouse model of pancreatic cancer. Tagged cells invaded and entered the bloodstream early, before any frank malignancy could be detected and was widely associated with EMT [77]. Circulating pancreatic cells maintained a mesenchymal phenotype, exhibited stem cell properties, and seeded the liver. EMT and invasiveness were most abundant at inflammatory foci, and induction of pancreatitis increased the number of circulating pancreatic cells, linking the increased risk of pancreatic cancer in sporadic and hereditary pancreatitis. Rhim et al. were subsequently able to detect circulating pancreas epithelial cells in patients with pancreatic cystic lesions [80]. Blood samples were analyzed using a geometrically enhanced differential immunocapture (GEDI) microfluidic platform with antibodies to EpCAM to capture circulating epithelial cells. Captured cells were then further characterized by staining with 4′, 6-diamidino-2-phenylindole (DAPI) to visualize nuclei and fluorescently conjugated antibodies to CD45, and CK19, a marker of epithelial-derived cells, or pancreas and duodenal homeobox protein-1 (Pdx-1). Thege et al. were able to further develop a microfluidic immunocapture system for capture of circulating pancreatic cells using parallel EpCAM and cancer-specific mucin 1 (MUC1) in a silicon microdevice [81]. They also detected a known oncogenic KRAS mutation in cells spiked in whole blood using immunocapture, RNA extraction, RT-PCR, and Sanger sequencing.

Huang et al. have gone on to show that dielectrophoresis has the potential to complement existing immunocapture techniques to improve capture performance of CTCs [78]. By carefully specifying the applied electric field frequency, they demonstrated that pancreatic cancer cells were attracted to immunocapture surfaces by positive dielectrophoresis whereas peripheral blood mononuclear cells were repelled by negative dielectrophoresis.

Circulating Free DNA (cfDNA)

Circulating free deoxyribonucleic acid has been used to screen for cancer [82], recurrence [83], and response to treatment [84]. Plasma contains approximately 1 μg ml of cfDNA [85], most of which is fragmented into multiples of 200 bp and comes from leukocytes and endothelial cells. In cancer patients, these levels can rise tenfold, during chemotherapy and radiotherapy [86]. Circulating free DNA is also elevated in many benign condition reducing specificity for cancer diagnosis [87]. Plasma DNA levels appear to decrease in acute pancreatitis [85]. A more promising approach is the detection of specific mutations in DNA isolated from plasma [88] and beyond that with next-generation sequencing.

Targeted Molecular Analysis

NGS or massively parallel sequencing methods can be applied very small amounts of DNA (ng levels), with prior amplification by PCR methods and fixed to nanobeads or enclosed in emulsion droplets. Deep Sequencing has been shown to be a viable approach to characterize circulating DNA in patients with diagnosed lung cancer [89] and screening of individuals at risk of sporadic retinoblastoma [90]. Yu et al. have used digital next-generation sequencing to detect low-abundance mutations in secretin-stimulated juice samples collected from the duodenum of subjects enrolled in Cancer of the Pancreas Screening studies at Johns Hopkins Hospital [91]. EUROPAC has also used NGS deep sequencing of Tp53 DNA isolated from pancreatic juice as part of its pilot screening program.

Prospectively, the flexibility of NGS may make it the technology of choice, but most research to date has been focused on identification of specific mutations in genes known to be associated with pancreatic cancer. Ideally, blood or even urine would be used as the source material, but pancreatic juice has the most intimate contact with the cells of the pancreatic ducts and so is the richest source of material from ductal cancers, PanIN and IPMN. Pancreatic cancer cells [92] and cells from IPMN [93] can be detected in pancreatic juice, but the number of cells is small even in advanced cancer [92].

Analysis of K-Ras Mutations

K-Ras mutations are the commonest mutations reported in pancreatic cancer [94] and are early events in pancreatic tumorigenesis. Over 90% of pancreatic cancers have been reported to have a mutation in codon 12 of the *K-Ras* gene [95] followed by mutations in codons 13 and 61 [96]. Sho et al. sued digital PCR (dPCR) to detect KRAS gene mutations in 44 pancreas FNAs including 34 formalin-fixed paraffin-embedded (FFPE) and 10 fresh samples [97]. The dPCR mutation analysis was successful in all preoperative FNA biopsies tested, and its accuracy was confirmed via comparison with resected tumor specimens. Moreover, dPCR revealed additional KRAS mutations representing minor subclones within a tumor that were not detected by Sanger sequencing. Maire et al. used Mutation Specific PCR (MSP) to detect K-Ras mutations in blood from PDAC patients [98] but similar mutations were also seen in patients with chronic pancreatitis and even healthy controls.

Trumper et al. achieved 33% sensitivity for pancreatic cancer using detection of *K-Ras* mutation in bile [99]. Similar levels of sensitivity have been reported using duodenal juice (25%) [100]. Specificity is poor with 7/93 patients with benign disease having mutation in bile [101] and 0/9 in duodenal juice [100].

Some groups have reported that detection of K-Ras in stool gives better sensitivity than bile, a huge advantage given a considerably less invasive procedure but with reduced specificity [102]. Work with prediagnosis stool samples from colorectal cancer patient suggests that molecular analysis is unlikely to give a great deal of discrimination from control patients [103], it is even less likely to be effective in patients with early pancreatic cancer.

K-Ras mutation analyses carried out in pancreatic juice gives sensitivity ranging from 32% to 89% and specificity from 33% to 100% [104]. Nearly all studies are that *K-Ras* mutations can be identified in pancreatic juice in patients with no evidence of malignancy, whether with chronic pancreatitis or other benign conditions such as biliary tract stones. There is however some discrimination for cancer patients and therefore the analysis might be useful in combination with other tests if the juice sample has already been collected for a more specific assay.

Analysis of Tp53 Mutations

Mutation specific approaches to analyze Tp53 mutations have been hampered by the existence of over 700 different pathological mutations, compared to seven common *K-Ras* mutations. Sequence specific approaches, such as MSP, would therefore only be possible with complex multiplex approaches [105]. Exosomes present in blood contain DNA, which can be amplified and sequenced directly; in this way, Tp53 along with *K-Ras* mutations were detected by simple Sanger sequencing [106].

Sensitivity of Tp53 mutations in pancreatic juice samples ranges from 14% to 60% with a specificity >80% [91] and Tp53 mutations have been reported in tissue from patients with chronic pancreatitis [107]. It has even proved possible to identify Tp53 mutations in duodenal aspirates by using a digital PCR approach combined with limiting dilution [108].

The Johns Hopkins Pancreas Cancer Screening program found that mutant Tp53/SMAD4 concentrations could distinguish PDAC from IPMN cases (AUC 0.73) and controls (AUC 0.82). Two of four patients who developed pancreatic cancer despite close surveillance had SMAD4/Tp53 mutations from their cancer detected in juice samples collected over 1 year prior to their pancreatic cancer diagnosis when no suspicious pancreatic lesions were detected by imaging [91].

Cancer-Associated Methylation

Although tumorigenesis is in general associated with a loss of DNA methylation, specific tumor suppressor genes are associated with increased silencing by methylation which can be detected by converting unprotected cytosine residues to uracil using bis-sulfite and then carrying out quantitative PCR using either primers specific for sequences containing cytosine (sequences protected by methylation) or uracil (unmethylated DNA), comparing the levels gives a measure of the degree of methylation. Alternatively, bis-sulphite treated DNA can be sequenced (typically pyrosequenced) revealing where cytosine residues have been protected. Cancer specific patterns of DNA methylation have been described in circulating plasma DNA [109], and Kisiel et al. [110] described a panel of methylated biomarkers (CD1D, KCNK12, CLEC11A, NDRG4, IKZF1, and PKRCB) which when used with K-Ras mutation analysis gave 75% sensitivity and 95% specificity comparing pancreatic cancer to normal pancreas and chronic pancreatitis.

Combination Testing of Molecular Markers in Pancreatic Juice

Yan et al. analyzed cell free pancreatic juice samples for *K-Ras* and Tp53 mutations combined with quantification of *CDKN2A* (p16) promoter methylation [61]. Functional p53 mutations were detected in 20/48 (42%) cases of pancreatic ductal adenocarcinoma. No p53 mutations were seen in 49 controls. Two p53 mutations were seen in 49 (4%) patients with chronic pancreatitis (4%). K-Ras mutations were seen in 31/57 (54%) of PDAC patients but also in 13/61 (21%) of controls and 23/67 (34%) of patients with chronic pancreatitis. Twenty out of 21 (95%) of PDAC patients had p16 promoter methylation levels above 0.1% compared to 6/22 (27%) of controls and 4/20 (20%) of patients with chronic pancreatitis; 13/20 (62%) of PDAC patients had p16 promoter methylation levels above 10% compared to 2/22 (9%) of controls and 3/20 (15%) of patients with chronic pancreatitis. A Bayesian analysis assuming a pretest probability of cancer of 1%, suggested that this approach could stratify risk of cancer between negligible and 90% in the case of FPC and between negligible and 50% in HP [61].

Wang et al. studied both *K-Ras* and Tp53 in combination, using DNA prepared from pellet and supernatant. By combining all results for Tp53 and *K-Ras,* they observed a mutation (either *K-Ras* or Tp53) in a sample (either pellet or supernatant) in 100% (21/21) of cancer cases [111]. Clearly, this demonstrates that some patients exhibit Tp53 mutations without *K-Ras* mutations, and that combination analyses are useful for enhancing the molecular diagnosis of pancreatic cancer [111], [112]. As Wang et al. observed no Tp53 mutations in their control group specificity was determined purely by their *K-Ras* results, it is unclear what specificity was obtained with a combination of results using cellular and using noncellular material [111].

Yu et al. undertook digital NGS assays using an Ion AmpliSeq Custom Panel to multiplex PCR and sequence of nine genes (122 amplicons in two primer pools) mutated in pancreatic ductal neoplasms (KRAS, GNAS, TP53, SMAD4, CDKN2A, RNF43, TGFBR2, BRAF, PIK3CA) [91]. Ninety-six aliquots of DNA from each patient's juice were made and each aliquot was subjected to NGS. The study was undertaken in 115 people with PDAC, IPMN), and controls. Cases with PDAC and IPMN were more likely to have mutant DNA detected in pancreatic juice than controls; mutant DNA concentrations were higher in patients with PDAC than IPMN or controls [91].

National Registries for FPC and High-Risk Individuals

The Purpose of Registries

A disease registry is a collaboration between researchers, consenting volunteer participants, and clinicians with a special interest in patients with the disease. Dedicated registries offer clear benefits for all stakeholders.

For participants on an FPC registry, the process of registration can include a realistic discussion to help clarify an individual's actual PDAC risk (often over

perceived by the individual), education on risk modification and increasing awareness of alarm or red flag symptoms. In addition, once registered, many participants feel they now have more credibility when discussing their concerns or fears with other clinicians, such as general practitioners for example. Registries may also be in a position to offer support for participants through patient/family networks.

Researchers will use information gathered from the registrants to develop a large, detailed epidemiological data set that can be interrogated to test and refine assumptions on the natural history of the disease. Registrants also offer researchers a proactive group of appropriate individuals on which to test the yield of various screening modalities as part of a secondary screening research study. Improvements in diagnostic modalities for detecting early pancreatic cancer have historically been hampered as the vast majority of research biological samples were obtained from individuals with advanced disease. Registries facilitate the opportunity for healthy participants to donate vital samples: blood, DNA, urine, and saliva for example. These samples, collected before diagnosis, may help in the development of novel biomarkers for early disease.

Registries are not however, without disadvantages: individuals with a family history of pancreatic cancer have a higher perceived risk of PDAC and higher levels of anxiety [113], and these concerns can be amplified by the process of registration and recruitment. Potentially, the most detrimental is the inevitable inclusion of false positive families and inappropriate individuals.

Pilot Studies on Screening of High-Risk Groups

There are numerous established International and National registries of FPC families and other high-risk groups in the USA, Europe, Canada, and Australia, and now newly established in Japan. Many of these registries are associated with screening programs or pilot studies. The published outcomes of various screening programs from groups including; Johns Hopkins Hospital (JHH), the University of Washington (UW), the Memorial Sloan-Kettering Centre (MSKC), the German National Case Collection for Familial Pancreatic Carcinoma (FaPaCa), the Spanish National Hereditary Pancreatic Cancer Registry (PanGen-FAM), the Danish national screening program and the Swedish screening program are summarized in Table 2. All these studies rely on EUS and MRI as screening modalities.

The NFPTR was the first registry in the world established at the Johns Hopkins by Ralph Hruban in 1994 and as of February 2013, they had recruited 1447 families with FPC. Groups in Europe closely followed such as the EUROPAC at Liverpool University established in 1996, and FaPaCa at Phillips University (Marburg, Germany) established in 1999.

Individuals recruited to NFPTR as part of the American Cancer of the Pancreas Screening (CAPS) Consortium. The first study in 2004 included 38 patients from FPC families and Peutz-Jeghers syndrome sufferers [47]. EUS and CT were the modalities of choice and ERCP was employed in the event of abnormalities detected by imaging. One invasive cancer was found along with an IPMN and two serous

cystadenomas (SCAs). The 2006 CAPS-2 study had 72 participants from FPC families and six had Peutz-Jeghers syndrome [114]. Sixty-seven participants had a spiral CT scan. At this time, ERCP was often employed as a screening modality and for collection of pancreatic juice. Sixty-four of these participants had successful ERCP, five of whom developed pancreatitis as a result. Suspected neoplastic lesions were identified in 17 cases. Of these, 10 continued with surveillance and seven proceeded to subtotal pancreatectomy, IPMN's and PanIN lesions but no cancers were found. One participant developed metastatic pancreatic cancer in an interval between screening [114]. The 2012 CAPS-3 study was a multicenter prospective cohort study [43] involving the Mayo Clinic (Rochester), University of California (Los Angeles), Dana Farber Cancer Institute (Boston), and MD Anderson Cancer Center (Houston). The majority of patients (195/216) in this study were from eligible FPC kindreds, 19 came from BRCA2 families and two had Peutz-Jeghers syndrome.

Patients were followed up for a mean of 28.8 months (range, 14–47.2) and the final diagnoses at study completion were confirmed or suspected BD-IPMN ($n = 82$), combined IPMN ($n = 2$), and pNET ($n = 3$). Pancreatectomy was performed on five individuals, none of whom had any evidence of invasive PDAC (one Whipple procedure, three distal, and one total pancreatectomy) and no major adverse events or mortality were reported [43].

The group from Washington University have also previously reported results for PDAC screening in75 patients, 15 had abnormalities on EUS and ERCP, all of whom had surgery (12 total and three distal pancreatectomy) [115]. The three that had distal pancreatectomy remain under surveillance. Histology revealed PanIN-3 lesions in 10 of the resected specimens and the remaining five contained PanIN-2. Although no cancers have yet been detected by screening, similarly to the JHH group, one participant of the screening program developed an unresectable pancreatic cancer in the interval between screens [115].

The FaPaCa registry is a national case collection for FPC families funded by the Deutsche Krebshilfe organization. Multiple centers have collected families with at least two first-degree relatives with confirmed PDAC since 1999, with the study being coordinated centrally by the Philipps-University of Marburg in Germany. The surveillance program has evolved following publication of the 5 year [116] and 10 year screening results [117] which demonstrated a relatively low diagnostic yield of potentially relevant lesions. Initial annual screening with MRCP and EUS was carried out between 2002 and 2010. From 2011, imaging consisted of annual MRI with MRCP and EUS every 3rd year or when suspicious alterations were detected by MRI. In collaboration with the Leiden and Madrid registries, between July 2002 and June 2015, 253 Caucasian IAR (210 Marburg, 30 Madrid, 13 Leiden) completed at least baseline imaging. The 253 IAR underwent a total of 813 MRI and 450 EUS, including FNA cytology in five IAR. Following MDT discussion, 21 IARs underwent pancreatic resection. Histopathological analysis identified six (2%) IAR with significant lesions, two with PDAC, (stages 1and 2b, respectively), three with PanIN3, and one with IPMN high-grade dysplasia [58]. Lesions were more often identified in IAR above the age of 45 years. In 21 IAR who underwent surgery, no clinically significant lesions were detected before the age of 50 years and potentially relevant lesions occurred significantly more often after the age of 50 years (13 and 2, respectively). The group concluded that it is safe to delay the start of screening in FPC kindreds until 50 years of age [58].

EUROPAC has a three yearly screening cycle, with EUS imaging at the end of each cycle, followed by collection of duodenal juice and molecular analysis the year after. In patients who did not have juice collection or who had a cancer-associated mutation in their duodenal juice, there was an annual pathway consisting of repeat blood testing and EUS. Any abnormalities identified in imaging or molecular tests were discussed at the supraregional pancreatic multidisciplinary team (MDT) meeting. The significance of positive molecular results is considered in the context of the age and perceived risk of the participant based on family history. The MDT may recommend further clinical investigations, advice surgery or propose that the participant undergoes annual surveillance or regular clinical review and/or follow-up.

The PanGen-Fam registry was established in Spain in 2009. Eligibility criteria include two or more cases of PDAC, Lynch syndrome with one case of PDAC in the family, melanoma and 1 PDAC case, Peutz-Jeghers syndrome, HP, and families with one case of PDAC occurring below 50 years of age. Screening consists of baseline imaging with CT and EUS; MRI is only performed if the latter are abnormal. Screening starts 10 years earlier than the youngest age at PDAC diagnosis in the family or at 40 years old, whichever comes first. For Peutz-Jeghers syndrome and HP families, screening starts at age 30 and at age 35 years, respectively. The follow-up frequency is stratified according to family risk and the results of previous tests. So far, screening has identified four cystic lesions and one pNET, and one patient who underwent resection had high-grade dysplasia [118].

The Swedish group based at Karolinska University Hospital includes members of FPC kindreds (as defined by the CAPS consortium), carriers of mutations in *BRCA2*, *BRCA1*, or *CDKN2A* with at least one first- or second-degree relative with PDAC, and verified germline carriers of a Peutz-Jeghers syndrome kindred [56]. This group performed a prospective observational study of 40 eligible participants with a genetic risk for PDAC who were referred between January 1, 2010, and January 31, 2013. All patients entered an MRI based screening protocol, where all participants underwent a baseline MRI/MRCP with secretin. If no abnormality was identified then additional screening was planned for 1 years' time. Patients only underwent an EUS with or without FNA if an abnormality was detected on MRI. The mean age of patients was 49.9 years and the mean length of follow-up was 12.9 months. The diagnostic yield for a pancreatic lesion including solid nodules, cysts, and isolated main duct dilation was 40%. Five patients (12.5%) required surgery, three (7.5%) for pancreatic cancer and two for IPMN with intermediate dysplasia. MRI revealed a pancreatic lesion in 16 patients (40%), an IPMN in 14 (35%) and PDAC in two (5%). One patient had a synchronous IPMN and PDAC [56].

The Dutch research group includes the Erasmus MC-University Medical Centre Rotterdam, the Academic Medical Centre Amsterdam, the University Medical Centre Groningen and the Netherlands Cancer Institute-Antoni van Leeuwenhoek Hospital [57]. They run an ongoing multicenter familial pancreatic cancer surveillance study where eligible asymptomatic individuals with an estimated $\geq$tenfold increased familial or inherited PDAC risk compared with the general population undergo screening from the age of 45 years or 10 years younger than the age of the youngest relative with PDAC, whichever occurred first. For patients with Peutz-Jeghers syndrome, the minimal age for inclusion is 30 years or 10 years younger than the age of the youngest relative with PDAC. Using their screening population, this group undertook a multicenter prospective blinded cohort study comparing EUS and MRI for the detection of clinically relevant pancreatic lesions at first-time screening in individuals at high risk for developing PDAC. This study identified two 9 mm solid lesions (one stage 1 PDAC and a multifocal PanIN2) both at EUS, and nine cysts $\geq$10 mm, in nine of the high-risk individuals screened (6%). Of the cystic lesions, six were detected both by EUS and MRI and three were detected by MRI

only [57]. These results support the current consensus that EUS is good at detecting small solid lesions and MRI is very sensitive at detecting cystic lesions.

A cost effectiveness study for screening for PDAC in IARs from the Netherlands has estimated the incremental cost-utility ratio (ICER) for screening. The ICER for patients with FPC was estimated at 28,834 US$ per life-year and 38,785 US$ per Quality Adjusted Life Years (QALY) [119].

Conclusion

Pilot studies of pancreatic cancer screening in high-risk individuals have shown that it is feasible but cost effectiveness remains challenging. The issues are the low yield of cancers in the screened population and the rate of interval cancers. The detection rates range from seven cancers in 79 participants [120] to no cancers in 227 participants [114]. The difference in yield is not explained by differences in screening modalities or frequency, as the approaches were very similar. The rate of screening failures (inoperable cancers) was similar in programs with high yields as in programs with low yields. The difference is therefore in cancer prevalence in the screened populations. This indicates that improving risk stratification to allow more targeted screening is essential. Further research is also warranted on how screening uptake can be optimized in the highest risk groups.

Given the low number of cancers so far detected by screening, it is difficult to make any firm conclusion about the best protocol for detecting early PDAC. The most commonly detected lesions are IPMN and following surgery, PanIN lesions. This supports the use of MRI for detection of cystic lesions and EUS for detecting small solid lesions. EUS however will struggle to detect early pancreatic cancer against a background of chronic pancreatitis, so other modalities and strict adherence to the screening protocol is required.

Text Boxes

Key Practice Points

- It is important to ask every pancreatic cancer patient about family history and to take anxiety about family history seriously.
- The finding of two cancer cases in a family is not enough to confirm an inherited predisposition. The number of cases must be placed in the context of the number of family members who did not develop cancer and look at the generations involved to determine phase of transmission.
- Where a family history is of concern, referral to a pilot screening study is appropriate. The protocol should take into account age and likely risk of individuals in the family before accepting the referral.

Published Guidelines

Consensus recommendations for secondary screening of high-risk groups were proposed at the Fourth International Symposium on Inherited Diseases of the Pancreas [13]. The following categories of high-risk individual were considered appropriate for inclusion in a research based screening program.

- Anyone with >2 first-degree, second-degree, or third-degree relatives with pancreatic cancer in the same lineage.
- Any known mutation carrier for *BRCA1*, *BRCA2, PALB,* or *CDKN2A* (p16), with at least one first-degree or second-degree relative with pancreatic cancer.
- A person with PJS.
- Mismatch repair gene mutation carriers (Lynch syndrome) with one affected first-degree relative.
- Anyone with two relatives in the same lineage (directly connected) affected with pancreatic cancer, at least one a first-degree relative of the candidate.
- An affected individual with hereditary pancreatitis, harboring a PRSS1 mutation.

Future Research Directions

- Selecting high-risk groups that are likely to benefit from screening.
- Identifying efficient and cost effective screening programs.
- Improvement in accuracy of existing biomarkers.
- New biomarkers and new combinations of biomarkers.
- Improved imaging modalities, such as novel imaging compounds for use with PET.

metastatic. Only 15–20% of patients diagnosed with pancreatic cancer have resectable or borderline resectable disease at diagnosis. Most patients are diagnosed with more advanced disease; approximately 30–40% of patients present with locally advanced, unresectable pancreatic cancer (LAPC) at the time of diagnosis, and another 40% have distant metastatic disease. Surgery provides the only chance of cure for patients with pancreatic cancer, but the likelihood of patients with unresectable disease ultimately proceeding to surgical resection is low. The management of these patients with locally advanced, unresectable disease is controversial, and there is no internationally accepted regimen. The data for the use of radiation therapy in the setting of LAPC will be discussed in this chapter.

Introduction

Pancreatic cancer carries a poor prognosis regardless of stage, and incidence and death rates are increasing. An estimated 53,070 pancreatic cancer diagnoses and 41,780 pancreatic deaths are projected for 2016 [1]. Pancreatic cancer is divided into four general categories, resectable, borderline resectable, locally advanced/unresectable, and metastatic. Only 15–20% of patients diagnosed with pancreatic cancer have resectable or borderline resectable disease at diagnosis. Despite potentially curative resection, the 5-year survival for patients undergoing pancreaticoduodonectomy is 10–20% [2]. Most patients are diagnosed with more advanced disease; approximately 30–40% of patients present with locally advanced, unresectable pancreatic cancer (LAPC) at the time of diagnosis, and another 40% have distant metastatic disease. Median survival in patients with locally advanced disease is 12–13 months [3], and in patients with metastatic disease at presentation, survival is approximately 6–11 months [4, 5].

Determination of resectability is based on computed tomography (CT) scan, magnetic resonance imaging (MRI), and endoscopic ultrasound (EUS) data collected at diagnosis. As surgical techniques are refined, the categorization of patients similarly changes. At present, LAPC is defined by encasement of more than 180 degrees around the superior mesenteric artery (SMA), celiac artery, or aorta, unreconstructable superior mesenteric vein (SMV), or occlusion of the SMV. There are emerging data to suggest that reconstruction of the celiac artery is technically feasible and safe, but this is a novel approach that is not widely practiced [6–10].

Surgery provides the only chance of cure for patients with pancreatic cancer, but the likelihood of patients with unresectable disease ultimately proceeding to surgical resection is low. The management of these patients with locally advanced, unresectable disease is controversial, and there is no internationally accepted

regimen. The data for the use of radiation therapy in the setting of LAPC will be discussed.

Radiation Alone Versus Chemoradiation

An early clinical trial addressing chemoradiation for LAPC was published in 1969 from Mayo Clinic and included patients with various types of GI cancers, 64 of whom had locally unresectable pancreatic cancer. These patients were randomized to either 5-fluoruracil (5-FU) or placebo, combined with 35–40 Gy radiation [11]. Median survival in the combined modality arm was significantly higher than in the radiation therapy-only arm (10.4 vs. 6.3 months, $p < 0.05$). The Gastrointestinal Tumor Study Group (GITSG) subsequently randomized 194 patients with locally advanced pancreatic cancer to receive split-course external beam radiation therapy (EBRT), either alone (60 Gy) or combined (40 or 60 Gy) with bolus 5-FU. The EBRT-alone arm was discontinued after an interim analysis demonstrated superior median time to progression and overall survival in the combined modality arms. One-year survival was 11% in the EBRT-alone group compared to 38% and 36% with 40 and 60 Gy, respectively. No significant differences were seen between high- and low-dose EBRT in the chemoradiation arms, although there were trends favoring the higher-dose arm in time to progression and survival [12, 13]. Thus, these two randomized studies demonstrated a modest survival benefit for combined modality therapy over EBRT alone.

A more modern clinical trial from the Eastern Cooperative Oncology Group (ECOG) also examined the question of radiation therapy alone versus concurrent chemoradiation. In this study, 114 patients were randomly assigned to EBRT alone (59.4 Gy) or the same EBRT regimen plus infusional 5-FU and mitomycin C (MMC). In contrast to the above trials, the concurrent chemoradiation arm was noted to have increased toxicity without any added disease-free survival or overall survival benefit. Likely contributing to this finding was the method of administration and dosing of 5-FU. In the prior GITSG study, 5-FU was administered as 500 mg/m^2 on the first 3 days of each course of 20 Gy radiation. For the ECOG study, 5-FU dosing was extrapolated from other gastrointestinal disease sites and given at 1,000 mg/m^2 daily on days 2 through 5 and 28–31. Additionally, mitomycin C was added to this already high-dose infusional regimen and likely further contributed to toxicity [14]. In a pooled analysis of both the GITSG and ECOG studies, in spite of the added toxicity from the ECOG chemotherapy regimen, chemoradiation increased survival over radiotherapy alone (hazard ratio [HR] for death 0.69, 95% CI 0.51–0.94) [15] (Table 1).

Chemotherapy Alone Versus Chemoradiation

The above data suggest that chemoradiotherapy is superior to radiation alone, but do not address whether concurrent chemoradiation provides significant benefit over chemotherapy alone for patients with locally advanced disease. Two trials, also from

Table 1 Prospective studies comparing radiation alone versus chemoradiation for LAPC

Trial	Intervention	Number of patients	Local recurrence	Disease-free survival (mo)	Overall survival (mo)	Acute toxicity, grade 3+	Late toxicity, grade 2+
Mayo Clinic 1969	RT + placebo	32	NR	NR	6.3	NR	NR
	RT + 5-FU	32			10.3		
					$p < 0.05$		
GITSG 1981	RT (60 Gy)	25	24%	2.9	5.3	NR	NR
	RT (40 Gy) + 5-FU	83	26%	7.0	9.7		
	RT (60 Gy) + 5-FU	86	27%	7.6	9.3		
			NS	$p < 0.01$[a]	$p < 0.01$[a]

	RT + 5-FU/ MMC	55		5.1	8.4	33%	
				NS	NS		

NR not reported, *NS* not significant

[a]Significant difference between RT alone and CRT (chemoradiation) arms; no difference between CRT arms

GITSG and ECOG, investigated this question in the 1980s. The GITSG study randomized 43 patients with locally unresectable pancreatic cancer to receive SMF (streptozocin, mitomycin C, and 5-FU) alone for 2 years or SMF chemotherapy with 54 Gy radiation followed by additional SMF chemotherapy. The trial was closed early due to poor accrual, but there was a statistically significant survival benefit to chemoradiation over chemotherapy alone (41% vs. 19%, $p < 0.02$) at the cost of increased toxicity in the CRT arm [16]. The ECOG trial randomized patients with unresectable gastric and pancreatic adenocarcinoma to receive either 5-FU alone or 40 Gy radiation with concurrent 5-FU. Of the 91 pancreatic cancer patients enrolled in the study, there was no difference in time to recurrence or overall survival in the chemotherapy alone versus chemoradiotherapy groups. Toxicity was significantly higher in the chemoradiation arm (27% vs. 51%, $p < 0.02$), but radiation dose at 40 Gy in 20 fractions was lower than modern treatment prescriptions [17].

The introduction of gemcitabine and the recognition of benefit in patients with metastatic disease stimulated the design of trials comparing gemcitabine to contemporary chemoradiation approaches with conflicting outcomes. The Fédération Francophone de Cancérologie Digestive (FFCD) and the Société Francophone de Radiothérapie Oncologique (SFRO) conducted a trial examining gemcitabine alone versus 60 Gy radiation plus concurrent 5-FU and cisplatin chemotherapy followed by gemcitabine alone. With 119 patients, there was a statistically significant survival advantage to gemcitabine alone over chemoradiation (13 months vs. 8.6 months, $p = 0.03$). Notably, a median survival greater than 10 months had not previously been reported in a multi-institutional phase II or phase III trial evaluating chemotherapy alone for this stage of disease. The acute toxicity in the chemoradiation arm was high leading to poor compliance, with only 42.4% of patients receiving at least 75% of the intended dose of chemoradiation, which likely contributed to the poor outcomes for the cohort. The median number of maintenance gemcitabine infusions was significantly less in the patients treated with chemoradiation as opposed to gemcitabine alone (6 vs. 10), and the median total dose of gemcitabine was also significantly less (6,845 vs. 15,000 mg/m^2). Factors that likely contributed to the poor tolerance were the inclusion of cisplatin, the high dose of radiation (60 Gy), and the treatment of regional nodes (larger treatment fields compared to treatment of just tumor and involved nodes) [18].

In a more recent study by Loehrer et al., also examining the use of gemcitabine with radiation, 74 patients were randomized to gemcitabine (600 mg/m^2 weekly) with radiation (50.4 Gy in 28 fractions to primary disease and regional nodes) followed by weekly gemcitabine (1,000 mg/m^2 weekly, for 3 of 4 weeks) versus gemcitabine alone (1,000 mg/m^2 weekly, for 3 of 4 weeks). Although the trial closed prematurely after accruing only 74 of a planned 316 patients, a statistically significant median survival benefit was seen in the arm that received chemoradiation compared to the arm that received chemotherapy alone, 11.0 versus 9.2 months, ($p = 0.017$). This benefit came at the cost of increased acute gastrointestinal toxicity (grade 3 or greater gastrointestinal toxicity 38% vs. 14%, $p = 0.03$). Additionally, overall grade 4 or greater toxicity was higher in the chemoradiation arm as compared to gemcitabine alone (41% vs. 9%). Thus, the addition of radiation to standard

Table 2 Prospective studies comparing chemotherapy alone versus chemoradiation for pancreatic cancer

Trial	Intervention	Number of patients	Local failure	Overall survival (mo)	Acute toxicity, grade 3+	Late toxicity, grade 2+
GITSG 1988	CRT (5-FU + SMF)	22	45%	9.7	NR	NR
	SMF	21	48%	7.4		
			NS	$p < 0.02$

chemotherapy resulted in a modest prolongation of median survival at the cost of acute toxicity. Notably, however, there were no differences in health-related quality of life outcomes between the two treatment groups beyond week 6, with long-term measurements taken at week 15 or 16 and at 9 months [19] (Table 2).

Induction Chemotherapy Prior to Chemoradiation

Given the lack of a consistently demonstrated survival benefit to upfront chemoradiation in patients with LAPC, differing treatment algorithms have been explored. Approximately one-third of patients with LAPC develop metastatic disease during initial treatment [20, 21]. To allow for the selection of patients without micrometastatic disease who would benefit from local therapy, studies have examined the use of upfront chemotherapy followed by chemoradiation for those patients who do not develop progressive disease.

A retrospective series of 181 patients with LAPC treated with gemcitabine-based chemotherapy as part of phase II and III trials by the European Groupe Cooperateur Multidisciplinaireen Oncologie (GERCOR) explored the question of upfront chemotherapy. Chemotherapy was given alone for 3 months in each of the various protocols; the decision to give concurrent chemoradiation or continue chemotherapy alone for patients with locally advanced disease without evidence of disease progression was as per protocol or at the discretion of the treating physician. In each of the studies, the concurrent chemoradiation regimen was 55 Gy of radiation

therapy with concurrent infusional 5-FU. Of the 128 patients that did not develop metastatic disease following upfront chemotherapy, 72 patients completed a course of chemoradiation, while 56 continued to chemotherapy alone. Analysis of their outcomes revealed significant improvement in progression-free survival with chemoradiation over chemotherapy alone (10.8 months vs. 7.4 months, $p = 0.005$) as well as overall survival (15 months vs. 11.7 months, $p = 0.0009$) [20]. While the retrospective nature of this study limited the broad acceptance of this approach, the results were hypothesis generating.

In a subsequent phase III study by Hammel et al. examining the utility of initial chemotherapy alone followed by chemoradiation, patients were randomized in a 2×2 factorial design to gemcitabine with or without erlotinib for 4 months followed by a second randomization for patients that did not develop progressive disease to two additional months of gemcitabine chemotherapy or chemoradiotherapy. Chemoradiation consisted of 54 Gy radiation therapy with concomitant capecitabine dosed at 1,600 mg/m^2 daily. Radiation fields included the primary tumor and nodal disease with margin with no prophylactic treatment to uninvolved nodal regions. While locoregional progression was less frequent (32% vs. 46%, $p = 0.04$) and delay to treatment reintroduction was longer in the chemoradiation arm as compared to the chemotherapy alone arm (6.1 months vs. 3.7 months, $p = 0.02$), at a median follow-up of 36.7 months, there was no overall survival difference (15.2 months vs. 16.5 months, $p = 0.83$) [3]. Potentially contributing to the shortcomings of the chemoradiotherapy arm were significant radiation protocol deviations; 50% of patients had minor protocol deviations and 18% had major deviations. Although these deviations were not found to be statistically significant, there was a trend toward poorer outcomes for the patients with major deviations, such that overall survival from first randomization was 17 months for patients with per protocol and minor deviations versus 13.4 months for patients with major deviations (HR, 1.43; 95% CI, 0.86–2.36; $p = 0.17$). Median survival from the date of the second randomization was 12.7 months for patients with per protocol and minor deviations versus 10.1 months for patients with major deviations ($p = 0.19$). An additional limitation of the study is the choice of chemotherapy, as the trial was designed prior to the routine use of FOLFIRINOX or nab-paclitaxel plus gemcitabine combination therapies, which have now been shown to be more efficacious in metastatic disease compared to gemcitabine monotherapy [4, 5].

Choice of Concurrent Chemotherapy

The recent LAP07 study discussed above did not demonstrate a survival benefit to chemoradiation over chemotherapy alone. While these data may influence clinical practice, many patients with locally advanced disease still ultimately undergo chemoradiation for a variety of reasons, including palliation. Consequently, choice of concurrent chemotherapy is relevant.

Early trials investigating various concurrent chemotherapy options include the GITSG study as well as a study from Taipei. In the study by the GITSG, 143 patients

were randomized to either radiation therapy with concurrent 5-FU or radiation with concurrent doxorubicin. Radiation was delivered to total dose of 60 Gy in a split-course regimen and included elective nodal volumes. Concurrent 5-FU was delivered at 500 mg/m^2 on the first 3 days of each course of radiation therapy. Overall survival was higher in patients treated with radiation plus concomitant 5-FU (8.5 months vs. 7.6 months), leading to acceptance of concurrent 5-FU as standard of care [22]. A study conducted by Li et al. compared radiation delivered with either concurrent 5-FU or gemcitabine. Radiation was given to gross disease as well as elective nodal basins to a total of 50.4–61.2 Gy; concurrent chemotherapy with 5-FU was dosed at 500 mg/m^2 and delivered for the first 3 days every 2 weeks, and concurrent gemcitabine dosing was 600 mg/m^2/wk. Patients that received concurrent gemcitabine had a statistically significant improvement in median overall survival (14.5 months vs. 6.7 months, $p = 0.027$) without increase in toxicity relative to the patients that received concurrent 5-FU. Additionally, patients in the radiation therapy plus gemcitabine arm had significant improvement in pain control, quality of life, and Karnofsky Performance Status (KPS) as compared to the 5-FU arm without significant increase in grade 3 or higher toxicity [23]. In spite of these findings suggesting that radiation with concurrent gemcitabine may be more efficacious as compared to concurrent 5-FU, this regimen has not been universally adopted, as this was a single-institution study with small patient numbers.

A more recent randomized phase II study, the SCALOP trial, explored the optimal concurrent systemic therapy by comparing radiation with concurrent gemcitabine versus capecitabine. Extrapolating data from other gastrointestinal malignancies, such as rectal cancer, led to the acceptance of concurrent capecitabine as equivalent to infusional 5-FU [24]. This has been further substantiated by uncontrolled trials that have used capecitabine in place of infusional 5-FU in patients with LAPC [25, 26]. In the SCALOP regimen, 74 patients with unresectable disease were treated with initial gemcitabine and capecitabine for 12 weeks (dosed at 1,000 mg/m^2 and 830 mg/m^2, respectively), and if patients did not develop progressive disease, they proceeded to chemoradiation with either concurrent gemcitabine or concurrent capecitabine. Both chemoradiation arms received 39.6 Gy to gross disease and involved regional nodes plus additional 10.8 Gy boost to the gross disease. There was no elective nodal irradiation. The primary endpoint of the trial was progression-free survival; at 9 months of follow-up, there was no statistically significant difference in this endpoint. Although not powered for survival, there was a statistically significant difference in median overall survival, which was 15.2 months in the capecitabine group and 13.4 months in the gemcitabine group (HR 0.39, $p = 0.012$). More patients in the gemcitabine group had grade 3–4 hematologic toxicity as compared to the capecitabine group, though non-hematologic toxicity was not significantly different. Additionally, quality of life metrics were not different between the two groups [27]. While the SCALOP trial may suggest apparent increased efficacy of 5-FU-based regimen over gemcitabine, this study should be interpreted carefully. The rationale for using gemcitabine with concurrent chemotherapy was to exploit the increased radiosensitization properties of gemcitabine as compared to 5-FU; however, the systemic contribution of

gemcitabine must also be considered. In the trial from Taipei, the gemcitabine delivered concurrently with radiation was dosed at 600 mg/m^2/week. The SCALOP study used only 300 mg/m^2/week of gemcitabine concurrent with radiation. While the patients in the SCALOP trial had previously received systemic doses of gemcitabine for 12 weeks prior to chemoradiation, this dose reduction during concurrent treatment could have contributed to the difference in outcomes between the study arms.

Role of Radiation Dose and Treatment Volumes

Despite efforts to improve outcomes for patients with LAPC with various novel chemotherapy regimens, induction chemotherapy, and concurrent chemoradiation, survival remains poor. Multiple studies have examined the use of hypofractionated radiation, intraoperative radiation therapy (IORT), image-guided radiation therapy (IGRT), intensity-modulated radiation therapy (IMRT), and stereotactic body radiotherapy (SBRT) as a means of increasing dose to the target tissue with hope that these techniques will improve outcomes.

Hypofractionation with Conventional Treatment

Dose escalation using conventionally fractionated regimens (1.8–2.0 Gy per fraction) was previously explored and did not demonstrate improvement in outcomes. The GITSG study, published in 1979, discussed previously, randomized patients to radiation with or without concurrent chemotherapy. Patients that received radiation alone were treated to a total of 60 Gy at 2 Gy per fraction in a split-course regimen. This regimen was compared to two other split-course chemoradiation arms, one that received 40 Gy radiation at 2 Gy per fraction and one that received 60 Gy at 2 Gy per fraction. As noted earlier, the radiation alone arm was discontinued early after interim analysis revealed inferior outcomes. Comparison of the two chemoradiation regimens revealed comparable outcomes in the 40 Gy and 60 Gy arms, suggesting potential for increased toxicity with dose escalation without added survival benefit [12].

More recently, new interest in hypofractionation has emerged, particularly in the setting of technologic advances that allow for more accurate targeting of both tumor and normal tissue. While this addresses the same basic hypothesis as the GITSG study, that increased dose should lead to improved local control and potentially improved survival, it also raises the issue of patient convenience. A retrospective review from the University of Texas at San Antonio and MD Anderson Cancer Center compared outcomes of patients treated concurrently with 5-FU and either 30 Gy radiation or more than 30 Gy radiation. Of the 107 patients included, 86 had been treated with 30 Gy in 10 fractions and 18 patients had been treated with 50.4 Gy in 28 fractions. There was no difference in local disease progression, development of distant metastasis, or overall survival for the two groups. Twenty-nine percent of the

high-dose group and 12% of the low-dose group were hospitalized for grade 3 treatment-related toxicity ($p = 0.05$) [28]. The results suggest that a shorter, hypofractionated regimen may be better tolerated than standard fractionation with similar rates of local and distant disease progression and equivalent median survival.

A prospective trial from Germany was performed for patients with either locally advanced or metastatic pancreatic cancer exploring various hypofractionated regimens with concurrent 5-FU chemotherapy. In this trial, patients were treated with 24 Gy in 8 fractions, 30 Gy in 10 fractions, or 36 Gy in 12 fractions. Grade 3 toxicity was seen in one patient. For the 20 patients with locally advanced disease included in this study, the median survival was 9 months, which is similar to survival times seen at the time of publication of that study in 2005 [29].

Intraoperative Radiation Therapy (IORT)

Although there is newfound interest in hypofractionation and dose escalation, the concept of hypofractionation, delivering large doses per fraction, has been a part of clinical practice in pancreatic cancer for decades. IORT is a long-standing technique that allows for the administration of a single, high-dose radiation treatment to areas of tumor involvement while sparing normal tissue by physically displacing or shielding organs at risk. Although not widely practiced, largely due to lack of randomized evidence and the invasiveness of the approach, IORT can provide reasonable rates of local control. A retrospective study of 194 patients with LAPC treated with IORT from Massachusetts General Hospital reported 2-year progression-free survival rates of 41%. Median overall survival was 12 months [30]. While encouraging, careful patient selection may have contributed to these numbers. Outside clinical trials, IORT should only be reserved for highly selected patients at institutions experienced at IORT for LAPC.

Intensity-Modulated Radiation Therapy (IMRT) and Image-Guided Radiation Therapy (IGRT)

Outside of the operating room, surrounding critical structures within the upper abdomen have limited the extent of dose escalation. Newer radiation techniques, including IMRT and IGRT, have allowed for dose escalation both with conventionally fractionated treatment and with hypofractionated therapies while respecting normal tissue tolerances. IMRT is a general term used to refer to a group of technologies that allow very conformal radiation fields to be delivered by altering the intensity of the beam. This is achieved by breaking the beam up into many smaller "beamlets." IMRT was a natural progression from the rapid increase in computing power applied to radiation treatment planning. With the advent of virtual simulation using CT scan and image reconstruction, the predecessor of IMRT, three-dimensional conformal radiotherapy (3D-CRT), gained wide use. This allowed

"beam's eye views" to be generated and radiation portals to be shaped to conform to tumor volumes and avoid critical structures. IMRT built on this concept by adding a multi-leaf collimator, where multiple leaves are able to slide in and out of the field to create a vast array of complex radiation portals. This can be either a dynamic process (leaves sliding while the beam is on) or static process (leaves slide into place, then dose is delivered). As a result of multiple leaf positions, or control points, the intensity of a beam from a single portal can be variable, rather than fixed. A combination of such modulated beams from different angles is used to produce the final dose.

During the treatment planning process, critical structures are identified and assigned dose constraints. The computationally intensive process of inverse planning using sophisticated software then respects these constraints while delivering the intended dose to the target. The result is a much more conformal radiation dose to target. This conformality is generated at the expense of increased low-dose exposure to a greater tissue volume. In part, this is due to the limitations imposed by the physics of photons, which deposit energy at the target, but also can generate a substantial exit dose.

The feasibility of dose escalation in pancreatic cancer has been explored in several dosimetric studies using IMRT. One study compared dose escalation of plans using 3D-CRT to two different kinds of IMRT, one where the boost was integrated and another where the boost was delivered sequentially [31]. In these plans, the dose was escalated from 54 to 64.8 Gy. The 3D-CRT plan often exceeded tolerance doses for normal tissues, including the small bowel, spinal cord, and liver, while both IMRT plans allowed for successful dose escalation without exceeding tissue tolerance and allowed for a reduced volume of the kidney receiving 20 Gy.

Another group conducted a dosimetric feasibility study using a dose optimization technique called generalized equivalent uniform dose (gEUD) [32]. They examined escalation of dose to the planning treatment volume (PTV, tumor with margin to cover microscopic disease and setup error). They also examined escalating the dose to the vascular margin, which is the margin that is most often involved following surgical resection and the site that generally precludes margin-negative surgical resection. These investigators demonstrated the feasibility of escalating the dose to the PTV from 52 to 66 Gy and to the vascular margin to as high as 85 Gy without exceeding tolerance dose to critical structures.

In a retrospective study by Ben-Josef and colleagues, 15 patients with pancreatic cancer (7 of whom had locally advanced, unresectable disease) were treated to a total of 61.2 Gy at 1.8 Gy per fraction to the gross tumor volume and 45 Gy to the surrounding lymph node basin. All patients received concurrent capecitabine. Overall, treatment was tolerated well with one patient developing grade 3 toxicity (gastric ulceration with bleeding that responded to medical therapy). In patients with unresectable disease, the 1-year actuarial survival was 69%. Conversion to resectability occurred in two patients, and these patients continued to be locally controlled at the time of study publication. Upon comparison of dose-volume histograms (DVHs) of IMRT versus standard 3D-CRT plans, the IMRT plans were noted to be more

conformal than the 3D-CRT plans. The median volumes of the small bowel receiving greater than 50 Gy or 60 Gy were reduced with IMRT over 3D-CRT treatment, and on normal tissue complication probability models, the small bowel complication probability was 9.3% with IMRT versus 24.4% with 3D radiation ($p = 0.021$) [33]. Though this study suggests that IMRT is a reasonable treatment method for patients with unresectable pancreatic cancer, it is limited by the fact that the median dose actually delivered was only 54 Gy, not 61.2 Gy, the study intended dose.

A study from the University of Chicago reported the outcome of 25 patients with pancreatic and bile duct tumors treated with IMRT plans [34]. In a subset of the patients, the IMRT plans were compared to conventional four-field 3D-CRT. The treatment was well tolerated, with 80% experiencing grade 2 or less acute GI toxicity. Median follow-up was 10.2 months. Only four patients experienced late grade 1 toxicity and one patient experienced late grade 4 toxicity. Comparison to 3D-CRT demonstrated a significant reduction of mean dose to the liver, kidneys, stomach, and small bowel.

In a subsequent prospective study from Ben-Josef et al., dose escalation using IMRT in conjunction with gemcitabine was explored. While the previous studies suggested that dose escalation with IMRT was safe and feasible, improvement in survival due to this intensification of local treatment was not shown. Given its enhanced radiosensitizing properties, concurrent gemcitabine along with increasing radiation dose was hypothesized to improve local control. The primary endpoint of the study was to identify the radiation dose associated with dose-limiting toxicity, defined as grade 3 or higher gastrointestinal (GI) toxicity, neutropenic fever, or deterioration of performance status to greater than or equal to 3 in 25% of patients. Patients were treated with induction and concurrent gemcitabine dosed at 1,000 mg/m^2on days 1 and 8 of each 21-day cycle. Radiation was delivered to the gross disease plus a 1 cm margin with escalating doses from 50 to 60 Gy, all in 25 fractions delivered over the course of 5 weeks. Fifty patients were included in the study, and dose-limiting toxicity was seen in 11 patients, including seven patients with grade 3 or 4 GI toxicity (nausea, vomiting, anorexia, or dehydration), three patients with duodenal bleed, and one patient with duodenal perforation. Two of the toxicities were seen at the 52.5 Gy dose, six were seen at 55 Gy, and three were at 57.5 Gy. Dose-limiting toxicity was felt to be reached at 57.5 Gy; the recommended dose was 55 Gy with a probability of a dose-limiting toxicity of 0.24. The 2-year freedom from local progression was 59% (95% CI 32–79) and median survival was 14.8 months, which was encouraging compared to historical control findings with median survival of 11.2 months at the time of publication [35]. Following treatment, 12 patients ultimately underwent surgery, 10 of which were margin negative; median overall survival for those that did undergo surgery was 32 months [36].

Providing further evidence that dose escalation can improve outcomes in patients with LAPC is a recent study from MD Anderson. In this retrospective review, 200 patients with LAPC with tumors greater than 1 cm away from luminal organs were treated with escalated doses of IMRT. The median dose delivered was 50.4 Gy, though there was a wide range of doses with various fractionation regimens. Dose escalation was achieved via a boost delivered to the gross disease plus a 2–5 mm

margin. All patients were treated with induction chemotherapy with either gemcitabine-based regimens or FOLFIRINOX in addition to concurrent chemotherapy with either gemcitabine- or capecitabine-based regimens. Radiation doses were subsequently compared using biologically effective doses (BED), calculated using the equation below, where n is the number of fractions, d is the dose per fraction, and α/β for tumors is 10:

$$\mathrm{BED} = nd\left[1 + \frac{d}{\alpha/\beta}\right]$$

The BED for a standard fractionation regimen of 50.4 Gy in 28 fractions is 59.47 Gy, and the BED for a dose-escalated and hypofractionated regimen of 57.25 Gy in 25 fractions is 70.36 Gy. Patients were stratified into low- and high-dose groups based on BED $<$70 Gy or BED $\geq$ 70 Gy. At a median follow-up of 9.6 months, patients in the high-dose group had superior overall survival as compared to the low-dose group (17.8 vs. 15.0 months, $p = 0.03$). Local-regional recurrence-free survival was also improved in the high-dose group (10.2 vs. 6.2 months, $p = 0.05$). There was no additional toxicity in the high-dose group [37].

Stereotactic Body Radiation Therapy (SBRT)

The modest increase in dose achieved with IMRT has been shown to be feasible and improve outcomes, but is still delivered over multiple daily fractions. Further dose increases had previously been limited by surrounding normal tissue tolerances. In order to deliver high, biologically effective doses of radiation therapy without damaging surrounding organs, more targeted delivery of radiation therapy was developed. This is termed stereotactic body radiation therapy (SBRT). Stereotactic refers to a technique for precisely directing a medical instrument or beam of radiation in three planes using coordinates provided by medical imaging with treatment delivered in one to five treatments. Stereotactic brain biopsy and stereotactic radiosurgery to the brain have been widely used by implementing an externally fixed frame to ensure precision. Early stereotactic radiosurgery to extracranial sites made use of a stereotactic body frame [38]. Since organ motion in the region of the pancreas can be significant, these early systems employed some form of motion management. More recent advances in extracranial stereotactic body radiotherapy have used internal and externally placed fiducials. Other image-guided stereotactic radiosurgery systems were subsequently developed, including the CyberKnife, which consists of a small linear accelerator mounted on a highly flexible robotic arm with six degrees of freedom. Such machines can direct beams of radiation from hundreds of different angles toward the target and produce a highly conformal treatment. These treatment machines can also image radiopaque fiducial markers placed in or near the tumor to account for intrafraction tumor motion [39]. The most recent versions of this technology have the ability to track the tumor during treatment, which is accomplished by placing external fiducial markers and correlating

their position relative to internal fiducial markers [40]. The improved accuracy in targeting that is gained through the various stereotactic techniques allows for a significant reduction in the margins normally given to the tumor. These reduced margins allow for tolerable toxicity profiles even in the context of higher, ablative doses of radiation. Extracranial stereotactic radiotherapy has been successfully employed in several different sites, including primary and metastatic liver and lung tumors [41], and several studies have been conducted to examine its feasibility and efficacy in pancreatic cancer.

Stereotactic radiosurgery for LAPC was evaluated in a phase I dose escalation study conducted at Stanford University [42]. A CyberKnife system was used with internally placed fiducials, and a breath-hold technique was employed. Dose was escalated from 15 to 25 Gy to determine maximum tolerated dose. The target volume received a maximum dose as high as 41.6 Gy. The mean dose to 50% and 5% of the duodenum was 14.5 and 22.5 Gy, respectively. The treatment was well tolerated. No patient receiving 25 Gy had grade 3 or greater toxicity. All patients included in the 25 Gy group had local control of their pancreatic tumors until death or at last follow-up. Despite these high local control rates, all patients experienced distant progression. In an effort to improve on the median survival of 8.0 months seen at the 25 Gy dose level, the same group of investigators later conducted a phase II trial using 45 Gy of IMRT with concurrent 5-FU followed by a stereotactic boost of 25 Gy. Although high rates of local control (94% 1-year freedom from local recurrence with median follow-up of 23 weeks) were again seen, the median survival in this group of 16 patients was only 33 weeks, largely due to distant disease progression. Additionally, higher toxicity was observed, with two of the 16 patients treated experiencing grade 3 GI toxicity (gastroparesis requiring parenteral management). The next report from the Stanford group included a group of 16 patients treated on a phase I trial that combined gemcitabine with SBRT in an effort to address both local and distant disease. In this study, patients achieved a median survival of 11.4 months with 50% of patients alive at 1 year; however, these results came at the cost of high rates of late GI toxicity, with five patients developing duodenal ulcers (grade 2), one patient developing duodenal stenosis (grade 3), and one duodenal perforation (grade 4) [43].

A subsequent phase II study was performed at Stanford. Twenty patients with LAPC were treated with 25 Gy delivered in a single fraction with priority given to meeting duodenal constraints [44]. The dose to 5% of the duodenum was limited to 22.5 Gy, and 50% of the volume of the duodenum could receive a maximum of 12.5 Gy. Treatment was delivered with linear accelerator (linac)-based SBRT with IMRT. PTV margins were 2–5 mm. One-year local control was 94%, and toxicity was comparable to conventionally fractionated chemoradiation, with a single grade 4 toxicity (duodenal perforation, 5%) and three grade 2 toxicities (duodenal ulceration, 15%) [45, 46].

Fractionated SBRT regimens have also been investigated in prospective studies. A linac-based SBRT regimen with 45 Gy delivered in three fractions was examined in a multi-institutional phase II study from Denmark. Twenty-two patients were enrolled on the study, and at 1 year of follow-up, local control rates were poor at 57%. Additionally, rates of toxicity were high, with 79% of patients experiencing

grade 2+ acute toxicity. Potentially accounting for the increased toxicity was the use of abdominal compression, which can move the duodenum and bowel closer to the target volume, inclusion of peritumoral edema in the target volumes, resulting in larger volumes, and larger PTV margins (5 mm in the transverse and 10 mm cranio-caudal directions) than those used in the Stanford regimens [47].

More recently, a fractionated SBRT regimen was explored in a multi-institutional prospective phase II trial of 49 patients from Johns Hopkins, Stanford, and Memorial Sloan-Kettering [48]. The primary endpoint of this study was rate of grade 2 toxicity with a fractionated SBRT regimen [43]. Prior to receiving SBRT, patients were treated with up to three cycles of gemcitabine; radiation was then delivered to a total of 33 Gy in five fractions with central review of treatment plans. This study had strict requirements, including fiducial marker placement, respiratory motion management, and stringent dose constraints. Similar to preceding data, there was a high rate of local control (79% at 1 year), and median overall survival was 13.9 months. A lower rate of toxicity was reported with this multi-fraction regimen versus single-fraction treatment, with one acute (2%) and three late grade 3+ GI toxicities (6%). A final report of the quality of life endpoints has not yet been published, but in a review, the authors noted no decline in quality of life with improvement in pain (Table 3) [49].

Particle Beam Therapy

Protons and other particles, including helium, neon, and carbon ions, behave differently in tissue than photon radiation. While photons deliver their energy relatively superficially with a gradual dose falloff, proton beams penetrate tissue to variable depths depending on energy; this energy is then deposited in a sharp peak, known as the Bragg peak. The rapid falloff of energy at a prespecified depth limits exit dose and energy transfer to surrounding normal tissues. Theoretical models suggest that the Bragg peak may result in decreased rates of toxicity with particle therapy, though clinical data, particularly in pancreatic cancer, are limited.

In a study by Hsiung-Stripp et al., two- and three-field proton treatment plans were compared dosimetrically to conformal X-ray plans for patients with LAPC. While tumor coverage was not different for the two treatment modalities, doses to critical organs, including the liver, kidneys, and spinal cord, were significantly lower with the proton plans. Doses to the duodenum were not explored [50]. A similar study by Zurlo et al. compared proton plans with five- and nine-field IMRT plans for two patients with LAPC. Dose constraints to the kidneys, liver, and small intestine were met with proton plans, but were not able to be met with the IMRT plans [51]. Although these studies suggest that proton treatment may be superior to photon therapy with regard to normal tissue toxicity, both 3D-CRT plans and IMRT plans are easily able to meet dose contraints with conventionally fractionated treatment in clinical practice. The main concern is dose to the duodenum, particularly in the setting of dose escalation. Given the proximity of the duodenum to the gross disease in LAPC, it has been hypothesized that by exploiting the Bragg peak, proton therapy should allow for decreased duodenal

Table 3 Prospective studies of stereotactic body radiation therapy for pancreatic cancer

Study	Intervention	Number of patients	Local control (1 year)	Median survival (mo)	Acute toxicity, grade 3+	Late toxicity, grade 2+

dose. While patient numbers were small, Kozak et al. compared conventionally fractionated photon treatment with 1.8 Gy delivered over 28 fractions to hypofractionated proton therapy with 25 CGE (cobalt gray equivalent) delivered over five fractions in nine patients. Mean doses to the duodenum were not statistically different between the two treatment types, suggesting that the dosimetric advantage of protons in the setting of LAPC may be limited [52].

A randomized trial comparing X-rays and helium ions was conducted at the Lawrence Berkeley Laboratory for patients with unresectable pancreatic tumors [53]. An RBE of 1.2 was assigned to the helium ion doses. RBE refers to the relative biological effectiveness of a particle beam, defined as the ratio of dose delivered to tumor cell kill, and allows for dose comparisons between photon and particle beam therapy. Patients were randomized to 60 Gy with split-course X-ray therapy concurrent with 5-FU or non-split-course 60–70 Gy equivalent (GyE) dose with helium ions concurrent with 5-FU. In the 49 evaluable patients, local control was estimated to be 10% in the helium-treated patients and 5% in the X-ray-treated patients

(p = not significant). Median survival was similar between the two groups (7.8 months in the helium-treated patients and 6.5 months in the photon group), and there were no significant differences in local control or metastasis-free survival. "Moderate-to-severe" gastrointestinal toxicity was seen in 33% of the helium-treated patients and 24% of those treated with photons.

The Heavy Ion Medical Accelerator group conducted early clinical investigations into the use of carbon ion treatment of patients with locally advanced as well as resectable pancreatic tumors [54]. Patients with unresectable disease were treated with doses escalated as high as 48 GyE in 12 fractions. Local control at 1 year was 81% and 1-year survival was 44% [55]. A more contemporary phase I/II study from the same group explored the use of carbon ion treatment with concurrent gemcitabine. The trial escalated both carbon ion doses from 43.2 to 55.2 GyE in 12 fractions with concurrent gemcitabine escalated from 400 to 1,000 mg/m^2. Dose-limiting toxicity was observed in 3 of the 76 patients enrolled (grade 3 infection in one and grade 4 neutropenia in two patients). One patient experienced a late grade 3 ulcer. Two-year freedom from local progression was 83%. Two-year overall survival rates were 35% for all patients and 48% in the high-dose group of patients without metastatic disease [56].

Radiation Treatment Planning Considerations

Simulation

Simulation technique varies depending on the selected radiation treatment modality. For patients undergoing non-SBRT therapy, either with 3D-CRT or IMRT, patients are typically imaged in supine position on an indexed wingboard or Vac-Lok bag (CIVCO Medical Solutions, Coralville, IA) with arms up. A CT scan is then performed with oral and IV contrast, which allows for better delineation of target and normal structures. A four-dimensional computed tomography (4DCT) can be helpful to assess the magnitude of tumor motion with normal respiration. For conventionally fractionated treatment, assessment of respiratory motion can also be achieved with fluoroscopic simulation. In this situation, patients are given oral contrast, and continuous X-ray beam images are taken with the treatment fields projected onto the imager to ensure that the treatment field completely encompasses the target throughout the respiratory cycle.

SBRT delivers highly conformal and precise radiation and requires additional imaging and technical considerations. Prior to simulation, fiducial markers are typically placed via endoscopic ultrasound in the tumor or in close proximity to the tumor; markers assist in target identification at simulation and treatment. Immobilization of patients is crucial for SBRT, and multiple different devices can be used, including an upper Vac-Lok (CIVCO Medical Solutions, Coralville, IA) on an indexed wingboard, Alpha Cradle (Smithers Medical Products, North Canton, OH), or BodyFIX (Elekta Instrument, Stockholm, Sweden). To account for respiratory motion, a four-dimensional computed tomography (4DCT) can be used.

Management of respiratory motion is more challenging with abdominal tumors than in other disease sites. For abdominal tumors, intrafraction and interfraction variation in target location due to respiration can be as much as 2–3 cm [57]. Given the precise nature of SBRT treatment, if motion exceeds 3–5 mm, respiratory motion management should incorporate active breathing control (ABC), breath-hold (preferably in end-expiration), or gating breath holding. There are data to suggest that end-expiration may allow for the most favorable anatomy to maximize therapeutic ratio [58]. Although abdominal compression is sometimes implemented to limit respiratory-related motion, this method has the potential to displace the duodenum and bowel toward the target volumes. Simulation imaging is then performed with a CT +/− MRI in the supine position with arms up. Both oral and IV contrast are generally used. At certain institutions, dual-phase IV contrast imaging is used, which allows for acquisition of arterial and portal venous phase images timed by bolus tracking. The use of multiphasic imaging allows for better delineation of the tumor, as pancreatic lesions are usually best seen in the portal venous phase [59]. Prior studies have suggested a relationship between pre-SBRT PET findings and clinical outcomes; some institutions perform a PET/CT simulation and utilize this for tumor response assessment post-SBRT [60, 61].

Definition of Treatment Volumes

Regardless of treatment modality, gross tumor volume (GTV) is identified based on simulation CT/MRI/PET and any other available diagnostic imaging. With conventionally fractionated treatment, a clinical target volume (CTV) is created, which includes nodal basins at risk for microscopic disease spread. These typically include the peripancreatic, pancreaticoduodenal, and portocaval nodes as well as nodal regions surrounding the celiac axis and superior mesenteric artery (SMA); splenic hilum nodes are often included for pancreatic tail lesions. The CTV is typically expanded by 5–10 mm to arrive at the PTV, which accounts for daily setup uncertainty.

Given the high doses that are used with SBRT, the treatment volumes for these hypofractionated regimens are much smaller. With multiphasic imaging performed for SBRT treatment planning, the GTV for each phase includes the primary tumor and potentially involved nodal disease. The GTV contours delineated in the various contrast phases are then combined to generate an internal target volume (ITV), which should be comparable to tumor motion identified on 4DCT. A PTV is then created based on a 2–3 mm expansion of the ITV, with consideration of adjacent normal structures, including the duodenum, stomach, and bowel, and additional coverage added as necessary, often in the retroperitoneum and along the vasculature. With proximity of the PTV to normal organs, selective underdosing of the PTV may be required to respect normal tissue constraints. Identification of an ITV for fiducial markers may also provide an additional reference for improved target identification during treatment delivery.

Treatment Planning

Conventionally fractionated radiation to the pancreas is delivered with 3D-CRT or IMRT. Typically 3D-CRT plans consist of opposed AP-PA beams with either opposed lateral or off-cord oblique beams to create a four-field approach. For a tumor in the pancreatic head, in order to ensure coverage of the nodal basins described above, the superior margin of the AP-PA fields should start around 1 cm superior to the porta hepatis, and the inferior border should lie around L2 or L3 to cover the entirety of the C-loop of the duodenum, depending on individual anatomy. The medial edge of the field should be shaped with an MLC (multi-leaf collimator) such that there is an approximate 1 cm margin along the C-loop of the duodenum. The lateral edge should be shaped to include an approximate 1 cm margin on the vertebral body to ensure inclusion of retroperitoneal nodal basins. The opposed lateral or oblique fields should have the same superior and inferior borders as the AP-PA fields; the posterior edge of the field should generally split the vertebral body; and the anterior field should allow for around 2 cm distance from the GTV. To avoid excess dose to normal tissue, the majority of the dose should enter through the AP-PA fields, while only 10–14 Gy should be delivered through the lateral or oblique fields.

SBRT benefits from the use of IMRT or VMAT to allow for delivery of ablative doses to the target while sparing normal tissue. More recently, flattening filter-free SBRT treatments have been explored, which allows for shorter treatment duration [62]. As discussed previously, the main concern with delivery of high doses of radiation per fraction is toxicity to the surrounding structures, particularly the duodenum. With single-fraction SBRT regimens used at Stanford, patients receiving 25 Gy in a single fraction had a higher rate of duodenal toxicity correlating with V15, V20, and Dmax (dose maximum, often normalized to 100%) [44]. With the transition to a multi-fraction regimen (33 Gy delivered in five fractions), a lower rate of toxicity was seen, as noted above [48]. The normal tissue constraints from this study serve as reasonable guidelines: the proximal duodenum (within 1 cm above and below the PTV), stomach, and small bowel with 9 cc $<$15 Gy, 3 cc $<$20 Gy, and 1 cc $<$33 Gy, the liver 50% $<$12 Gy, both kidneys 75% $<$12 Gy, and spinal cord 1 cc $<$8 Gy. Typical dose distributions for 3D-CRT, IMRT, and SBRT plans can be seen below (Figs. 1 and 2).

Treatment Delivery

Regardless of radiation treatment approach, image-guided radiation therapy (IGRT) to verify the target and normal tissues prior to delivery of treatment is recommended. This can be accomplished with a number of different techniques, including kV or fluoroscopic onboard imaging as well as cone beam CT (CBCT) just prior to treatment. Typically daily CBCT is used with SBRT, but there are data to suggest that CBCT may underestimate the abdominal motion of pancreatic lesions. Therefore, CBCT should be used to evaluate the location of normal tissue, and fluoroscopic

images evaluating the alignment of fiducial markers should be used to complement CBCT information [57].

Future Directions

The high propensity of metastatic spread seen with pancreatic cancer and deaths related to metastatic disease limits the value of intensive local therapies. As systemic treatments improve, however, locoregional control will become increasingly important, and continuing efforts to optimize radiotherapy delivery are worthwhile.

A phase II trial from the Radiation Therapy Oncology Group (RTOG) attempted to address both the question of intensifying systemic therapy and local therapy in an effort to improve overall survival in patients with locally advanced disease. Unfortunately, the study recently closed due to poor accrual. Patients in the study were treated with neoadjuvant chemotherapy with gemcitabine plus nab-paclitaxel followed by intensified chemoradiation to 63 Gy in 28 fractions with concurrent capecitabine [63].

Given the low overall survival of patients with LAPC and high rates of distant progression, even in the setting of local disease control, more effective combined modality treatments are needed. A phase III study from Stanford is currently examining the safety and efficacy of a chemotherapy regimen known as modified

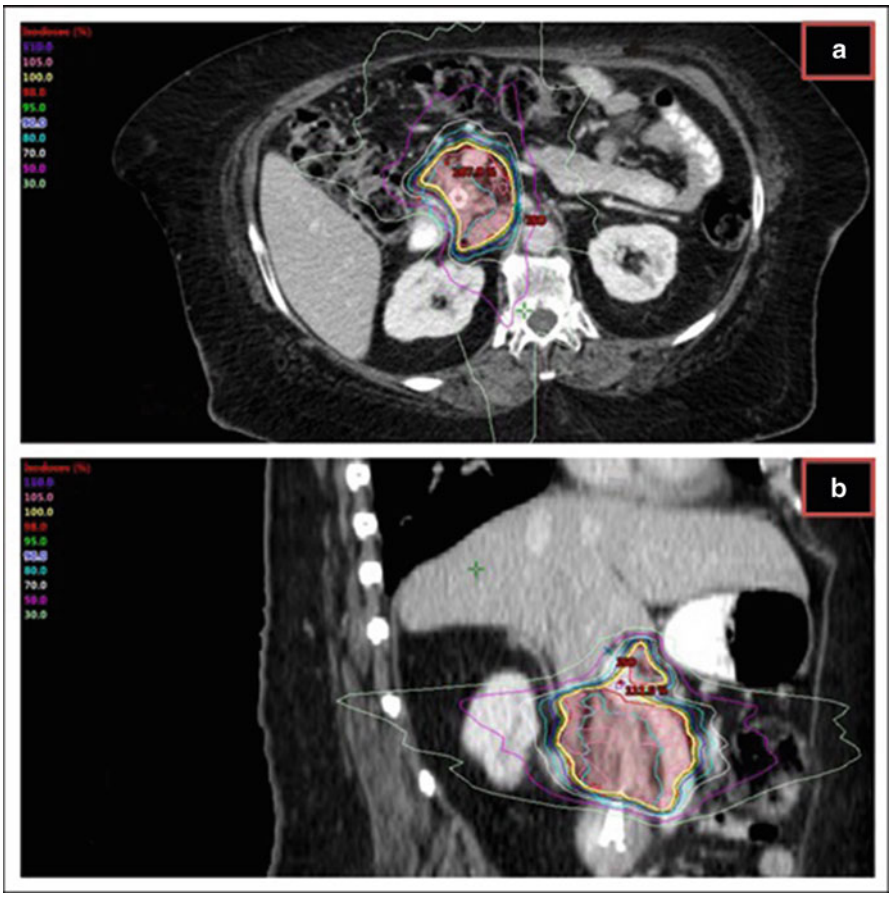

Fig. 2 SBRT treatment plan. Dose distribution with external beam SBRT technique for LAPC. (**a**) Axial image. (**b**) Sagittal image. *Red*, PTV; *cyan*, ITV

FOLFIRINOX (mFFX) alone or with the addition of SBRT in patients with LAPC [64].

Beyond chemotherapy, there is also an increasing interest in the role of immune therapies, with ongoing studies of whole cell tumor vaccines [65]. SBRT has also spurred much interest as a potential complement in the form of immunosensitization in many disease sites and may further enhance these systemic therapies [66].

Conclusion

Surgery remains the only option for cure for patients with pancreatic cancer. Approximately 40% of patients with pancreatic cancer present with locally advanced disease. The optimal management of these patients remains controversial, and there

is no internationally accepted regimen. Ideally, patients with locally advanced, unresectable disease should be treated on clinical trial. For most, an initial period of chemotherapy is appropriate. The period of upfront chemotherapy allows for selection of patients without development of overt metastatic disease; patients who do not progress through upfront chemotherapy may be appropriate for a number of subsequent regimens, including chemoradiation, continuing chemotherapy alone, or SBRT. While it is reasonable to reassess patients for resectability following these treatments, conversion to resectable disease is rare and the frequency of a complete resection with long-term survival is low. However, with advancements in radiation therapy as well as systemic therapy, including the use of more targeted and immune therapies, outcomes for patients with LAPC are likely to improve.

Vaccine Therapy and Immunotherapy for Pancreatic Cancer

Lei Zheng and Elizabeth M. Jaffee

Contents

Abstract

Recent advances in the tumor immunology field of research have enriched our knowledge of how tumor cells initially evade immune surveillance and how existing tumors actively suppress immune recognition of their progression. Based on these advances, strategies for immunotherapy have been developed to

enhance antitumor immunity and to target the mechanisms underlying tumor evasion and immune tolerance. These immunotherapy strategies have been employed in the design of novel treatments for pancreatic cancer and are being tested in preclinical studies and human clinical trials. Evidence of immune activation has been demonstrated in a number of these studies and, in some cases, correlated with clinical responses. However, a number of challenges must be addressed before the true potential of immune-based therapies can be determined. Consequently, future studies need to focus on identifying new pancreatic cancer-associated antigens and on identifying and targeting the immune checkpoints that inhibit effective immune cell activation. In addition, the development of these new therapies will require designing clinical trials that efficiently assess combinations of biologics that target multiple immune pathways and incorporate validated predictors of immune response. Finally, demonstrating the success of these new therapies will likely require establishing new criteria to evaluate clinical responses that are associated with immune-mediated mechanisms of tumor control.

Tumor Immunology and Pancreatic Cancer

Tumor Antigen Recognition and Immune Surveillance

The concept of cancer immune surveillance has been formulated based on the hypothesis that cancer cells are recognized as "non-self" and capable of inducing a rejection reaction. Cancer cells, although deriving from their normal counterparts, are distinguished by the expression of mutated, truncated, misfolded, improperly modified, overexpressed, aberrantly localized, or embryonic proteins. Autoantibodies against these proteins are detected in some cancer patients. These antibody-targeted proteins are considered to be tumor-associated antigens (TAAs). There is now ample evidence to demonstrate that spontaneous humoral and cellular immune responses can be detected in many cancer patients including those with pancreatic cancer.

Accumulating evidence from animal models provides strong support for the concept that tumor cells are recognized by host immune surveillance mechanisms (Fig. 1). Tumor cells expressing MHC class I genes can present tumor antigens directly to the predominant "killer cell" that mediates the rejection of tumor cells. These so-called $CD8^+$ or cytotoxic T lymphocyte (CTL) cells express clonotypically unique T cell antigen receptors (TCRs) that specifically recognizes a particular tumor antigen bound within the cleft of a major histocompatibility complex (MHC) class I molecule (human leukocyte antigen (HLA) type 1 in human). The recognition of

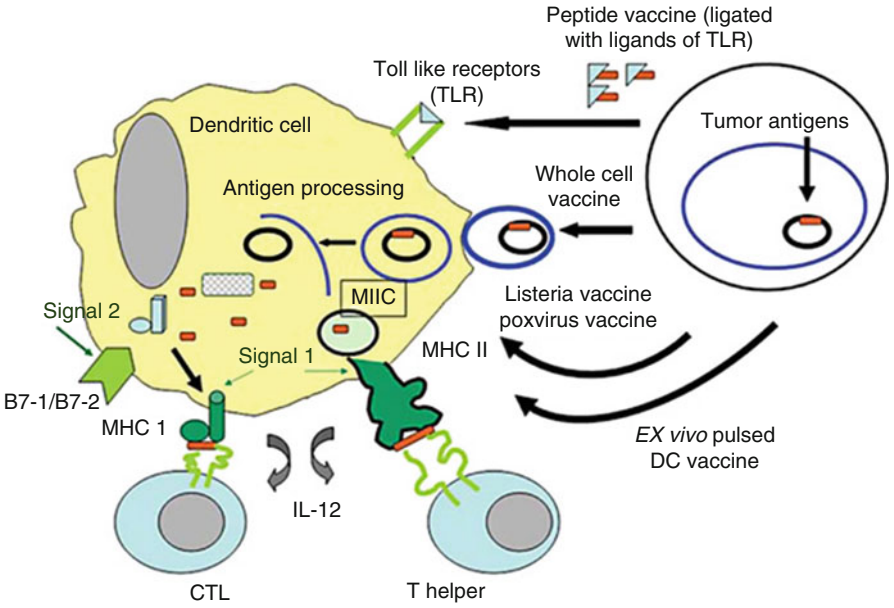

Fig. 1 APCs provide cross-presentation of tumor antigens and signals 1 and 2 for effective T cell activation. Dendritic cells (DC) are the most efficient APCs. These cells take up exogenous antigen from antigen-delivering vaccines [peptide, whole tumor cell, bacterial vector (*Listeria monocytogenes*), and viral vector (Pox virus vaccines)] and process these antigens on MHC class I and II molecules. Each vaccine has specific mechanisms for antigen entry. Some vaccines provide maturation signals to the DC by stimulating through Toll-like receptors (adjuvants, bacterial and viral vectors can do this). Activation of the DC results in enhanced presentation of antigen on MHC II and cross-presentation of antigen onto MHC class I molecules (signal 1) and the upregulation of signal 2 (B7-1/B7-2). Activation of DC also results in the production of pro-inflammatory cytokines such as IL-12 which further propagate T cell responses

antigen by TCR provides *signal 1* that is essential for T cell activation. Antigen recognition depends on the expression of MHC class I molecules on tumor cells. However, this signal alone is not enough to effectively activate a T cell. It is now well known that T cell activation also requires the binding of one or more co-stimulatory signals to its receptors on T cells, thereby providing what is termed *signal 2* [1]. However, most tumor cells are epithelial derived and therefore naturally lack expression of these important co-stimulatory signals. Instead, the successful activation of a T cell to recognize and lyse a tumor requires activation of professional antigen-presenting cells (APC), usually dendritic cells (DCs). DCs play a dominant role in processing and presentation. These cells have specific machinery for efficient uptake and processing of antigen onto their MHC molecules. They process exogenous antigens onto MHC class II for $CD4^+$ T cell activation and through, cross-presentation, onto MHC class I for $CD8^+$ T cell activation.

Historically, most cancers including pancreatic adenocarcinoma have been regarded as poorly immunogenic. More recent studies, however, have confirmed

the existence of tumor-reactive T cells and antibodies in the majority of cancer patients. For instance, a recent study reported that all pancreatic cancer patients investigated had high frequencies of tumor-reactive T lymphocytes in their bone marrow [2]. This concept is further supported by experimental evidence showing that mice with a variety of immunodeficiencies are more susceptible to carcinogen-induced and spontaneous tumors [3]. The central roles of immune effector cells such as B cells, T cells, natural killer (NK) cells, natural killer T cells (NKT), γδ-T cells, as well as type I and II interferons (INFs) and perforin, have long been proposed as cellular and cytokine mediators of cancer immune surveillance [4].

Immunoediting and "The Immunology of Carcinogenesis"

Cancers develop in patients who have a functional immune system with the potential to maintain surveillance against malignant cells. The model of cancer immunoediting has been proposed to delineate the carcinogenesis process as a dynamic equilibrium and disequilibrium process of immune surveillance and tumor escape [4]. The first step of immunoediting is the elimination phase. In this phase, immune surveillance successfully eradicates the developing tumor cells. This is started with the recognition of transforming cells by innate immune cells such as NK, NKT, γδ-T, and DCs. Following the maturation and migration of DCs to lymph nodes, these cells activate T cells, the adaptive component of the immune response. Tumor antigen-specific $CD4^+$ and $CD8^+$ T cells home to the site where the tumorigenesis process is initiating and CTLs eliminate the antigen-expressing cells that are undergoing transformation.

The second step is the equilibrium phase. During this phase, immune surveillance continues to eliminate tumor cells, while resistant tumor cells are selected out under pressure from the same elimination process. The random mutations in the genome of cancer cells may make them more susceptible to elimination. However, if the cancer cells acquire the wrong mutations that result in alterations in the expression of tumor antigens, the elimination process targeting these cancer cells would be weakened. Genetic instability and epigenetic alterations, which accompany the tumorigenesis process from normal cells to their malignant variants, provide opportunities for malignant cells to become less immunogenic cancer variants. The equilibrium phase may continue as long as abnormal cells derived from the tumorigenesis process can be eliminated by immune surveillance. Nonetheless, this equilibrium may eventually be disrupted and the immunoediting process reaches its final step, the escape phase. In this phase, cancer variants acquire genetic or epigenetic alterations making them insensitive to immunologic detection and elimination and are selected out. As a result, these transforming cells acquire dysregulated growth potential. Loss of tumor antigen expression is probably the most straightforward way for cancer cells to evade immunologic detection. Cancer cells always need to maintain some "non-self" features to distinguish them from their normal counterparts. However, cancer cells are able to sculpture the host immune system, for

example, by taking advantage of immune checkpoints (see below), and establish immune tolerance to these "on-self" features.

Mechanisms of Immune Tolerance

Alteration in T Cell Signal Transduction and Cytokine Regulation

Inflammatory signals are now recognized as contributors to the development and progression of most cancers. Cytokines, in particular, are often dysregulated during the process of tumorigenesis (Table 1). Pro-cancer cytokines are produced by many cells within the tumor's microenvironment including: stromal cells, APCs, regulatory T cells, endothelial cells, and the tumor cells themselves. These cytokines often downregulate activated cancer-targeted T cells, the mediators of antitumor immunity. Examples of two well-studied cytokines, TGF-β and IL-10, are described in detail below.

TGF-β

TGF-βs are regulatory molecules that affect multiple biological processes, including carcinogenesis and immune homeostasis via binding to its receptor, TGF-βR. TGF-βR is a heterodimer formed by TGF-βRI and TGF-βRII. TGF-b is a negative growth regulator. Binding of TGF-β to TGF-βRI activates TGF-βRII, which phosphorylates Smad2 and Smad3 and leads to their translocation into nuclei in a complex with SMAD4/DPC4 [5]. It is conceived that this nuclear translocation process allows Smad4/Dpc4 to function as a DNA-binding transcription factor in regulating genes involving cell growth, migration, and metastasis. Both SMAD4/DPC4 and TGF-β are thought to be tumor suppressors. Downregulation of

Table 1 Summary of mechanisms of immune tolerance

Mechanisms of immune tolerance	Regulatory components of tolerance
Alteration in T cell signal transduction and cytokine regulation	Upregulation of TGF-β signaling and IL-10
	Downregulation of IL-12 and IFN-γ
Tolerance induced by regulatory DCs and regulatory signals of DC differentiation	Immature DCs
	Upregulation of VGEF, COX-2, IL-6, and MCSF
	Downregulation of GM-CSF, IL-4, IL-12, and IFN-γ
Downregulation of co-stimulatory signals	Downregulation of B7-1 and B7-2
Immune checkpoints at the molecular level	Presence and/or upregulation of CTLA-4, PD-L1/B7-H1, PD-L2/B7-DC, B7-H3, B7-H4, PD-1
Cellular checkpoints of immune activity	Regulatory T cells (Tregs)
	Myeloid-derived suppressor cells (MDSC)
	Tumor-associated microphage (TAM)
Altered metabolism in immune cells	Upregulation of IDO, arginase and nitric oxide synthase, etc.

SMAD4/DPC4 mainly through loss of heterozygosity is found in 50–70% of advanced pancreatic cancers [6]. In the absence of a direct downregulation of SMAD4/DPC4, abnormal TGF-β signaling would still lead to the suppression of the function of SMAD4/DPC4. Reciprocally, downregulation of SMAD4/DPC4 renders tumor cells resistant to TGF-β-induced growth inhibition. Although TGF-β signaling suppresses tumor cell proliferation, it also plays an important role in negatively regulating immune cell function, rendering T cells tolerant to tumor growth. For example, genetic mice that are deficient in TGF-β or its receptor develop lethal autoimmune disease or severe inflammatory disease [5]. Furthermore, mice surviving to adulthood are resistant to challenge with tumors such as thymoma and melanoma. These studies provide evidence that T cells are direct targets of TGF-β and TGF-β regulates T cell responses specific for tumors.

TGF-β regulates a number of T cell populations and, in doing so, facilitates tumor growth and progression [5]. TGF-β suppresses $CD8^+$ T cells through multiple signaling pathways. It was suggested that TGF-β can suppress the expression of perforin, which is a key mediator of $CD8^+$ T cell killing of its target cells. In addition, suppression of IFN-γ production by $CD8^+$ T cells is thought to be mediated by Smad2 and Smad3, both of which are recruited to the promoter of INF-γ upon TGF-β-treatment. TGF-β regulation of $CD4^+$ T cells is less well understood. TGF-β potentially inhibits differentiation of Th1 and Th2 cells by inhibiting their lineage specification transcription factors such as T-bet and GATA-3. In addition, TGF-β induces expression of another transcription factor, FoxP3, which is a marker of $CD4^+$ $CD25^+$ Tregs. TGF-β is an important regulator of the homeostasis of Tregs (see below). In addition, TGF-β is a potent inhibitor of IL-12-induced production of IFN-γ in NK cells, suggesting its regulatory role in NK cell functions. Taken together, TGF-β represents an important mechanism of immune tolerance to tumors [5].

IL-10

Interleukin-10 (IL-10) is another important cytokine that mediates immune tolerance to tumors. IL-10 was initially identified as a molecule produced by Th2 cells and that inhibit productions of Th1 cytokines [7]. Ample evidence suggests that IL-10 blocks Th1 cell differentiation and proliferation and inhibits monocyte differentiation into DCs. In addition, IL-10-treated DCs fail to stimulate the cytotoxic activity of $CD8^+$ T cells. In addition, there is also evidence that IL-10 has direct effects on tumor cells to inhibit antitumor immune responses. For example, in human cancers, increased IL-10 expression and increased IL-10-producing immune cells are detected. IL-10 also downregulates HLA class I expression on tumor cells, thereby facilitating tumor escape from recognition by T cells. In one mouse model, transgenic expression of IL-10 results in a higher growth rate of an immunogenic lung carcinoma; whereas anti-IL-10 antibody or anti-IL-10 receptor antibody results in enhanced immune response to that same tumor. IL-10 is a pleiotropic molecule that displays both immunostimulatory and immunoregulatory activities. It has been shown to promote antitumor immune

responses in other mouse tumor models. Conceivably, the dual effect of IL-10 may originate from the differential roles of IL-10 on different tumor types. Therefore, it remains to be established how IL-10 regulates immune responses in two opposite directions [7].

Tolerance Induced by Regulatory DCs

A number of APCs are involved in the induction and maintenance of antitumor immune responses including DCs, monocytes/macrophages, and B lymphocytes [1]. DCs are the most potent among these APCs. As described above, to induce tumor immunity, sufficient numbers of functional APCs must present in situ, be able to capture, process, and present tumor-associated antigen, and subsequently stimulate TAA-specific T cells. Accumulating evidence has revealed that DCs have both a T cell activating and regulatory role in the induction and maintenance of antitumor immune response. Which role these cells play will depend on the initial signals provided within the context of the inflammatory response to the tumor.

The function of regulatory DCs can be characterized by the maturation state of these cells, specifically the surface molecules that they express. Matured DCs express high levels of surface markers such as CD40, CD80 (B7-1), CD83, and CD86 (B7-2) and produce high levels of IL-12 [8]. Mature DCs are functional and capable of inducing potent TAA-specific T cell immunity. Immature or partially differentiated myeloid DCs induce either suppressive T cells or T cell unresponsiveness. The interaction between the tumor environment and DCs provides another mechanism of tumor evasion [8]. Myeloid DCs arise from the same progenitor cells that also give rise to monocytes and macrophages [1]. However, the presence of functional immunogenic mature DCs is rare in human tumors. Many factors in the tumor environment may be responsible for the suppression of DC differentiation and maturation. Examples of these factors include VEGF, IL-6, MCSF, and COX-2 [8]. VEGF and COX-2 have been shown to suppress DC differentiation and maturation. IL-6 and macrophage colony-stimulating factor (MCSF) have been shown to switch DC differentiation toward macrophage differentiation. In addition, tumor cells, tumor-associated macrophages, and regulatory T cells produce IL-10 and TGF-β, which also suppress DC maturation and function. On the contrary, DC differentiation cytokines, such as GM-CSF and IL-4, as well as the Th1-type cytokines IL-12 and IFN-γ, are decreased in the tumor environment [8].

Downregulation of Co-stimulatory Signals

It is clear that the signals generated solely by TCR recognition of antigens are insufficient to activate T cells to an effector state. In fact, when T cells receive the only signal 1 through TCR engagement without additional co-stimulatory signals, they enter an unresponsive or anergic state. Signal 2, which is required for T cell activation, can be delivered by a number of co-stimulatory molecules [9]. The prototype of co-stimulatory molecules is B7-1 (CD80) and its homologue B7-2 (CD86). B7-1 and B7-2 co-stimulate T cells by interacting with the CD28 receptor on T cells. Unfortunately, co-stimulatory molecules are rarely expressed by tumor cells, representing another mechanism for the establishment of immune tolerance at

the local tumor site [9]. Therefore, the most successful vaccine approaches would be expected to stimulate immune responses through transfer of antigen to DCs, which naturally provide the necessary co-stimulatory signals when they present tumor antigenic peptide on MHC molecules to the T cell via TCR recognition.

Immune Checkpoints at the Molecular Level

CTLA-4

The positive regulatory effects of co-stimulatory signals are balanced by the presence of a number of co-inhibitory molecules. Although the binding of B7-1 and B7-2 to their CD28 receptor on T cells provides co-stimulatory signals, they can act as co-inhibitors when they bind to the cytotoxic T lymphocyte antigen 4 (CTLA-4) on T cells. The latter provides a co-inhibitory signal and decreases T cell activation both by outcompeting CD28 for ligand binding and inhibiting the signaling cascade that would be activated through the B7-1/B7-2-CD28 axis. CTLA-4 binds B7-1 and B7-2 with roughly 20-fold higher affinity than CD28 [10]. When naïve T cells are presented with antigen on B7-1 and B7-2-expressing APCs, they are co-stimulated because resting T cells express CD28 but not CTLA-4. Upon activation, CTLA-4 is expressed on T cells, thereby placing a "break" on the immune activation process (Fig. 2). The maintenance of the balance between stimulatory and inhibitory signals provides a mechanism to dampen unwanted responses once foreign antigens (infectious proteins) are cleared and ensures the tolerance to self-antigens and prevents autoimmune diseases. Knockout of CTLA-4 in mice confirms the importance of this signaling pathway since these mice succumb to lethal autoimmunity [11].

The discovery of this immune regulatory mechanism establishes the concept of immune checkpoints. CTLA-4 is the prototype of the molecules that govern immune regulation. It is likely that immunologic checkpoints serve two biological purposes. One helps generate and maintain self-tolerance among T cells specific for self-antigens. The other restrains the amplitude of normal T cell responses so that they do not "overshoot" in their natural response to foreign pathogens. The same immunologic checkpoint also gives tumor cells a chance at immune evasion. During tumor development, however, the balance leans toward co-inhibitory signals; and the presence of checkpoints plays a crucial role in the establishment of immune tolerance to tumors.

As a single intervention, anti-CTLA-4 monoclonal antibodies (mAb) can induce $CD8^+$ T cell-dependent tumor regression in tumor-bearing mice [11]. The primary activity of CTLA-4 mAb seems to be the prevention of CTLA-4 binding with B7-1 (CD80) or B7-2 (CD86). Combining CTLA-4 blockade with GM-CSF-secreting vaccination produces a synergistic antitumor effect compared to either alone in the non-immunogenic B16 melanoma mouse model [11]. Similarly, treatment with anti-CTLA-4 mAbs synergized with vaccination against a prostate-specific antigen (PSA) to induce antitumor effects in a transgenic model of spontaneous prostate cancer (TRAMP mice) [11]. Synergy with tumor vaccines has also been documented with synthetic peptide and DC vaccines. Anti-CTLA-4 antibody,

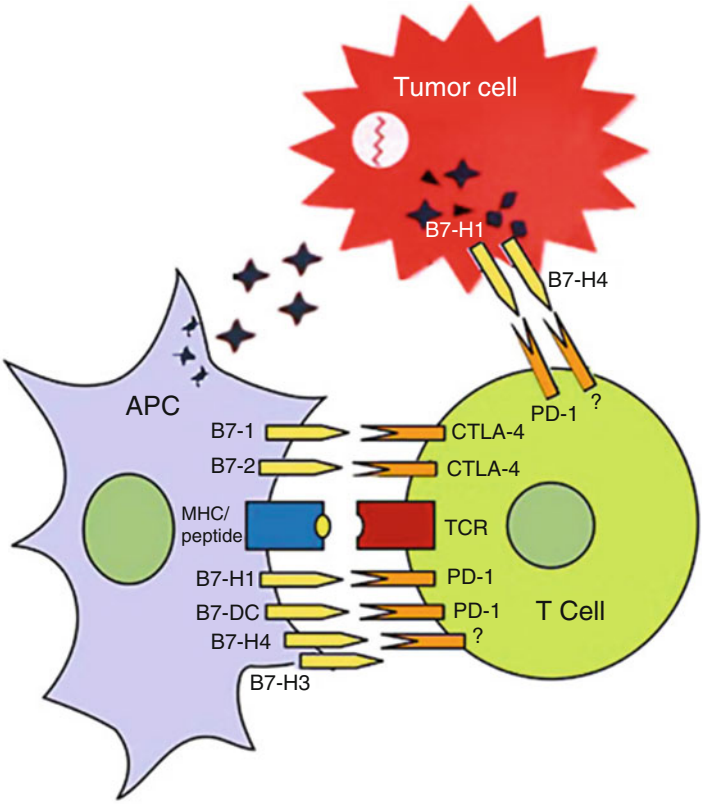

Fig. 2 Co-inhibitory signals and immune checkpoints. Tumor cells lack natural expression of co-stimulatory molecules such as B7-1/2. Therefore, T cells are not activated by tumor cells directly. When tumor cells provide signal 1 (HLA-peptide interacting with the TCR) without signal 2 (co-stimulation), T cell tolerance rather than activation results. Tumor cells may also express co-inhibitory molecules such as PD-L1/B7-H1 and B7-H4 and, by binding to their receptors on T cells, downregulate activated T cells. Tumor cells, tumor antigen peptide vaccines, or whole-cell vaccines can provide tumor antigens in a form appropriate for efficient processing and presentation by professional APCs, which then cross-present tumor antigens and have the potential to activate T cells. However, B7-1/B7-2 on APCs can also bind to the CTLA-4 receptor on T cells and deliver inhibitory signals that suppress T cell activation. Moreover, co-inhibitory molecules such as PD-L1/B7-H1 and PD-L2/B7-DC are present on APCs and can also provide inhibitory signals to T cells. These co-inhibitory molecules together with their ligands, CTLA-4 and PD-1 on T cells, respectively, constitute the immune checkpoints that are currently known to suppress antitumor immunity

ipilimumab, either alone or in combination with anti-PD-1 antibodies is now approved for treating advanced melanoma as described below in detail.

PD-L1, PD-L2, and Their Shared Receptor, PD-1

As discussed above, T cells harbor a natural co-inhibitory axis such as B7-1/B7-2-CTLA-4 that interacts with professional APC systemically (Fig. 2). In addition to

these systemic signals, T cells also express co-inhibitory signaling pathway that interacts with tumor cells and other cells within the tumor microenvironment. PD-L1 (B7-H1), another member of the B7 family, is an example of a co-inhibitory signal found on both DC and on many mouse and human tumor types [12]. Although resting T cells, B cells, and monocytes do not express PD-L1, they express high level of PD-L1 on their cell surface following activation. In contrast, DCs constitutively express PD-L1. Many types of tumor cells have been shown to have increased expression of PD-L1; and the tumor microenvironment can also stimulate the expression of PD-L1 on regulatory DCs [12]. In fact, both IL-10 and VEGF, two negative regulators of DC maturation and function, stimulate PD-L1 expression in myeloid DCs infiltrating human ovarian tumors and their draining lymph nodes [12]. PD-L1 also has a close homologue, PD-L2 (B7-DC), also in the B7 family. Expression of PD-L2 appears to be restricted to DCs and monocytes. PD-L2 also appears to be a co-inhibitory molecule [13]. Both PD-L1 and PD-L2 are ligands of PD-1, which is another inhibitory regulator expressed on the T cell surface (Fig. 2).

PD-1 shares significant homology with CD28, the receptor of co-stimulatory signals, B7-1 and B7-2 [14]. Its expression is induced upon activation of $CD4^+$ and $CD8^+$ T cells, B cells, and monocytes. PD-1 ligation to B7-H1/B7-DC causes inhibition of T cell activation and proliferation, which results in cell cycle arrest without apoptosis. The phenotype of PD-1 knockout mice is characterized by organ-specific autoimmunity [15]. PD-1 is particularly expressed by tumor-associated T cells, a significant fraction of which are Tregs [14]. Studies suggest that these tumor-associated, PD-1-expressing T cells can suppress antitumor immunity. So far, these PD-1-expressing tumor-associated T cells, through co-inhibitory signaling via PD-L1, have been shown to suppress IL-12 production by myeloid DCs, thus counteracting the positive effect of co-stimulatory signals. However, blocking PD-L1 has been shown to enhance myeloid DC-mediated T cell activation, allowing for suppression of growth of ovarian carcinoma xenografts following adoptive transfer of these cells into mice [12]. Administration of monoclonal antibodies (mAb) against PD-1 and B7-H1 has produced CTL-mediated antitumor effects in mice [14]. Therefore, tumor-associated PD-1 expression on T cells represents an additional mechanism of tumor evasion when B7-H1 is expressed by the progressing tumor. As described below in detail, anti-PD-1 and anti-PD-L1 antibodies have been approved for treating a number of malignant diseases.

B7-H3 and B7-H4

The B7 family is an expanding group of regulatory molecules expressed on professional APCs and some tumors. B7-1 and B7-2 were the first to be characterized followed by B7-H1 and B7-DC. B7-H4 is a more recently identified member of the B7 family [13]. Although B7-H4 protein expression is not as widely expressed as the other family members, aberrant expression has been demonstrated in human ovarian tumor-associated macrophages (TAMs) and human lung, breast, ovary, and renal cell carcinomas [13]. In addition, its expression can be upregulated in tumors following exposure to IFN-γ in vitro. Several lines of evidence support a role for B7-H4 in

mediating the immunosuppressive function of TAMs. B7-H4-positive TAMs are significantly more suppressive than B7-H4-negative TAMs. Blocking B7-H4 on TAMs disables their suppressive capacity. Furthermore, constitutive B7-H4 expression renders normal macrophages suppressive. B7-H4 has also been shown to interact with other tumor microenvironmental factors. For example, IL-6 and IL-10, which can be secreted by tumor cells, TAMs, or Tregs, stimulate monocyte/microphage B7-H4 expression. In contrast, GM-CSF and IL-4 reduce B7-H4 expression [16]. In addition, another B7 member, B7-H3, has also been proposed to be a co-inhibitor [12]. It is noteworthy that all these B7 molecules appear to have a dual function in immune regulation. Similar to B7-1 and B7-2, ligation of these B7 molecules can generate both positive and negative signals in T cells, depending on the context in which these T cells recognize their cognate antigen [12].

Regulatory T Cells Represent a Cellular Checkpoint of Immune Activity

Both mouse and human studies strongly support a major role for Tregs in mediating immune tolerance to tumors. These cells are characterized by high expression of $CD4^+$, $CD25^+$, and the FoxP3 promoter. These cells normally prevent autoimmune diseases by suppressing host immune responses when antigen load has been cleared. However, a growing number of reports have demonstrated that these cells are also recruited to tumor sites to inhibit antitumor immunity [17]. $CD4^+$ $CD25^+$ $FoxP3^+$ Tregs normally comprise a small subset of the overall $CD4^+$ T cell population. However, their proportion is significantly elevated within the tumor microenvironment of many types of cancer. The cell surface molecule CD25 – encoding the IL-2 receptor protein – has been used as a marker for isolating Tregs. However, its expression is not restricted to Treg and is also detectable on many other activated lymphocytes including effector lymphocytes that mediate the antitumor immune response. The Forkhead box protein P3 referred to as FoxP3 has emerged as a highly specific marker of $CD4^+$ Tregs in both mice and humans [18]. Mutation of FoxP3 in mice and human causes a loss of Tregs and the production of an X-linked-recessive inflammatory disease and multisystem autoimmune syndrome. Furthermore, FoxP3 expression correlates well with suppressive activity of Tregs in both mice and humans.

While it is difficult to target a nuclear transcription factor like FoxP3, other Treg-selective cell and cell surface molecules have been identified. These molecules provide an opportunity to evaluate the selective targeting of Treg function (Fig. 2). One, designated glucocorticoid-induced tumor necrosis factor receptor (GITR), is a TNF receptor family member [19, 20]. Administration of anti-GITR antibodies enhances antitumor immunity in some murine systems, and it has been suggested that anti-GITR antibodies diminish the susceptibility of effector T cells to suppression by Tregs [21]. A second molecule, LAG-3, is a CD4 homologue that is selectively expressed on the surface of Tregs. Ectopic expression of LAG-3 confers suppressor activity upon $CD4^+$ T cells [22]. Blocking LAG-3 with a monoclonal antibody then inhibits the suppressive activity of Tregs. While surface expression of LAG-3 is very low on circulating Tregs, it is upregulated on Tregs in tissues and

tumors, suggesting that its role may be on activated Tregs at the site of immune suppression [23]. Although CTLA-4 is expressed on both effector T cells and Tregs, it plays an important role in suppressing effector T cells and mediating the suppressive function of Tregs. The exact role of CTLA-4 in conferring Treg function remains to be established because patients treated with anti-CTLA-4 antibodies do not show significant changes in the number or function of peripheral Tregs [24].

$CD4^+$ Tregs require antigen-specific activation or polyclonal TCR stimulation to exert their suppressive function. Once they are activated, they can suppress $CD4^+$ and $CD8^+$ T cells in an antigen-nonspecific manner. Several mechanisms have been proposed to explain how $CD4^+$ Tregs inhibit effector T cells. Most naturally occurring $CD4^+$ $CD25^+$ Tregs and antigen-specific Tregs both function through a cell-to-cell contact-dependent mechanism, while some antigen-induced Tregs can also suppress immune responses through soluble factors, including IL-10 and/or TGF-β-dependent mechanisms.

Tumors have been shown to induce rapid expansion of $CD4^+$ $CD25^+$ FoxP3 + Tregs in humans and mice, leading to delayed rejection of immunogenic tumors [25]. Conversely, elimination of these Tregs elicits potent antitumor immune responses leading to tumor eradication in mice [26]. Accumulated evidence has suggested the requirement of tumor-specific and pathogen-specific antigens for activating Tregs. The identity of these antigens remains largely unknown. These studies however support the existence of antigen-specific Tregs and the importance of tumor-infiltrating Tregs in suppressing antitumor immunity [27].

Other Immunosuppressive Cell Types

A distinct group of bone marrow-derived cells recently termed myeloid-derived suppressor cells (MDSC) are also directly involved in the suppression of immune responses to cancer. This cell population as well as aforementioned tumor-associated macrophages (TAM), respectively, may represent two other cellular checkpoints of immune activity. MDSC express both myeloid lineage differentiation antigen Gr-1 (Ly6G and Ly6C) and α_M integrin CD11b and represent 20–30% of normal bone marrow cells, 2–4% of all nucleated splenocytes, and are practically absent in lymph nodes. Inoculation with tumor cells or the development of spontaneous tumors results in a marked systemic expansion of these cells; and consequently, these cells become easily detectable in lymph nodes or tumor sites [28]. MDSC may exert an immunosuppressive effect in both an antigen-specific and nonspecific manner. It seems that at the tumor site, the immunosuppressive activity of MDSC is antigen nonspecific and is primarily mediated by the production of nitric oxide (NO) in combination with high arginase activity. Dysregulation of L-arginine metabolism in immune cells at the tumor site is reviewed in the next section [28]. In one genetic and spontaneous pancreatic tumor model, the presence of MDSC at the tumor site strongly correlates with the lack of tumor-infiltrating effector T cells with a near mutual exclusion. More interestingly, infiltration of immunosuppressive cells including MDSC, TAM, and Tregs, together with the lack of effector T cells, occurs at the early premalignant stage in pancreatic tumor development [29].

Altered Metabolism in Immune Cells

A number of metabolic pathways have been found to be altered in immune cells and to be associated with cancer development. Interest in indoleamine-2,3 dioxygenase (IDO) has grown rapidly with the discovery that IDO activity is critical for generating tolerance to foreign antigens [30]. IDO is one of two enzymes that degrade the essential amino acid tryptophan in mammals by catalyzing the initial, rate-limiting step in the pathway that produces nicotinamide adenine dinucleotide (NAD). In cancer, IDO is overexpressed in both tumor cells and stromal immune cells. When overexpression of IDO results in reduced tryptophan levels, antigen-dependent T cell activation in the tumor microenvironment is impaired [30]. In addition to tryptophan metabolism, the metabolism of L-arginine in tumor cells and its microenvironment is also altered in association with tumor growth. Arginase and nitric oxide synthase, two enzymes involved in L-arginine metabolism, are both over expressed. Accumulating evidence has supported the role of these enzymes as negative regulators of immune response to tumors [31]. Therefore, these altered metabolic pathways are likely utilized by cancer cells to induce immune tolerance.

Tumor Microenvironment is the Site Where Immune Tolerance is Established

One may ask why only antitumor immunity is specifically affected when so many aspects of the immune system response are deregulated. Indeed, only a minority of patients develop cancers due to their inherited immune deficiency. The majority of cancer patients have a healthy immune system and respond to other antigen stimulus such as infectious agents normally. This highlights the importance of the tumor microenvironment and tumor-infiltrating immune cells in establishing immune tolerance specifically to the developing tumor.

The tumor's microenvironment is the place where tumor cells interact with both immune cells and tissue-specific stromal cells. Depending on the inflammatory milieu at the time, this interaction may either restrain the proliferation, survival, invasion, and metastasis of tumor cells or facilitate tumor development and progression. Obviously, the tumor's microenvironment is also the place where tumor cells induce innate immune responses and where tumor antigens are processed and presented by DCs. An effective immune response is achieved by the homing of effector T cells to this microenvironment. At the same time, antitumor immune responses are also facing a strong immunosuppressive network and immune checkpoints (Fig. 3). Such an immunosuppressive network and the involved immune checkpoints must also be activated in this tumor microenvironment. Thus, the complex interaction occurring within the tumor's microenvironment is a dynamic process that at times involves opposing activity by the immune components that promote immune response and thereby inhibit tumor growth, as well as by those that impede immune response and facilitate tumor growth.

Cancers develop in part because the forces promoting the antitumor immune components are outcompeted by the inhibitors of the antitumor response within the tumor's microenvironment. There is an imbalance of mature versus immature DCs,

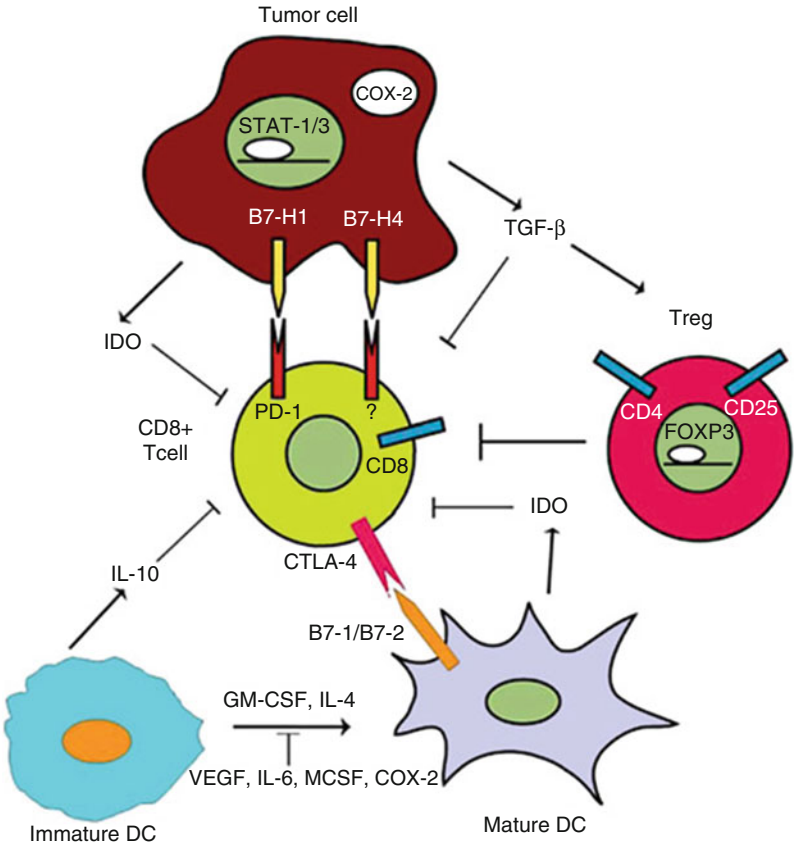

Fig. 3 An immunosuppressive network within the tumor microenvironment. The tumor's microenvironment is composed of a powerful immunosuppressive network, which includes immunosuppressive cells (e.g., Tregs), immunosuppressive cytokines (e.g., TGF-β, IL-6, MCSF, IL-10), and inhibitory signals provided by co-inhibitory molecules (e.g., PD-L1/B7-H1, PD-1, CTLA-4) on tumor cells, DCs, and T cells. In addition, immature DCs become predominant in the tumor microenvironment and contribute further to this immunosuppressive network. Moreover, tumor cells sculpt its microenvironment by secreting inhibitory molecules (e.g., upregulating IDO), rendering the microenvironment unfavorable for T cell activation

stimulatory versus inhibitory molecules, and effector T cells versus Tregs (Fig. 3). Increasing evidence suggests that immature DC is predominant in the tumor microenvironment, that co-inhibitory molecules such B7-H1 are highly expressed in tumor cells, and that Tregs are shown to infiltrate the tumor sites [8]. These imbalances start to occur at the earliest stages of tumor formation. One preclinical study has demonstrated that Tregs are already infiltrating the pancreatic in situ neoplasms (PanINs) that develop as a precursor to pancreatic tumors [29]. The author group has found that $FoxP3^{+}$ Tregs are infiltrating the majority of resected pancreatic tumors regardless of stage of these tumors (unpublished data). In addition to Tregs, two other

immunosuppressive cell types, MDSC and TAM, are also easily detected in the tumor sites and appear in the early-stage premalignant lesions during the development of mouse pancreatic tumors [29]. These studies strongly suggest that regulatory cells and molecules that are involved in immune checkpoint pathways are major components of the tumor microenvironment and likely from the earliest time of tumor initiation and development. In addition, tumor cells can sculpt their microenvironment and render it favorable for tumor escape. This is exemplified by the above described IDO pathway of immune cell regulation. By overexpressing IDO, tumor cells and their stromal cells create an environment that does not favor the proliferation and survival of effector T cells. Taken together, all evidence so far leads to the fact that the tumor microenvironment is the place where immune tolerance is established.

Limited by resources, tumor immunology research efforts have been focused on the systemic and peripheral immune responses and its associated regulation. To truly understand the immune tolerance mechanisms in the tumor microenvironment, however, it has become clear that the future delineation of these downregulatory pathways will require repetitive sampling of the tumor microenvironment. Understanding this dynamic process will lead to future therapeutic strategies that aim to re-sculpt the tumor microenvironment and render it favorable for antitumor immunity.

Immunotherapy Strategies

Passive Immunotherapy

Monoclonal Antibodies

The development of hybridoma technology has allowed the rapid production of monoclonal antibodies (mAbs) to target a single epitope. Since then, there has been a significant emphasis on the development of monoclonal antibodies that target tumor antigens and initiate tumor lysis either through direct signaling or through the delivery of a toxin conjugated to the monoclonal antibody. Advances in recombinant DNA technology allow the production of chimeric antibodies that contain the variable, antigen-specific region of the murine antibody and the constant regions of human antibodies. A further technology development is now allowing the production of fully humanized antibodies when mice genetically engineered with the human immunoglobulin gene is immunized with a human antigen. The first mAb approved for the treatment of cancer is rituximab (Rituxan), a chimeric anti-human CD20 mAb. Since its approval in 1997, many other mAbs have been approved for the treatment of cancer, and hundreds are undergoing preclinical and clinical evaluation [32] (the first nine approved mAbs listed in Table 2).

Rituximab is a chimeric anti-CD20 mAb that binds to human B lymphocytes and has been approved for treating B cell malignancies such as non-Hodgkin's lymphoma (NHL) either as monotherapy or in combination with chemotherapy. Ibritumomab tiuxetan (Zevalin) and tositumomab (Bexxar) are two radioimmunoconjugates directed against CD20. Trastuzumab (Herceptin) is a humanized

Table 2 Monoclonal antibodies with their approved indications

Generic name	Trade name	Antigenic target	mAb type	Approved indications
Rituximab	Rituxan	Anti-CD20 mAb	Chimeric	B cell malignancies
Trastuzumab	Herceptin	Anti-Her-2 mAb	Humanized	Her-2 expressing breast cancer
Alemtuzumab	Campath	Anti-CD52 mAb	Humanized	Chronic lymphocytic leukemia
Cetuximab	Erbitux	Anti-EGFR mAb	Chimeric	Metastatic colon cancer, squamous cell carcinoma of head and neck
Bevacizumab	Avastin	Anti-VEGF mAb	Humanized	Metastatic colon cancer, stage IV non-squamous NSCLC, metastatic breast cancer
Panitumumab	Vectibix	Anti-EGFR mAb	Humanized	Metastatic colon cancer
Gemtuzumab	Mylotarg	Anti-CD33 mAb	Humanized	Acute myeloid leukemia
Ibritumomab	Zevalin	Anti-CD20 mAb	Radioimmunoconjugated	B cell malignancies
Tositumomab	Bexxar	Anti-CD20 mAb	Radioimmunoconjugated	B cell malignancies

B cell malignancies include non-Hodgkin's lymphoma
mAb monoclonal antibody, *NSCLC* non-small cell lung cancer

mAb designed to bind to the extracellular domain of the human Her-2/neu receptor, a member of epidermal growth factor receptor (EGFR) family. It has been approved since 1998 for the treatment of metastatic Her-2-overexpressing breast cancer and was recently approved for the adjuvant treatment of Her-2-overexpressing breast cancer. Alemtuzumab (Campath-1H) is a humanized anti-CD52 mAb that is approved for the treatment of drug-resistant chronic lymphocytic leukemia (CLL). Cetuximab (Erbitux) is a chimeric mAb directed against Her-1, a member of EGFR family. Cetuximab was initially approved for the treatment of metastatic colorectal carcinoma and is now also indicated for the treatment of patients with squamous cell carcinoma of the head and neck. Bevacizumab (Avastin) is a humanized anti-angiogenic mAb that targets the vascular endothelial growth factor (VEGF). Bevacizumab is indicated in combination with 5-fluorouracil as first-line treatment

for metastatic colorectal cancer, advanced or metastatic non-squamous, non-small cell lung cancer, and metastatic breast cancer. Panitumumab (Vectibix) is a humanized mAb directed against EGFR and is approved for the treatment of metastatic colorectal cancer. Gemtuzumab ozogamicin (Mylotarg) is a humanized anti-CD33 mAb conjugated to calicheamicin, a cytotoxic antibiotic. CD33 is a glycoprotein receptor expressed on normal and monomyeloid hematopoietic progenitor cells. Gemtuzumab ozogamicin is approved for the treatment of patients with acute myeloid leukemia (AML).

The in vivo antitumor mechanisms of these monoclonal antibodies are proposed, including specific blockade of the function of proteins that they are directed against, antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), growth inhibition, apoptosis, and chemo- and radiosensitization of tumor cells, and enhanced antigen processing and prevention by DC [32]. Many more mAbs are being evaluated in preclinical and clinical studies, including those for the treatment of pancreatic cancer. These studies in the following sections will be discussed below.

Adoptive T Cell Transfer

T cells are considered the most powerful tools of the adaptive immune response that are capable of specifically recognizing and lysing tumors including pancreatic cancers. Adoptive transfer of T cells has been tested in preclinical and clinical studies [33]. In an early study, mice bearing disseminated leukemia were successfully treated by a combination of cyclophosphamide and adoptive transfer of syngeneic immune lymphocytes. Another early study showed that an injection of spleen cells activated in vitro by IL-2 resulted in tumor rejection. The antitumor effect of adoptive T cell transfer has been further supported by clinical studies showing that adoptive transfer of highly selected tumor-reactive T cells could mediate tumor regression. However, a number of obstacles remain to be overcome before adoptive T cell transfer can be applied routinely for the treatment of many patients with cancer [33]. These obstacles include overcoming the feasibility of routinely expanding to therapeutic numbers of an activated population of T cells specific for the tumor and maintaining a prolonged activated state in patients following adoptive transfer. More recent studies would suggest that successful treatment of cancer with adoptively transferred T cells requires a pre-conditioning chemotherapy regimen that inhibits mechanisms of in vivo T cell downregulation [34].

Immunesuppressive cells such as Tregs are probably the main mechanistic obstacle to overcome for adoptive T cell transfer to achieve potent antitumor activity in vivo. Others include the competition between endogenous T cells and adoptively transferred T cells for cytokines important for their growth and activation, and the difficulty for transferred cells to traffic to the tumor site and into the tumor. To overcome these obstacles, lymphodepletion to remove endogenous T cells and Tregs was tested in combination with adoptive T cell transfer. Other solutions have been proposed to enhance migration of T cells toward tumors including transducing transferred T cells with chemokine receptors. As retroviral gene transfer involves

extensive in vitro stimulation, which triggers T cell differentiation but also loss of expression of certain chemokine receptors and adhesion molecules, new protocols have been proposed to avoid in vitro T cell activation [33].

From a feasibility point of view, the requirement of ex vivo culture and sophisticate techniques is a major limitation for the translation of adoptive T cell transfer into routine oncology practice. Moreover, it is difficult for any single laboratory to isolate antigen-specific T lymphocytes reproducibly. Chimeric antibody receptor T cell therapy overcomes this challenge by providing antigen specificity through genetic engineered antibody receptors [35]. This technology has demonstrated its success in treating lymphoblastic malignancies and showed its promising efficacy in other hematologic malignancies. However, CAR T therapy is associated with cytokine release syndrome, which could become fatal and thus limit the application of CAR T therapy [36]. There are also enthusiasms of developing CAR T therapies for solid malignancies including pancreatic cancer [36]. Nevertheless, CAR T therapies in solid tumors face additional challenges including the difficulty for CAR T cells trafficking into tumors.

Cloned T cell receptor (TCR) genes can be used to produce T lymphocyte populations of desired specificity and offers new opportunities for antigen-specific T cell therapy. Several groups have demonstrated the feasibility of retroviral TCR gene transfer to produce antigen-specific TCR expressing T cell populations that function in vivo [33]. Recently, human mesothelin-specific TCRs have been cloned; and mouse mesothelin-specific TCR-cloned T cells were found to be able to enter the pancreatic tumors that are spontaneously developed in transgenic mice and highly resemble human pancreatic ductal adenocarcinoma [37].

Sipuleucel-T (Provenge) is one of few DC-based vaccines that have been tested in late phases of human studies [38]. Sipuleucel-T is made with mature, autologous DCs obtained from the patient via a standard leukapheresis. The antigen-loaded DCs are reinfused to the same patient in 3–4 days following the initial leukapheresis. Two phase III studies for the treatment of metastatic hormone-refractory prostate cancer patients have been completed. Although the primary endpoint, time to disease progression was not met, overall survival was improved with a statistical significance in patients treated with Sipuleucel-T compared with those treated with placebo [38]. Sipuleucel-T eventually became the first FDA-approved cancer vaccine and is indicated for metastatic hormone-refractory prostate cancer [39]. Like Sipuleucel-T, other DC-based immunotherapies demonstrate their safety in the clinical trials and showed their promising efficacy results. Because DC-based vaccines are different from conventional drugs and require multiple procedures with sophisticate technologies, the feasibility of such an immunotherapy modality being a routine cancer treatment has remained a challenge. Another major concern with the current form of DC vaccines is the lack of studies that have evaluated the best routes of administration and the best preparations for optimal immunization of large numbers of patients. Unfortunately, current methods have significant patient-to-patient variability within a given study and between different studies.

Targeting CTLA-4

As the major obstacles for effective antitumor immunity are immunologic checkpoints, the cells (Tregs) and molecules that convey checkpoint signals have become the targets for immunotherapy. Many agents have been or are being developed to target immunologic checkpoints. Among them, monoclonal antibodies specific for CTLA-4 was the first of the class tested in preclinical models and human studies. The studies of monoclonal antibodies against mouse CTLA-4 have been reviewed above.

Human CTLA-4 monoclonal antibodies have also been developed. Ipilimumab and tremelimumab, two different humanized monoclonal antibodies directed to human CTLA-4, have been independently tested in multiple clinical studies including phase III clinical trials in advanced melanoma [40, 41]. These trials have led to the FDA approval of ipilimumab for melanoma. However, grade III/IV autoimmune toxicity is also highly notable and can in some cases result in death if not treated quickly and effectively. In particular, colitis has been observed in approximately 30% of patients treated, often requiring steroid intervention for alleviation of symptoms [40, 41].

Targeting PD-1

PD-1 blockade monoclonal antibodies in the class of checkpoint inhibitors are subsequently approved by the US Food and Drug Administration (FDA). Pembrolizumab and nivolumab are both humanized monoclonal antibody directed again human PD-1.

Nivolumab has been approved by FDA to treat advance melanoma as the first-line therapy, metastatic non-small cell lung cancer (NSCLC) as a second-line treatment, renal cell carcinoma as the second-line therapy, metastatic or recurrent squamous cell carcinoma of the head and neck as the second-line therapy, and recurrent Hodgkin's lymphoma. Pembrolizumab has been approved by FDA to treat advanced melanoma and PD-L1-positive metastatic NSCLC as the first- and as the second-line therapies [42–52]. No dose-limiting toxicity has been observed in the phase I studies of either antibody.

These antibodies have a lower toxicity profile than anti-CTLA antibody [42, 43]. This is anticipated on basis of the result of PD-1 knockout mice developing mild strain-dependent, organ-specific autoimmunity, in contract to CTLA-4 knockout mice that develop lethal multi-organ autoimmunity [15]. Second, it may have a relatively specific role in blocking T cell suppression in the tumor microenvironment. This assumption was made upon the evidence showing that PD-L1, the PD-1 ligand, is highly expressed in a variety of human tumors [53]. In contrast, the CTLA-4 ligands are systemically expressed on APCs. Similar to CTLA-4 blockade, preclinical models have shown that PD-1 blockade synergizes with tumor vaccines [54].

Targeting B7 Family and Other Checkpoint Molecules

Other co-inhibitory molecules in the immune checkpoints are also potential targets for therapy. Monoclonal antibodies specific for co-inhibitory molecules, PD-L1/B7-H1,

PD-L2/B7-DC, B7-H3, and B7-H4, have been tested in preclinical models and have all been shown to augment T cell immunity [13]. As described above, these ligands can also deliver costimulatory signals, presumably through different receptors. Therefore, it will be more challenging to employ therapeutics that targets these molecules. Extensive preclinical modeling of these checkpoint inhibitors should inform the early clinical trials as to the best way to employ the targeted agents. Nevertheless, anti-PD-L1 antibodies have been shown to have similar antitumor efficacies and safety profiles as anti-PD-1 antibodies in multiple cancer types [42, 43]. Moreover, atezolizumab, an anti-PD-L1 antibody, has been approved by FDA to treat the advanced urothelial carcinoma as the second-line therapy [55].

In addition, therapeutic agents that target other checkpoint molecules such LAG-3, TIM-3, etc. are also being tested in clinical trials as single agents or in combination with anti-PD-1/PD-L1 antibodies [56].

Targeting IDO

IDO is a molecule secreted within the tumor's microenvironment that also functions as an immune checkpoint through regulating T cell metabolism. A small number of studies have offered evidence that IDO inhibition with 1MT or other small-molecule inhibitors can exert antitumor effects [30]. Although 1MT by itself was unable to elicit tumor regression, the delivery of 1MT in combination with a variety of classical cytotoxic chemotherapeutic agents elicited regression of mammary tumors in HER-2/neu transgenic mice. Immunodepletion of CD4+ or CD8+ T cells from the mice before treatment abolished the combinatorial efficacy observed in this model, confirming the expectation that 1MT acted through activation of T cell-mediated antitumor immunity. In addition, small-molecule inhibitors of IDO including several thiohydantoin derivatives of tryptophan have been identified, and administration of these inhibitors resulted in the same pattern of antitumor properties as 1MT. IDO has a number of appealing pharmacodynamic features as a target for drug developments. Design and development of more efficient IDO inhibitors is underway. Phase I/II studies of IDO inhibitors for human cancers have shown promising results [57, 58].

Targeting Tregs

Tregs are the key cellular component of immune checkpoints. So far, none of the targeted strategies are able to specifically block or deplete Tregs in human cancer patients. Anti-CD25 antibodies have been proposed to deplete Tregs. However, in the setting of human vaccine trials, this strategy would likely be flawed because CD25 is expressed on both CD4+ CD25+ Tregs and newly activated effector T cells. Indeed, clinical trials using ONTAK (an IL-2 toxin fusion protein that binds CD25) show either inefficient elimination of Tregs or both depletion of Tregs and suppression of some important aspects of tumor-specific immune responses [59]. Also, CTLA-4 blockade does not completely overlap with Treg inhibition. Studies of cyclophosphamide, a chemotherapeutic that inhibits Treg populations when given in immune-modulating doses or in very high dose, are elucidating some of the

specific mechanisms for inhibiting Tregs. It cannot be overemphasized that therapeutic strategies targeting Tregs are in high demand.

Adoptive T Cell Transfer for Pancreatic Cancer Immunotherapy

Adoptive T cell immunotherapy has also been tested in advance pancreatic cancer. Twenty patients with unresectable or recurrent pancreatic cancer were treated by both dendritic cells pulsed with MUC1 peptide (MUC1-DC) and cytotoxic T lymphocytes (CTL) sensitized with a pancreatic cancer cell line expressing MUC1 (MUC1-CTL). Peripheral blood mononuclear cells (PBMCs) obtained from an individual patient were separated into adherent cells for induction of MUC1-DCs and floating cells for MUC1-CTLs. Following ex vivo activation, MUC1-DC and MUC1-CTL were transferred back to the patient. Patients were treated from 2 to 15 times. One patient with multiple lung metastases experienced a complete response. Five patients had stable disease. The mean survival time was 9.8 months. Only grade I toxicity was observed. It would be difficult to distinguish between the effects of DC therapy and adoptive T cell transfer in this study. Nonetheless, this study suggested that adoptive immunotherapy with MUC1-DC and MUC1-CTL is safe and may be feasible for pancreatic cancer [60]. MUC1-specific and mesothelin-specific CAR T therapies are also being tested in the clinical trial [61, 62].

Development of Pancreatic Cancer Vaccines

Antigen-Specific Vaccines

Tumor Markers as Vaccine Antigens

The vaccine trials in pancreatic cancer were first designed to target a defined pancreatic cancer antigen. However, such an approach requires a comprehension of pancreatic cancer antigens that are immunogenic. For a long time, tumor markers have been an obvious option. The idea has been that molecules associated with pancreatic cancer and used for diagnostic purposes, e.g., CEA, MUC1, gastrin, etc. could also be used as therapeutic vaccines [63] (Table 3).

The high level of expression of both CEA and MUC1 by pancreatic cancers suggested that combining vaccination against both antigens might be appropriate in this disease. In one study, a phase I trial was conducted using an admixture of vaccinia virus expressing MUC1 with a vaccinia-CEA-TRICOM vaccine for priming followed by booster immunizations using fowlpox-CEA-TRICOM. This prime and boost regimen was based on preclinical studies showing that sequencing these pox viruses in this way enhanced antigen-specific immunity against the tumor while avoiding vaccinia-specific immunity that might mask cancer-specific immunity in patients who were previously vaccinated with vaccinia to prevent small pox disease [64]. Patients with metastatic or locally advanced pancreatic cancer who had failed prior chemotherapy were eligible. A second phase I trial was carried out using the

Table 3 Current progresses on human pancreatic cancer vaccine studies

Studies	Patient characters	Vaccine type and treatment	Immunologic analysis	Clinical efficacy
Phase I PANVAC-VF [65]	Eight evaluable patients, advanced pancreatic cancer, heavily pretreated	CEA-MUC1-TRICOM in poxvirus plus recombinant GM-CSF	Antigen-specific T cell responses in five out of eight patients; significant increase in OS in patients who generated anti CEA- and/or MUC1-specific immune responses compared with those who did not (15.1 vs. 3.9 mo, $P = 0.002$)	Median OS of 6.3 mo
Phase III PANVAC-VF (unpublished)	250 patients, metastatic pancreatic cancer	CEA-MUC1-TRICOM in poxvirus plus recombinant GM-CSF versus best supportive care	Not reported	No improvement in overall survival
Phase III gastrin peptide [66]	154 patients, advanced pancreatic cancer, unwilling or unsuitable to take chemo	Peptide vaccine (G17TD) versus placebo	Not reported	Median OS of 151 versus 83 d, $p = 0.03$
Phase III gastrin peptide [67]	Advanced pancreatic cancer	Gemcitabine + peptide vaccine (G17TD) versus gemcitabine + placebo	Not reported	OS (178 vs. 201 d) TTP (118 vs. 118 d) RR (21 vs. 23%)
Pilot study of mutant ras peptide [68]	5 patients	Peptide vaccine	2/5 showed immune response specific for individual ras mutations and also had a relatively longer survival. These two patients demonstrated vaccine-induced CD4+ and CD8+ T cell response specific for ras epitopes containing G12D mutation	2/5 had a relatively longer survival

Phase II study of mutant ras peptide [69]	48 patients: 10 surgically resected; 38 with advanced pancreatic cancer	Peptide vaccine plus recombinant GM-CSF	Peptide-specific immunity induced in 58% of patients. Patients with advanced cancer demonstrating an immune response to the peptide vaccine showed prolonged survival compared to nonresponders (median OS 148 vs. 61 d)	Median OS (responders vs. nonresponders): 148 versus 61 d
Phase II mutant ras peptide [70]	11 patients: 5 resected pancreatic cancer, 6 resected colon cancer	Peptide vaccine Adjuvant treatment	Specific immune responses to the relevant mutant ras peptide were detected in 5 out of 11 patients	A mean disease-free survival of 35.2 + months and a mean OS of 44.4 + months
Phase I/II GV1001 [71]	48 patients, non-resectable pancreatic cancer	Telomerase peptide vaccine plus GM-CSF	Immune responses measured as DTH and in vitro T cell proliferation were observed with the highest ratio in the intermediate dose group	Median OS for the intermediate dose group was 8.6 mo, significantly longer than the low- and high-dose groups
Phase III GV1001 [73]	1065 patients, locally advanced or metastatic pancreatic cancer	Chemotherapy (gemcitabine plus capecitabine) versus chemotherapy and sequential or simultaneous GV1001 vaccine	Not reported	Chemotherapy alone: 7.9 months; sequential chemoimmunotherapy: 6.9 months; concurrent chemoimmunotherapy: 8.4 months. not significantly different
Phase I/II personalized multiple peptide [75]	20 patients, metastatic pancreatic cancer	Multi-peptide vaccine	Vaccination-augmented peptide-specific T cell responses and IgG titer were observed in 72% and 78% of the patients, respectively	Median OS was 8.5 mo: 5 PR; 11 SD.

(*continued*)

Table 3 (continued)

Studies	Patient characters	Vaccine type and treatment	Immunologic analysis	Clinical efficacy
Phase I HSPPC-96 [76]	11 patients, advanced pancreatic cancer	Autologous tumor-derived gp96 heat-shock protein – peptide complex combinatorial treatment with gemcitabine	Autologous anti-HSPPC-96 ELISPOT reactivity increased significantly in only one of 5 patients examined	Three of 10 treated patients were alive without disease at 2.6, 2.7, and 5.0 years follow-up. Median OS was 2.2 years
Phase I allogeneic pancreatic cancer vaccine [77]	14 patients, resected adenocarcinoma of pancreas	GM-CSF secreting, allogeneic whole-cell vaccine, adjuvant treatment in sequence with chemoradiation	3/14 subjects developed DTH to autologous tumor cells	3/14 subjects experienced prolonged disease-free survival
Phase II allogeneic pancreatic cancer vaccine [78]	60 patients, resected pancreatic adenocarcinoma	GM-CSF secreting, allogeneic whole-cell vaccine, adjuvant treatment in sequence with chemoradiation	Correlation between disease-free survival and the induction of mesothelin-specific T cell responses	1 year survival, 86%; 2 year survival, 61%; median OS, 24.8 mo
Phase I/II allogeneic pancreatic cancer vaccine [80]	50 patients, advanced pancreatic cancer, $\geq$ 2 prior chemotherapy regimens	GM-CSF secreting, allogeneic whole-cell vaccine cohort A ($n = 30$), vaccine alone; cohort B ($n = 20$), Cy + vaccine	Detected the enhanced mesothelin-specific T cell responses in vaccinated patients	Clinical response: cohort A, 5 SD, 23 PD; cohort B, 6 SD, 11 PD; TTP & OS: cohort A, 1.4 & 2.3 mo; cohort B, 1.9 & 4.7 mo
Phase I MUC1-pulsed DC-based vaccine [74]	20 patients, advanced pancreatic cancer	DCs pulsed with MUC1 peptide plus CTL sensitized with MUC1-expressing pancreatic cancer cells	Not reported	One patient with multiple lung metastases experienced a complete response. Five patients had SD. Mean OS 9.8 mo

SD stable disease, *PR* partial response, *PD* progressive disease, *mo* month, *d* days, *wk.* weeks, *Cy* cyclophosphamide, *TTP* time to progression, *RR* response rate

PANVAC-VF regimen. This consists of priming with PANVAC-V (a single vaccinia vaccine co-expressing CEA, MUC1, and TRICOM) followed by three booster doses of PANVAC-F (fowlpox vaccines expressing the three transgene components). The vaccines were administered ever 2 weeks by subcutaneous injection followed by local recombinant GM-CSF adjuvant for 4 days. Monthly booster vaccinations for up to 12 months were provided for patients without progressive disease. Antigen-specific T cell responses were observed in 5 out of 8 evaluable patients (62.5%). Median overall survival was 6.3 months and a significant increase in overall survival was noted in patients who generated anti CEA- and/or MUC1-specific immune responses compared with those who did not (15.1 vs. 3.9 months, respectively; $P = 0.002$). Although the subject number is small in this study, a median overall survival of 6.3 months in advanced pancreatic cancer patients who had been heavily pretreated with chemotherapy appeared favorable and thus led to a phase III trial in advanced pancreatic cancer patients [65]. This randomized controlled phase III clinical trial enrolled 250 metastatic pancreatic cancer patients. Patients were randomized 1:1 to either vaccine or best supportive care. Patients randomized to the PANVAC-VF arm of the trial received 2×10^8 pfu of PANVAC-V followed by 100 μg GM-CSF. Subsequently, these patients receive 1×10^9 pfu PANVAC-F also followed by GM-CSF. Patients who did not have progressive disease received monthly booster immunizations. Unfortunately, this study did not meet their primary efficacy endpoint of improving overall survival [64]. There are many proposed reasons for the failure to show significant activity. The most likely reason is that this study provided a vaccine to patients with significant immune-tolerizing mechanisms, thereby precluding access and function of vaccine-induced T cells in this patient population.

Another large antigen-specific vaccine study tested a peptide vaccine, G17DT, that targets the antigen, gastrin. In this study, 154 pancreatic cancer patients unsuitable or unwilling to take chemotherapy were treated with either placebo or a gastrin peptide vaccine. Median survival was 151 days in the vaccine group versus 82 days in the placebo group ($p = 0.03$). In the previous phase II study, anti-gastrin antibody responders demonstrated significantly greater survival than antibody nonresponders. Immune response endpoints have not yet been reported for this phase III study [66]. Nonetheless, in a follow-up study in which patients with advanced pancreatic cancer were randomized to receive gemcitabine with or without G17DT, there was no major difference between gemcitabine plus vaccination with G17DT versus gemcitabine plus placebo for overall survival (178 days vs. 201 days), time to tumor progression (118 vs. 118 days), or response rate (21% vs. 23%) [67]. Thus, the approach of using tumor markers as vaccine antigens may or may not be effective, depending on the vaccine approach employed and on the patient population in which the vaccine is being tested. It is conceivable that immune tolerance to these antigens have been established long before carcinogenesis is initiated since these antigens are also expressed by the normal tissue from which the tumor derives. It would be unlikely to easily overcome tolerance to these self-antigens as such a tolerance is critical for the protection of the normal cells.

Oncoproteins as Vaccine Antigens

Another vaccine approach takes advantages of genetic and epigenetic changes that occur during the carcinogenesis process. This approach is attractive because it provides an opportunity for targeting tumor-specific antigens. Several pancreatic cancer-associated oncoproteins have been used as vaccine targets. As mentioned above, Kras mutations occur frequently in pancreatic cancers. In a pilot trial of a mutant Kras peptide vaccine, two out of five pancreatic cancer patients showed immune response specific for individual Kras mutations and also had a relatively longer survival. These two patients demonstrated vaccine-induced CD4+ and CD8+ T cell responses specific for Kras epitopes containing the substitution from glycine to valine at codon 12 [68]. In a second trial, mutant Kras peptide vaccine was given to 48 patients (10 surgically resected and 38 with advanced disease) together with GM-CSF as an adjuvant. Peptide-specific immunity was induced in 58% of evaluable patients. Patients with advanced cancer demonstrating an immune response to the peptide vaccine showed prolonged survival compared to nonresponders (median survival 148 days vs. 61 days, respectively) [69]. A follow-up phase II study of this vaccine as an adjuvant treatment in pancreatic cancer and colorectal cancer was also reported. Vaccinations were given every 4 weeks, up to a total of six vaccines. Specific immune responses to the relevant mutant ras peptide were detected in five out of 11 patients. Furthermore, the five pancreatic cancer patients have shown a mean disease-free survival of 35.2 + months and a mean overall survival of 44.4 + months [70]. Although the survival outcome appears positive, it is difficult to judge the exact benefit of the vaccine with such a small subject number in this study. None of these vaccine studies report serious adverse effects, however, suggesting that such an approach is safe and feasible and warrants further investigation particularly in combination with other therapies.

As telomerase is reactivated in most tumor cells, it has also become a target for peptide vaccines. In a dose escalation phase I/II study, 48 patients with newly diagnosed non-resectable pancreatic cancer were treated with peptide vaccines (GV1001) targeting the hTERT subunits of telomerase. GM-CSF was also used as an adjuvant. The vaccine was injected intradermally eight times over a period of 10 weeks followed by monthly booster vaccinations. The vaccine was tested at three dose levels and was well tolerated. Immune responses measured as delayed-type hypersensitivity (DTH) to the immunizing peptides and in vitro T cell proliferation were observed with the highest ratio in the intermediate dose group. Consistently, median survival for the intermediate dose group was 8.6 months, which was significantly longer than the low- and high-dose groups [71]. Thus, a prospective, phase III, controlled, multicenter, randomized clinical trial (TELOVAC) is comparing combination gemcitabine and capecitabine therapy with concurrent and sequential GV1001 treatment in locally advanced and metastatic pancreatic cancer was followed. The rationale for the combinatorial therapy with gemcitabine and vaccination is based on a report suggesting that patients vaccinated during the first week of chemotherapy following surgical resection mounted both cellular and humoral

responses to a standard panel of microbial antigens measured 12 weeks after vaccination [72]. A second report further suggested that T cells from patients undergoing gemcitabine treatment were functional and that gemcitabine may decrease memory T cells and promote naïve T cell activation. The phase III study of GV1001 was designed to test the hypothesis that combining cancer vaccines with standard gemcitabine treatment in patients with pancreatic cancer is feasible and may result in synergistic effects. This study was conducted at multiple centers by the Pancreatic Cancer Subgroup of the National Cancer Research Institute in the United Kingdom and randomized 1062 patients to receive either chemotherapy alone, chemotherapy with sequential GV1001, or chemotherapy with concurrent GV1001. Nevertheless, it failed to demonstrate the survival benefit of GV1001 in either sequential or concurrent combination with chemotherapy [73].

Although much still needs to be learned about the optimal antigens for pancreatic cancer vaccination, the ideal antigen will likely lack of pre-existing tolerance, be selectively expressed by the tumor, and indispensable for maintaining the malignant phenotype of the tumor cells. Oncoproteins are a category of antigens that may have all of these features. However, it has become apparent that even mutated tumor-associated antigens can be viewed as "self-antigen" by the body. As described above, the establishment of tolerance parallels the process of carcinogenesis. Moreover, carcinogenesis varies from one patient to another. None of the events are shared by all patients with a given tumor type including pancreatic cancer. Even for the same oncoprotein, different mutations may occur in different patients. Thus, it is almost impossible to employ the same oncoprotein peptide to vaccinate all patients even though the HLA type would not be considered as a variable factor. Finally, it would be wrong to assume that an oncoprotein plays a critical role in maintaining the malignant phenotype of the tumor cells at all times during tumor development and progression. With an instable genome, a tumor cell could easily acquire additional mutations which render the original oncogenic mutation dispensable for the maintenance of the malignant phenotype. It is not difficult to conceive that the resulted tumor variants, designated antigen loss variants, occur frequently under the pressure of immune surveillance. Therefore, it is unlikely that any single antigen would become an ideal vaccine target. Meanwhile, even an ideal vaccine needs to be combined with a treatment that can break the multiple mechanisms that contribute to immune tolerance.

DC-Based Vaccines

Several antigen pulsed DC vaccines have been designed for pancreatic cancer treatment. A phase I/II clinical trial of the vaccine composed of MUC1 peptide loaded DCs was tested in 12 patients with resected pancreatic cancer; however, most patients did not exhibit an overall increase in T cell functionality at the completion of the trial compared to pre-vaccine levels [74]. As mentioned earlier, DC vaccines have not been standardized between studies and between patients within a study. Therefore, the results of studies like these are difficult to assess due to interpatient variability as well as intrapatient variability of the administered treatments.

Mixed Antigens as Vaccine Targets

Personalized vaccines that target multiple tumor antigens have been explored as alternative approaches to overcome the need for knowing the best antigen or antigens to target in a given patient and to bypass the potential loss of expression of a single antigen. In one personalized vaccine approach, peripheral blood mononuclear cells and plasma were obtained from each individual patient to examine their cellular and humoral responses to 23–25 peptides prior to vaccination. Only the reactive peptides (maximum of four) were then administered to the patient. In a recent phase I/II study, gemcitabine was given intravenously once a week for three out of every 4 weeks, in sequence with the administration of three or four reactive peptides given once a week. Twenty patients with metastatic pancreatic adenocarcinoma were treated, resulting in a partial response in 5 patients and stable disease in 11 patients. The median overall survival was 8.5 months. Vaccination-augmented peptide-specific T cell responses and IgG titers were observed in 72% and 78% of the treated patients, respectively. Correlation between clinical responses and immune responses were not reported [75].

Another vaccine approach that potentially targets multiple tumor antigens is the heat-shock protein-peptide complexes. This vaccine approach takes advantage of the in vivo noncovalent binding between chaperone proteins and tumor antigens. When this complex is purified from tumors, both heat-shock proteins and tumor antigens are obtained. Such an approach has bypassed the requirement of knowledge of the exact tumor antigens when such knowledge is still scarce. Gp96 heat-shock protein – peptide complex (HSPPC-96) – is the best studied of these approaches. Immunization with gp96 peptide complexes led to their uptake by skin DCs through CD91 (a heat-shock protein receptor) followed by cross-presentation of the gp96-chaperoned peptides by the DCs and stimulation of T cells. Phase I/II trials with this approach in human melanoma, renal carcinoma, and colon carcinoma have demonstrated potential clinical activity, though the phase III trial in stage IV melanoma did not show significant survival benefit from this vaccine approach over physicians' choice of treatments. A phase I pilot trial of immunotherapy with autologous tumor-derived HSPPC-96 as an adjuvant therapy for resected pancreatic adenocarcinoma has also been completed. Six weeks after surgery, patients were given HSPPC-96 subcutaneously once a week for 4 weeks. At the time of the report, three of ten treated patients were alive without disease at 2.6, 2.7, and 5.0 years follow-up. Median overall survival was 2.2 years. This study demonstrates the feasibility of preparing HSPPC-96 from pancreatic adenocarcinomas. Nonetheless, autologous anti-HSPPC-96 ELISPOT reactivity increased significantly in only one of five patients examined. There was no observed correlation between immune responses and prognosis [76].

Thus, although personalized multi-antigen vaccine approaches are potentially attractive, they require either resected tumors to purify antigen-containing complexes or peripheral blood to identify reactive peptides. Similar to autologous whole-cell vaccines, such approaches would be less convenient and less reproducible for the clinical practice.

Allogeneic Whole-Cell Pancreatic Vaccines

Both autologous and allogenic vaccine approaches have demonstrated bioactivity in preclinical and clinical studies. Although autologous vaccines would insure that the most immune-relevant antigens are being employed for immunization for a given patient, it is not feasible to obtain enough autologous tumor cells for effective immunization of most patients with pancreatic cancers. Therefore, whole-cell allogeneic vaccines have become an appealing approach since few tumor antigens have so far been identified for pancreatic cancer. Three clinical trials testing an allogeneic GM-CSF secreting tumor vaccine approach alone and in combination with other targeted interventions in patients with resected and metastatic pancreatic cancer have been conducted and completed to date. More than 200 patients have been treated with multiple immunizations, and this approach has been shown to be safe and feasible for patients with all stages of pancreatic cancer. These studies have also demonstrated the safety of the vaccine when given in combination with a number of chemotherapeutic agents and radiation therapy. These studies are summarized below.

The phase I study of an allogeneic GM-CSF-secreting tumor vaccine in patients with resected pancreatic cancer was the first clinical trial to test the hypothesis that allogeneic GM-CSF secreting pancreatic tumor cell lines can prime a systemic immune response in patients with resected pancreatic adenocarcinoma. Fourteen patients with stage 2 or 3 disease received an initial vaccination 8 weeks following resection. This was a dose escalation study in which patients each received 10^7, $5X10^7$, 10^8, and $5X10^8$ vaccine cells. Study patients were jointly enrolled in an adjuvant chemoradiation protocol for 6 months and then given three additional vaccinations 1 month apart at the same original dose that they received for the first vaccination. Toxicities were limited to grade I/II local reactions at the vaccine site and self-limited systemic rashes. Systemic GM-CSF levels were evaluated as an indirect measure of the longevity of vaccine cells at the immunizing site. GM-CSF levels peaked at 48 h following vaccination. The vaccine sites were also evaluated as a measure of the local immune reaction to the vaccine. Eleven of 14 patients demonstrated a local inflammatory response. Postvaccination DTH responses to autologous tumor cells were observed in one of three patients receiving 10^8 and in two of four patients receiving $5X10^8$ vaccine cells [77]. The three DTH responders are the only long-term survivors, and all are still disease-free for more than 10 years. A follow-up phase II study of the GM-CSF-secreting pancreatic tumor vaccine has also been completed at Johns Hopkins Hospital in 60 patients with operable pancreatic cancer. Although the final analysis has not yet been reported, early analysis suggests that there is an overall survival benefit compared with historical controls [78].

The phase I allogeneic vaccine study provided an opportunity to identify candidate targets of the immune response. Immunized lymphocytes from the three disease-free survivors were used in a functional genomic approach to screen genes found to be overexpressed in pancreatic cancers. One gene product, mesothelin, has been reported to serve as a candidate target of T cells responses using this antigen discovery approach. Only the patients demonstrating disease-free survival benefit

also demonstrated a postvaccination induction of mesothelin-specific CD8+ T cells that remained detectable for up to 4 years following treatment without additional boosts [79]. Preliminary data suggests that CD8+ mesothelin-specific T cells are also detected in patients with prolonged disease-free survival in the follow-up phase II study [78].

The GM-CSF secreting, allogeneic vaccine alone and in sequence with immune-modulating doses of cyclophosphamide (Cy) were tested in a phase II study for patients with stage 4 pancreatic cancer who failed gemcitabine-containing chemotherapy. This trial was sponsored by Cell Genesys, Inc., and conducted at both Johns Hopkins Hospital and the US Oncology Group. This was a two-cohort, non-randomized study. Thirty patients in cohort A were administered with vaccines alone; and 20 patients in cohort B- 20 were administered Cy 250 mg/m^2 IV 1 day prior to each vaccination. The results demonstrated that the administration of a GM-CSF-secreting, allogeneic pancreatic cancer vaccine either alone or in sequence with Cy is feasible, safe, and tolerated by patients with advanced pancreatic cancer, the majority of which had received $\geq$2 prior chemotherapy regimens. The median number of vaccines administered was two to patients in cohort A and three to patients in cohort B. Treatment-related adverse events reported in more than 5% of patients included local vaccine injection site reactions, fever, rigors, and rash. Grade 3/4 treatment-related events identified in one patient included leukocytosis, dehydration, and fatigue. Thus, the toxicities (local and systemic) related to the vaccine alone or in sequence with Cy have been low grade and self-limiting. This study represents the first demonstration that integrating immunomodulatory doses of Cy with a GM-CSF-secreting vaccine in patients with advanced pancreatic cancer is safe and feasible to administer. Although this was not a randomized controlled study, stable disease lasting a median of 18 weeks was observed in 16.7% of patients treated by vaccines alone and 40% of patients treated by the combination of vaccines and Cy. Median survival was 2.3 months and 4.7 months, respectively, in a patient population that had received more than two prior chemotherapies. Unlike patients with resected cancers, mesothelin-specific T cell responses were detected at baseline in most patients treated on this study. In addition, there was a trend toward prolonged progression-free survival in those patients who demonstrated persistent and higher avidity mesothelin-specific T cell responses with therapy [80].

Based on early clinical studies, it is possible that allogeneic whole-cell vaccine approaches for pancreatic cancer treatment can bypass the prerequisite for knowing which antigens are dominant pancreatic cancer-associated antigens. However, it should be recognized that identification of dominant pancreatic cancer antigens is still crucial for the assessment of tumor-specific T cell responses and for the future development of multi-antigen targeted vaccine approaches for treatment and possibly prevention of pancreatic cancer. As mentioned above, the whole-cell vaccine approach provides a resource of patient materials for identifying dominant pancreatic cancer antigens. After dominant antigens have been identified, antigen-specific vaccines can be developed to test whether antigen-targeted approaches can induce more specific and more potent antitumor immune responses when the most dominant antigens are delivered in a non-antigen limited formulation. As mentioned above,

vaccines that target multiple specific antigens are the most ideal approach, which further underscores the importance of identifying dominant pancreatic cancer antigens through the use of whole-cell vaccine studies. Antigen-specific vaccines will be discussed in more detail below.

New Strategies for Pancreatic Tumor Whole-Cell Vaccine

Several studies are ongoing to improve on the current GM-CSF-secreting allogeneic vaccine approach. For example, it is still not clear how long to vaccinate following the initial immunizations that were given to patients on the original phase I and II studies conducted at Johns Hopkins. Therefore, a phase II study to evaluate the long-term boosting effect of the GM-CSF-secreting allogeneic pancreatic tumor vaccine is underway. Patients who are eligible for this study are those who have received the same vaccine through prior phase I and phase II trials and remain disease-free since the surgical resection of their primary pancreatic adenocarcinoma. Those who are vaccine naïve may also be eligible for boosters after first receiving four primary vaccinations on a monthly basis. All eligible patients will receive a vaccine boost every 6 months until they have disease progression, or withdraw from the study, or the vaccine source is consumed. The study has recently completed the accrual phase (Laheru et al., personal communication). Mesothelin-specific CD8+ T cell responses are being used to evaluate the induction and maintenance of vaccine-induced immune responses.

As another example, this same allogeneic vaccine approach is being combined with immune-modulating agents to determine if it is possible to improve on the overall outcomes if immune tolerance mechanisms are abrogated. As one example, a phase II trial of the GM-CSF-secreting allogeneic pancreatic tumor vaccine in combination with Erbitux (cetuximab) for the treatment of advanced pancreatic adenocarcinoma is underway at the Johns Hopkins Hospital to test whether cetuximab can enhance the immune priming capabilities of the vaccine. In this study, an immune-modulating dose of cyclophosphamide is also being given 1 day prior to each vaccination to inhibit T regulatory cells (Laheru et al., personal communication). As another example, this same vaccine was given in combination with the anti-CTLA-4 mAb in a pilot study testing the safety and induction of mesothelin-specific CD8+ T cell responses. The study population consists of 30 patients with locally advanced, unresectable, or metastatic pancreatic adenocarcinoma. This is a two-arm study in which 15 patients each received either (1) ipilimumab alone or (2) an allogeneic granulocyte-macrophage colony-stimulating factor (GM-CSF)-secreting pancreatic tumor whole-cell vaccine in combination with ipilimumab. Patients receive each treatment every 3 weeks for a total of four induction doses (weeks 1, 4, 7, and 10). At the week 22 evaluation, patients who have had evidence of a response or stable disease were offered the maintenance phase where they received the originally assigned treatment every 12 weeks. Subjects who had early progression followed by stable disease (SD) or better between weeks 14 and 22 were also eligible for maintenance phase treatments. CA19-9

declines in association with the combination treatment of GVAX and ipilimumab were seen for 7/15 patients. In contrast, 0/15 patients receiving ipilimumab alone had CA19-9 declines. Median overall survival (OS) was 3.7 months for arm 1 and 5.7 months for arm 2 ($p = 0.072$). The percentage of patients alive after 1 year also favored the combination arm (7% vs. 27%) [81]. The best RECIST response was SD in two patients in arm 1 and two patients in arm 2. Using the immune-related RECIST criteria, arm 2 had an additional patient with SD for 81 weeks. The quality of the responses in the two arms was different. Patients with SD on arm 1 had continuous disease progression that did not reach the 20% growth cutoff for 7 and 22 weeks. Arm 2 had three SD responses (one patient demonstrated a regression starting at week 14 that was maintained until week 31, another patient's disease stabilized starting at week 22 and was maintained for 81 weeks, and the third SD was maintained for 71 weeks while that patient was on study). This pilot study has supported the combination immunotherapy strategy for pancreatic cancer treatment.

In addition to the allogeneic whole-cell vaccine studies at the Johns Hopkins Hospital, studies with alpha-1,3-galactosyltransferase-expressing allogeneic pancreatic tumor cells represent another allogeneic vaccine. NewLink Genetics Corporation is conducting one phase II adjuvant study of low dose HyperAcute(R)-Pancreatic Cancer Vaccine in combination with chemoradiation and another phase II adjuvant study of standard dose HyperAcute(R)-Pancreatic Cancer Vaccine, both in subjects with surgically resected pancreatic cancer. HyperAcute(R)-Pancreatic Cancer Vaccine is a cancer vaccine comprised of irradiated allogeneic pancreatic cancer cells transfected to express murine alpha-1,3-galactosyltransferase, which results in the expression of murine alpha-1,3-galactosyl (alpha-gal) carbohydrate residues on cell membrane glycoproteins and glycolipids of the vaccine pancreatic cancer cell allograft. Murine alpha-gal epitopes, not present on human cells, induce a hyperacute rejection of the vaccine pancreatic cancer cell allograft. The hyperacute rejection involves the binding of pre-existing human anti-alpha-gal antibodies (which naturally occur against gut flora) to murine alpha-gal epitopes, resulting in the rapid activation of ADCC toward allograft cells. It is hoped that the host immune system will then attack endogenous pancreatic cancer cells, resulting in ADCC toward endogenous pancreatic cancer cells. The phase I trial and phase II trial had demonstrated the safety, feasibility, and potential efficacy of this vaccine in patients with surgically resected pancreatic adenocarcinoma [82]. Nevertheless, the efficacy of this vaccine failed to be substantiated by the phase III study comparing gemcitabine alone and gemcitabine in a sequential combination with the HyperAcute-Panceatic Cancer Vaccine.

Combination Vaccine Therapy

At Johns Hopkins Hospital, a phase I study of recombinant Listeria vaccine targeting mesothelin, which is overexpressed in pancreatic adenocarcinoma as mentioned above, was conducted for the treatment of mesothelin positive advanced malignancies including pancreatic adenocarcinomas. This therapeutic vaccine, CRS207, was

found to be safe and capable of inducing both innate and adaptive immunity to antigens. CRS207 was subsequently tested in sequential combination with GVAX and administrated to patients with metastatic pancreatic cancer. In this phase IIa trial for metastatic pancreatic cancer that progressed through multiple lines of chemotherapy, priming with GVAX followed by boosting with CRS207 was compared to GVAX alone [83]. Overall survival for all patients receiving GVAX + CRS207 was 6.1 months and significantly longer than 3.9 months for those receiving only GVAX. However, the phase IIb study comparing this combination vaccine platform versus CRS207 alone versus single-agent chemotherapy for metastatic pancreatic cancer as a second line or second line above therapy failed to demonstrate that GVAX + CRS207 or CRS207 alone would be superior over single-agent chemotherapy [84]. It should be noted that as many as 40% of the patients who were assigned to the arm of single-agent chemotherapy dropped off the study and the majority of them went to receive combinational chemotherapy regimens. Nevertheless, the GVAX + CRS207 combination vaccine strategy remains valuable as a vaccine platform for further clinical testing, particularly in combination with immune checkpoint inhibitors as described below.

Perspectives

Identification of New Pancreatic Cancer Antigen

The optimal cancer vaccine will target a panel of immune-relevant antigens specific for a given cancer type and be administered in sequence with relevant immune-modulating agents that bypass multiple mechanisms of immune tolerance. Thus, the search for defined pancreatic cancer antigens is still a high priority in the field of tumor immunology. An ideal pancreatic cancer antigen for the vaccine delivery must have the following characters. First, an ideal antigen is one that is specifically expressed by tumor cells relative to normal tissue. A vaccine based on such an antigen may spare the attack of normal cells by vaccine-induced immunity and may be less susceptible to immune tolerance. If mutated gene products are expressed in neoplasm and subsequently neoepitopes are recognized by T cells, they may become neoantigens. A vaccine based on neoantigens is likely less susceptible to immune tolerance. However, the patient's immune system must be tolerant to these neoepitopes; otherwise, it would not have allowed the neoplasm to grow. The major tolerance may lie in the barriers for T cells recognizing neoepitopes to traffic into the tumors. Therefore, an effective immunotherapy must overcome these barriers. Second, as discussed above, it might be a wrong assumption that mutated antigens are not recognized as self-antigen by immune surveillance mechanisms. In fact, non-mutated antigens may have some advantage over mutated antigens. Specifically, a vaccine designed based on a non-mutated antigen may be applicable to many patients, whereas vaccines designed based on a mutated antigen must be individualized. Third, the best antigens, whether mutated or not, should be critical for the development and maintenance of the malignant phenotype. However, an antigen that

is only critical for a certain step in the tumorigenesis process may not be the best target. As discussed above, tumors may develop antigen loss variants once this step of tumorigenesis has occurred.

Identifying candidate pancreatic tumor antigens has been a great challenge. Although there have been a number of genetic- and protein-based approaches that have attempted to identify all types of tumor antigens, few have succeeded. Several approaches have identified a large panel of melanoma-associated tumor antigens. One approach utilized cDNA libraries to T cell clones isolated from growing melanomas. A second approach utilized similar T cell clones to screen antigenic peptides eluted off of HLA molecules and purified by HPLC and mass spectrometry. Although they are important approaches, both had limitations. Specifically, T cell clones were required to identify specific antigens, yet few T cell clones exist against most cancers. Second, these approaches were labor intense and did not necessarily yield generalizable antigens. Finally, both approaches used lymphocytes from patients with actively developing tumors and thus may not have identified the most immune-relevant antigens that serve as the best targets of immune response.

A number of recent approaches that utilize immunized reagents from responding patients and are more rapid methods of antigen identification have been employed to identify pancreatic tumor antigens. One approach uses differential gene analyses to identify genes that are highly expressed in pancreatic cancer relative to normal tissue. As one example, a serial analysis of gene expression (SAGE) approach was employed to identify genes overexpressed in pancreatic cancer [85]. Using this approach and immunized lymphocytes from an allogeneic, GM-CSF-secreting vaccine clinical trial, this group identified mesothelin as a candidate target [79]. Mesothelin is rarely expressed in normal cells, but is highly expressed in several malignancies including near 100% of pancreatic adenocarcinomas. It is a transmembrane glycoprotein member of the mesothelin/megakaryocyte potentiating factor (MPF) family. Recent studies suggested that the function of mesothelin may be important for cancer cell proliferation and migration.

Once a target is identified, it is important to design a series of studies to validate the role of the target as a predictor of who will and who will not respond to a therapy. It is also important to confirm that the target is indeed recognized by immunized T cells. The CD8 T cells from the patients who have received the GM-CSF-secreting allogeneic whole-cell vaccines thus provided materials to evaluate the immunogenicity of mesothelin in pancreatic cancer patients. The immunologic analysis of the patients in the phase I allogeneic pancreative vaccine trial demonstrated that only the three patients who are long-term survivors and also demonstrated a postvaccination DTH response to autologous tumor cells at 28 days following vaccination also demonstrated a postvaccination induction of $CD8^+$ T cells to the mesothelin epitopes predicted by computer algorithms. This difference in detection of mesothelin-specific T cell responses was statistically significant at a $p < 0.001$ by the fisher exact test. These data suggested that it is possible to use mesothelin responses as a predictor of vaccine response in pancreatic cancer patients. In addition, this analysis

demonstrated that $CD8^+$ T cells from one of the patients recognized the natural epitope expressed by the pancreatic tumor [79]. These findings require further validation in larger clinical trials to confirm the value of this antigen as an immune-relevant target of the immune responses.

As discussed above, the identification of mesothelin as a pancreatic tumor antigen has led to the development of mesothelin-specific vaccines, which have been tested in preclinical and clinical studies. As aforementioned, mesothelin is also a target of passive immunotherapy with anti-mesothelin antibodies. These studies and future antigen-targeted studies will provide the critical patient reagents to confirm that mesothelin is indeed an immune target expressed by pancreatic cancers.

A second approach is to take advantage of humoral response in cancer patients and to use their sera to screen antigens. A number of proteomic-based approaches have been used for this purpose. Serological analysis of recombinant cDNA expression libraries (SEREX), serological proteome analysis (SERPA), and protein microarray technology are all being employed. Some tumor-associated antigens were identified by SEREX in the 1990s. With the development and wide application of mass spectrometry technology, SERPA have been used more frequently. Such an approach can employ the vaccine cells themselves as the proteome or other cancer cells. The whole-cell extract from cell lines can be fractioned by techniques such as isoelectric focusing (IFE) and separated by 2D protein electrophoresis (2DE). Immunoblots can then be used to screen immunized sera. Although few pancreatic tumor-specific antigens have been identified using these approaches to date, it is expected that these approaches will identify new immune targets and potential biomarkers in the near future.

Current Developments of Immunotherapy

Focus on Targeting Immune Checkpoints

The current development of immunotherapy is focus on developing strategies that overcome immune tolerance, in particular, strategies that target immune checkpoints (Table 1, Fig. 3). As discussed above, agents that target various mechanisms of immunosuppression have been developed and are currently being investigated in preclinical models or in human studies.

As described above, ipilimumab, a monoclonal antibody that blocks CTLA-4, was approved in 2013 by the FDA for treating advanced melanoma and has become the first immune checkpoint inhibitor indicated for the treatment of cancer diseases. Since 2014, PD-1 and PD-L1 blocking antibodies have been approved by the FDA to treat melanoma, non-small cell lung cancer, renal cell carcinoma, squamous cell carcinoma of head and neck, bladder cancer, and Hodgkin's lymphoma. Immune checkpoint inhibitors as a single agent were shown to induce objective responses in approximately 20–30% of patients with these FDA-approved indications. Half of these responses are durable [86]. However, blocking CTLA-4 and PD-1/PD-L1 as

single therapy has not been effective for pancreatic cancer. How to sensitize pancreatic cancer for immune checkpoint blockade treatments is a priority focus [86].

Focus on Combinatory Therapies

Immune checkpoints targeting agents alone are not ideal treatment strategies for pancreatic cancer and for many other cancers. Pancreatic cancer and checkpoint inhibitor-insensitive cancers are characterized by their immune quiescent tumor microenvironments which are lack of effector immune cell infiltration. On the other hand, vaccines activate tumor-specific T cell immunity and induce the infiltration of effective immune cells. If the vaccine approach is combined with immune modulators, the combinatorial therapy may have a synergistic effect on antitumor T cell activation. Indeed, such a synergy is supported by several preclinical studies. On another hand, the safety of cancer vaccines is supported by most studies that have been so far conducted. The combinatorial therapy is not expected to add any toxicity to that already observed with either agent.

Recently, a study of GVAX given as both neoadjuvant and adjuvant therapy for resectable pancreatic cancer, either alone or with immune-modulating doses of cyclophosphamide to deplete regulatory T cells, was completed [87]. Pathological examination of pancreatic tumor tissue resected just 2 weeks following a single neoadjuvant dose of GVAX identified the formation of novel vaccine-induced, immunologically active, tertiary lymphoid aggregates, organized lymph node-like structures that are not observed in tumor tissue resected from unvaccinated patients. However, activated T cells secrete interferon-γ, which in turn upregulates the PD-1/PD-L1 pathway. These data support an emerging concept that vaccines are required to induce a T cell response that is capable of infiltrating the tumor's microenvironment. However, vaccination is just the first step toward establishing an effective antitumor immune response, converting the pancreatic cancer's tumor microenvironment into an environment similar to what is observed in melanomas exhibiting infiltrating but immunosuppressed T cells prior to immunotherapy treatment. Thus, treatment with GVAX primes the pancreatic cancer's tumor microenvironment for anti-PD-1/PD-L1 antibody therapy. This concept was further supported by demonstrating in a preclinical model of pancreatic cancer that combining anti-PD-1 or anti-PD-L1 antibodies with GVAX enhances the infiltration of effector T cells into pancreatic tumors as well as the cure rate in pancreatic tumor-bearing mice [54, 88]. Thus, vaccination can prime previously unresponsive tumors to become an immune responsive tumor and open the door for novel combination immunotherapies for the majority of immune quiescent tumors.

The above concept has been further developed into a combination immunotherapy strategy, which is being tested in multiple clinical trials for pancreatic cancer including one to test the combination of GVAX + CRS207 and nivolumab for metastatic pancreatic cancer; one to test the combination of GVAX, pembrolizumab, and stereotactic body radiation for locally advanced pancreatic cancer; and one to test the combination of GVAX and nivolumab as neoadjuvant and adjuvant therapy for resectable pancreatic cancer [86].

Optimal Predictors of Antitumor Immune Response

As an immunotherapy does not attack tumor cells directly, but through activating the immune system, it is critical to assess the immune response in every study of immunotherapy. In particular, it is important to ask if the vaccine causes an immune response and if there is any evidence of a clinical response associated with the induced immune response. It might be straightforward to assess the immune response induced by the peptide vaccines, which already have pre-defined immunogenic epitopes. In contrast, it would be more difficult to assess the immune response induced by a whole protein antigen or a whole-cell vaccine. Thus, the recent identification of new targets of the immune response as well as the recent development of new technologies that will allow the identification of new targets in the future should facilitate the assessment of immune-based therapies in treated patients.

As one learns more about immune responses in patients, it is becoming clear that assessing the number of induced T cells is not enough to predict whether a treatment is effective. Traditionally, methods such as ELISA and ELISPOT assays have been used to assess the number and cytokine production of treatment induced T cells. However, more recently, preclinical models have suggested that other parameters such as T cell avidity or potency might be a better predictor of an optimally functioning T cell [89]. The identification of mesothelin as an immune-dominant antigen provides a surrogate marker for immune analysis of the whole-cell pancreatic tumor vaccine. So far, the studies of mesothelin epitopes have also provided an opportunity for better understanding the T cell response in a comprehensive manner. Using dilutional tetramer technology that has recently become available, an analysis of T cell avidity was performed in selected patients from the above described phase II pancreatic GVAX study in metastatic pancreatic cancer. In this pilot study, it was found that the avidity of posttreatment T cells specific for mesothelin epitopes correlated with overall survival. Thus, it will be interesting to assess if the avidity of T cells can serve as an even better predictor of clinical responses in patients receiving adjuvant pancreatic vaccines.

Another challenge that needs to be addressed is whether the analysis of T immune responses targeted at a single antigen can predict who will and will not respond to therapy. Different patient may have different antigen-specific T cell responses depending on a number of factors including the dominant antigens expressed by their tumors and the mechanisms of tolerance that are suppressing the different T cell populations. The same can be said for humoral responses to tumors. It is also not clear which type of responses are most predictive of clinical responses. T cell responses are difficult to analyze with current technologies, especially since it is not clear what parameters of a T cell best predict their activity. Humoral responses, however, are much easier to assess and more standardized. It is likely that analysis of both T cell and humoral responses will require assessing responses to a panel of antigens specific to a given tumor type.

Finally, there is yet an even greater challenge to overcome. The vast majority of studies have examined only T cell or antibody responses in peripheral blood, which

may not always correlate with a patient's response to their tumor. It is very difficult to access most primary or metastatic tumors, especially pancreatic tumors. However, future studies will need to take on this challenge and build in mechanisms by which to sample pancreatic tumors. This is best done by acquiring both pretreatment and posttreatment samples through tumor biopsies. Designing neoadjuvant studies can also allow access to treated tumors. It is important to point out that these patients are providing the scientific community and other patients with the most valuable of resources to better understand this cancer.

Evaluating Clinical Response in the Immunotherapy Studies

It is proposed that cancer vaccines are a therapeutic modality where one should evaluate "patient response" more so than tumor response. It has been argued that standard criteria for tumor response assessment such as RECIST criteria may not be appropriate for the evaluation of immunotherapy. This debate is exemplified by the above described Sipuleucel-T studies did not meet the primary endpoint of disease-free survival, although overall survival was found to be improved by the immunotherapy with a statistical significance [90]. Such a phenomenon has become more common for immunotherapy than anticipated. Immunotherapy does not target tumor cells directly, but through activating the immune system. It is possible that an immunotherapy may induce a durable immune response which eventually suppresses the tumor growth, but is not strong enough in the beginning to cause tumor regression in most of patients. These patients would have been considered to have disease progression and taken off the study based on the RECIST criteria. In addition, it is also possible that some immune-based therapies cause an increase in tumor burden radiographically initially, due to an immune infiltrate, even though the patient feels symptomatically improved. Now, it is known that this is a pseudo-progression that is not uncommon among patients who are receiving immune checkpoint inhibitors [40]. Therefore, immune-related RECIST criteria have been developed for evaluating patients' response in clinical trials of immunotherapy. In some clinical trials, asymptomatic radiographic disease progression may be allowed to keep the patients on study. As long-term clinical outcome are often not predictable early during the course of immunotherapy, how to evaluate clinical responses in immunotherapy studies is still quite challenging and remains to be improved.

Individualized Immunotherapy

Immunotherapy is very different from traditional chemotherapy based on the range of toxicities and the diversity of host responses to the therapy. It is not difficult to conceive that, even to the same tumor, each individual may have a different immune response. It should also be recognized that any of immunotherapy approach may

only be effective in a portion of patients. Thus, the importance of predicting immune responses in the patients receiving immunotherapy is underscored. If a patient's immune response to a particular therapy can be predicted, the next step is to individualize the immunotherapy and design a personalized therapy for this patient. In the future, all immunotherapy studies should be designed toward a defined patient population. One can thus envision that immunotherapy will be customized for delivery to patients based on a panel of antigenic targets specific for a given tumor and on a panel of immune checkpoints that are specific to both the cancer type, cancer stage, and even the individual patient.

Conclusion

Key Research Points

- Recent advances in the tumor immunology field of research have enriched our knowledge of how tumor cells evade immune surveillance and antitumor immunotherapy. Such mechanisms of immune tolerance have been recognized, including:
  - Alterations in T cell signal transduction and cytokine regulation.
  - Tolerance induced by regulatory dendritic cells (DC) and regulatory signals of DC differentiation.
  - Downregulation of co-stimulatory signals.
  - Induction of co-inhibitory signals.
  - Immunosuppressive cells such as regulatory T cells (Tregs), myeloid-derived suppressor cells (MDSC), and tumor-associated microphage.
  - (TAM) altered metabolism in immune cells.
  - The role of the tumor microenvironment in the establishment of immune tolerance is highlighted.

Future Scientific Directions

The future research of pancreatic cancer tumor immunology and immunotherapy should be focused on:

- Identification of new pancreatic cancer antigens
- Development of strategies that target immune checkpoints
- Development of combinatorial therapies of vaccines and immune modulators
- Development of biomarkers for the prediction of antitumor immune responses to new therapies
- Establishment of new criteria to evaluate clinical responses in immunotherapy studies
- Individualized immunotherapy

Clinical Implications

The following strategies of pancreatic cancer immunotherapy are being developed and are under preclinical and clinical testing:

- Monoclonal antibodies
- Adoptive T cell transfer
- Antigen-specific vaccines including peptide vaccines, recombinant vaccines, and dendritic cell-based vaccines
- Allogeneic, GM-CSF-secreting, whole-cell vaccines
- Targeted agents specific for immunologic checkpoints
- Chemotherapy as immune modulators
- The combination of different immunotherapy strategies

Abstract

Pancreatic cancer surgery has undergone considerable changes during the last decades. While it has been associated with high morbidity and mortality in the 1970s and 1980s, improvements in preoperative diagnosis, perioperative management and surgical techniques have made pancreatic resections highly standardized, safe procedures. Centralization of pancreatic surgery at high volume hospitals has contributed significantly to these developments. In particular, the development of interventional radiology has allowed for non-operative management of complications after pancreatic surgery. Further improvements may be achieved through minimally-invasive approaches using laparoscopy and/or robotic resections. Milestones in long term outcome improvement were the studies of the ESPAC group which demonstrated that adjuvant chemotherapy is highly beneficial for all pancreatic cancer patients, regardless of their tumor stage. The latest ESPAC study demonstrated further improved outcomes with simple adjuvant treatment through a combination of gemcitabine and capecitabine. There has also been exciting progress in the therapy of borderline resectable pancreatic cancer. Neoadjuvant protocols using Folfirinox chemotherapy with or without sequential chemoradiation showed promising response and resection rates. Future studies will assess novel approaches in prevention of postoperative pancreatic fistula rates, in more intensive multimodality treatment and in early diagnosis to improve prognosis.

PF	Pancreatic fistula
RCT	Randomized controlled trial

Introduction

Pancreatic cancer surgery has considerably evolved during the last 30 years. Bramhall and colleagues have analyzed treatment and survival in 13.560 patients with pancreatic cancer from 1957 to 1986 from the West Midlands Region Cancer Registry [1]. Two 20 year time periods (from 1957 to 1976 and 1977 to 1986) were analyzed. Resection rates were only 2.6%. Interestingly, 30 day postoperative mortality decreased from 45.2% to 27.6%, whereas 1-year survival increased from 23.8% to 30.6%. Chemotherapy or radiochemotherapy were very rarely used in both periods with 1.9% and 0.9%, respectively. 1-year survival in the overall cohort was 1.3% and

2.0%. These data exemplify the vast progress that pancreatic cancer surgery has made in the past. They show an extremely low rate of resection and of overall survival and that surgery was the only treatment option available. Chemotherapy or chemoradiation were almost never used. Bramhall et al. thus concluded that "the present approach to treating pancreatic cancer in the United Kingdom leaves considerable room for improvement". Interestingly, they also argued that cases suitable for resection should be centralized, e.g. that considerably more cross-referrals should occur than at that time. A similar paper had been published by Michelassi in the Annals of Surgery in 1989 where they described their experience with 647 consecutive pancreatic cancers [2]. They described 90 partial resections and 29 total pancreatectomies. Perioperative mortality was 19% and 5-year survival was low with a total of 14% in all groups. These data demonstrated that surgery was the only hope of cure for pancreatic cancer. However, at that time it was mainly restricted to tumours of the head of pancreas because those of the body and the tail were usually diagnosed late, when metastases had already occurred. Thus, many papers from the 1980s concluded that early diagnosis of pancreatic cancer would be the way to go. Safi and co-authors in 1986 published a paper where they analyzed the importance of CA 19-9 for the prognosis and potential early diagnosis of pancreatic cancer. They demonstrated that 92% of all pancreatic cancer patients had an elevated CA 19-9 of above 37 U/ml, whereas CA19-9 was usually not increased in benign pancreatic diseases. Importantly, they also demonstrated that CA 19-9 was a valid follow-up marker after resection. However they could not clarify whether CA 19-9 was a good marker for early stage carcinoma (stage T1 – T2) [3]. The significant progress made in pancreatic cancer surgery and also in multimodal treatment is best demonstrated when comparing the Kaplan-Meier survival curves from the paper by Michelassi [2]and by the most recent data from the ESPAC trials. While in Michelassi's publication, 5-year survival was 8.8%, current 5-year survival with surgery and adjuvant chemotherapy is 28.8% [4]. The milestones of evolution of pancreatic cancer surgery that have allowed such an increase of 5-year survival rates are the recognition of the importance of centralization of cases, of improved perioperative management and surgical techniques, as well as the more wide-spread use of adjuvant chemotherapy. Most recently, improvement of outcomes for patients with stage 3 and "advanced" stage 2 disease has become a center of interest of international surgical research efforts. Here, novel polychemotherapy regimens in neoadjuvant treatment for locally advanced and borderline resectable cancers offer the hope of further increasing survival rates of these specific subgroups of patients.

Specific Aspects of Evolution in Pancreatic Cancer Surgery

Center Effects

Since the early years 2000s it has become obvious, that centralization of pancreatic cancer surgery significantly improves outcomes after resection. In this respect, John Birkmeyer and collegues have published a landmark paper in the New England Journal of Medicine in 2002 [5]. They analyzed mortality after complex surgical procedures in centers compared to outcomes in regional hospitals. Centers were

defined depending on the number of procedures performed per year. This number depended on the type of procedure performed where for example in colectomy the highest volume centers were defined as those performing more than 124 procedures per year whereas for pancreatic resections high volume centers were defined as those performing more than 61 resections per year. Center effects were most pronounced for complex procedures such as esophagectomies and pancreatic resections. In pancreatic resections, postoperative mortality ranged from 14% to 16% in hospitals where one to two yearly resections were performed to less than 3.8% in those institutions where more than 60 procedures were performed. These data were updated in 2011 and again published in the New England Journal of Medicine [6], demonstrating a decreasing mortality by 19% conferred to a center effect – explained by increased hospital volumes. There were two major reasons underlying these effects, one was that in general more patients were operated on diseases of the pancreas in the US while at the same time there was a centralization of patients to higher volume hospitals. The paper also demonstrated that not only should patients be operated on at high volume hospitals but that at those hospitals outcomes were further improved when high volume surgeons were selected to perform the operation. The most recent publication in this aspect comes from Lidsky and co-authors [7] where 7,806 pancreatic cancer patients were analyzed. Of those, 773 travelled a short distance to a low volume hospital for surgery whereas 758 travelled a long distance to a high volume center to have their pancreatic cancer operation. Thirty and 90 day mortality was significantly lower in the long travel high volume hospitals with two versus 6.3% and 6.5% versus 11.3%, respectively. In addition, the authors demonstrate that the rates of negative margin resections were lower in the high volume hospitals. These effects also translated into long term survival were travelling a long distance to a high volume center was beneficial for overall survival. The authors conclude that these data support ongoing efforts of centralized care for patients undergoing pancreatic cancer surgery.

In conclusion, centralization of pancreatic cancer surgery has had an enormous effect on short and long term outcomes and efforts will be necessary to further improve outcomes by centralizing pancreatic cancer care.

Adjuvant Therapy

One of the most important groups that significantly contributed to the improvements in pancreatic cancer outcomes is the European Study Group for Pancreatic Cancer (ESPAC). Founded in 1992, its initial aims are still valid with the development of an international scientific exchange forum, of combination and consolidation of current pancreas cancer research and the management of collaborative research efforts. As described above, there was no real standard of adjuvant therapy for resectable pancreatic cancer in the early 1990s. The ESPAC group thus developed the ESPAC-1 trial where 541 patients were randomized (in a 2×2 factorial design) into the following adjuvant treatment arms: chemotherapy versus no chemotherapy, chemoradiation versus no chemoradiation [8]. In essence, this landmark study

demonstrated that adjuvant chemotherapy significantly increases survival as compared to no chemotherapy. Interestingly, survival was worse with chemoradiation than with no chemoradiation. This has led to a change of clinical practice (at least in Europe), where adjuvant chemotherapy has become standard while adjuvant chemoradiation has been almost universally abandoned. The next step was the ESPAC-3 trial which compared adjuvant chemotherapy with 5-FU (the "novel" standard from the ESPAC-1 trial) with gemcitabine. Here, 5-FU and gemcitabine were shown to be equally effective [9]. The most recent ESPAC-4 study compared adjuvant gemcitabine with gemcitabine plus capecitabine, demonstrating even better survival in the combination chemotherapy arm. Median survival with gemcitabine and capecitabine was 28 months, compared to 16 months with gemcitabine alone [4]. Thus, the current standard of care in adjuvant pancreas cancer treatment should be this combination chemotherapy protocol. These data again exemplify the enormous progress that has been made in pancreatic cancer treatment and the importance of international collaborations to achieve the goal of performing high-quality multicentre studies with the aim to create evidence and practice-changing results.

Neoadjuvant Approaches

Neoadjuvant treatment for pancreatic cancer has been carried out in an extremely low number of patients for a long time. There were several reasons for this, of which the main reason was that there was no effective chemotherapy or chemoradiation to allow for downstaging of the tumor. With the advent of the polychemotherapy regimen with Folfirinox [10], many efforts started to evaluate the efficacy of Folfirinox in patients with borderline resectable or locally advanced pancreatic cancer. Very recent data from several institutions world-wide [11–14] have demonstrated response rates of up to 60% with FOLFIRINOX and of about 50% with Gem-Abraxane (Gemcitabine plus albumin-coupled Paclitaxel). Pre-treatment with Folfirinox has also revitalised extensive surgical approaches with arterial resections and reconstructions, which had been almost abandoned for a long time because of high mortality and low oncological effectiveness [15]. After pre-treatment however, quite some groups have demonstrated that negative margins can be achieved with extensive resections [16], including the hepatic or superior mesenteric artery – and more often than not, also the superior mesenteric/portal vein. Further research into outcomes after these very specific and aggressive resections is necessary to define their value for patients with stage 3 or advanced stage 2 disease (after neoadjuvant treatment).

Laparoscopic Distal Pancreatectomy

Laparoscopic and robotic approaches are increasingly performed for all indications in pancreatic surgery [17]. DP as the most commonly performed type of minimally invasive resection is regarded as a standard today although concerns regarding oncological radicality are still discussed controversely and there is still no high-level

evidence that laparoscopic DP offers advantages although available studies have shown that it may be superior to open DP in terms of blood loss and hospital stay [18]. As laparoscopic DP was initially preferred in benign indications and small pancreatic lesions offering a technically easy operation [19]. Consequently, the available data on laparoscopic DP for PDAC are still limited but steadily increasing. One of the earliest studies [20] was published by Patterson and colleagues in 2001, demonstrating morbidity rates comparable to open surgery series but a shorter length of hospital stay. The authors concluded that laparoscopic distal pancreatectomy appears to be safe for benign diseases. A large number of mainly single-center experience reports followed, of which Table 1 shows an overview [21, 22]. Because of an increasingly standardized and internationally comparable technical approach, recent research has focused on extending the indications for laparoscopic distal pancreatectomy, on improving oncological outcomes and on analysing cost-effectiveness. The most recent Cochrane meta-analysis confirmed that laparoscopic distal pancreatectomy seems to be beneficial in many aspects but that data quality is low and that randomised trials are urgently needed to better define the value of the minimally-invasive approach [18].

Laparoscopic Pancreaticoduodenectomy

Minimally-invasive PD for PDAC has not gained widespread acceptance yet, however, the numbers of this procedure are increasing. However, it is a technically demanding operation with a considerable learning curve. In addition, experience with advanced laparoscopy is almost mandatory but is not yet reflected in the curricula of most of the HPB fellowship programs. Thus, only few surgeons worldwide have accumulated relevant numbers of laparoscopic pancreato-duodenectomies

Table 2 Studies on open and laparoscopic pancreato-duodenectomy including ≥30 patients

	Type of PD	No. of patients	Operation time	PF	DGE	Mortality	Hospital stay
Wellner et al. [34]	Open	40	410 min	28% (B/C)	28% (B/C)	0	16 days

nm not mentioned

(Table 2). In such centers, outcomes of open and laparoscopic Whipple procedures are comparable in terms of safety of the procedure and of postoperative morbidity. However, it has to be noticed that in most series, considerably longer operation times are reported and laparoscopic procedures are associated with higher costs in terms of technical devices. How far these disadvantages can be compensated by an enhanced postoperative recovery of the patients and a potentially shorter hospital stay remains unclear as the currently available studies show trends but allow no definite conclusions (Table 2). Furthermore, long term oncological outcomes are not clear and further analyses are required to define whether oncological results will be adequate as well as to confirm the above-mentioned potential advantages (i.e. in terms of blood loss or shorter hospital stay) in randomized controlled trials which are not available to date.

Robotic Resections

While robotic distal pancreatectomy is performed at quite some centers world-wide (Table 3), only a few surgeons have adopted robotic pancreato-duodenectomy. However, there are some institutions where this procedure is performed at significantly increasing numbers and where outcomes are comparable to open surgery. Most recently, a multi-institutional analysis from the US compared results of open and robotic pancreato-duodenectomy [36]. The authors performed a multivariable analysis that demonstrated longer operative times with robotic resections, but reduced blood loss and less major complications. Mortality, rates of clinically relevant pancreatic fistula rates, length of hospital stay and readmission rates were comparable. In terms of oncological radicality, the operative approach was no predictor of margin status or the number of lymph nodes harvested. However, long term data of outcomes after robotic pancreaticoduodenectomy for pancreatic cancer

is still missing. These data will be of enormous importance to define the value of robotic resections in pancreatic surgical oncology.

Perioperative Management

The evolution of perioperative management is characterized by efforts to improve routine procedures and to create evidence in randomized controlled trials. Important achievements in this field include routine preoperative biliary drainage for jaundiced patients, routine intraoperative drain placement as well as nutritional management and complication management.

Pre-operative Biliary Drainage

For many years, pre-operative biliary drainage in jaundiced pancreatic cancer patients had been an intensively discussed issue. Some studies suggested that all patients should have biliary stenting to relieve jaundice while others suggest to drain almost no patient – unless there was significant impairment of liver function or the presence of clinically relevant cholangitis. In 2010, a randomized trial on biliary drainage versus no drainage was published in the New England Journal of Medicine, demonstrating that routine biliary stenting in patients with bilirubin levels less between 2.3 and 14.6 mg/dl was associated with significantly more postoperative infectious complications (mainly wound infections) than in the group of patients who underwent surgery right away [42]. This paper has changed clinical practice in

that routine pre-operative biliary drainage in jaundiced patients should not be performed anymore. However, it is mandatory to proceed with surgery as quickly as possible. Because this is not possible in many health systems world-wide, biliary stenting still is performed at considerable numbers. A future question will thus be whether prophylactic antibiotic treatment will be of value in this particular group of patients.

Placement of Intra-abdominal Drains in Pancreaticoduodenectomy

In most centers, the routine placement of intra-abdominal drains is performed for every type of pancreatic resection. For PD, this approach has recently been challenged on the basis of two randomized trials [40, 43]. Both studies showed that a routine drainage placement is not beneficial in terms of complication prevention and consequently a selective drainage use should be preferred. In contrast, another trial published in 2014 [44], showed a negative effect of drain omission with an increase in severe postoperative morbidity and even mortality. However, the findings of this trial may be interpreted with caution as the multicenter setting may have caused a bias. Most recently, an RCT from several German centers [43] clearly demonstrated that there is no need for routine placement of drains in pancreaticoduodenectomy. In particular, there were comparable numbers of re-interventions, of in-hospital mortality and morbidity. Rates of clinically relevant postoperative pancreatic fistula and fistula-associated complications were significantly lower in the no-drain group. In conclusion, there is level 1 evidence that no drains should be placed in pancreaticoduodenectomy unless very specific conditions may force the surgeon to do so.

Management of Postoperative Complications

Pancreatic surgery has shown a significant decrease in postoperative morbidity and mortality during the last decades. Historic mortality rates ranging between 20% and 50% have continuously decreased which is not only attributed to surgical progress but also to developments in complication management. Although rates of postoperative pancreatic fistula still remain relatively high, this potentially life-threatening event has been turned into a manageable complication in most patients [45]. A variety of factors has contributed to the enormous reduction in fistula-associated deaths. First and foremost, advances in interventional radiology have allows for a reduction of re-operations which were (and are still) associated with considerable mortality. The most important intervention is the CT-guided drainage of postoperative fluid collections around the pancreatic anastomosis – which are in the vast majority of cases a result of a pancreatic fistula – combined with effective antibiotic therapy [46]. In addition, postoperative haemorrhage as a result of a persisting pancreatic fistula has become a much rarer complication; and, once it occurs, this problem can frequently be dealt with through interventional coiling or stenting [47]. More and more experience with complex cases in centers with high number of yearly

cases has also allowed for much earlier recognition of postoperative complications [48]. Consequently, modern PDAC surgery is shifting towards extended resections, including vascular resections as well as multivisceral approaches, as even these operations can be performed with good perioperative results and are feasible in experienced hands today.

Elderly Patients

While advanced age has been considered a contraindication to extensive pancreatic surgery for a long time, many recent reports demonstrate that pancreatic resections can be performed safely even in octogenarians [49, 50]. However and as with younger patients, co-morbidities need to carefully weighed against the potential benefit conferred by resection of the tumor [51]. If these precautions are not taken pre-operatively, morbidity and mortality tend to be significantly higher in patients older than 80 years.

Resection of Precursor Lesions

One of the most exciting fields in pancreatic surgery in the last decade has been the evolution of treatment of cystic lesions of the pancreas. Because of higher resolution and more widely available imaging, the incidence of pancreatic cysts (mainly IPMNs) has increased dramatically [52]. This is particularly challenging because the vast majority of these cystic lesions are benign, while at the same time, these lesions are the only clinically relevant precursors of pancreatic cancer. Thus, surgical resection of the pre-malignant proportion of these cysts allows for the first time for true early diagnosis and treatment of pancreatic cancer; this is in turn the only truly curative approach for a subgroup of patients (not yet) suffering from this disease – and could thus be called prophylactic pancreatic cancer surgery. However, there are a large number of obstacles. Firstly, a clear pre-treatment diagnosis of the exact cystic entity can often not be achieved. This holds particularly true for side branch IPMN which are the most common (suspected) entity found on cross-sectional imaging. Secondly, it remains very difficult to judge the malignant potential of many of the cystic lesions that are usually incidentally detected; unless clear features for a high risk of malignancy are identified. Such features have been classified in the most recent consensus criteria for IPMN, called the Fukuoka criteria. Here, a group of worrisome features and of high risk stigmata were defined, where the latter carry a high enough risk of malignancy to justify immediate resection [53]. Besides this consensus statement, the European guidelines for the management of cystic pancreatic lesions [54] have approached the management of these precursor lesions. Despite these publications, there is ongoing controversy regarding the timing and extent of surgery, especially in branch duct IPMN and this is one of the most evolutionary fields at the moment and the potential to prevent pancreatic cancer development by precursor resection at the correct point of time is a unique chance to improve the fatal prognosis of this disease.

Conclusion

In the last two decades, pancreatic cancer surgery has become an instrumental and central part of abdominal surgical oncology. While it had once been associated with unacceptably high rates of morbidity and mortality, highly standardized surgical techniques and tremendous advances in perioperative management have allowed to make these resections very safe and effective procedures. Certainly, the advancement of interventional radiology has greatly contributed to this development. Adjuvant treatment has also been transferred from an experimental approach to daily clinical practice and has significantly increased survival in the group of resected pancreatic cancer patients. Neoadjuvant treatment with multimodality regimens or with poly-chemotherapy seems to have similar effects in the group of patients deemed unresectable for a long time. Further detailed research will however be necessary to determine the true value of pre-operative treatment in pancreatic cancer. Resection of cystic lesions and in particular of IPMN has for the first time allowed for resection of a precursor of pancreatic cancer. As with neoadjuvant treatment, many areas of uncertainty remain and international, multi-center efforts will be required to operate on more patients with potentially malignant cystic lesions while not operating on those with truly benign cysts.

Abstract

The recent revolution in cancer genetics offers the promise of using genetic information to individualize patient treatment. In pancreatic cancer, numerous studies have described a genetic landscape characterized by a set of commonly mutated genes aggregated into core molecular pathways accompanied by numerous but infrequently mutated genes. Studies have also demonstrated significant intratumoral heterogeneity. Resistance against chemotherapeutic agents has also been attributed to difficulty of drug delivery through a rich stromal microenvironment. For these reasons, therapeutic development against pancreatic cancer has been challenging, and a number of promising agents have failed clinical trial testing. Personalized models have been studied as a tool for testing candidate drugs to select the most efficacious treatment. The patient-derived xenograft (PDX) is a well-established preclinical tool to improve the drug screening and development. The PDX model requires adequate tissue for transplantation, and failure is common. A recently described, innovative three-dimensional organoid culture platform can be exploited for genomic and functional studies at the level of the individual patient for personalized treatment approach. Organoid technology may fill the gap between cancer genetics and patient trials and allow personalized therapy design. Combination of genome-based medicine and individualized model-based drug screening may fulfill the promise of precision medicine for pancreatic cancer.

Keywords

Precision medicine · Three-dimensional organoid culture · Patient-derived xenograft (PDX) · Genomic-based medicine

Introduction

The field of oncology is rapidly evolving from treating large, unselected populations to targeting small numbers of patients using deep evaluation of molecular features and selection of the most appropriate treatment. President Obama announced the launching of a Precision Medicine Initiative in his 2015 State of the Union Address, and he requested 215 million dollars to fund this endeavor in the fiscal year 2016. The time is right to pursue this strategy, using the individual patient's genetic information to guide individualized therapy. The significant revolution in cancer genetics is allowing, for the first time, the gathering of enormous amounts of genomic information, including the assessment of complete cancer genomes, to aid in clinical decision-making. From this approach, numerous potential targets have emerged for individual patients that may potentially be linked to clinical response.

Genomic-based treatment has already provided examples of remarkable success stories. The development of Imatinib to treat CML and GIST, BRAF inhibitors to treat melanoma, HER2 antibodies to treat HER2 positive breast cancer, and EGFR inhibitors and ALK inhibitors to treat nonsmall cell lung cancer are just some

examples that have dramatically changed the treatment paradigms and improved the survival of patients.

Targeted therapy development continues to evolve rapidly, and this approach has intuitively expanded to precision medicine. NCI-Molecular Analysis for Therapy Choice (NCI-MATCH) (ClinicalTrials.gov number, NCT02465060) is a clinical trial to treat cancer patients according to their molecular abnormalities using DNA sequencing from biopsy specimens. The drugs included in this trial are approved by US Food and Drug Administration (FDA) for another cancer indication or are being tested in clinical trials and have shown a promising result against solid tumors such as breast, colon, lung, prostate, or lymphoma with specific mutations. The AURORA clinical trial is expected to establish detailed molecular profiling of metastatic breast cancer for deeper understanding of the molecular biology, promising to lead to personalized cancer medicine (ClinicalTrials.gov number, NCT02102165).

Pancreatic ductal adenocarcinoma (PDA) remains one of the most deadly cancers worldwide, with 5-year survival below 7%. Surgical resection, the only potentially curative treatment for PDA, is performed in only 15 to 20% of PDA patients, as most cases are diagnosed at a late stage when surgery is not possible. Recent advances in chemotherapy, such as development of the FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan, and oxaliplatin) regimen, and gemcitabine and nanoalbumin-bound paclitaxel, have extended the survival of PDA patients. Although other types of cancer patients are treated based on specific markers, there are no effective markers for targeted therapy in PDA.

The epidermal growth factor receptor (EGFR) inhibitor, erlotinib, the only FDA approved targeted agent for treating PDA, only marginally extends overall survival in combination with gemcitabine. Poly-ADP-ribose polymerase (PARP) inhibitors have shown promising preliminary results [1]. This agent was first reported for BRCA1/2 positive breast cancer and ovarian cancer.

Recent expression analysis has identified four molecular subtypes of PDA [2]. This and other integrated molecular analyses are expected to give insights with therapeutic relevance. One hypothesizes that treatments could be individualized based on a patient's molecular subtype. For example, immune modulators could be tested in patients with an immunogenic subtype. In terms of precision treatment, categorizing some specific patients according to active, available drugs is a logical way forward. Recent clinical trials have shown the efficacy of PARP inhibitor for patients with BRCA1/2 or PALB2 mutations [3, 4]. The frequency of BRCA1/2 deficiency is 5–8% in the general population and 12–15% in certain groups such as Ashkenazi Jewish patients with a family history of breast cancer. Patients with BRCA deficiency driven tumors have increased sensitivity to platinum agents. In addition to platinum agents, BRCA deficient cancers have shown high sensitivity to PARP inhibitors. Recent sequencing data suggest that mutations in BRCA pathway component genes and surrogate measures of defects in DNA maintenance (genomic instability and the BRCA mutational signature) have potential implications for therapeutic selection for PDA in the absence of BRCA or PALB2 mutations [5].

Personalized medicine for PDA patients will be based on an enhanced understanding of biological features of PDA, advancement of technology, and treatment development. Advances in technology currently allows for faster and less expensive whole-genome, exome, and transcriptome analyses compared with traditional Sanger-based methods, enabling routine and rapid characterization of genetic and pathway alterations. Some trials are already underway to test this concept. In the IMPaCT (The Individualized Molecular Pancreatic Cancer Therapy) trial [6], HER2 amplification, KRAS wild-type, and mutations in DNA damage repair pathways (BRCA1, BRCA2, PALB2, ATM) are assessed for guiding treatment. Another approach utilizes the patient derived xenograft (PDX) mouse model, a so-called avatar model. The PDX represents a valuable preclinical tool for studying human cancer biology and patient response to treatments, which suggest the potential for precision medicine. Due to the short survival seen in PDA, participants of clinical trials are often unable to be treated according to their molecular analysis due to their worsening conditions or progression of their disease. For precision medicine to be effective in PDA, developing rapid analyses is a prerequisite.

Genetic Screening and Genomic-Based Treatment

Based on rigorous molecular pathology studies and genomic analyses, the generally accepted model of carcinogenesis describes a stepwise progression from normal pancreatic epithelia to pancreatic intraepithelial neoplasia (PanIN) and finally to frank adenocarcinoma with accumulation of accompanying signature mutations. Recent genomic analyses of PDA have revealed a complex mutational landscape [2, 5, 7]. More than 90% of PDA carry activating KRAS mutations. Mutations in KRAS are seen in all stages of PanIN. Inactivation of tumor suppressor genes such as TP53, Smad4, and p16 are seen with progressive PanIN development and occur at rates of more than 50%. The prevalence of recurrently mutated genes then drops to ~10% which aggregate into core molecular pathways including KRAS, WNT, NOTCH, DNA damage repair, RNA processing, cell cycle regulation, TGF-β signaling, SWI-SNF, chromatin regulation, and axonal guidance. For a number of reasons, including inter- and intra tumor heterogeneity, and an inability to target commonly mutated genes, development of targeted and effective therapeutics remains challenging.

Jones et al. [8] reported a core set of 12 cellular signaling pathways altered in PDA, including apoptosis (100%), DNA damage control (83%), regulation of G1/S phase transition (100%), hedgehog signaling (100%), homophilic cell adhesion (79%), integrin signaling (67%), c-Jun N-terminal kinase signaling (96%), KRAS signaling (100%), regulation of invasion (92%), small GTPase–dependent signaling (other than KRAS) (79%), TGF-β signaling (100%), and Wnt/Notch signaling (100%). Jones and colleagues determined the sequences of 23,219 transcripts, representing 20,661 protein-coding genes and found that PDA contains an average of 63 genetic alterations, the majority of which are point mutations. They collected

24 PDA DNA samples from 10 PDXs and 14 cell lines from 17 patients with surgically resected and 7 patients who underwent a rapid autopsy. Normal tissues were obtained from tumor-negative duodenum, liver, or spleen. These 12 pathways are genetically altered in the great majority of pancreatic cancers. However, the pathway components that are altered in any individual tumor vary widely and the specific genes altered in each tumor are largely different. In addition, it is difficult to determine whether each identified mutation plays a functional role in the pathway or process identified.

Biankin et al. [7] performed exome sequencing and copy number analysis of early (stage I and II) PDA. Biankin and colleagues identified substantial heterogeneity with 2016 nonsilent mutations and 1628 copy-number variations from the analysis of informative 99 tumor samples. They defined 16 significantly mutated genes, reaffirming known mutations (*KRAS*, *TP53*, *CDKN2A, SMAD4*, *MLL3*, *TGFBR2, ARID1A,* and *SF3B1*), and uncovered novel mutated genes including additional genes involved in chromatin modification (*EPC1* and *ARID2*), DNA damage repair (*ATM*), and other mechanisms (*ZIM2*, *MAP 2 K4*, *NALCN*, *SLC16A4,* and *MAGEA6*). Pathway-based analysis of recurrently mutated genes identified mechanisms known to be important in cancer: G1/S checkpoint machinery, apoptosis, regulation of angiogenesis, and TGF-β signaling. They identified frequent and diverse somatic aberrations in genes described traditionally as embryonic regulators of axon guidance, particularly SLIT/ROBO signaling which suggested the potential involvement of axon guidance genes in pancreatic carcinogenesis.

Bailey et al. [2] reported that mutated genes aggregated into 10 molecular mechanisms, including activating mutations of KRAS in 92%; disruption of G1/S checkpoint machinery (TP53, CDKN2A, and TP53BP2) in 78%; TGF-β signaling (SMAD4, SMAD3, TGFBR1, TFGBR2, ACVR1B, and ACVR2A) in 47%; histone modification (KDM6A, SETD2, and ASCOM complex members MLL2 and MLL3) in 24%; the SWI/SNF complex (ARID1A, PBRM1, and SMARCA4) in 14%; the BRCA pathway (BRCA1, BRCA2, ATM, and PALB2: 5% germline, 12% somatic); WNT signaling defects through RNF43 mutation (5%); and RNA processing genes, SF3B1, U2AF1, and RBM10 (16%).

Genomic instability is a characteristic feature of almost all human cancers. Germline mutations in DNA mismatch repair (MMR) genes have been reported in hereditary cancers. With regard to the molecular basis of genomic instability in sporadic cancers, recent genome-wide studies by the use of Sanger sequencing reported that mutations in DNA repair genes and mitotic checkpoint genes were infrequent. Wang et al. sequenced the exomes of 15 human PDA-derived cell lines and their matched normal samples and identified a total of 1517 somatic mutations. Among them, 56 genes were recurrently mutated in two or more cell lines and showed dramatically increased rate of both indels and substitutions involved in all nine core signaling pathways. They revealed that MLH1 expression levels appear to be correlated with the mutation rates. Among the MMR proteins, the loss of MLH1 is the most common cause of MSI [9].

Epigenome

While a significant effort has been made to understand the somatic genetic alterations acquired in PDA, research into epigenetic mechanisms has expanded our understanding of altered gene expression in PDA. Research has focused on several well-characterized epigenetic mechanisms, including DNA methylation, histone modification, and microRNAs. It is increasingly understood that multiple epigenetic mechanisms are indeed crucial in the development and progression of PDA. In addition to genetic changes, epigenetic alterations add another layer of complexity and contribute to the heterogeneity of PDA.

Studies on chromatin dynamics alone are unveiling the existence of robust machineries that can mediate epigenetic changes in pancreatic cells. These findings highlight the need to further our insight into how epigenetic mechanisms are able to independently and cooperatively influence gene regulation and thereby PDA development.

Furthermore, it is important to emphasize one of the characteristics of epigenetic mechanisms of gene regulation – their reversibility. This feature provides a unique target for the introduction of specific therapeutic interventions for PDA.

Nones et al. reported a large-scale methylation and expression profiling study of 167 PDA compared with 29 adjacent nonmalignant pancreas. A total of 11,634 CpG sites associated with 3522 genes and pathway analysis revealed an enrichment of aberrantly methylated genes involved in core signaling pathways including TGF-β, WNT, integrin signaling, cell adhesion, stellate cell activation, and axon guidance. Notably, they revealed epigenetic suppression of SLIT-ROBO signaling and upregulation of MET and ITGA2 expression, which is correlated with poor outcome. Biankin et al. identified genomic aberration of ROBO1 in 11% and SLIT in 10% of PDA samples. Nones et al. suggested that hypermethylation of SLIT-ROBO is a more widespread mechanism of inactivation of this pathway. From the 58 tumors 48% showed hypermethylation of all four genes (ROBO1, ROBO3, SKIT2, and SLIT3). Tumor suppressor genes with a low incidence of mutations may be inactivated by epigenetic mechanisms more frequently. DNA methylation cooperating with other genetic mechanisms alter key signaling pathways critical to cancer development [10].

Chromatin regulators such as HDACs and BET proteins are currently being analyzed as potential strategies for PDAC patients [11, 12].

Transcriptomic PDA Subtypes

Treatment outcomes are improved by targeting drugs according to tumor subtypes in other cancers. Identification of therapeutic molecular subtypes in PDA has been challenging. Collisson et al., for the first time, demonstrated three gene expression subtypes using a 62-gene signature (PDAssigner; [13]) applied to laser capture–microdissected epithelial PDA tumors. They designated these subtypes as classical, quasimesenchymal (QM), and exocrine-like. Classical PDA [14] is

characterized by high adhesion-associated ribosomal and epithelial gene expression, and elevated GATA6 expression, which is essential for pancreatic development [13]. QM-PDA showed high expression of mesenchymal-associated genes. Exocrine-like PDA shows high expression of tumor cell–derived digestive genes. However, in 19 human and 15 mouse PDA cell lines, only the classical and the QM-PDA subtypes were identified, suggesting that currently used PDA cell lines inadequately represent the heterogeneity of human PDA. They showed that classical PDA lines are relatively more dependent on Kras and more sensitive to erlotinib than QM-PDA lines. Conversely, QM-PDA lines are more sensitive to gemcitabine than classical PDA. However, the drug sensitivity of the exocrine-like subtype has yet to be determined.

The presence of the exocrine-like subtype was validated by Noll and colleagues [15], by deriving matched exocrine-like PDA patient-derived xenograft tumors and cell lines. In addition, they showed that the exocrine-like PDA subtype is resistant to small-molecule drugs dasatinib, erlotinib, and paclitaxel and that this resistance is mediated by a cell-autonomous CYP (cytochrome P450) 3A5-dependent drug detoxification mechanism. CYP3A5 also contributes to acquired drug resistance in other subtypes of PDA and in other malignancies.

They identified the subtype by two surrogate markers, HNF1A for exocrine-like PDA and KRT81 for QM-PDA. Classical PDA was defined as double negative of these markers. HNF1A+ cases are more differentiated whereas KRT81+ cases are less differentiated. Exocrine-like PDAs were found to have the best survival rates.

Moffitt et al. [14] identified two tumor subtypes as classical and basal-like and two stromal subtypes as normal and activated by digitally separating tumor, stromal and normal gene expression. The Collisson classical and QM subtypes appeared to be a mixed collection of genes from the Moffitt basal-like and stromal subtypes. Although the basal-like tumor subtype, which is molecularly similar to basal tumors in bladder and breast cancers, demonstrated worse outcomes, basal-like tumors showed better response to adjuvant therapy. The activated stromal subtype showed worse prognosis than normal stromal subtype. The KRAS mutation encoding G12D was associated with basal-like subtype, and the KRAS-G12 V allele was higher in African Americans. In addition, Collisson and colleagues demonstrated high inter-patient tumor heterogeneity and low heterogeneity between primary and metastatic sites.

Bailey et al. [2] demonstrated four subtypes of PDA using RNA-sequencing data from 96 bulk tumors with high epithelial content. They named these subtypes squamous, pancreatic progenitor, immunogenic, and aberrantly differentiated endocrine exocrine (ADEX). These four subtypes were associated with specific histological characteristics. Squamous showed adenosquamous carcinoma, pancreatic progenitor and immunogenic showed mucinous noncystic (colloid) adenocarcinoma and carcinoma arising from IPMN, and ADEX showed acinar cell carcinoma. Three of four subtypes overlap with the Collisson subtypes with the exception of immunogenic subtype. The Collisson QM, classical, and exocrine-like subtypes correspond to the Bailey squamous, pancreatic progenitor, and ADEX subtypes, respectively. The immunogenic class shares many of the characteristics of the pancreatic progenitor class but is uniquely associated with a significant immune cells infiltration.

Proteomics

Proteomics research offers the promise of discovering biomarkers for improvement of early diagnosis and prediction of response to therapy. Several candidate protein biomarkers have been investigated to date. Unfortunately, many of these biomarkers are not specific for PDA or in situ lesions, as they are detected in patients with pancreatitis and other conditions such as smokers. Examples include carbohydrate antigen (CA) 19–9 [16], carcinoembryonic antigen (CEA) and peanutagglutinin (PNA)-binding glycoproteins [17], human telomerase reverse transcriptase (hTert) [18], and matrix metalloproteinase-2 (MMP-2) [19]. More recent attempts to leverage circulating tumor cells and circulating free DNA have yielded similar results [20].

Different sources of pancreatic biomarkers have been evaluated, including blood serum and plasma, duodenal and pancreatic juice, and PDA tissue [21]. Various protein expression detection techniques have been developed, of which the mass spectrometry–based approach is perhaps the most promising. Comprehensive studies to catalog PDA specific proteins have been performed previously, including those by our group [21, 22, 23]. The clinical applicability of these studies was limited by the low concentrations of PDA specific proteins in peripheral blood. Current work is focused on developing and applying novel labeling techniques to improve sensitivity, multiplexing, and quantitative accuracy [24, 25].

A recent study reported proteomic and phosphoproteomic analysis of PDA tissue samples and normal tissue via a LC-MS/MS workflow. The investigators identified new candidate markers such as HIPK1 and MLCK from 2101 proteins identified [26]. They also demonstrated proteins involved in cell migration (Rho guanine nucleotide exchange factors and MRCKa) and formation of focal adhesion by phosphoproteomic analysis. They ascertained phosphorylation sites of known drug targets and suggested Fyn, ERK2, AKT1, and HDAC are potential targets for PDA treatment.

Humphrey et al. reported phosphotyrosine profiling of ATCC PDA cell lines and PDX cell lines they established by immunoaffinity-coupled high-resolution mass spectrometry [27]. They revealed three subtypes of ATCC cell lines, which are associated with cell-cell adhesion and epithelial-mesenchymal transition, mRNA metabolism, and receptor tyrosine kinase (RTK) signaling, respectively. One subtype of PDX cell lines is associated with RTK signaling and showed sensitivity to EGFR inhibitor, erlotinib. These results suggest that a phosphosignature may provide a predictive biomarker for response to targeted therapies.

Metabolomics

Targeting cancer metabolism requires personalized diagnostics for clinical success. Daemena et al. [28] identified three highly distinct metabolic subtypes through broad metabolite profiling of 38 PDA cell lines. One subtype was defined by reduced proliferative capacity, whereas the other two subtypes (glycolytic and lipogenic)

showed distinct metabolite levels associated with glycolysis, lipogenesis, and redox pathways, which were confirmed transcriptionally. The glycolytic and lipogenic subtypes showed striking differences in use of glucose and glutamine and showed differential sensitivity to inhibitors of aerobic glycolysis, glutaminolysis, lipid synthesis, and redox balance. In PDA clinical samples, the lipogenic subtype is associated with the Collisson classical subtype, whereas the glycolytic subtype is associated with the Collisson QM-PDA subtype. These findings suggest the utility of broad metabolite profiling to predict sensitivity of tumors to a variety of metabolic inhibitors.

Metabolism in Pancreatic Cancer: Clues from Metabolomics

PDA patients demonstrate many metabolic alterations including signs of muscle wasting, cachexia, fatigue, and changes in lipid and glucose metabolism. These changes cause alterations in levels and distributions of metabolites and recent technological advances have allowed for metabolomic profiling of a variety of relevant biological samples such as serum, tissue, and urine, with the potential for impacting diagnosis, prognosis and therapy. Detecting metabolic markers have been of intense focus in PDA. Many screens have been performed and these studies point to an important role of several metabolites and metabolic pathways.

It is generally understood that the development of tumors requires not only the ability to proliferate uncontrollably but also altered metabolic programs to sustain this rapid expansion. While there are changes common to multiple cancer types such as upregulated glucose uptake and lactate production, known as the Warburg effect, the metabolic profiles of individual tumors and tumors at different stages of development also possess unique features due to the heterogeneous nature of cancers. PDA tumors take up increased amounts of glucose to fuel biosynthetic processes, display elevated glutaminolysis to maintain redox balance, and scavenge fatty acids as well as amino acids from extracellular space to synthesize macromolecules such as lipids and proteins. These metabolic adaptations are the results of oncogenic signaling active in PDA and tumor microenvironment modulation, which collectively meet the cell's demand to accumulate biomass and proliferate.

Transcriptomic analysis leveraging a doxycycline inducible $Kras^{G12D}$ expressing genetically engineered mouse model (GEMM) and targeted liquid chromatography-tandem mass spectrometry (LC-MS/MS) metabolomics revealed that $Kras^{G12D}$ is essential for glucose utilization through stimulation of glucose uptake and channeling of glucose intermediates into the hexosamine biosynthesis pathway for protein glycosylation and pentose phosphate pathways (PPP) for ribose production [29]. This functional validation of several $Kras^{G12D}$-regulated metabolic enzymes provides candidate therapeutic targets and associated biomarkers for the PDA oncogenic signature.

Kottakis et al. [30] provides evidence for a broader role of metabolic and epigenetic crosstalk in cancer pathogenesis, revealing that LKB1 mutant PDA cells have a marked dependency on pathways linking glycolysis, serine metabolism,

and DNA methylation. Their study provides evidence that coupled metabolic and epigenetic states have a more general role in cancer pathogenesis and suggest that LKB1 status is a genetic marker for DNA methyltransferase inhibitor responsiveness.

Recently, studies have focused on communication between tumor and stromal cells, which support tumor cell survival, growth, and proliferation. Notably, this crosstalk includes release of metabolites. Many studies have focused on the role of stromal cells as nutrient suppliers for PDA. Macropinocytosis-mediated internalization of extracellular proteins and their subsequent intracellular degradation was demonstrated as a mechanism for amino acid supply in Ras-transformed cancer cells. These findings suggest the inhibition of macropinocytosis as a promising strategy for therapeutic targeting in a subset of cancers.

Zhao et al. [31] show that fibroblasts smuggle essential nutrients to cancer cells via exosomes, and disable oxygen-based energy production in cancer cells. Oxygen-based energy release was dramatically reduced in the exosome-absorbing cells, and glucose-based energy release increased. They found that contents of the exosomes contain proteins, fatty acids, and other important molecules, which are used by PDA to proliferate. These findings suggest that preventing exosomes from smuggling resources to starving cancer cells might be an effective strategy to treat cancers. Stroma-tumor crosstalk remains under investigations, and this phenomenon reinforces the complexity of PDA. These studies provide new hints regarding the origin of metabolites and approaches to deprive tumors of their benefits.

RNA-sequencing of the PSC transcriptome revealed that, during activation, PSCs decrease expression of genes implicated in lipid storage and lipid metabolism and also increased expression of genes with tumor-supporting potential including cytokines, growth factors, ECM components, and signaling molecules such as Wnt. The transcriptomes of PSCs isolated from patients with PDA identified a PSC "cancer signature" [32]. These analyses also revealed that PSCs express high levels of the vitamin D receptor (VDR), which is maintained in the cancer-associated PSCs. Transcriptome analysis of preactivated and activated PSCs grown in the presence or absence of VDR ligand showed that the vitamin D receptor (VDR) acts as a master genomic suppressor of the PSC activation state. VDR ligand reduces fibrosis and inflammation in a murine pancreatitis model and enhances the efficacy of a coadministered chemotoxic agent. These results highlight a potentially widely applicable strategy to modulate stroma-associated pathologies including inflammation, fibrosis, and cancer.

To identify the marker for early diagnosis of PDAC, a number of studies have been performed in serum and, tissue and urine. In a study using gas chromatography mass spectrometry (GC/MS) on serum samples from patients with pancreatic cancer, Kobayashi et al. [33] investigated a diagnostic model based on four serum metabolites (xylitol, 1;5-anhydro-d-glucitol, histidine, and inositol) and found the profile to outperform both CA 19–9 and CEA for diagnosis.

Recently, Mayers et al. [34] reported that branched-chain amino acid (BCAA) serum levels are elevated 2–5 years before the onset of carcinogenesis in PDA, suggesting that BCAA elevation is an independent risk factor for PDA. Metabolic

changes alter systemic amino acid profiles together with changes in plasma BCAA concentrations in the precancerous phase or extremely early stages of PDA. However, BCAA levels return to normal levels within the 2 years before confirmation of cancer. In addition, the results of a mouse study indicated that the period of BCAA elevation was bell-shaped and only temporary. Fukutake et al. [35] indicated novel plasma free amino acids (PFAA) profiles from a large cohort of PDA patients. Concentrations of 19 PFAAs were measured by liquid chromatography–mass spectrometry. Plasma serine concentrations were especially elevated, while tryptophan and histidine concentrations were diminished in PDA patients compared with healthy control subjects. The PFAA profiles of PDA patients with stage 0–IIB disease, the resectable stage subgroup, were similar to those of all other PDA patients. This study identified characteristics of PDA phases, and the PFAA index is a promising biomarker for screening and diagnosis of PDA.

Zhang et al. found specific alterations in free fatty acid (FFA) metabolites, which were decreased in cancer patients [36]. Alterations in the lipid metabolism network included key lipolytic enzymes. Gene expression of these lipases was significantly decreased in pancreatic tumors as compared with nontumor tissues, leading to a reduction in FFA. These results may open new therapeutic options for targeting PDA.

Urinary metabolomics was explored using nuclear magnetic resonance (NMR) spectroscopy to investigate metabolomics profiles in the urine of PDA patients. A distinct urinary metabolomics signature was found in urine of patients with newly diagnosed PDA [37], which reliably could separate patients with PDA and controls with benign disease. Of particular interest was the finding that the increased urinary metabolomic profile decreased after surgical R0 resection.

While metabolomics studies using different technology platforms and samples from various tissue types can provide further insight into cancer biology, the current challenge with these results is confirming validity and reproducibility. Markers and panels appear to change across studies and technological platforms, thus making it difficult to find any one panel with a superior diagnostic, predictive, or prognostic value over the other. Metabolomic profiles of PDA patients have been reported in several previous studies, among which, several amino acid profiles were similar, although there were some obvious discrepancies. First, previous studies included relatively small numbers of subjects compared with the recent studies, which included the largest number of subjects to date. Second, differences may have occurred because of variations in sample preparation conditions and analytical methods. Third, metabolite profiles exhibit diurnal fluctuations and are largely dependent on recent meals. Furthermore, leaving collected blood samples at room temperature is known to alter plasma amino acid concentrations. Furthermore, genetic, racial, and geographical elements may also be factors impacting metabolic profiles, all issues which should be clarified in future research.

Tumors are often highly heterogeneous, with distinct areas dependent on different signaling pathways. Tumor cells adapt and reprogram their metabolism to cope with different environmental conditions. All this makes metabolomic mapping quite difficult. With the hypoxic versus normoxic mosaic, PDA perfectly reflects the

idea that different metabolic environments may be found within a single tumor mass, an area worthy of further study. As with other fields of study, tumor metabolism likely results from disturbances in several pathways and will require more sophisticated approaches going forward.

High-Risk Patients

Up to 10% of PDA occur in families with at least two affected first-degree relatives and these are designated familial pancreatic cancers (FPC). FPC is associated with a 2.3- to 32-fold increased risk of PDA development.

The International Cancer of the Patients Screening (CAPS) Consortium has recently reported a suggested guideline for screening, surveillance, and management of high-risk individuals with an inherited predisposition to PDA [38]. A consensus for a screening program to detect and treat T1N0M0 margin-negative PC and high grade dysplastic precursor lesions (pancreatic intraepithelial neoplasia and intraductal papillary mucinous neoplasm) was reached that the following groups should be offered screening (only to individuals who are surgical candidate): (1) first-degree relatives (FDRs) of the cancer patients from a familial pancreatic cancer cohort with at least two affected (FDRs); (2) patients with Peutz-Jeghers syndrome; and (3) p16, BRCA2 and hereditary nonpolyposis colorectal cancer mutation carriers with at least a single affected FDR. The initial screening should include EUS and/or MRI. However, consensus was not reached on the beginning and the end age of screening/surveillance and the interval of the examination. Their conclusions also included requirements for further studies, and the clinical management should occur at high-volume centers with multidisciplinary teams.

Recent advances in sequencing technology revealed PALB2 and ATM as FPC susceptibility genes, together explaining 3% to 5% of FPC cases. A further 8% to 15% of FPC patients have been reported to harbor other susceptibility genes, including BRCA1, BRCA2, CDKN2A, MLH1, MSH2, MSH6, PMS2, PRSS1, STK11, and TP53. Recent whole genome sequencing demonstrated deleterious variants in the candidate genes BUB1B, CPA1, FANCC, and FANCG as more frequent in FPC patients, many of which are associated with DNA repair or chromosomal stability. CPA1 gene variants have been shown to predispose to chronic pancreatitis, which is strongly associated with an increased risk of PDAC [39].

For FPC patients harboring BRCA1, BRCA2, or PALB2, targeting DNA repair with poly (ADP-ribose) polymerase 1 (PARP-1) inhibitors, platinum compounds, or mitomycin C showed therapeutic benefits [5].

Precision Medicine Clinical Trial

Although we have made great progress in understanding of PDA biology, translating these advances to effective, precision medicine remains a daunting challenge. Both the promise and challenge are illustrated in the IMPaCT (Individualized Molecular

Pancreatic Cancer Therapy) trial [6]. In this study, HER2 amplification, KRAS wild-type, and mutations in DNA damage repair pathways (BRCA1, BRCA2, PALB2, ATM) were screened in 76 samples derived from 93 patients.

In this trial, some challenges are illustrated. Of the 22 eligible patients identified for targeted therapy, none were able to receive treatment on protocol because of declining performance status or death. Median time from consent to molecular targeted analysis was 21.5 days. Delays occurred at external testing facilities ($n = 6$) and the requirement for a repeat biopsy ($n = 1$). These delays resulting from molecular analysis before treatment initiation are critical in PDA because of the rapid progression of this disease. Von Hoff and colleagues [40] showed that 17.9% (19/106) of participants were unable to be treated according to molecular analyses in a separate molecularly guided study due to worsening physical condition or progression of disease.

Allowing treatment to commence during analysis has not overcome the time lag and perhaps using molecular analysis performed during first-line therapy to guide second-line therapy may be a more practical approach. Randomization in certain studies can also be a deterrent to patient participation.

A paucity of material for molecular analysis remains a major problem. While FNA samples are mainly used for diagnostic material for metastatic PDA patients, the material that remains for molecular analysis is frequently unsuitable. These samples yield low amounts of DNA which is of poor quality for sequencing. Furthermore, as PDA tissue is of low cellularity, limiting eligibility to biopsy samples with cellularity as high as the cancer genome atlas (>60%) would exclude many patients.

Using surrogate biospecimens to perform molecular analysis is a promising approach to overcome some of these obstacles, for example, circulating tumor cells [41] or cell-free DNA. Innovative in vitro approaches, such as expansion of small numbers of tumors cells in three-dimensional organoid culture, can generate adequate numbers of tumor cells, for molecular analysis. Significant efforts are under way to explore these approaches for clinical applicability. Cancer knowledge networks also need to be built to store the results of molecular analysis and medical data of patients, which can then be shared in comprehensive ways among scientists, health care workers, and patients.

Preclinical Models

Cancer Cell Lines

Cancer cell lines have been important tools for drug development. Studies from The Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC) have established comprehensive catalogs of cancer genes involved in tumorigenesis.

Large-scale drug sensitivity screens in cancer cell lines have been performed to identify potential active drugs. The National Cancer Institute Developmental Therapeutics Program has studied and developed more than 100,000 chemical

compounds using 60 human cancer cell lines (NCI-60) since 1990, and this panel of cell lines continue to be used for in vitro drug screening and development.

Two recent projects, the Genomics of Drug Sensitivity in Cancer (GDSC) and the Cancer Cell Line Encyclopedia (CCLE) have evaluated genetic correlations of drug sensitivity. GDSC assembled 639 human tumor cell lines and 130 drugs for screening. CCLE described gene expression, chromosomal copy number, and massively parallel sequencing data from 947 human cancer cell lines and the drug response of 24 compounds across 479 cell lines.

PDA cell lines continue to play an important role in studying biology and drug development. Phenotype and genotype of many of these cell lines are well established. Cell lines are homogeneous, grow rapidly in culture, and are easy to study.

Collison et al. [13] evaluated 19 human and 15 mouse PDA cell lines and showed these cell lines do not cover all subtypes of PDA found in patients. They compared their data sets from 27 human microdissected tumors to human and mouse cell lines. Cell lines most closely modeled either classical or QM-PDA subtypes. Classical type was more dependent on Kras than QM-PDA as determined by RNAi. Kras targeted therapy, therefore, may be effective against classical type tumors [42]. QM is more sensitive to gemcitabine than classical and classical is more sensitive to erlotinib than QM.

Generating cancer cell lines results in certain alterations in biologic properties, such as genetic alteration, alteration in growth and invasion properties, and loss of specific cell populations. In addition, cell lines are usually established only from more aggressive tumors and hence are not representative of complex tumor heterogeneity.

Garnett et al. screened 639 human cancer cell lines, representing most tissue types and a wide range of genetic diversity of human cancers to uncover new biomarkers of sensitivity and resistance to cancer therapeutics, using 130 drugs under clinical and preclinical investigation. Cell lines were subjected to sequencing of the full coding exons of 64 commonly mutated cancer genes, copy number analysis, and expression profile. In addition to well-established targeted therapies, such as BCR-ABL-positive CML, BRAF-mutant melanoma, and EGFR-mutant lung cancer, they showed sensitivity of EWS-FLI1-positive Ewing's sarcoma cell lines to PARP-inhibitors [43].

Iorio et al. [44] analyzed somatic mutations, copy number alterations, and hypermethylation across a total of 11,289 tumors from 29 tissue types and reported how these alterations can be mapped onto 1001 human cancer cell lines and correlated with sensitivity to 265 drugs. They demonstrated that a sufficiently large panel of cancer cell lines recapitulates oncogenic alterations in primary tumors. However, many genetic alterations occurring at low to moderate frequencies (2–5%) are only represented by a single cell line or not at all, and coverage by cancer type is variable. They analyzed the most predictive data types in pan-cancer and cancer-specific analyses. In cancer specific analyses, genomic features generated the most predictive models, while in the pan-cancer analyses, baseline gene expression data was less informative.

Cell Line Base Xenograft Model

Mouse models are the most experimentally tractable mammalian systems for advancing basic understanding of cancer biology. The xenograft mouse model has been widely used as a tool for preclinical drug screening. Human cancer cell lines can be transplanted either orthotopically or ectopically (usually subcutaneously) into immunocompromised mouse. T-cell deficient nude athymic, B and T lymphocytes deficient severe combined immunodeficient (SCID) and SCID on nonobese diabetic background (NOD/SCID) are commonly used host mice.

Among mouse models, the subcutaneous xenograft is a convenient and economical approach and allows for convenient tumor size assessment. Xenografts have facilitated analyzing the efficacy of compound testing, and most currently approved therapies have been preceded by xenograft testing. While xenograft screening in the earliest stages of drug development can be informative, the extensive screening by the NCI demonstrates a moderate predictive value for their xenograft models, and a poor correlation between the therapeutic efficacy in xenografts and in humans [45]. For PDA, a low correlation between in vitro testing data and clinical utility was also reported [46] .

Subcutaneous tumors are a homogeneous mass with limited stromal infiltration and rarely metastasize. Orthotopic transplantation, where cancer cells are transplanted into the relevant tissue of origin, is better than subcutaneous transplantation for modeling tumor stromal interactions. As metastatic models, cancer cells can be injected intravenously, commonly in the tail vein to model lung metastases, or intraventricularly to model systemic metastases. To model liver metastases, cancer cells are injected into the portal vein or spleen. These transplantation systems can be adapted to many different cancer types.

There are also several shortcomings for xenograft mouse models. Host (SCID and nude) mice are immune deficient and not useful for testing of immunomodulatory agents. In addition, in these systems the immunodeficient state of the mouse results in the failure to completely recapitulate the complex tumor-stromal interaction and the impact on drug response of the tumor microenvironment. These are important considerations particularly in PDA, which is characterized by an abundant stromal reaction and unique heterogeneity. Xenograft studies typically use only a few human tumor cell lines, the oncogenomic profiles of which represent only isolated combinations of the wide spectrum of genetic and epigenetic mutations that are resident in the tumors found in human patients. The reliance on small numbers of homogeneous cell lines is a fundamental weakness.

Genetically Engineered Mouse Model

By using pancreas-specific conditional activation or knockout of clinically relevant PDA-related genes and signaling pathways, genetically engineered mouse models

(GEMM) of PDA have been described and are now a well-established tool. Histologically, PDA GEMMs generally develop differentiated ductal adenocarcinoma with abundant stromal components including a robust desmoplastic reaction. Some GEMMs develop sarcomatoid or undifferentiated tumors, which are rare in human pancreatic cancer. With regard to TGF-beta signaling, SMAD4 gene mutation or deletion is frequently observed in human PDA tumors; however, mice engineered with pancreas specific Kras activation together with Smad4 knockout were reported to develop cystic tumors of the pancreas, a precancerous lesion distinct from PanINs, intraductal papillary mucinous neoplasms, or mucinous cystic neoplasms [47].

An excellent review of a large number of mouse models was performed, and describes several differences between the pathology identified in GEMMs and that seen in human tumors [48]. First, human PDA tends to be moderate or poorly differentiated, whereas many of the GEMMs produced anaplastic carcinomas. Second, most neoplasms in humans show a single direction of differentiation, whereas multilineage differentiation, including acinar differentiation, was often seen in GEMMs. Third, pancreatic intraepithelial neoplasia in humans often, although not always, occurs in the pancreatic duct. By contrast, many of the duct lesions in GEMMs arose in the background of diffuse acinar-ductal metaplasia. Fourth, most human pancreatic carcinomas are solitary, whereas multifocality, not surprisingly, is commonly seen in GEMMs. Finally, intense desmoplasia is a characteristic feature of invasive ductal adenocarcinoma in humans. By contrast, little desmoplasia is seen in some GEMM carcinomas. Each of these models has its own unique strengths and weaknesses in advancing our understanding of pancreatic neoplasia, to identify target-specific biomarkers to assess drug action and discover resistance mechanisms.

PDA GEMMs have been utilized to make important discoveries. One of the earliest studies described how PDA GEMMs appear to recapitulate the tumor microenvironment better than xenograft tumor models. The GEMM also recapitulated chemotherapy resistance, similar to what is seen in the human disease [49]. One of the most commonly used GEMMs for evaluating preclinical therapeutic agents is the PDX-1-Cre; LSL-$Kras^{G12D}$; LSL-$p53^{R172/-}$ (KPC) model [50]. The KPC model recapitulates the clinical features of PDA including hemorrhagic ascites and cachexia. This model also demonstrates metastases to liver, lung, peritoneum, and lymph nodes and a short median survival of approximately 5 months. Histopathologically, tumors generally demonstrate ductal adenocarcinoma with dense stromal desmoplasia; however, sarcomatoid and anaplastic tumors do also occur. Unlike xenograft models using immunocompromised mouse, GEMMs have an intact immune system and stromal reaction. An intact tumor microenvironment was important for the preclinical study of PEGPH20 [51], a PEGylated human recombinant PH20 hyaluronidase. The glycosaminoglycan hyaluronan (HA) is abundant in PDA stroma and transduces signaling through CD44 to regulate receptor tyrosine kinases and small GTPase activity which play important roles in angiogenesis, epithelial-mesenchymal transition, and chemoresistance [52]. PEGPH20 treatment increases intratumoral delivery of chemotherapeutic agents by digesting HA. These preclinical studies have prompted further clinical development of PEGPH20, which is currently in randomized phase III testing for the treatment of advanced PDA

(NCT02715804). Hedgehog pathway inhibition was first reported to inhibit the stromal component in KPC mice, which increased the delivery of gemcitabine to tumors and improved survival in combination with gemcitabine [49]. Unfortunately, in a randomized phase II clinical trial, the hedgehog pathway inhibitor IPI-926 in combination with gemcitabine was ineffective. Using a separate GEMM, Rhim et al. demonstrated that prolonged hedgehog inhibition as a monotherapy led to more aggressive tumor behavior [53]. These results suggest GEMM models are a useful tool to evaluate the efficacy of drugs targeting tumor microenvironment and mechanism of efficacy of chemotherapeutic agents. GEMM models also play an important role in evaluating immune modulating agents. Feig and colleagues reported that KPC models do not respond to antagonism of the immune checkpoints anti-cytotoxic T lymphocyte-associated protein 4 (α-CTLA-4) and α-programmed cell death 1 ligand 1 (α-PD-L1), as is seen in human clinical trials. However, the depletion of cancer-associated fibroblast enabled control of tumor growth using these inhibitors. Treatment with a CXCL12 receptor inhibitor resulted in T cell accumulation in tumors and potentiated anticancer effects of α-PD-L1 [54]. GEMMs can be used to understand the disease biology and drug development, particularly focused on tumor microenvironment and immune response.

It is evident that an understanding of genetic events and signaling pathways is crucial for the development of effective targeted therapies in PDA. GEMMs will continue to play a significant role in the crucial first step of drug discovery and target validation. Pdx1-Cre; LSL-$Kras^{G12D}$; $Pten^{flox/flox}$ mouse model which demonstrates elevated mTOR (mammalian target of rapamycin) signaling showed response to mTOR inhibitor [55]. In clinical trial, mTOR inhibitor did not show the efficacy for unselected pancreatic cancer patients. However, patients with mutations in mTOR pathway showed efficacy for mTOR inhibitor [55]. A Ptf1a-Cre; LSL-$Kras^{G12D}$; $Tgfbr2^{flox/flox}$ mouse model was used to assess the efficacy of the EGFR inhibitor erlotinib in combination with gemcitabine [56]. Systematic studies using 2D cancer cells of cancer genomes and drug efficacy implied the efficacy of EGFR/ERBB2 inhibitors against cancer cells with Smad4 mutation [44].

Recent whole genome sequencing, exome sequencing and RNA sequencing studies revealed some characteristics of PDA, but these subtypes are not predictive for drug sensitivity. GEMMs recapitulate many of the features of human PDA. GEMMs can be useful to evaluate drug response against PDA patients with specific genetic backgrounds. With regard to the discovery of specific biomarkers in cancer patients, it is necessary to collect large numbers of specimens because of interindividual variability, which makes the discovery of biomarkers difficult. However, the use of a GEMM, designed to develop the desired cancer with a predicted latency could allow for identification of candidate biomarkers, which can then be validated in human clinical samples.

By using tetracycline-regulated and CRE-inducible alleles, the timing, duration and tissue compartment of gene expression or inactivation can be further controlled. An alternative method for generating GEMMs uses the CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats/CRISPR-associated proteins) gene-editing system. Chiou and colleague reported CRISPR-mediated targeting of liver

kinase B1 (LKB1) in combination with Kras expression [57]. In this study, they also reported in vivo gene editing by retrograde injection of adenoviral-Cre and lentiviral-Cre into the pancreas of LSL-KRas^{G12D}; p53$^{flox/flox}$ mice.

GEMMs are an important tool for studying biology and drug development. GEMMs are customizable to perturb any number of genetic alterations, which will hopefully continue to lead to more effective therapies.

Patient Avatars

Patient-Derived Xenograft

For a number of reasons previously discussed, the establishment of cell lines is not an effective strategy for personalized medicine. The principal limitation of conventional 2D cell line–based xenograft models is their poor predictive value with regard to clinical outcome [58]. Generally, PDX models have been reported to retain the principal characteristics of donor tumors both histologically and biologically. An analysis of genetic profiles show good concordance between primary tumors and the models derived from them, except discordance in genes involved in the stromal compartment and immune function, which is due to the replacement of the human stroma by murine elements. Although the gene expression profile of PDX models is similar to the original tumor, cell lines developed from the same specimen demonstrate a different expression profile that is not restored by in vivo subcutaneous propagation in mice in SCLC. In PDA models, similar results have been observed in which the frequency of mutations in genes such as TP53 or RAS closely mirrors the frequency of these mutations in human samples [59, 60].

PDX models are an attractive preclinical tool to improve drug screening and development. PDX models are expected to faithfully model the human patients from whom the tumor is derived, both with regards to cancer biology and response to treatments. Personalized PDX models have been studied as a tool for testing candidate regimens which may be effective for treating the patient's own tumor [61]. Evaluating the relationship of drug response with genetic information could lead to the discovery of new biomarkers of drug efficacy. These results suggest that PDX models hold promise for precision medicine in PDA.

One study found a good correlation between response in patient derived PDX and clinical response to gemcitabine in PDA patients [62]. Drug response of PDX models has been reported to be stably maintained across generations (up to 10 passages) [59].

Hidalgo et al. found in a pilot study that treatment of PDA patients with drugs selected according to preclinical PDX drug screening was predictive of tumor response, which suggests that response in PDX models correlates with clinical outcome [63]. This work showed that the combination of nab-paclitaxel and gemcitabine is effective in PDX models of PDA, which correlated with the clinical efficacy of this combination. This regimen has subsequently been demonstrated to provide a survival benefit for patients with advanced PDA in a randomized phase III

study. Likewise, failure to exert antitumor efficacy in PDX models correlates with negative clinical results. This is illustrated in PDAC for agents such as the SRC inhibitor saracatinib and the mTOR inhibitor sirolimus, for which lack of efficacy in unselected PDX preclinical studies predicted failure of the same strategy in the clinic [61]. Based on these data, PDX models have now become an integral part of the preclinical screening of new anticancer agents.

The concordance between PDX models and human trials with regard to biomarkers of drug susceptibility and drug resistance is an important finding. In PDA, PDX studies with gemcitabine identified expression of the gemcitabine-activating enzyme deoxycytidine kinase as a predictor of drug efficacy [59, 64]. Likewise, PDX models have been used to identify metabolic as well as imaging biomarkers. PDX models are also versatile tools for simulating resistance when exposed to treatment strategies used in the clinical setting and to study strategies for overcome resistance.

In most patients, derivation of a personalized PDX for guiding therapy is not feasible for a combination of reasons such as failure of the tumor to engraft, lack of effective agents, and length of time required for a complete study [62, 63]. For patients whose tumors do not take in mice or those who require a long time to be established and characterized, an alternative to a personalized PDX strategy could be to determine treatment choices based on drug responses in a similar, established PDX. Biopsies of primary tumors or metastases would be molecularly characterized and compared with available PDX collections from the same pathology, for which responses to chemotherapies and targeted agents have been previously determined.

PDX models generally rely on surgical specimens, which provide large quantities of tumor tissue. As most PDA patients are inoperable, it is more useful to generate PDX from smaller samples, such as fine-needle aspiration for personalized therapy. Four to eight months are required to generate PDX models for preclinical treatment study. The success rate of engraftment is about 60% and it is important to establish the best engraftment methods according to the phenotype of cancer. Human cancer stroma included in the cancer specimens are replaced rapidly by mouse stromal cells including fibroblasts, inflammatory cells, blood vessels, and immune cells. PDX models require an immunocompromised mouse host which limits the ability to evaluate immune modulators, such as vaccines, anti-PD-1, and anti-CD40 antibodies.

PDX models may also be used as part of co-clinical trials. In co-clinical trials, a personalized PDX model is developed from a patient enrolled in a clinical trial and treated with the same experimental agents to emulate clinical response by using appropriate endpoints such as response rate or tumor growth delay. The availability of a larger collection of models extensively characterized at the histologic, molecular, and genomic level would enable these larger screens. Biologic and genetic comparisons between sensitive and resistant models can be explored for the prioritization of biomarkers for inclusion in clinical studies.

This strategy permits the assessment of drug response simultaneously in the patient and mouse model, providing an interesting platform to investigate biomarkers of susceptibility and resistance, as well as interrogation of novel combination strategies to overcome emergent resistance pathways. Novel approaches, such

as short-term primary cultures or organoids, are being developed and are expected to be used for preclinical screening studies.

Organoid: A Promising New Model

New and innovative culture approaches have been developed which address several obstacles to studying and treating PDA. As previously discussed, samples for genetic screening are frequently unsuitable, of low cellularity, yield low quantities and poor quality DNA for sequencing. 2D cell lines established from human PDA samples are useful; however, the process of cell line establishment results in clonal loss, therefore cell lines do not accurately reflect tumor heterogeneity.

Loss of tumor heterogeneity is a similar weakness of 2D cell line–based xenografts. While studies of PDX models have demonstrated the presence of dense desmoplastic stroma, maintenance of tumor heterogeneity, and good correlation between drug response and human clinical response, transplant success rates are biased towards more aggressive tumors and require a large piece of tumor tissue. PDX models require 4 to 8 months before drug screening can be performed. GEMMs recapitulate the stromal reaction, genetic mutations and progression from normal to PanIN to adenocarcinoma; however, GEMMs lack the genetic and cellular heterogeneity which can only be captured in the human disease.

New 3D culture techniques have been developed in the past decades, providing a new tool with the potential for addressing many of the issues described above.

The first description of this long-term culture system, termed organoids, was reported by Sato et al. [65]. Sato and colleagues used cells derived from the murine small intestine. Several key growth factors appear important for long-term organoid maintenance. For example, supplementation with Wnt ligand supports crypt proliferation, epidermal growth factor (EGF) supports intestinal proliferation, Noggin induces expansion of crypt numbers, inhibition of anoikis is necessary, and finally, laminin-rich Matrigel acts as an extracellular matrix and supports intestinal epithelial growth. At the same time, another long-term culture was established by Ootani et al. [66] for small and large intestine. Successively, long-term 3D culture methods were described for other organs such as stomach, liver, and mammary gland. In addition, long-term 3D culture system was described for malignant tumors derived from breast, colon, and prostate. More recently, normal pancreas and PDA organoid systems have been established.

Boj et al. [67] described an organoid culture system for both normal and neoplastic epithelial cells derived from both mice and humans. Pancreatic organoids are embedded in Matrigel, which contains essential components of a basement membrane. The culture media contains Wnt3a, Noggin, EGF, and R-spondin-1, which are key growth factors. For human organoid culture, FGF10, nicotinamide, A83–01, and prostaglandin E2 are additionally required. Pancreatic organoids can be passaged indefinitely except for human normal organoids, which generally can only be cultured for 20–25 passages. PDA organoids can be expanded from a minimal piece of tissue, such as from a fine needle aspiration (Fig. 1).

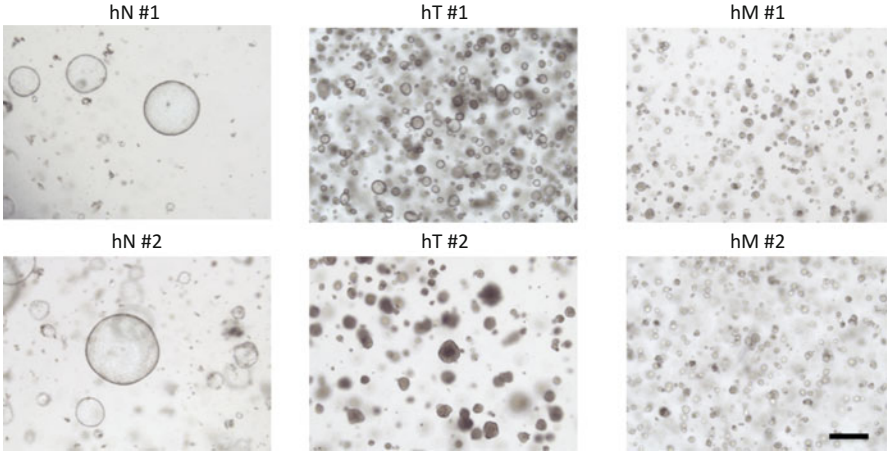

Fig. 1 Representative images of human organoid cultures established from normal tissues (hN), primary tumors (hT), and metastatic tumors (hM). Bar: 500 μm

Expansion of small amounts of tumor or normal tissue to large-scale organoid cultures allows for parallel precision medicine analysis including drug screening, genomic, transcriptomic, metabolomics, and proteomic analyses. Boj et al. performed gene expression analysis comparing mouse normal, PanIN, and tumor organoids and showed similar changes in gene expression patterns comparing mouse PanIN and tumor organoids to normal organoids, as seen with oncogenic Kras activation in KrasG12D mice. These analyses demonstrated the ability of the organoid system to characterize molecular alterations associated with PDA progression. Proteomic analysis of mouse normal, PanIN, and tumor organoids was also performed. Few protein expression changes were seen comparing mouse PanIN and tumor organoids, whereas many more changes were seen comparing mouse normal and PanIN organoids, or mouse normal and tumor organoids. Gene Set Enrichment Analysis (GSEA) of RNA sequencing and proteomic data comparing mouse PanIN to normal organoids revealed up regulated genes and proteins involved in glutathione metabolism and biological oxidations, consistent with previous studies. Similar to the PDX mouse model, organoid transplant mouse models are a promising tool for drug screening and studying biology. Using organoids for in vitro drug screening is possible a couple of months after samples are collected. Organoids can be reliably established from virtually every patient sample. Preliminary studies suggest maintenance of tumor heterogeneity even after several passages.

Interestingly, orthotopic transplantation of organoids develops a full spectrum of lesions associated with disease progression, including early PanIN and late PanIN, invasive ductal adenocarcinoma, and metastasis. This model is a promising tool to study the earliest stage of human cancer to understand fundamental biology and to identify biomarkers of early disease.

Hunag et al. generated pancreatic progenitor cells from pluripotent stem cells in 3D culture and induced differentiation of their organoid progenitor cells into

pancreatic exocrine cells which express ductal and acinar markers [68]. They adapted their culture condition for growing human PDA. Among 20 human pancreatic samples, they established 17 tumor organoid lines and showed similar morphological and cytological features to those of the primary tumors they were derived from after 16 days in 3D culture. They transplanted 50,000 cells subcutaneously and tumors grew within 4–7 weeks. Xenograft tumors demonstrated similar histoarchitecture to the primary tumor or origin and also maintained histological heterogeneity. They tested an EZH2 (enhancer of zeste homolog 2) inhibitor against human tumor organoids and suggested the usefulness of organoids as a platform for personalized drug testing, although they were not able to correlate organoid response to patient outcomes.

Walsh et al. established mouse and human organoids for drug testing and optical metabolic imaging (OMI) which probes the fluorescence intensity and lifetime of NAD(P)H and FAD [69]. After mechanical digestion, organoids are embedded in Matrigel and subjected to drug testing and optical metabolic imaging. This method does not allow for passage of organoids but can be useful as a tool to evaluate drug response for personalized medicine. They observed three distinctive morphologies of murine PDAC including spherical organoids (type 1), symmetric organoids (type 2), and fibroblasts. Type 1 and type 2 organoids are positive for epithelial markers. Type 1 organoids show the greatest OMI index and type 2 organoids showed the smallest OMI index. Optical redox index ratio of type 2 organoids was lower than that of type 1 organoids and fibroblast. Organoids were treated with a JAK2 inhibitor, MEK inhibitor, PI3K inhibitor, and combinations to evaluate drug-induced metabolic changes, which revealed heterogeneous metabolic responses among cell populations [69]. Human PDAC organoids demonstrated a broad spectrum of morphologies, which were difficult to classify into subtypes. They showed that the OMI index reduction was detected with gemcitabine treatment and gemcitabine with JAK2 inhibitor treatment.

Li et al. cultured organoids with both epithelial and mesenchymal components from embryonic pancreas using an air-liquid interface culture method with an inner collagen gel-containing transwell with direct air exposure. This system does not require exogenous factor supplementation [70].

Wetering et al. [71] reported the establishment of a “living biobank” from 20 colorectal cancer patients. They demonstrated that the organoid culture platform can be exploited for genomic and functional studies at the level of the individual patient for personalized treatment approach. Organoid technology may fill the gap between cancer genetics and patient trials, complement cell-line- and xenograft-based drug studies, and help to achieve an effective, personalized therapy approach.

Conclusion

Integrated genomic, epigenomic, and transcriptomic analyses are generating biological insights with potential therapeutic relevance in PDA. The recurrently mutated genes aggregate into core molecular pathways including KRAS, Wnt,

Notch, DNA damage repair, RNA processing, cell cycle regulation, TGF-β signaling, SWI-SNF, chromatin regulation, and axonal guidance. Genomic-based treatment has resulted in paradigm changing therapies for other cancers, dramatically improving survival and cures. However, this remains an unfulfilled promise in PDA due to apparently untargetable mutations, high resistance to available chemotherapeutic agents, and the difficulty of drug delivery through a rich stromal component. In addition, individual tumors have infrequently mutated genes, result in significant inter- and intratumoral heterogeneity. Due to this diversity, therapeutic development has been challenging. Familial pancreatic cancer patients harboring BRCA or PALB2 may have sensitivity to PARP-1 inhibitors, platinum compounds, or mitomycin C. In the IMPaCT (The Individualized Molecular Pancreatic Cancer Therapy) trial [6], HER2 amplification, KRAS wild-type, and mutations in DNA damage repair pathways (BRCA1, BRCA2, PALB2, ATM) were targeted for treatment. Personalized PDX models have the potential to identify effective drug therapies, however, with significant limitations, including a long lead-time and large amounts of tumor tissue for testing. The three-dimensional organoid culture platform can be exploited for genomic and functional studies at the level of the individual patient for personalized treatment approach. Organoid technology may fill the gap between cancer genetics and patient trials and allow personalized therapy design, although further studies to validate this approach are needed (Fig. 2). A combination of genome-based medicine and individualized model drug screening may prove to be the key tools needed for precision medicine for PDA (Table 1).

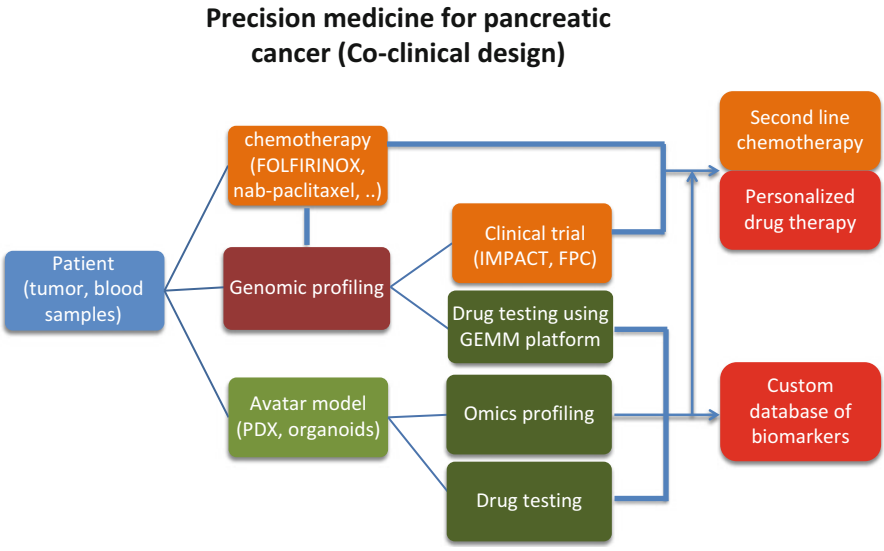

Fig. 2 The design of precision medicine

Table 1 Summary of main characteristics of different preclinical models

	2D cell lines	2D cell line–based xenograft	GEMMs	PDX	Organoids	Organoid-based transplant
Cost of maintenance	+++	++	+	+	+++	++
Success rate of initiation	+	++	+++	++	+++	++
Expansion	+++	+	++	+	+++	+

Abstract

Decades of research focused on the genetic basis for development of pancreatic ductal adenocarcinoma have yielded tremendous discoveries. Clues to increase our understanding of the underlying biology of disease, the time along which the disease develops, and the potential vulnerabilities of disease are being elucidated daily. Alongside this genetically driven paradigm, researchers have uncovered the phenomenon of dramatically altered protein expression in the absence of an associated gene mutation. Through a mechanism termed epigenetics, the transcription and translation of genes can be dramatically altered by a variety of mechanisms including DNA methylation and histone modification. The fundamental concepts of epigenetics and major molecular agents that participate in setting the epigenome are reviewed herein. For each mechanism, the pharmacologic agents available for current use and the research underlying their approval are discussed. The potential impact of epigenetic pharmacology in pancreatic cancer is discussed in turn, and future directions of current research efforts are outlined.

Introduction

Pancreatic ductal adenocarcinoma (PDAC) is the fourth leading cause of cancer-related death in the United States [1]. With a mortality rate that approaches the incidence, the outcomes following diagnosis are dismal. There are many reasons that account for this statistic: advanced stage at presentation, aggressive underlying tumor biology, and relative inefficacy of standard therapies. It is the latter that often drives mortality. Whereas progress with systemic therapies has led to prolonged survival in many malignancies (including breast, colon, and gastrointestinal stromal tumors), cytotoxic chemotherapeutics have negligible benefit in survival after a diagnosis with PDAC. Research to associate genetic profiles with treatment response has also yielded disappointing findings. Alternative mechanisms of disease biology and treatment response are in active development.

Introduction to Epigenetics

The central dogma of molecular biology posits that genetic information coded in DNA is transcribed into RNA and translated into protein. Protein then functions in

such a way to ensure that the phenotype expressed by a cell accurately reflects the cell's underlying genotype. The recognition of this oversimplification occurred in parallel with the discovery of the genome itself, as it was clear that cells containing the same genome expressed widely disparate phenotypes (e.g., note the differences between a hepatocyte and a melanocyte). Even today the forces driving the development of a particular phenotype remain incompletely understood; however, the mechanisms used by cells to establish these differences are increasingly being unraveled. Examples of these mechanisms include variable transcription from the DNA, regulation of RNA translation, and regulation of protein expression.

With transcription alone, it is important to remember that the DNA is not always freely available for copy into RNA. At baseline, portions of the genetic code are twisted and wrapped around alkaline proteins, termed histones [2]. These histones, together with the DNA and other nuclear proteins, form tightly spiraled nuclear structures, called nucleosomes, which can promote or restrict access to DNA by the translational machinery of a cell. Further, even when not tightly bound to histones, specific residues of the DNA can be shrouded behind methyl groups (CH_3) prohibiting their transcription (as discussed later in this chapter). In cases such as these, when DNA is wrapped into tight complexes or covered by methylation, the expression of genes can be significantly altered.

Epigenetics is the term used to characterize the mechanisms of variable gene expression leading to disparate cellular phenotypes due to changes in a chromosome, without changes in the underlying sequence of DNA [2]. Though chromatin structure and nucleotide methylation are commonly cited examples of epigenetic variability, there are many other potential cellular processes with the capacity to exert epigenetic influence on a cell. These include changes in RNA or microRNA profiles that bind and augment the structure or function of histones, changes in nuclear protein composition that may fundamentally alter the microarchitecture between histones, or metabolic changes that can modify epigenetic protein binding or affinity. Commonly, these global changes within a cell can result in histone modifications by way of acetylation, ubiquitylation, sumoylation, and methylation.

Epigenetic changes are believed to be heritable with a potential impact just as great as germ line mutations in the DNA sequence [2]. Even after gestation and throughout the duration of life, epigenetic events are durable and persist from one cell division to the next. Importantly, however, the epigenetic profile of a cell (i.e., the epigenome) can be dynamic, reacting to environmental signals and allowing for changes to accumulate. At times this is likely a protective mechanism, helping to guide cellular fate during embryogenesis and adult cell renewal [2]. In stark contrast, alongside genetic mutations that drive malignancy, there are changes to the epigenome that appear to be early events in cancer tumorigenesis. In this chapter, the rationale for broadening research into novel therapeutics based on recent epigenetic studies is highlighted. The current mechanisms of epigenetic control are detailed as a framework from which to discuss potential pharmacologic therapies. Finally, ongoing studies and anticipated future work are highlighted.

Epigenetics: Definitions and Basic Mechanisms

Despite an increasing understanding of the DNA mutational landscape driving cancer, the progress made in developing therapeutics has been disappointing. While there are many reasons for this, one prominent hypothesis rests on the vast machinery that regulates the expression of the cell's genotype. In a simplified model, each gene encoded by DNA would be transcribed into RNA, be translated into protein, and then contribute to a cell's fate through the protein-protein interactions detailed in biochemical and molecular biologic texts. In reality however, there are dramatic differences in the ultimate production of protein encoded from one gene to the next on the chromosome. Some of this variability is due to regulation of RNA translation or protein-level degradation. However, much of this variability is due to differences in the amount of DNA transcription that occurs at each gene location on the chromosome and is controlled by local factors. These local factors, that change the gene expression patterns in a cell, can be due to two nuclear phenomena in the epigenome. First, changes in gene expression can result from the nuclear protein interactions with DNA that form chromatin (the local arrangement or "micro-architecture" of the chromosomes). The resulting microarchitecture is sometimes referred to as the "histone code" [3]. Second, gene expression can be augmented by the direct methylation of DNA residues. Finally, microRNA and other noncoding RNA molecules can have profound effects on gene expression.

Chromatin Modification: Histone Modification, The "Histone Code"

The microarchitecture of chromosomes within the nucleus of a cell is dependent upon the relationship between the DNA and nuclear proteins (Fig. 1). In some cases, the DNA may be loosely splayed open in a bath of transcription factors and electrolyte solution, termed euchromatin. In other areas, the DNA is tightly bound to spherical nuclear proteins with the nucleotides shielded from view, termed heterochromatin. It is this relationship, between the DNA and alkaline-rich proteins called histones, which is the major determinant of chromosome shape and function. Around each histone core, approximately 160 base pairs of DNA are wrapped. Together this complex is called the nucleosome. Each nucleosome may also bind tightly to a neighbor or be distanced from each other and stand apart at length. The positioning of nucleosomes in relation to their neighbors helps to form macrostructures termed chromatin. Chemical modifications to the core of histone proteins are the major determinants of chromatin arrangement (Fig. 1) [4].

Over the past two decades, major strides have been made to increase understanding of the mechanisms controlling the epigenome. Expression of genes along any length of DNA is dependent upon the arrangement of the chromatin and nucleosomes. As transcription start sites are wrapped tightly, the transcription machinery cannot intercalate with the DNA to facilitate gene expression. In contrast, as the start sites in the DNA move away from the nucleosome, they become more available for transcription. Nuclear proteins that function within intricate complexes control these

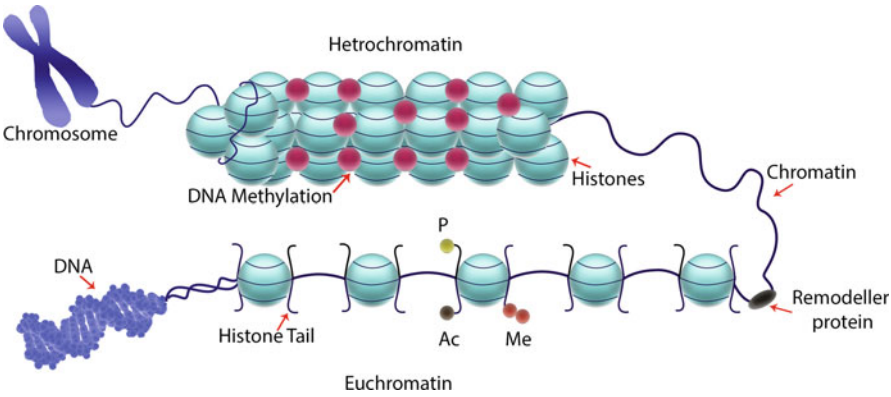

Fig. 1 The architecture of epigenomic landscape. The chromatin platform is an agile hub of activities switching genes "on" and "off" by regulating positioning of nucleosomes (*blue circles*). The unwinding of the chromatin leaves the transcription start site nucleosome free for transcriptional activities. Modifications of nucleosome histone tails (*blue lines* extending from *circle*) regulate the process, including DNA methylation (*red circles*), serine phosphorylation (P; *yellow circle*), lysine acetylation (Ac; *brown circle*) and lysine methylation (Me; *orange circle*), and nucleosome remodeler complexes protein required for moving nucleosomes (*black oval*)

epigenetic factors. These proteins are known as the writers, erasers, readers, and remodeler proteins and are discussed further below (Figs. 1 and 2) [4]. In general, these proteins are vital to cell maturation as their function in manipulating the epigenome can have profound effects on the proteome and phenotype of the cell. Through functions to add, remove, and interpret the "histone code," the proteins in these four classes are at the core of epigenetic determinants of cellular fate (such as maturation) [3].

Beyond maturation however, alteration of the epigenome by these proteins can also have profound effects during the dedifferentiation that leads to carcinogenesis. Two potential examples of this would include epigenome-based inactivation of tumor suppressor genes or activation of oncogenes [4]. The great promise in targeting therapy toward these epigenetic events is based on their potentially reversible nature. As discussed later in this chapter, the reversibility of these epigenetic events mirrors the flexibility seen in cellular differentiation during development [5]. For example, as mammalian cells mature from pluripotent progenitor cells to a differentiated phenotype, epigenetic control of gene expression through mechanisms such as histone modification, DNA methylation, and changes to noncoding RNA is key to appropriate differentiation. These epigenetic mechanisms are flexible, being modified as cells reach their differentiated states before settling into a more permanent epigenome [5]. Just as the epigenome is modified during development, data is mounting to support the role of epigenome modification in the dedifferentiating process that is the hallmark of the cancer phenotype. Further, once a gene is silenced, it remains heritable in somatic cells.

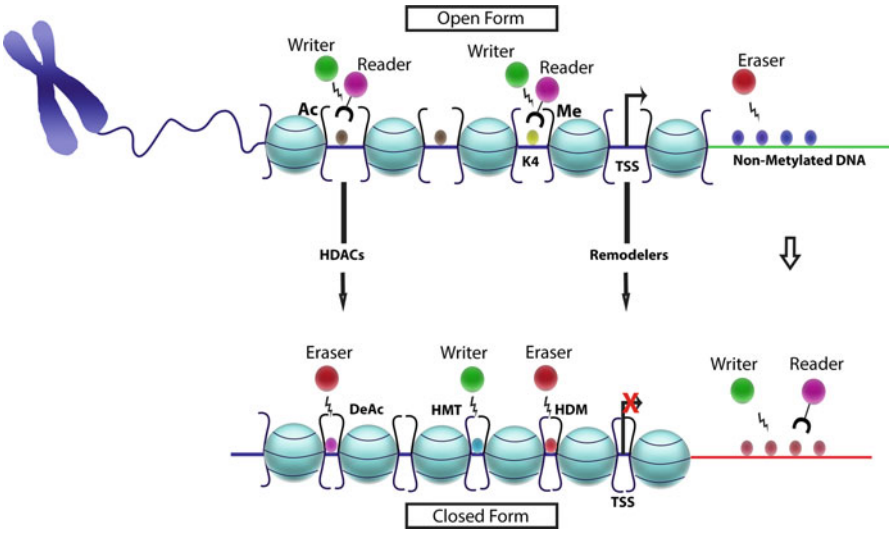

Fig. 2 The epigenomic 4Rs. For open chromatin form (*top*), which exposes the promoter region for transcriptional epigenetic switch in the form of writers (*green circles*), readers (*pink circles*), and erasers (*red circles*), and generally no DNA methylation in associated CpG islands (*yellow circle*). Nucleosomes (*blue circles*) are in an open conformation around the transcription start site (TSS). Writer enzymes in the form of histone methyltransferases (HMTs) add acetyl (Ac), methyl (me), and phosphorylation (P) marks to histone proteins (acetylated lysine, *brown circles*; methylated lysine, *yellow circles*). These regulated chromatin architectural (open and closed form) changes and gene expression regulation. Readers containing specialized domains bind to these distant marks, which are critical for binding to specific modification states. Erasers such as histone deacetylases (HDACs), lysine demethylases (KDMs), and phosphatases are involved in the removal of epigenetic marks. As the chromatin is modulated to the inactive state (bottom), with promoter DNA hypermethylation, it is associated with a more closed form of chromatin near transcription start site (TSS). HDACs, which erase histone acetylation (pink circle), writers (HMTs), which change active histone methylation marks to repressive ones such as H3K9me3 (blue circle) and HDMs, acting as antagonist to HMTs can all impact the epigenome. Another set of writers (DNMT) establish methylation of CpGs at promoter regions (*small red circle*), and readers for this methylation are methylcytosine-binding proteins (MBDs). *Abbreviations*: *HDACs* histone deacetylase, *HMT* histone methyltransferase, *HDMs* histone demethylases

DNA Methylation

DNA methylation refers to the state in which a methyl group (CH3) is bound to a nucleotide on the chromosome. This occurs almost exclusively on cytosine residues that precede guanine in the sequence CpG in the mammalian genome (Fig. 3). Both the distribution of CpG sequences across the genome and the degree to which these sequences are methylated are highly variable [6, 7]. The vast majority of the DNA is relatively poor in CpG density. There are, however, small regions of DNA with highly concentrated repeats of CpG that are known as CpG islands. These islands are frequently found adjacent to gene promoter regulatory sites. The CpG islands adjacent to gene promoter sites remain relatively free of methylation. In stark contrast, CpG dinucleotides in the vast majority of the remaining genome (i.e., not

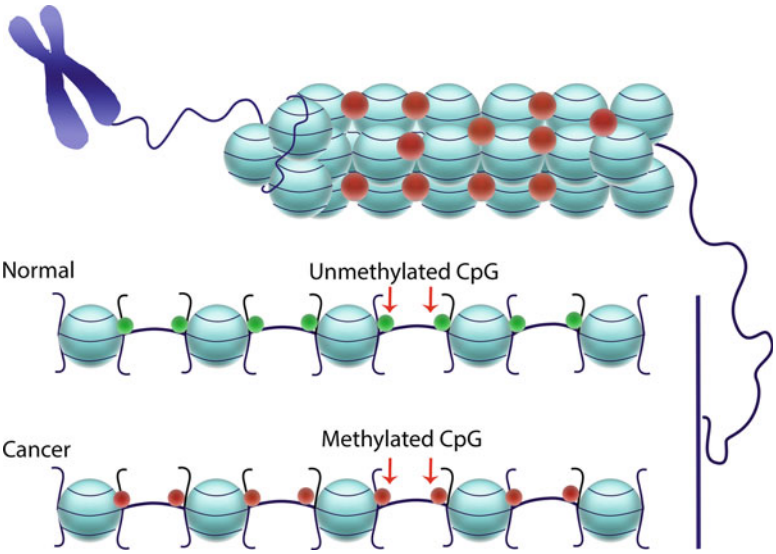

Fig. 3 DNA methylation patterns in normal and disease condition. In a normal cell, the promoter CpG islands (*top*) generally lack CpG site DNA methylation (*green circle*), whereas gene body is heterogeneous for DNA methylation in CpG dinucleotides. In cancer (*bottom*), many genes are heavily methylated in the promoter region of CpG islands, which represses chromatin landscape and leads to abnormal gene silencing. Whereas surrounding region is hypermethylated in the promoter regions with a gain in function

near gene promoter sites) tend to be heavily methylated. This includes heavily methylated areas present at repetitive DNA elements such as Alu (*Arthrobacter luteus* restriction endonuclease-characterized short DNA stretches), long interspersed nuclear elements (i.e., LINEs), and pericentromeric repeats [4, 8].

A growing body of literature is characterizing the effects of CpG island methylation in the cell during embryogenesis, mature cell division, and cellular dedifferentiation found in cancer. The key mechanistic association links increasing methylation of the dinucleotide sequences in CpG islands and decreased gene expression. Methylation-directed gene silencing is critical during embryogenesis, not only directing proper differentiation and maintaining cell lineage but also in ensuring genome stability [5]. Additionally, the phenomenon of gene imprinting, when heritable gene expression is controlled through epigenetic mechanisms (i.e., parental strand-specific expression), is reestablished during this period of embryogenesis [4].

Disorders in methylation can have profound effects on the fate of the cell and host. For example, certain inherited diseases are a result of gene imprinting rather than gene mutation. The neurodevelopmental disorders, Prader-Willi and Angelman syndromes, are two often cited examples of diseases of imprinting [9]. In Prader-Willi, for example, one predominant mechanism is driven by aberrant DNA methylation that silences genes along the maternal allele of 15q11-13 and loss of paternal

genes. This leads to a disorder characterized by mild to moderate cognitive defects (affecting speech, attention, executive function, and mood) that occurs in approximately 1 in 20,000 live births.

As fully differentiated cells divide and renew, opportunities for alterations in DNA methylation profiles exist. As cancer develops, DNA methylation is commonly altered. Fundamental changes in the epigenome include a relative global hypomethylation paired commonly with focal hypermethylation of CpG islands typically in gene promoters [2, 8]. These changes alter the nucleosome structure and global gene expression profiles. Additionally, specific hypermethylation in the promoter region of tumor suppressor genes, such as *Breast Cancer 1 (BRCA1)* or *Von Hippel-Lindau Tumor Suppressor (VHL)*, is commonly encountered and results in silencing of genes critical to the integrity of a cell. It is important to note that once DNA methylation is acquired, it is heritable in somatic cells and can contribute to malignancy [5]. Contemporary research efforts aimed at understanding the hypermethylome of cancer have shown that methylation-associated gene silencing is commonly seen in many tumor types, including colorectal, breast, pancreas, and gastric, amongst others [4, 8]. Generally, hundreds of genes show methylation in many cancer subtypes as demonstrated by the efforts by The Cancer Genome Atlas (TCGA) consortium [10]. Work is now progressing in understanding which of these gene-silencing events are epigenetic drivers rather than simply passenger events.

Beyond the focal hypermethylation, there are associated changes in histone marks including trimethylated histone 3 lysine 27 (H3K27me3), trimethylated histone 3 lysine 9 (H3K9me3), and many others [4]. Finally methylation in selected promoter regions, such as that adjacent to *MutL homolog 1 (MLH1)*, can drive changes to the underlying genome itself. Work by Herman and colleagues demonstrated that *MLH1* promoter hypermethylation drives microsatellite instability in selected carcinomas [11].

Epigenetic Mechanisms in Pancreatic Cancer Carcinogenesis

Original investigations into the role of the tumor suppressor genes, such as *p16*, in PDAC suggested that this family of proteins played a pivotal role in tumorigenesis [12]. Mechanistically, p16 is involved in a cell cycle regulatory complex that functions to arrest the cell at the G1 phase of division. The p16 protein, in particular, is responsible for control of cyclin-dependent kinase 4 (Cdk4) binding to cyclin D1 and subsequent progression through G1. Initial work by Caldas and colleagues found that genetic inactivation was present in 82% of tumors studied [12]. Nevertheless, one-fifth of tumors possessed wild-type (WT) *p16*, which led subsequent investigators to study other potential mechanisms of inactivation of this pathway [12].

The role of gene silencing through epigenetic mechanisms, such as DNA methylation patterns (Fig. 3), was of particular interest in follow-up studies [11, 13]. After confirmation of *p16* WT status in seven PDAC samples, a PCR-based methylation screen targeting the 5′-CpG islands of *p16* was used to investigate the

epigenome. In all but one, homogenous methylation patterns were detected for all *p16* transcripts, which resulted in a loss of downstream p16 protein and subsequent loss of growth suppressor function [14]. DNA methylation patterns were subsequently evaluated in depth for pancreatic cancer. Global methylation profiling assays identified nearly 60 candidate genes, which had altered expression due potentially to changes in methylation [14]. In the same work, candidate methylation markers of gemcitabine responsiveness were also proposed. Subsequent data have similarly shown extensive epigenetic changes in pancreatic cancer with methylation-associated transcriptional activation of many genes that are silenced early during cancer development [15]. These hypermethylated genes are often preferentially poised toward bivalency with both active and silencing histone marks, and environmental pressures may push toward inactivation of many of these genes by DNA methylation [16].

Similarly, the role of the epigenome in oncogene activation has been demonstrated in cell culture and xenograft models of PDAC [17]. Affecting a similar point in the cell cycle, G1-phase progression (as well as G1-S transition), the oncogene *c-myc* is a transcription factor responsible for upregulation of a variety of gene products with function in cell cycle progression, apoptosis, and cellular transformation [18]. In a study by Koenig et al., the regulation of *c-myc* gene expression demonstrated epigenetic changes driven by intracellular calcium concentration that controls the response of the calcineurin/cellular nuclear factor of activated T-cell (NFAT) pathway [17]. Specifically, NFAT binds to an element of the DNA adjacent to a *c-myc* proximal promoter and induces chromatin structural modification to allow for protein-promoter interactions driving c-myc protein translation. Importantly, and in a manner that provides insight into the pharmacologic rationale of targeting the epigenome, the depletion of NFAT abrogated c-myc protein expression leading to G1 arrest and decreased tumor growth in both in vitro and xenograft models of PDAC [17].

While a full review of the epigenetic mechanisms of disease is outside the scope of this chapter, and can be found in detail in chapter ▶ "Epigenetics and Its Applications to the Progression Model of Pancreatic Cancer", it is worth noting that the pancreas methylome clearly plays a role in PDAC [15]. In both in vitro models and patient tumor specimens, Yi et al. showed that cancer-specific promoter DNA methylation for two particular genes, *Basonuclin 1 (BNC1)* and *A Disintegrin-Like and Metalloprotease with Thrombospondin Type 1 (ADAMTS1)*, corresponds with early-stage PDAC [15]. The presence of PDAC-specific methylome changes may in fact hold promise in new early detection (disease-specific biomarker) and treatment paradigms. As such, it is this work in particular that makes a chapter such as this, focusing on epigenetic pharmacology, particularly relevant [15]. Lastly, there are important germ line mutations of critical regulatory elements of the epigenome that occur with some frequency in pancreatic cancer [19]. For example, the *AT-Rich Interaction Domain 1A* (*ARID1A*) gene is frequently mutated in many cancers of gastrointestinal cell origin, including from 2% to 8% of pancreatic tumors, and suggests that aberrant chromatin remodeling in this disease may be driven in part by acquisition of somatic mutations [19].

Pharmacological Strategies

Though there is clearly interplay and cross talk between the various effectors of epigenetics, for the purposes of a pharmacologic discussion, these will be addressed independently. It is important to remember, however, that the mechanisms of action for many of the agents discussed in the ensuing section are multifaceted. To facilitate discussion and understanding, a list of commonly researched agents and their current research point/approval status is noted in Table 1.

Table 1 Commonly researched agents, the current status of research and approval status if applicable

	Drug	Preclinical / Early phase	Approved / Disease
Single Agents			
DNMTi	Azacitidine		Approved/MDS
	DAC		Approved/MDS
	SGI110	Phase I/II	*MDS, AML, Ovarian, hepatocellular, Colon*
HDACi	Vorinostat		Approved/CTCL
	Romidepsin		Approved/CTCL
	Valproic acid		Approved/CTCL
	Pivanex (AN-9)	Phase I/II	*CLL, NSCLC*
	Entinostat	Phase I/II	*Approved/AML, MDS*
	Panobinostat	Phase III	*Hodgkin's Lymphoma, Kidney Cancer*
	Belinostat	Phase I/II	*Relapsed or refactory acute myeloid leukemia*
	Givinostat	Phase I/II	*Chronic myeloproliferative neoplasms*
	Pracinostat	Phase I/II	*AML, MDS, Metastatic sarcoma*
	Panobinostat	Phase III	*Hodgkins Lymphoma, multiple myeloma*
	Rocilinostat	Phase III	*Multiple Myeloma, CRC, Melanoma*
HATi	Curcumin	Phase III	*Breast Cancer, CRC, multiple myeloma*
HMTi	Tazemetostat	Phase I	*ALL, MLL*
	EPZ-5676	Phase I	*NHL, Breast cancer*
	GSK126	Preclinical	*Hematological Malignancies, NHL*
BETi	GSK525762	Phase I	*NUT midline carcinoma*
	JQ1	Preclinical	*AML, Multiple myeloma, NUT midline carcinom*
Combination			
Epi-Chemo	Vorinostat/5FU/Leucovorin		*CRC*
	SGI-110/Irinotecan		*CRC*
Epi-Immune	Aza/Romidepsin/PD-1		*CRC*
	SGI-110/GVAX/CY		*MDS*
Epigenetic priming with other drugs	AZA/Entinostat		*NSCLC, CRC*
	Romidepsin/Aza		*NSCLC*
	Radiotherapy/Vorinostat		*GI cancer*
	Vorinostat/Gemcitabine/paclitaxel/Sorafenib		*Pancreatic Cancer*
	Valprolic acid/hydralazine/Cisplatin		*Cervical Cancer*
	Vorinostat/Capecitabine/Cisplatin		*Gastric Cancer*

Targeting the Effectors of DNA Methylation

In general, there are several unique effectors of DNA methylation that play prominent roles in different biologic systems or at different times during cell maturation. While small noncoding RNA can play a role in directing DNA methylation (and is discussed later in this chapter), the family of catalysts that does the majority of work is known as DNA methyltransferases (DNMTs) [20]. These enzymes facilitate transfer of a methyl group from a donor (commonly *S*-adenosyl-L-methionine or SAM) to the 5′ position of the cytosine in CpG elements. Of note for the discussion to follow regarding pharmacotherapy, SAM exists in a balance with *S*-adenosyl-L-homocysteine (SAH). There are three primary DNMTs identified in mammalian studies: DNMT1, DNMT3A, and DNMT3B. Isoforms of DNMT3A and DNMT3B contribute to DNA imprinting and de novo methylation, while DNMT1 appears to be most important in maintenance of methylation [21].

The conserved elements of DNMT across family members appear to include a conserved sequence motif that binds to SAM [21]. Similarly, all family members have motifs toward the N-terminus, which serves to localize the protein to its nuclear target. For DNMT1, function includes interaction with the DNA replication complex at the replication fork whereby methylation maintenance is carried out as DNA is newly synthesized [22]. As each methylated CpG dipeptide is replicated, DNMT1 rests at the methylation site, flips the cytosine into its catalytic pocket, and facilitates methyl group transfer from SAM before moving along with the DNA replication complex [22].

Preclinical rationale for manipulation of DNMT family members in oncologic therapy is derived from several early studies to elucidate function of the protein. Following discovery of the gene, studies investigating function in cell lines demonstrated that mutation of DNMT1 caused no noticeable changes in embryonic stem cells [23]. Drastically, however, when a similar mutation was bred into the germ line of mice, a uniformly lethal phenotype was obtained. This initial work demonstrated that DNA methylation via DNMT1 function was both necessary and sufficient for preserved in vivo cellular maturation.

Interestingly, further work on methylation has demonstrated the agility of these enzymatic complexes. For example, when studying methylation after replication of X chromosome in cells passaged in tissue culture models, Riggs et al. demonstrated that omissions and errors occurred in as many as 5% of sites for each cell division [24]. These data raised the rational interest in targeting methylation as an oncologic therapy for several reasons. First, the tumorigenesis model whereby spontaneous epigenetic changes may impact phenotype alongside genetic mutations was recognized. Second, the flexibility of cellular processes controlling methylation and subsequent gene expression was proposed to be more "accessible" (or targetable) than corresponding changes in the underlying genome.

Given that initial studies associated oncogenesis with tumor suppressor gene hypermethylation, initial attempts to target DNMT function have focused on inhibition of the protein. Compounds found to inhibit DNMT can be broadly divided into

two categories: nucleoside analogs and non-nucleoside inhibitors [25]. The first generation to be discovered was nucleoside analog compounds initially believed to function as antimetabolites in cytotoxic regimens for leukemia [26]. The hypomethylation that results from therapy with two analogs of cytidine, 5-azacitidine and 2′-deoxy-5-azacitidine (DAC), was discovered after cellular differentiation was noted as a by-product of treatment in embryonic cell line studies [26]. Work to clarify the mechanism of action of these two agents has subsequently been elucidated. After entry into the cell, azacitidine and DAC are incorporated into the RNA and DNA of proliferating cells and recognized by DNMT during replication. Rather than catalyzing methylation, DNMT is irreversibly bound to the nucleotide analog due to substitution of nitrogen for the standard carbon on position 5 of the ring [25]. The differences between azacitidine and DAC are due to their molecular makeup. Azacitidine is a ribonucleoside that is incorporated preferentially into RNA rather than DNA. DAC, in contrast, is a deoxyribonucleoside and can only incorporate into DNA. These compounds both tend to have different mechanisms with different doses. Traditional use with high-dose administration causes direct cytotoxicity due to antimetabolite and DNA intercalation effects. In contrast, low-dose administration has been shown to effect demethylation with little cytotoxicity [27].

The US Food and Drug Administration has approved both azacitidine and DAC for the treatment of myelodysplastic syndrome and certain classes of lymphoma. Additionally, in the European Union, DAC is approved for acute myelogenous leukemia. Work by Silverman and colleagues in hematologic malignancies has shown us that the efficacy of these drugs is slow and responses are seen after several months [28]. As such, testing the efficacy of these epigenetic drugs in solid tumors has to be done carefully with the caveat that current clinical trials are performed in advanced cancers in patients who are rapidly progressing.

Utility of these compounds in solid tumors is under active investigation, but results have been hampered by early use of high doses of these drugs in the paradigm of using maximally tolerated doses similar to cytotoxic drugs and the resultant frequent side effects on bone marrow suppression from high doses [27]. However, in recent years low doses of these compounds have been tested in some solid cancers. Recently the Stand Up To Cancer/AACR consortium funded several trials with combination epigenetic therapy with a DNMT inhibitor, 5-azacitidine, along with an HDAC inhibitor entinostat in lung, colorectal, and breast cancers (discussed in detail below). In pancreatic cancer, for example, there is a wealth of preclinical data that suggests promise for DNMT inhibition either as a single agent or in multi-agent combination therapies. In cell culture models, administration of DNMT inhibitors has been repeatedly demonstrated to have profound effects on cellular growth and tumorigenicity of pancreatic cancer stem cells [29–31]. Additionally, preclinical models suggest a profound sensitization to other cytotoxic chemotherapeutics can be conveyed by low-dose DNMT inhibition. Telomerase activity, critical for cellular immortalization, has also been shown to be impacted by DNMT inhibition [32]. Finally, in vivo testing of DNMT inhibition has validated much of the data from cell culture

experiments: slowing progression of PDAC, extending survival, and sensitizing tumors to combination therapy [33].

A recent search of clinicaltrials.gov notes two trials evaluating the efficacy of DNMT inhibition in human subjects with pancreatic cancer. The first, NCT01845805, evaluates azacitidine in a phase II setting as monotherapy (versus an observation control) after completion of adjuvant therapy in resected pancreatic adenocarcinoma. First opening in April 2013 through the Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, this trial is due to accrue 80 patients. The intended patient population for this trial includes those with node-positive disease, margin-positive disease, and/or elevation in CA 19-9. The second trial, NCT02847000, evaluates DAC in combination with tetrahydrouridine (to improve biodelivery) in a phase 0/I setting. Accrual for this second trial has not yet begun. Studies in pancreatic cancer so far have been limited with single-agent therapy given the rapidly aggressive nature of the disease and the slow onset of action seen with these compounds.

The toxicities that are encountered when using cytidine analogs are well documented from use in other settings. In general, there are two distinct profiles that arise from azacitidine and DAC therapy and depend on dose. At high dose, myelosuppressive effects are most common and reflect the cytotoxic antimetabolite profile that characterized their early discovery and use [27]. Importantly, however, the goal of epigenetically directed therapy is to avoid overt cytotoxicity by using low-dose therapy [27]. In these settings, the frequency of side effects are few and morbidity is low [34]. Ongoing work with second-generation nucleoside analogs (such as the DAC prodrug, guadecitabine or SGI-110) aims to increase bioavailability, limit cytotoxicity at higher doses, and improve efficacy [25, 35]. An initial trial testing guadecitabine in hematologic malignancies has shown promising bioavailability of this drug [35].

Non-nucleoside analogs are also of interest in epigenetic drug discovery. While sharing the core mechanism of action, inhibition of DNMT, non-nucleoside analogs do not require DNA intercalation to exert pharmacologic effect. In general, the majority of compounds in this class were discovered to have effects on the methylation profile of cells as a secondary finding [25]. Examples of compounds include certain flavonoids, hydralazine, procainamide, and curcumin. Each compound, or compound family, is purported to have their own distinct mechanism of action. For flavonoids, an indirect effect due to catechol-*O*-methyltransferase (COMT)-mediated accumulation of *S*-adenosyl-L-homocysteine (SAH) is thought to cause DNMT inhibition from SAM/SAH disequilibrium [25]. Hydralazine is thought to be a direct enzyme inhibitor through binding of the active site of DNMT, though this remains highly debated in the field [36]. In general, the use of flavonoids, hydralazine, and curcumin has all demonstrated the capacity to impact pancreatic cancer cell growth and induce apoptosis in vitro [37].

The efficacy of non-nucleoside analogs in the clinic is also promising, though data lags behind that of their nucleoside analog counterparts. Perhaps the best data are from trials involving hydralazine administration in combination with other

antitumor agents. Combination with valproate, for example, has demonstrated a limited capacity to resensitize patients to chemotherapeutics (a topic which will be discussed further later in the chapter), and hydralazine monotherapy was associated with reestablishment of tumor suppressor gene expression in otherwise untreated cervical cancer [36]. To date, there are no ongoing clinical trials evaluating the efficacy of non-nucleoside analogs for the prevention or treatment of pancreatic cancer.

Targeting the Effectors of Chromatin Structure and Function

The structure of chromatin can vary based on the markers which are affixed to the individual histone protein. These conformal rearrangements can dramatically alter the function of chromatin, including its capacity to bind nearby structures such as adjacent chromatin or nearby DNA strands. Based on this structure and function, the expression of genes can be regulated. In a simplistic view, the effectors that mark histones and change chromatin function can be divided into four classes. These are sometimes referred to as the "four Rs of epigenetics" and include the *r*emodelers, w*r*iters, e*r*asers, and *r*eaders (Figs. 1 and 2) [4].

These broad categories reflect differences in the function of the various proteins involved. For example, remodelers can be protein or noncoding RNA that often work in complexes to initiate the process of chromatin remodeling [38]. Epigenetic writers and erasers also often function in complexes of larger proteins as the enzymatic catalysts of histone modification [38]. As implied by the name, writers are responsible for labeling the histones with epigenetic marks. This family of catalysts has many members and can mark by facilitating transfer of acetyl, phosphoryl, hydroxyl, methyl, and many other moieties to the histone. In general, the focus of histone modification occurs at the amino-terminal peptide regions that are exposed at the periphery of the chromatin complex. Erasers are a family of enzymatic proteins that remove the marking of histones. Finally, epigenetic readers are responsible for identifying the epigenetic information laid down and facilitating changes in gene expression profiles (Figs. 1 and 2) [4, 8]. Remodelers help to arrange the histone and chromatin structure.

A historical view of epigenetics posited that increased marking of histones resulted in chromatin unfolding and directly correlated with increased gene expression. We now know that the relationship is complex and that both down- and upregulation of gene expression can be seen with histone modification [39]. Nevertheless, research has begun to wade into the nuanced world of these four protein families in attempts to discover new therapies for pancreatic cancer. While all four (remodelers, writers, erasers, and readers) may represent druggable targets, there are certain classes that lend themselves to therapeutic manipulation easier than others. For example, the enzymatic function of writers and erasers has enabled researchers to screen for and identify inhibitors of these enzymes (many of which are clinically approved for use and discussed below) [38, 40]. An additional class of epigenetic pharmacologic agents being studied focuses on disruption of the protein-protein

interactions central to the function of the reader proteins. The bromodomain inhibitors (or bromodomain and extraterminal, BET, inhibitors of reader protein function) are the classic example of this latter class of agents and will also be discussed later in this chapter [41].

Histone Deacetylase (HDAC) Inhibition: The Prototypical Agent for Histone Modification

In the eraser family of proteins, histone deacetylase (HDAC) and histone lysine demethylases are the two major members [40]. While work to target lysine demethylases is limited [42, 43], the HDAC inhibitors are a particularly well-described and well-studied class of medications that act on this epigenetic eraser family of proteins. There are several HDAC inhibitors that are approved for clinical use for various hematologic malignancies including vorinostat and panobinostat (Table 1). The original discovery of this class of agents was made following empiric compound screens for antitumor agents; only subsequently were the mechanisms of action elucidated [44]. Follow-up work has demonstrated that most of these agents have little-to-no sensitivity for targeting individual HDACs (as opposed to the whole class of proteins) and have potent effects on "off-target" enzymes in related classes [45]. Nevertheless, enthusiasm for this pharmacologic class has not waned, and there are currently more HDAC inhibitors in clinical trials than any other class of epigenetic agent.

The effects of HDAC inhibition on tumorigenesis is an area that has grown exponentially over the past decade. Proposed mechanisms of action include a direct effect on cell death via apoptosis and DNA damage accumulation, cell cycle arrest, reversal of dedifferentiation, and enhanced tumor immunogenicity [40]. Induction of apoptosis can occur via both the intrinsic and extrinsic pathway through gene modification of proteins such as the death receptors (DR4, DR5, FAS) and their ligands [46]. DNA damage repair mechanisms can also be fundamentally altered, and the resulting accumulation of errors can lead to apoptosis or autophagy [47]. The same line of investigation also discovered a toxic accumulation of reactive oxygen species was associated with increased DNA damage and proposed a role of HDAC in native metabolic homeostasis. Work on the mechanistic drivers of cell cycle arrest implicated direct transcriptional changes in genes such as *p21*, *p15*, *p19*, and *p57* [40]. Finally, an immunomodulatory component contributing to HDAC inhibitor efficacy was recently suggested after studies of murine models of carcinogenesis found an intact immune system was necessary for antitumor effect [48].

There are several classes of medications with a proposed mechanism of HDAC inhibition. The two broad categories include pan inhibitors (not HDAC isotype specific and with significant "off-target" effects) and inhibitors that purport to target a specific class of HDAC enzyme. The latter are far less common. Historically, hydroxamates and their derivatives were the most common HDAC inhibitors. These agents are composed of three domains: a cap region with surface recognition motifs, an active zinc-binding group that acts to perform its catalytic function, and a nonspecific linker region. Compounds belonging to this class include vorinostat and panobinostat. These agents generally target several classes of HDAC in addition

to having effects on other cellular lysine deacetylases that act on both nuclear and cytoplasmic protein targets [40, 45]. The nonspecific nature of these agents is principally due to the relative availability of the catalytic domain when these compounds are in their native forms.

The second class of HDAC inhibitors belong to a family known as the benzamides. These agents are characterized by more complex cap and linker regions which increase specificity of binding and limit the activity of the zinc-binding group for a particular HDAC class (generally class I HDAC). The most commonly studied agents in this family of medications are entinostat and mocetinostat [40, 49]. Novel compounds in this family are being frequently described and tested, such as the HDAC class 3 inhibitors RG2833 and RGFP966 [40]. Finally, other attempts to develop HDAC-specific therapies involve agents that architecturally abandon the traditional cap-linker-zinc catalyst mold of prior generations of agents. Thiol derivatives, which shroud the zinc-binding region within a complex ring structure, are one example of this class. The most well-described agent in the thiol class is romidepsin [40, 50].

The clinical utility of HDAC inhibition is limited thus far to patients with hematologic malignancies. Vorinostat, for example, has demonstrated modest efficacy in the treatment of refractory cutaneous T-cell lymphoma [51]. In this supporting work, 8 of 33 patients achieved a partial response with a median time to disease progression beyond 6 months in heavily pretreated patients. These findings, along with work done by many other groups, warranted granting of approval for use in this disease by the United States Food and Drug Administration [40]. The study of other HDAC inhibitors, such as romidepsin and belinostat, has also led approval of these agents for clinical use in selected hematologic malignancies [52]. A recent comprehensive review of HDAC inhibitor trials notes that over 350 clinical trials are currently ongoing to evaluate the efficacy of these agents, with most focused on hematologic tumors [40].

Belinostat is an interesting case study that represents a novel process of clearance for clinical use: accelerated approval. In July 2014, the FDA granted accelerated approval to belinostat (a relatively nonspecific HDAC inhibitor) for relapsed or refractory peripheral T-cell lymphoma [53]. The dose was chosen through a standard phase I dose escalation study that characterized the common side effects of nausea, vomiting, fatigue, fever, and anemia. As a monotherapy in second line or beyond disease, belinostat was found to convey an overall response in approximately one-quarter of patients. Given the accelerated approval paradigm, the end points of overall or progression-free survival were not reported. Importantly, this agent was never tested against control in any of the pre-approval trials, and as such a comparison end point of overall or progression-free survival would be inappropriate (and was not used to determine FDA status). Finally, subsequent studies of combination therapy of belinostat (and other HDAC inhibitors) with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) in early-phase clinical trials have been encouraging [54]. This experience clearly reflects the dire outcomes in relapsed and refractory peripheral T-cell lymphoma. The parallels (regarding the devastating

prognosis) with advanced pancreatic adenocarcinoma are glaring, and interest in accelerated approval for novel therapeutics in that disease is growing.

The use of these agents in solid tumors is still investigatory, though early reports are promising in selected diseases and when HDAC inhibition is combined with other agents. In breast cancer, for example, there is mounting evidence that targeted epigenetic therapy with HDAC inhibitors can reestablish sensitivity of tumors to antiestrogen therapy. This work was spearheaded in part by Merino and colleagues after successful results from early-phase clinical trials [55]. There are currently trials actively recruiting subjects in phase III for entinostat in combination with an aromatase inhibitor for patients who develop endocrine therapy resistance [56]. This trial is not alone as a recent search of clinicaltrials.gov reveals over a dozen trials registered testing entinostat in breast cancer, with correlative translational research providing clues to the underlying mechanistic rationale for treatment response or failure. Recent work from another of these trials suggests that combination therapy with immunomodulatory agents may be a rational strategy [57].

Combination therapy may be efficacious in other solid tumor models. Data from a phase I/II trial at Johns Hopkins University found that combination epigenetic therapy with azacitidine and entinostat produced responses in some patients with refractory advanced non-small cell lung cancer [58]. Data showed a median survival of 6.4 months in heavily pretreated patients, more than 2 months longer than historical controls. Of the 45 patients enrolled in the study, all of whom received the epigenetic treatment, 19 were able to undergo subsequent chemotherapy, and several had positive responses to treatment. In all, seven patients remain alive, including two who began the therapy nearly 4 years ago. Two other notable results combining azacitidine and entinostat include a phase II trial in advanced breast cancer (NCT01349959) and a phase II trial in metastatic colorectal cancer (NCT01105377) which have recently been completed as part of the Stand Up To Cancer consortium. The breast cancer trials included randomization by hormone receptor status and an optional continuation arm to investigate if epigenetic therapy can resensitize hormone-resistant patients to therapy [59].

In pancreatic cancer models, there has been little published to date suggesting that HDAC inhibition is a viable single-agent strategy for in vivo tumor response [38, 40]. This is despite growing in vitro data suggesting that HDAC plays an important role in pancreatic cancer cell growth, apoptosis, and downregulation of selected tumor suppressor genes [60]. Recapitulating the models developed in other tumor systems, there is in vitro evidence to suggest that combination strategies with HDAC inhibition and nucleoside analogues are promising in pancreatic cancer [61]. In this work by Arnold et al., vorinostat treatment of three pancreatic cancer cell lines resulted in cell cycle arrest and gemcitabine sensitization that appeared to be *p21* dependent.

There are other compounds that demonstrate histone acetyltransferase inhibition that are also worth noting. Many of these are derivatives from natural compounds such as curcumin, anacardic acid, and garcinol [4]. Other compounds, such as BIX-01294, chaetocin, and 3-deazaneplanocin A (i.e., DZNep), can be included in the

category of histone methyltransferase (HMT) and histone demethylase (HDM) inhibitors and are at various preclinical stages of development [8].

Targeting the Reader Proteins, a Relatively New Approach

The importance of the reader proteins in the structure and function of chromatin was highlighted by the discovery of mutations in the PHD domain (plant homeodomain – Cys4-His-Cys3 motif). PHD fingers are involved in chromatin-mediated gene regulation. Co-effectors of this function include the transcriptional coactivators p300 and CBP, polycomb-like protein (Pcl), trithorax group, the Mi-2 complex, the corepressor TIF1, the JARID1 family of demethylases, and many more [62]. Specific mutations in the PHD finger have been found to abrogate the protein's ability to bind protein effector partners and result in various disease conditions including carcinogenesis and immunodeficiency syndromes [62]. Thus, chromatin readers give us a unique opportunity for targeted therapies.

The best example of targets in the reader family of proteins are the bromodomains and extraterminal (BET) family of proteins. In brief, BET protein studies demonstrate a range of activity with the capacity to impact molecular function across a wide array of cellular processes [63]. They not only interact with the chromatin but also seem to function alongside other core nuclear protein complexes to affect DNA damage repair and transcriptional regulation. These findings have paved the way for the identification of potential BET bromodomain inhibitors as novel anticancer agents. Currently three BET inhibitors (I-BET762, JQ1, and I-BET151) are currently in preclinical models [4, 64]. These agents have been shown to bind to BRD2, BRD3, and BRD4 with a capacity to inhibit their engagement with acetyl-lysine residues. To date, effective antitumor properties have been demonstrated in several murine models of carcinogenesis and nearly two-dozen clinical trials are underway in a variety of advanced malignancies as tracked by clinicaltrials.gov.

Targeting the Associated Complexes in Epigenetics: Noncoding RNA and Protein-Protein Interaction

The role of ancillary pathways of epigenetic control to complement DNA methylation and histone modification is a relatively recent discovery. For example, it is becoming more evident that noncoding RNA plays an important role in the regulation of epigenetic processes [65]. In contrast to the central dogma of molecular biology, wherein RNA is supposed to code for amino acids, this family of nucleotides contains members that impart direct effects on cellular function or phenotype without translation into protein. These RNA transcripts are variable in length and can function both within the nucleus and in the cytoplasm. Effector functions of noncoding RNA can vary from epigenetic control (including chromatin remodeling or direction of methylation) to direct gene expression through transcriptional control and binding of DNA or posttranscriptional processing [66]. Examples include tRNAs, snRNAs, miRNAs, siRNAs, piRNAs, tiRNAs, spliRNAs, and sdRNAs among others. In general, the letters preceding RNA in each family provide clues

as to function. For example, siRNA tends to have a gene-silencing function. There are several key transcripts with known function via epigenetic mechanisms of control: Kcnq1ot1, Airn, Xist, and HOTAIR, for example [66]. Importantly, however, the role of microRNAs can be broad as nonspecific binding and "off-target" effects are as likely with this mechanism (as they are with other mechanisms of epigenetic control).

Perhaps one of the first studies to establish a potential role for noncoding RNA in oncogenesis was performed by Yu et al. and published in 2008 [67]. In this work a leukemia model of tumorigenesis was used to demonstrate the power of antisense RNA to silence tumor suppressor gene function. Specifically, with exogenous overexpression of an antisense noncoding RNA targeting *p15*, investigators demonstrated decreased gene expression and increased tumor growth associated with heterochromatin formation and DNA methylation [67]. A translational link was provided in that natural expression of this antisense construct appeared to be associated with decreased *p15* expression from patient samples.

There is strong preclinical rationale to support the role of noncoding RNA transcripts in solid tumors such as pancreatic cancer. First, global transcriptome analyses suggest that as many as 70% of all genes are susceptible to silencing through the effects of naturally occurring siRNA products present in nearby genetic code [68]. Second, members of another noncoding RNA family have already been shown to have effects on the development of pancreatic cancer [69]. MicroRNAs (miRNAs) are generally short RNA transcripts with the capacity to alter gene expression through any of the mechanisms described above. In pancreatic cancer, miRNA-17-92 has been suggested to be a key molecule in the restriction of tumorigenesis of cancer stem cells [31]. Interestingly, the discovery of this link was made after analysis of cancer stem cells' response to therapy aimed at targeting another epigenetic mechanism of gene expression, methylation through DNMT1. Another suggestion of the role that microRNA plays in pancreatic cancer derives from classic high-throughput discovery, necessity, and sufficiency experiments performed in cell line studies of pancreatic cancer [69]. These authors used a methylated DNA immunoprecipitation chip assay to discover that miRNA-615-5p was hypermethylated and silenced. Overexpression of this particular microRNA led to growth inhibition and decreased migration and invasion. Mechanistic studies suggested that miRNA-615-5p acts through effects on insulin-like growth factor 2 (IGF2), itself a heavily imprinted gene that is subject to epigenetic control. The direct influence, whether epigenetic, transcriptional, or posttranscriptional, between miRNA-615-5p and IGF2 is not clear, though the driver of expression (or silencing) of the actual microRNA is clearly through epigenetic mechanisms.

Drug Resistance in Pancreatic Cancer: An Epigenetic Problem?

There are four core mechanisms that have been proposed for acquired drug resistance in cancer therapy: reactivation of an oncogenic pathway, activation of parallel signaling pathways (i.e., bypass mechanisms), pathway-independent tumor cell

growth, and secondary alterations in the targets of selected drug therapy [70]. Classically, these have been described as mechanisms driven by genetic drift in tumorigenesis. It is increasingly being recognized, however, that epigenetic mechanisms of acquired resistance to therapy are important [71]. It is plausible that the relatively quick changes in cancer phenotype that occur during development of therapeutic resistance are driven more by the quick and directed epigenetic mechanisms of gene expression rather than the relatively slow and undirected process of acquired novel gene mutations [71]. Preventing or reversing these epigenetic mechanisms of acquired resistance could lead to more effective systemic therapy and extend survival [6, 71].

In pancreatic cancer there are two core bodies of work that support the hypothesis of epigenome-controlled therapeutic resistance. The first, led by Qin and colleagues, investigated the patterns of resistance that develop in pancreatic cancer cell line models to treatment with gemcitabine (until recently, the gold standard monotherapy in pancreatic cancer) [72]. Results demonstrated a cellular phenotype with dramatically upregulated expression of the 14-3-3σ protein. This protein is one member of a family that is known to bind a number of signaling proteins including key oncogenic effectors. Crucially, the σ isoform has been associated with particularly poor prognosis in pancreatic adenocarcinoma [73]. Mechanistic work to uncover the driver of 14-3-3σ overexpression implicated epigenetic regulation as the root cause. Under gemcitabine therapy, *14-3-3σ* is demethylated by DNA methyltransferase 1 and ubiquitin like with PHD and ring finger domains 1 (Uhrf1) [72]. When gemcitabine therapy was suspended, the epigenome partially reverted to its previous state of heavy methylation of *14-3-3σ*. These findings implicate epigenetic control of gene expression in the acquisition of therapeutic resistance and highlight the promise of targeted epigenetic therapy in combination treatments for this disease.

The use of combination chemotherapeutics using epigenetic agents with standard chemotherapeutics is beginning to show promise in selected tumor systems. As mentioned previously for breast cancer, the combined use of entinostat with all-trans-retinoic acid (ATRA) and doxorubicin resulted in significant tumor regression in xenograft modeling [55, 59]. This work has consequently led to clinical trials that are ongoing, including one successful phase II and an ongoing phase III trial [59]. Additionally, in ovarian cancer patients with platinum-resistant tumors, administration of low-dose 5-aza-2′-deoxycytidine was associated with resensitization to platinum agents (improved objective response rates and progression-free survival) which has led to an ongoing phase III trial (NCT00477386) [74]. Finally, work at Johns Hopkins in heavily pretreated metastatic colon cancer is now trialing guadecitabine (SGI-110) with irinotecan versus standard of care in a randomized phase II setting (NCT01896856). These trials reinforce the notion that future work in PDAC will focus on combination therapy utilizing epigenetic pharmacotherapy with standard cytotoxic, immunotherapy, or future targeted approaches [65].

Future Directions

While current epigenetic therapeutic approaches in solid tumors have showed minimal responses, the future for this therapy remains full of potential. Previous research, focused mainly on the effect of changes in DNA sequence on drug efficacy, failed to account for the changes in the proteome that were not driven by mutational burden. An increasing recognition of the importance that epigenetic factors play on disease biology and treatment response is driving current research. There are several barriers that remain, however, including a deeper understanding of the biology of the epigenome, a recognition of which epigenetic players are targetable and which are bystanders, and the pharmacodevelopment of novel compounds.

Additionally, the integration of targeted epigenetic therapies into clinical patient care will require multidisciplinary cooperation. Similar to data supporting multimodality treatment (surgery, cytotoxic chemotherapeutics, and radiation therapy) to maximize outcomes in pancreatic cancer, the goal of future epigenetic therapeutics will be to integrate novel drugs into a clinically relevant treatment model to allow for continued multidisciplinary care. In this respect, one would expect that epigenetic therapy should be well tolerated with few side effects. This is in keeping with work described earlier in this chapter in which maximal epigenetic benefits could be achieved at relatively low, noncytotoxic doses. Other than the aforementioned approaches, hormone therapy, immunotherapy, and other molecularly targeted therapies may change the landscape of treatment for pancreatic cancer in the future, and it is imperative that epigenetic therapies "play nice" with these other novel treatments as well.

Finally, it is well recognized that pancreatic ductal adenocarcinoma is a disease in need of better biomarkers. This would aid in both the early detection of disease and determining an optimal treatment paradigm. The traditional model of characterizing patient disease largely ignores the underlying biology of a patient's tumor and relies instead on needle biopsy for histopathologic diagnosis, blood measurement of a cell-surface carbohydrate (CA19-9), and imaging. One could certainly envision a future where a more robust analysis of disease biology is performed at key points in a patient's course of disease (from diagnosis to key points in treatment algorithms and therapeutic switches). It is becoming increasingly evident that an analysis of the epigenome would provide valuable data in this future paradigm.

Conclusion

Epigenetic influence on oncogenesis is becoming accepted as an increasingly important aspect of disease onset and progression. The biology responsible for epigenetic control is now becoming clear with key underlying mechanisms that include DNA methylation, histone modification, and noncoding RNA interactions. With clarification of the mechanisms, proteins involved are being characterized with increasing

detail. Targeting of key players is already in use in the clinic for certain tumors, and work is ongoing to broaden the utility of these FDA-approved agents. Importantly, epigenetic targeting appears to have a key role in both direct cellular cytotoxicity and in maintaining tumor response to current chemotherapeutics. As such, the future role of targeted epigenetic therapy in pancreatic cancer will likely include a multimodality approach and take advantage of improving surgical, cytotoxic chemotherapeutic, and radiotherapeutic advancements.

Abstract

Despite decades of research and efforts at improving survival, pancreatic ductal adenocarcinoma (PDA) has become the third leading cause of cancer-related deaths in the United States. In fact, by 2020, it is projected to become the second leading cause of cancer-related deaths in the United States. Personalized, or precision, medicine has resulted in improving patient outcomes in other tumor systems. However, for pancreatic cancer patients, there are a limited number of evidence-based targeted therapeutic options that are currently available. Significant advances in DNA sequencing technology have resulted in the identification of a number of genetic mutations and the delineation of core signaling pathways important in PDA. This has subsequently resulted in an advanced understanding of the genetic drivers of the progression of this disease. Facile sequencing technology has moved the field closer to a personalized approach to treating pancreatic cancer. Improvements to the personalized therapy approach will likely result from several factors including the delivery of tumor sequencing results in a clinically relevant timeframe, the development of better targeted drugs, and perhaps a molecular-targeted approach to aspects of PDA biology beyond mutations in the deoxyribonucleic acid (DNA). These advances will allow clinicians to enroll patients in appropriate-matched clinical trials in a timely manner. In this chapter, the opportunities and limitations of a targeted, personalized approach to treating PDA will be discussed.

Introduction

Pancreatic ductal adenocarcinoma (PDA) remains a largely deadly disease with a 5-year survival of only 9% for all stages combined [1]. Currently, it is the third leading cause of cancer-related deaths in the United States and it is on pace to become the second leading cause by 2020 [2]. This mortality rate is due to a number of factors such as aggressive tumor biology; lack of early screening and prevention strategies; and ineffective targeted treatments. Thanks to large-scale high-throughput sequencing studies, our understanding of the molecular driving events in pancreatic tumorigenesis has increased over the past few decades. However, unlike in other cancers, this has not resulted in a similar increase in effective targeted treatment options that are available in the clinic. In fact, the mainstay of pancreatic cancer treatment remains largely conventional and includes surgery for the minority of patients who are diagnosed with resectable disease, and cytotoxic therapy [3–5].

The clinical aggressiveness observed in PDA is due, in part, to its cellular complexity and its ability to survive in a harsh tumor microenvironment. These

factors likely contribute to resistance to many therapies. First, PDA is associated with a dense stromal reaction. The tumor mass is composed mainly of the tumor microenvironment, and it includes mostly nonneoplastic cells, such as fibroblasts and lymphocytes, and noncellular connective tissue [6, 7]. Additionally, the PDA tumor microenvironment also includes a vasculature, but this cancer is classically hypovascular [8]. This is evident when these tumors are visualized with contrast-enhanced computed tomography imaging, which shows hypoattenuated lesions when compared to the well-enhancing normal surrounding pancreatic parenchyma [9]. PDAs are also genetically complex. Though common driver-mutations are present in essentially all PDAs (i.e., high-frequency mutations, such as *KRAS*), there are a significant number of low-frequency mutations of which the clinical significance has yet to be determined [10–12]. It is this degree of genetic diversity that increases the complexity when considering targeted therapy. For instance, it is unclear which low-frequency mutations contribute to the tumorigenesis in PDA by allowing the tumor to overcome a selective pressure and whether they confer a growth advantage. Some of these low-frequency aberrations may simply be passenger mutations [13]. Additionally, assuming that low-frequency mutations are important in PDA tumorigenesis, it raises the question whether using targeted therapies that will impact a small subset of patients will result in meaningful improvement in overall outcomes in PDA.

This chapter will provide a basic overview of DNA sequencing technology that is available today and how it has contributed to our understanding of dysregulated pathways in PDA. Current targeted therapies and outcomes of precision medicine-based clinical trials in PDA will be reviewed, along with other potential therapeutic strategies that go beyond the targeted approach.

Advances in DNA Sequencing and Its Implications in PDA

Sequencing in PDA

Emerging technologies in sequencing, such as next-generation sequencing (NGS) or whole-exome sequencing (WES) or whole-genome sequencing (WGS) strategies, have been used in PDA to determine its genomic landscape as well as its pathologic progression from precursor lesions into PDA [14, 15]. NGS is a powerful tool that allows for parallel sequencing of multiple genes in one test. Compared to WES, WGS and determination of copy-number alterations (CNAs) provide a more granular view of the genomic landscape of the tumor. WGS and CNAs allow the measurement of alterations in DNA structure (i.e., deletions, amplifications, insertions, and translocations) and result in an improved understanding of the patterns of chromosomal instability that are often observed in PDA [16, 17].

When compared to other tumors, sequencing of PDA is not a simple exercise. In part, this is due to the characteristic desmoplastic stroma that makes analysis of pure tumor epithelial cells difficult. Some of the ways to circumvent this limitation in sequencing PDAs include developing patient-derived cell lines or using laser

microdissection, both are methods that enrich the tumor epithelial content [18]. Despite these apparent limitations, over 1300 PDA genomes or exomes have been sequenced, which has added to our understanding of the molecular drivers in PDA (Table 1). More current studies that utilize NGS have focused on WGS and more detailed genomic analyses, combined with ribonucleic acid (RNA) sequencing for a better characterization of PDAs [19, 20]. Despite the increase in utilization of

such sophisticated high-throughput studies, novel high-frequency mutations, beyond the key players such as *KRAS*, have not been identified. However, identification of novel pathways and also subtyping PDA has emerged as a promising deliverable of this work [19, 21].

The first extensive WES analysis of PDA was first published in 2008 by Jones and colleagues [10]. This study used samples from 24 human cell lines and xenografts and utilized Sanger sequencing to sequence 20,661 genes. Genetic alterations that were identified were variable and included point-mutations, deletions, and amplifications. The authors were able to reproducibly identify well-described mutations in *KRAS*, *CDKN2A (p16), TP53*, and *SMAD4* in PDA genomes. Reproducible alterations in other genes, such as *ARID1A, TGFBR2*, were identified, but these were found in lower frequencies. Ultimately, the researchers were able to identify 69 genes that were altered in the 24 analyzed samples. Thirty-one of these were further subdivided into 12 core-signaling pathways that were found to be altered in 67–100% of the sequenced samples. Several pathways were found to be genetically altered in 100% of the tumor samples, such as apoptosis and KRAS signaling pathways. This clustering of genetic alterations along with molecular signaling pathways in this first high-throughput analysis provided a practical approach to support this research movement.

Following Jones and colleagues, a number of other studies provided sequencing of PDA samples. A recently published study by Bailey and colleagues would follow Jones and colleagues to provide the next large-scale sequencing data in PDA [19]. Using NGS, the authors performed a whole-genome analysis of 456 PDA samples. They identified 32 mutated genes, which were then grouped into 10 pathways that were consistently dysregulated. Moreover, when expression analyses were performed, they were able to group PDAs into four subtypes: squamous, pancreatic progenitor, immunogenic, and aberrantly differentiated endocrine exocrine. Furthermore, these PDA subtypes were correlated with discernable histopathologic characteristics.

A study by Makohon-Moore and colleagues extended these NGS studies. Utilizing very strict inclusion criteria, the authors evaluated primary tumor and metastatic lesion samples by using WGS of patients that were treatment-naïve [31]. The goal was to determine the degree of genetic heterogeneity between primary tumors and metastatic lesions. This is important since it may impact a patient's response to therapy. For example, if there is significant intratumoral heterogeneity between two different samples in the primary tumor or between the primary tumor and a metastatic lesion, it is likely that a patient would develop early resistance to targeted treatment. However, if the primary tumor is genetically similar to a metastatic lesion, it is plausible that both tumors would be sensitive to the initial therapy [34, 35]. A total of 39 samples were evaluated (26 from metastatic lesions, 3 from different regions of the primary tumor, and normal tissue) in four patients. There was a limited variability of driver mutations in untreated patients with metastatic PDA (mPDA) that were present in the primary tumor and the metastatic lesions. This suggests that in patients with metastatic cancer, there may be a clinical benefit afforded by using targeted therapies geared towards driver mutations in the primary tumor.

Moving forward, the goal is to continue the genetic characterization of PDA, to understand how these genetic aberrations relate to the clinical features of the patient's disease, and to identify therapeutic targets. Moreover, there will be a continued trend and interest to further continue to characterize dysregulated pathways and subtypes of PDA.

Current Clinical Use of Next-Generation Sequencing in PDA and Its Implications

There has been an emergence of studies that attempt to link/associate patients' tumor mutations with currently available targeted therapies. The goal of these studies is to take advantage of the opportunities offered by NGS to characterize genetic pathways that drive a specific PDA and to match it to an available targeted therapy. One such trial has been the Individualized Molecular Pancreatic Cancer Therapy (IMPaCT) Trial from Australia [36]. This was a feasibility trial that aimed to demonstrate the ability to successfully acquire patient samples and to provide quality genomic data for three molecular targets: *HER2* amplification, *KRAS*, and mutations in DNA repair pathways (*BRCA1*, *BRCA2*, *PALB2*, and *ATM*). The goal was to evaluate whether it would be feasible to provide sequencing results in a clinically relevant timeline. Inclusion criteria included newly diagnosed PDA patients who either received one cycle of gemcitabine for metastatic disease or patients who were treatment-naïve. Patients were randomized in a 1:1 fashion and offered standard therapy (gemcitabine) versus personalized treatment (gemcitabine plus targeted therapy) depending on the patient's genetic aberrations. At the time that the results of the trial were reported, no patients were successfully treated on the protocol.

The Pancreatic Cancer Action Network (PanCAN) has also launched the Know Your Tumor® Initiative with the goal of providing sequencing data to patients and their oncologists in order to facilitate the use of targeted therapy or clinical trial enrollment. The initial experience resulted in 117 patient sequencing reports, with the identification of an "actionable" finding in approximately 40% of cancers (actionable findings were defined as the availability of a targeted therapy in an identified molecular abnormality in any cancer type or predicted response based on pathway or mechanism-defined for the identified target) [37]. This resulted in 43% of patients being referred to high-priority clinical trials and 53% were recommended in the direction of off-label targeted therapy [38].

A similar multi-institution trial has been designed and implemented in the United States by the authors (MJP and JRB), with the goal of randomizing 60 patients along standard treatment and molecularly targeted therapy (MTT). This trial is also supported by PanCAN and the American Association of Cancer Research. Sequencing of 600 genes and protein expression analyses will be undertaken to further predict the patient's response to either standard therapy or MTT. The results of this trial are forthcoming. PanCAN has also implemented a multi-institution clinical trial called Precision Promise. Its aim is to promote data-sharing by promoting a number

of substudies that investigate different therapies under the same clinical trial umbrella in an effort to expedite the breadth of targeted therapies available to patients with PDA. A similar trial is being implemented in England, called PRECISION-Panc, where multiple subtrials will be carried out under the same umbrella clinical trial. The goal will be to provide molecular profiling of patients' tumors followed by enrolling patients in clinical trials that utilize the targeted approach [12].

In addition to the trials described, there are a number of currently active trials that are based on identifying genetic aberrations for which targeted therapy is available. These include clinical trials, commonly referred to as basket trials, from the National Cancer institute (NCI) including NCI-Molecular Analysis for Therapy Choice (MATCH) Trial, NCI-Molecular Profiling-Based Assignment of Cancer Therapy (MPACT), and Initiative for Molecular Profiling and Advanced Cancer Therapy (IMPACT 2) [39–41]. These studies are not specific for patients with PDA; however, they are likely to recruit patients with PDA based on the trial designs.

The Use of Targeted Therapy in the Treatment of PDA

History of Precision Medicine and its Role in PDA

One of the earliest examples of precision oncology in clinical practice is the use of imatinib in patients with chronic myeloid leukemia (CML) that harbor the Philadelphia chromosome (i.e., the *BCR-ABL* mutation) [42]. The successful clinical use of mutation-targeted therapies has remained elusive in PDA. Even though the number of US Food and Drug Administration (FDA)-approved mutation-targeted therapies has increased over the years and has resulted in an improvement in outcomes in other cancers, similar results have not been realized in PDA.

In PDA, the use of targeted therapy is limited largely due to the fact that many alterations tend to result in loss-of-function in genes that would traditionally be considered tumor suppressors genes (TSGs). In general, TSGs halt cell proliferation, disrupt the cell cycle, and can initiate apoptosis; therefore, the inactivation of TSGs is a critical event for the progression of tumorigenesis. Since rescue of this genotype would require TSGs to regain function, this limits the use of small molecule compounds or drugs that generally are most effective against inhibiting oncogenes (i.e., in the setting of gain-of-function mutations), and not "turning on" an already "turned off" gene. High-frequency TSG mutations are common in PDAs (e.g., *TP53, CDKN2A*) and limit the personalized approach. At the present time, perhaps the most effective personalized therapy for PDA is targeting the BRCA pathway, which contains genes that are known TSGs, resulting in *synthetic lethality* (see next section). Perhaps the resurrection of gene therapy will become a clinical reality. If this happens, one can imagine real precision therapy, wherein specific TSGs can be sequenced in individual tumors and a matched gene therapy option can be utilized (e.g., SMAD4 overexpression for SMAD4 deleted tumors).

Pathways Dysregulated in PDA and Opportunities for Targeted Therapies

Historically, mutations or genomic alterations of *KRAS, CDKN2A (p16), TP53, and SMAD4* have been implicated in the development of pancreatic intraepithelial lesions which ultimately lead to the development of PDA [43, 44]. More generally, multiple pathways are dysregulated in PDA and, in theory, targeted therapies can be used to exploit their specific function. Figure 1 demonstrates commonly altered pathways in PDA and downstream effectors that play a role in tumorigenesis. The remainder of this section will expand on these pathways and provide an overview of therapeutic strategies and options that can be utilized in patients with PDA. Though there have been mixed results with targeting some genetic aberrations, it is the degree and frequency of dysregulation in key cellular processes that make them ideal therapeutic targets in PDA. Therefore, an understanding of the role of individual pathways that are activated or deactivated in PDA will be instrumental to successfully target them in a personalized manner.

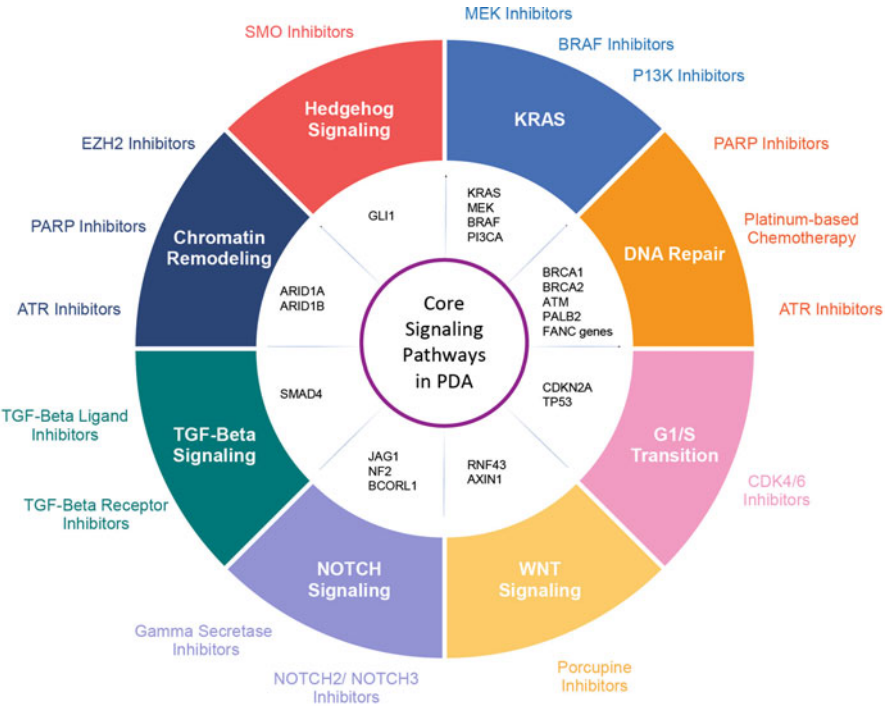

Fig. 1 Core signaling pathways implicated in PDA, genetic aberrations implicated in tumorigenesis, and potential targeting strategies

Targeting KRAS Signaling and Its Downstream Effectors

The *RAS* family of oncogenes consists of *HRAS, NRAS,* and *KRAS* and one or more isoforms of this gene are mutated in most cancers [45]. The *KRAS* pathway is one of the best-characterized pathways in cancer and *KRAS* mutations are frequently observed in PDA, occurring in roughly 95% of tumors [43, 44, 46]. Activity of KRAS is tightly regulated, and under nonpathologic conditions, it exists in an inactive state (i.e., bound to GDP). Extracellular signals, such as growth factors, result in activation of KRAS and the conversion of GDP to GTP and activation of its downstream targets. *KRAS* mutations are found in PDA precursor lesions, so they are believed to occur early in the progression of PDA. Point mutations in *KRAS* often occur in codons 12, 13, or 61 resulting in a constitutively active GTPase that is unable to hydrolyze GTP. This results in sustained signaling of a number of downstream KRAS targets that affect cell survival, proliferation, cell cycle progression, apoptosis, and metabolism [45]. The importance of *KRAS* mutations in the initiation of PDA has been underscored by experiments that utilize genetically engineered mouse models (GEMMs), in which mutant *KRAS* is driven to be specifically expressed in the pancreas [47–50].

Targeting KRAS has been difficult to date, and in fact, KRAS is thought to be an "undruggable" target by some [51]. The NCI has started a program that is specifically geared to the development of KRAS inhibitors [52]. The difficulty with developing a small-molecule to target KRAS is, in part, due to the fact that it has a high affinity for GTP. GTP is abundant in the cell, and it effectively blocks access to the active site of the protein by other small molecules. Targeting farnesylation, one of the post-translational modifications of KRAS which affects its localization to the cell membrane, has not resulted in any significant clinical benefits either [53]. Similarly, specifically targeting the localization of KRAS to the cell membrane, which is dependent on PDEδ, with the use of PDEδ inhibitors has shown some success in xenograft models [54]. Targeting mutant *KRAS* with siRNA has been done in xenograft models, but this has yet to be translated to the clinic [55, 56]. In humans, KRAS siRNA was well tolerated and perhaps even efficacious in patients with locally advanced PDA [57].

Considering the difficulty with targeting KRAS directly, a significant amount of effort has been placed in targeting the downstream effector pathways. KRAS-driven tumors are believed to be dependent on MEK signaling for continued proliferation [58]. Therefore, MEK inhibitors have also been tested in preclinical models with positive results, which have not been reproduced in clinical trials. CI-1040A and AZD6244, two potent MEK inhibitors, have been investigated and were found to be ineffective in patients as second line therapy or as combination therapy with capecitabine in a randomized phase 2 trial [59, 60]. Similarly, trametinib in combination with gemcitabine, when compared to gemcitabine therapy alone, was not found to be superior in a randomized phase 2 trial for patients with treatment-naïve mPDA [61]. These clinical trials underscore the importance of targeting multiple effector pathways simultaneously [62, 63]. For example, concurrent inhibition of MEK and phosphoinositide 3-kinase (PI3K) or AKT may be required to overcome

the limitations of targeting and inhibiting a single pathway [64–66]. This is due to the fact that there are data to suggest that activation of the PI3K pathway results in resistance to MEK inhibitors [64]. However, despite this, a combination of PI3K and MEK inhibition was not associated with increased survival when compared to modified FOLFOX in patients who failed prior gemcitabine therapy [67]. There have also been studies that have demonstrated synergism with the use of EGFR inhibitors and MEK inhibitors, especially in patients with wild-type *KRAS* tumors [68, 69]. Erlotinib, an epidermal growth factor receptor (EGFR) inhibitor, is currently FDA-approved for use as a second line therapy for recurrent, mPDA [70]. Moving forward, the combination of many of these therapies along with new targeted agents may be beneficial. In regards to a personalized approach, targeting *KRAS* mutations would certainly make this an all-inclusive line of therapy (i.e., one size fits all treatment, since the majority of PDAs harbor *KRAS* mutations). However, some investigators are studying whether specific *KRAS* amino acid changes, even at the same codon, might be more targetable than others.

Targeting the G1/S Checkpoint

CDKN2A (p16), a TSG, is another high-frequency mutation in PDA, found in over 95% of tumors [10]. It is a cyclin-dependent kinase inhibitor that functions to stop the transition of the cell from entry into S-phase by inhibiting the kinase activity of CDK4 and CDK6 [71–73]. In PDA, alterations in p16 expression can be due to promoter hypermethylation, homozygous deletions, or single-allele loss with a concomitant mutation in the second allele [74, 75]. All of these lead to inactivation of p16, which subsequently result in increased phosphorylation of Rb-1. This leads to deactivation of Rb-1 and progression through the G1-S cell cycle checkpoint, resulting in increased cell proliferation [74, 76].

In mutant *KRAS*-driven cancers, the loss of p16 is common and results in cell cycle dysregulation. Considering this, there is significant interest in recapitulating the function of p16. However, since *CDKN2A* is a TSG and therapies that result in reinstatement of its expression are limited, there is significant interest in suppressing activity of its targets, CDK4 and CDK6. CDK4/6 inhibitors, such as palbociclib and abemaciclib, have been developed and used in other tumor types and a number of other diseases [77, 78]. In PDA, both in vivo and in vitro studies have shown mixed results with the use of these inhibitors [79–81]. In PDA, inhibition of this pathway is currently being investigated. Actively enrolling trials include a phase I clinical trial evaluating the efficacy of palbociclib and gedatolisib, a PI3K/mTOR inhibitor, in patients with a number of solid tumors, including PDA (NCT03065062) and a phase I dose-escalation study evaluating palbociclib in combination with nab-paclitaxel in mPDA (NCT02501902). Another phase I/II clinical trial is evaluating the safety and efficacy of ribociclib in combination with Everolimus in patients with refractory mPDA (NCT02985125). Lastly, another phase Ib dose escalation trial is evaluating the safety of ribociclib in patients with advanced solid tumors and may recruit patients with PDA (NCT02703571). The results of these studies will be forthcoming.

TP53 is a common TSG mutated in most solid tumors and is mutated in 75% of PDAs [82]. *TP53* is a transcription factor which modulates the expression of genes that are implicated in cell cycle arrest and apoptosis in the setting of DNA damage or cellular stress [83]. Generally, a mutation accompanied with loss of heterozygosity (LOH) in the second allele leads to its inactivation. Once cells lose *TP53* expression, it allows them to bypass the G1-S cell cycle checkpoint, which again, results in increased cell proliferation [76]. Similar to p16, targeting of p53 is difficult since it is also a TSG. Due to this, it has become attractive as a target in tumor immunotherapy. The modified vaccinia virus ankara vaccine expressing p53 (p53MVA) has had some success in preclinical models [84]. Currently, it is being investigated in a clinical trial that includes patients with PDA (NCT02432963), but the success of this therapy is still unknown. A number of preclinical models have attempted to reactivate TP53 with the use of small molecules, such as APR-246 [85, 86]. An ongoing phase II clinical trial is evaluating the efficacy of SGT-53, liposomal nanocomplex tumor-targeting delivery of the wild-type p53 gene, in combination with gemcitabine and nab-paclitaxel in patients with mPDA (NCT02340117). To date, there have not been any clinically relevant therapies that have resulted in recapitulation of TP53 function that have resulted in a clinical benefit for patients with PDA [86, 87]. However, since it is commonly disrupted in PDA, the pursuit of targeting this genetic lesion is a worthy cause [88].

Exploiting BRCAness and DNA Damage Response and Repair Pathways

Genetic alterations in *BRCA1/2* and other DNA damage response and repair genes (the DNA damage repair, DDR, pathway) are observed in 5–17% of PDAs [11, 26]. Furthermore, germline mutations in *BRCA1* and *BRCA2* have been shown to increase a patient's risk of developing PDA 3.5–10-fold [89], as have mutations in the Fanconi anemia genes (i.e., *FANCC, FANCG,* and *FANCN/PALB2*) [90–92]. One of the features of tumors that harbor *BRCA*-related mutations or alterations in the DDR pathways is chromosomal instability [11, 23, 93]. Such mutations have been exploited in ovarian cancer, since tumors that are deficient in DDR have increased susceptibility to platinum-based therapy especially when combined with poly-ADP-ribose polymerase (PARP) inhibitor therapy [94].

This increased susceptibility to platinum-based therapy has been studied in PDA and has shown promising results. Golan and colleagues retrospectively reported on a large cohort of 71 patients with *BRCA1* or *BRCA2* associated tumors. They found that in patients with stage 3 and 4 disease who received platinum-based therapy ($n = 22$), when compared to those who received non-platinum based therapy ($n = 21$), there was improved in median overall survival (22 vs. 9 months, $p < 0.039$) [95].

As a result of the findings from preclinical models and retrospective studies, prospective trials have investigated the utility of PARP inhibitors in patients with PDA and germline mutations in DDR pathways. PARP inhibitors (PARPi) are a class of drugs that cause an accumulation of single-stranded breaks (SSB) in DNA. Once the replication fork encounters a SSB, it may result in termination or the formation of

a double stranded break (DBS); cells that are BRCA-deficient are unable to repair these DSB via homologous recombination leading to cell death through mitotic catastrophe [96, 97]. This is a concept referred to as *synthetic lethality* [98]. A number of clinical trials have either recently been reported or are currently ongoing in order to investigate the safety and efficacy of PARPi in patients with *BRCA1/2* or *PALB2* mutations and have shown encouraging results [99–101]. At the present time, PARPi are perhaps the most promising avenue that utilizes targeted therapy that may be beneficial to a subset of patients with PDA. Further research will need to show whether tumors that harbor *BRCA1/2* mutations are equally as sensitive to PARPi and platinum-based therapy. Moreover, it is important to remember that other genes are commonly mutated in the DDR pathway in PDA. These include *ATM, ATR, RAD51, RAD51C,* and *RPA1*. Identification of these targets has raised the possibility of use of ATM and ATR inhibitors in PDA and in other tumors [102]. In fact, there are a number of preclinical models or clinical trials ongoing that are evaluating the use of these therapies in combination with PARP inhibitors and platinum-based chemotherapy [103–105]. These studies will address the question of whether mutations in the DDR pathway result in the same cancer phenotype. Lastly, to maximize the benefit afforded with PARPi therapy, both alleles must be inactivated. Therefore, the role of NGS is underscored here where reliable sequencing results must be available to clinicians in order to maximally utilize this targeted therapy.

Chromatin remodeling and mutations in SWItch/sucrose non-fermentable (SWI/SNF) nucleosome complex are common in many tumors [106, 107]. The SWI/SNF nucleosome is a complex that consists of ATP-dependent chromatin remodeling factors that control the transcription of a number of genes by altering the chromatin structure [108, 109]. Loss of *ARID1A*, one of the components of the SWI/SNF complex, is the most common event (albeit, one that occurs at an overall low-frequency) and it behaves as a TSG in PDA [19, 110, 111]. Mutations in other subunits of the SWI/SNF complex have also been observed, and these include *ARID1B, SMRCA4,* and *SMRCA2* [112]. Recent studies have demonstrated that the use of PARP or ATR inhibitors results in increased sensitivity in tumor cells that are deficient in *ARID1A* [113, 114]. This preclinical data can be used to expand the use of PARP and ATR inhibitors in patients with PDA who may harbor mutations in the SWI/SNF complex.

Role of SMAD4/TGF-β Signaling

TGF-β signaling has been implicated in pancreatic cancer; a mutation in at least one of the genes in the pathway is present in almost all PDAs [10, 115, 116]. One of the commonly dysregulated genes in this pathway is *SMAD4,* also known as *DPC4,* a TSG that is located on chromosome 18q. It encodes for a transcription factor that plays a role in the transforming growth factor beta (TGF-β) signaling pathway [117, 118]. In PDA, aberrations in *SMAD4* can occur due to homozygous deletions or LOH, coupled with a point mutation that results in its inactivation. Mutations that result in loss of SMAD4 expression are found in 55% of PDAs. Furthermore, mutations in *SMAD4* occur late in the progression of PDA tumorigenesis and are believed to play a role in the metastatic potential of this tumor [15, 119–121].

Targeting of this pathway would be clinically useful, considering the frequency with which it is lost along with other elements of this signaling pathway. Inhibition of this pathway can occur by inhibiting the ligand-receptor interaction with the use of TGFβ ligand inhibitors or with the use of TGFβ receptor inhibitors [122, 123]. The use of these compounds is currently being evaluated in a number of other solid tumors. In PDA, LY2157299, a small molecule inhibitor of the TGF-β receptor I kinase, was evaluated in a phase II double-blind clinical trial in combination with gemcitabine in patients with unresectable PDA. This trial showed an improvement in overall survival and progression free survival with the doublet, with an acceptable toxicity profile [124].

Despite the importance of targeting the loss of *SMAD4*, there have been no synthetic lethal or other targeted therapies that have been used experimentally or clinically to specifically target this molecule. However, due to the pattern of expression of *SMAD4*, especially in metastatic lesions, it has been proposed to serve as a prognostic marker for poor prognosis [125]. There have been some studies that suggest that in patients with locally advanced PDA that exhibit *SMAD4* expression would be suited for chemoradiation, compared to patients with loss of expression of *SMAD4* who may not benefit from such intensified local therapy [126, 127].

Targeting the Wnt Signaling Pathway

Alterations in the Wnt signaling pathway are common in many gastrointestinal malignancies. Perhaps the best example of this is mutation of the *APC* gene and its role in colorectal tumorigenesis [128]. Mutations in the *APC* gene are relatively uncommon in PDA, especially when compared to other genes within the pathway. These include *RNF43, AXIN1/2,* and *GATA6* [129–131]. A number of studies have shown that Wnt signaling is required for the initiation and progression of PDA [131]. Wnt signaling results in expression of β-catenin/TCF4 transcription factor, which in turn results in expression of RNF43. *RNF43* encodes an E3 ligase which is responsible for ubiquitination and degradation of Frizzled receptors [132]. Therefore, mutations in *RNF43* result in constitutive signaling through the Wnt signaling pathway. The difficulty in targeting genes within the Wnt signaling pathway is reflective of our current limitations in targeting TSGs. However, the use of LGK974, which is an inhibitor of Wnt ligand secretion, has shown promising results [130, 133].

Targeting NOTCH Signaling in PDA Tumorigenesis

The NOTCH signaling pathway is important in a number of malignancies, including PDA [134, 135]. The importance of NOTCH signaling in PDA is further established by GEMMs that demonstrate that, in the setting of oncogenic *KRAS*, its activation is necessary for the initiation and progression of PanINs [136, 137]. Moreover, NOTCH signaling has been shown to promote "stemness," epithelial-mesenchymal transition, and chemoresistance [138–140]. And aberrations in expression in the NOTCH signaling pathway have been associated with poor clinical outcomes in patients [141, 142].

Though *NOTCH* mutations are uncommon, studies have shown that other components of the pathway are amplified and result in overexpression [26]. In in vivo and in vitro experiments, there is a strong body of evidence that supports suppression of the NOTCH signaling pathway as therapeutically relevant strategy in PDA [143–146]. Options of inhibition of NOTCH signaling include inhibitors of gamma-secretase, which is required for transduction of signaling through the pathway. More specifically, interactions with the cell-membrane protein NOTCH by one of its ligands initiate proteolytic cleavage of the protein at both its intra- and extracellular sites. Gamma-secretase is necessary for cleavage of NOTCH in the intracellular space. Once NOTCH has been cleaved, it then translocates to the nucleus and modulates the expression of its target genes [147].

The use of gamma-secretase inhibitors has been explored in clinical trials. A clinical trial to evaluate the safety and efficacy of PF-03084014, a gamma-secretase inhibitor, in PDA has been terminated (NCT02109445). Another trial is currently in place, but not actively recruiting, which will evaluate BMS-906024, another gamma-secretase inhibitor, in solid tumors and may accrue patients with PDA (NCT01292655). Another agent, RO4929097, has been evaluated in patients with previously treated mPDA. Though the study showed that this agent was well tolerated in patients with mPDA, development of this compound has been discontinued by Roche [148].

Another strategy for the targeting of the NOTCH pathway includes the use of monoclonal antibodies. This strategy has shown promising results in xenograft tumors in mice when used in combination with chemotherapy [149]. In clinical trials, however, this therapeutic approach has not been as successful. The use of tarextumab (OMP-59R5), a fully human Notch2/3 monoclonal antibody, has been evaluated in a randomized, placebo-controlled, phase Ib clinical trial in patients with untreated mPDA in combination with gemcitabine and nab-paclitaxel and was shown to be well tolerated, safe, and have some antitumor effects [150]. However, when this combination therapy was studied in a phase 2, nonrandomized, placebo-controlled clinical trial, the results did not reveal any improvement in overall survival in patients with mPDA as a first line therapy [151]. Like many potential targeted therapies, the preclinical data to support targeting of the NOTCH pathway are robust; however, the clinical data thus far have not been as promising. This is highlighted by the importance of this pathway in the tumorigenesis in PDA. Improvements in approaches to target components of the NOTCH signaling pathway may result in promising therapies that can become available in the clinic.

Targeting the Hedgehog Signaling Pathway

In mammals, Hedgehog signaling is important in embryonic development and differentiation gastrointestinal tissue. Beyond the embryonic period, it plays a role in tissue homeostasis and has been implicated in the pathogenesis of a number of diseases [152–154]. In PDA, overexpression of Hedgehog is seen early in the development of PanIN-1 s and in preinvasive or invasive epithelium; however, its expression is absent in normal pancreas tissue [155, 156]. Overexpression of hedgehog in abnormal pancreatic tissue depends on expression of oncogenic KRAS, which suggests that Hedgehog is a downstream effector [157]. Yet the question

remains whether the role of Hedgehog is dependent on intracellular signaling alone within tumor epithelial cells, or whether it is as a consequence of aberrant ligand signaling in the tumor microenvironment.

The role of Hedgehog signaling has been extensively studied in mouse models that have helped delineate its mechanism [158–160]. Based on GEMMs, the role of Hedgehog ligand was determined to be important in PDA tumorigenesis. In a study by Nolan-Steveaux and colleagues, a mouse model was generated in which SMO-deficient pancreatic progenitor cells (which are insensitive to Hedgehog signaling) were shown to develop PDA at a similar rate as wild-type SMO controls [161]. Moreover, both the SMO-deficient and SMO-wild type mice developed equivalent expression of the Hedgehog ligand and inhibition of GLI1 in both of the groups resulted in increased apoptosis and decreased cell growth [161]. This model suggested that stromal Hedgehog ligand-dependent signaling and non-canonical Gli signaling in tumor epithelial cells are important in KRAS-dependent PDA tumorigenesis [161].

This finding has been further expanded to focus on the Hedgehog ligand, which is produced by tumor epithelial cells, which results in SMO-dependent activation and signaling of adjacent stromal cells (i.e., cancer-associated fibroblasts, CAF) along a canonical signaling pathway [162]. This leads to desmoplasia – one of the hallmarks of PDA. CAFs and cancer-associated stem cells have been implicated in their role in PDA. Co-culture of tumor epithelial cells and CAFs that have been isolated from PDA results in increased proliferation, colony formation, invasion, and resistance to gemcitabine both in vitro and in vivo [162–165]. Downstream effectors of the Hedgehog signaling pathway, such as SMO or GLI1, are two potential avenues to provide inhibition of this pathway. The SMO-inhibitor, LDE225, has been evaluated in a phase Ib in patients with locally advanced or mPDA in combination with gemcitabine [166]. GDC-0449, also an SMO inhibitor, has shown success in pre-clinical models [167]. However, when this compound was evaluated in combination with gemcitabine in patients with mPDA, there was no improvement in outcomes when compared to gemcitabine treatment alone [168]. Though there is variability in regards to the success of targeting this pathway, there continues to be much interest in targeting the Hedgehog signaling pathway in PDA. Lastly, targeting of cancer-associated stem cells has also been attempted with the use of monoclonal antibody and is currently being investigated with the use of a "cancer stemness" inhibitor, BBI608 (NCT02231723) [169]. Therapeutic strategies, such as this one, provide a unique way to target vulnerabilities in PDA that go beyond genetic alterations.

History of Ex Vivo Modeling and the Importance of Preclinical Models in a Personalized Approach to PDA

Molecular and pathologic studies have established a model for progression of PDA, with oncogenic *KRAS* having an integral role for the inception of tumorigenesis [50]. As discussed in the prior section, a number of genetic aberrations contribute to the tumorigenesis and progression of PDA [47]. The use of genetically engineered

mouse models (GEMMs) has been instrumental in our understanding of the initiation and progression of PDA [47]. Moreover, GEMMs have increased our understanding of the role of the tumor microenvironment in PDA and of ligands that are important in dysregulated pathways [161, 170]. Additionally, preclinical models, such as human cell lines, xenograft tumor models, and patient-derived tumor xenografts, have been used to understand the biology of PDA and to identify new therapeutic targets for patients. An exhaustive discussion of ex vivo models is beyond the scope of this chapter, but two new techniques, discussed below, have the potential to significantly propel targeted therapy in PDA: conditionally reprogrammed cells and organoids.

Conditionally reprogrammed cells are a relatively new technique for tumor modeling that allows for quicker regeneration of patient-derived tumor cells that can be used for drug-sensitivity testing [171, 172]. Most recently, three-dimensional culture of patient derived tissue in the form of organoids has been heralded as the next generation ex vivo culture model for PDA [173]. Mouse- and patient-derived organoids have been derived by a number of laboratories around the world and have been genetically modified using CRISPR technology or have been used to test drug sensitivities [174–176]. Organoids can be established from surgical specimens and from biopsy specimens. This model allows for the establishment of a pure tumor epithelial population of cells that recapitulates the genomic make-up of the initial tumor specimen [177, 178].

There are a number of preclinical models that are available for translational studies that have attempted to recapitulate the genetic diversity that PDAs exhibit. There are pros and cons that are associated with each model, and at the present time, patient-derived organoids represent perhaps the most promising preclinical model that is available to researchers. There are still many questions that need to be addressed with organoids, including whether the genetic complexity that is seen in the primary tumor is maintained in the organoid. Still, this model can result in an improvement in our understanding of the tumorigenesis and the role or low-frequency mutations in the progression of PDA. This model has already been exploited with intestinal organoids that have been transformed into colorectal carcinoma utilizing genetic engineering [179]. This preclinical model can be used to understand the role of low-frequency mutations by helping delineate those that are truly necessary for tumorigenesis versus those that are just passenger mutations. Having an understanding of the low-frequency mutations that confer survival to PDA tumor cells can then be exploited for targeted drug-development. Ongoing work (including work from JRB's laboratory) will validate the significance of this model for the pancreatic cancer research community and for the promise of precision therapy.

Beyond Genetic Alterations: Finding Alternative Targets

Considering the genetic diversity that is observed in PDA, another option would be approaching the treatment of this devastating disease by utilizing novel therapeutic approaches. For example, in melanoma, the use of immunotherapy has revolutionized

the treatment paradigm and has resulted in impressive patient outcomes [180–182]. In patients with PDA, the treatment approach would most likely require a combination therapy, in part, due to the genetic diversity that PDA exhibits allowing for compensation to occur along another pathway with targeted blockade. Therefore, other innovative ways of delivering therapy to patients with PDA may be targeting key cellular processes in order to take advantage of a genetic vulnerability, such as the use of PARPi therapy. In this section, alternative strategies to provide "targeted" therapy in PDA in ways that are novel and go beyond genetic alterations that are obtained from tumor sequencing will be discussed.

Role of Posttranscriptional Modification

Synthesis of messenger RNAs (mRNAs) is one of the essential functions of the cell. Once mRNAs undergo modifications in the nucleus, they are transported to the cytoplasm where they can be involved in a number of functions. Posttranscriptional gene regulation is a key cellular mechanism in which cells are able to modulate gene expression [183]. Regulatory mRNA elements can be present in any portion of the transcript (i.e., 5′-untranslated region (UTR), 3′-UTR, and in some instances even within the coding regions) [184, 185]. These regulatory elements lend themselves to regulation by RNA binding proteins (RBPs) and noncoding RNAs (i.e., microRNAs). Under nonpathologic conditions, posttranscriptional modification and regulation of gene expression are important in many cellular processes. However, there is also increasing evidence that posttranscriptional modification of mRNA transcripts plays an important role in tumor initiation and progression [186, 187]. In the following section, posttranscriptional modification by RBPs and how they can be used as predictors for aggressiveness, response to therapy, or potential therapeutic targets will be explored.

Role of RNA Binding Proteins in PDA Tumorigenesis

RNA-binding proteins (RBPs) are master regulators of mRNA processing and play a role in many vital cellular functions [188]. In cancer, RBPs play a powerful role in driving tumorigenesis, as they are expressed at high frequencies [189].

Perhaps one of the most well-studied RBP is Human Antigen R (HuR), also known as embryonic lethal, abnormal vision, and Drosophila-like 1 (ELAVL1) [190]. HuR is primarily expressed in the nucleus; however, upon exposure to stress, such as nutrient deprivation, hypoxia, or DNA damage, HuR translocases to the cytoplasm. HuR coordinates a pro-survival network of gene expression by binding to mRNA targets that support cell-survival functions [191, 192]. In vitro, silencing of HuR has been shown to result in decreased tumor growth, impaired migration and invasion, and anchorage-independent growth [193]. Moreover, a number of studies have also demonstrated downstream pro-survival targets of HuR that are important in tumorigenesis [8, 194–196]. Finally, a CRISPR knock-out model of HuR in PDA has demonstrated a unique xenograft lethal phenotype in PDA tumor cells [197].

HuR has been shown to be important as both a therapeutic target and a potential biomarker in PDA. Small molecule inhibitors of HuR have been used both in vivo and in vitro [8, 198, 199].

Targeting of HuR by small molecule compounds or siRNA nanoparticle strategies have shown great promise; and there is a hope that these strategies will make it into early phase human trials within the next few years. To date, HuR has also been extensively studied as a biomarker in PDA. In one study, patients with high cytoplasmic HuR have been associated with higher T-stage [200]. And a subsequent study showed that in patients with high cytoplasmic HuR, 5-FU-based therapy as associated with longer disease-free survival when compared to gemcitabine treatment [201]. Additional studies are needed to further elucidate the utility and role of HuR as a biomarker in patients with PDA. HuR may also represent another therapeutic option in PDA, as a drug sensitizer, in order to target a critical drug resistant network in PDA cells, especially in the tumor microenvironment where cells are exposed to low glucose, hypoxic conditions.

Epigenetic Regulation and its Role in PDA

Epigenetic modifications of DNA, such as histone deacetylation (HDAC) or DNA methylation, have been implicated in tumorigenesis and in metastasis [202]. As an example, in PDA, inactivation of *CDKN2A* can often times occur due to methylation at its promoter [203]. And this concept, where silencing of TSGs occurs via epigenetic silencing, is not uncommon or unique to PDA. Moreover, epigenetic reprogramming and regulation have also been implicated in metabolic changes in metastatic lesions. This was evaluated in a study by McDonald and colleagues, where matched primary and metastatic samples of PDA were studied in 16 samples from 5 patients [204]. Interestingly, the genetic diversity between the primary tumors and metastatic lesions was unchanged, reaffirming the results from a prior study by Makohon-Moore and colleagues [31]. Yet cells present in metastatic samples had acquired and selectively maintained epigenetic control of a malignant gene expression phenotype in the absence of driver mutations that are metastasis specific.

Targeting of epigenetic regulation has been attempted in PDA with the use of HDAC inhibitors, such as vorinostat, which results in inhibition of tumor growth in vitro and in vivo [205–207]. Vorinostat has also been used in clinical trials (NCT00958688), where it was used in combination with 5-FU and radiation in patients with locally advanced PDA; however, the study has been terminated and there are no reported results. A DNA methyltransferase inhibitor, 5-azacytidine, has also been evaluated in patients with advanced PDA in combination with gemcitabine. This study has also been terminated.

Currently enrolling clinical trials that are targeting epigenetic regulation as a therapeutic strategy include a phase II clinical trial in which resected patients with node or margin positive disease who have completed adjuvant therapy go on CC-486 (oral azacytidine) (NCT01845805). Another utilizes decitabine and tetrahydrouridine in patients with mPDA who have failed other therapy (NCT02847000). Therapeutic

strategies that aim to target epigenetic modification/reprogramming may be a novel approach for targeted treatment in patients with PDA. This will most likely be further realized as our understanding of the role of epigenetic regulation in metastatic lesions expands, possibly lending itself as a viable therapeutic option in patients with advanced disease.

Multi-omic Profiling and Its Role in PDA

A new approach in biological analysis is one where data from multiple sources (e.g., omes) are utilized. This includes genomics, proteomics, epigenitome, transcriptome, etc., in order to study biomarkers and therapies [208]. Multi-omic profiling has been explored in PDA by the authors (MJP and JRB) in order to further delineate the relevance of genetic aberrations found in PDA [37, 209]. Multiple platforms exist in order to take advantage of multi-omic profiling, but at the present time, most utilize NGS. With the use of this strategy, phosphoproteomic data have been provided to clinicians successfully and used to guide therapy [38, 210].

Though still in its relative infancy in PDA, the approach to characterizing patients based on multi-omic profiling is powerful and holds a lot of promise. It also integrates a number of important aspects of the patient's tumor, such as its genetic composition and epigenetic modifications, and offers an opportunity to provide targeted therapy.

Dysregulation in Axon Guidance Pathways in PDA

Sequencing studies have revealed that in PDA there are aberrations in axon guidance pathways [19, 20]. Other studies have also found epigenetic regulation in *SLIT-ROBO, ITGA2*, and *MET*, members of the axon guidance pathway [211]. Under nonpathologic conditions, expression of genes in the axon guidance pathways is important in embryogenesis. However, in cancer, their aberrant expression has been linked to increasing the predisposition of tumor formation and progression [212–214]. The exact role of these factors in tumorigenesis is not yet elucidated in PDA and how it may contribute to cell migration, angiogenesis, and cell survival. Considering the degree of dysregulated expression that exists in this gene subset in PDA, additional studies are needed to further elucidate their role. However, these molecules may be potential effective targets in PDA and in other cancers in a personalized manner.

Targeting the Tumor Microenvironment

One of the hallmarks of PDAs is its pronounced desmoplastic reaction, which makes up the tumor microenvironment (TME), with a paucity of tumor epithelial cells [6]. As discussed before, in PDA, the tumor microenvironment has a very important role

in PDA tumorigenesis and has been shown to interact with the tumor epithelial cells resulting in tumor progression [215–217]. Cells that are associated with the tumor stroma include inflammatory, immune, mesenchymal, and endothelial cells [218]. Cancer-associated fibroblasts (CAFs), an example of mesenchymal cells, have also been shown to impose epigenetic and metabolic regulation of tumor epithelial cells [219]. Additionally, activated pancreatic stellate cells, which give rise to CAFs, play an important role in the deposition of extracellular matrix components and the production of cytokines and growth factors [220, 221].

A number of signaling pathways that are dysregulated have been found to be important in the maintenance of the tumor stroma and may be potential therapeutic targets in PDA. TGFβ signaling, as discussed above, is commonly dysregulated in PDA. Ligands produced by the tumor epithelial cells can result in activation of its signaling cascade in stroma cells due to paracrine action, which has been shown to lead to fibroblast proliferation [222, 223]. This interaction is what also makes the use of TGFβ inhibitors a promising therapeutic strategy in PDA. Hedgehog signaling, as discussed in the *Targeting NOTCH signaling in PDA tumorigenesis* section, is also another attractive targeted therapeutic strategy due to its role in the desmoplastic reaction that's common in PDA. The tumor stroma has also been evaluated as a prognostic marker. In a study by Bever and colleagues, the density and activity of the stroma was evaluated and high-stromal density was found to be associated with a longer disease-free survival [224]. Other studies have shown that undifferentiated PDA is associated with increased vascularity, raising the potential of VEGF inhibitors as another targeted therapy [225].

Considering the important role of the TME in PDA, especially as mediated by immune cells, a number of compounds have been used to target this specific interaction. In a multicenter, randomized, placebo-controlled, and double-blind clinical trial, ibrutinib, a Burton's tyrosine kinase (BTK) inhibitor, is being evaluated in combination with nab-paclitaxel and gemcitabine for patients with mPDA as a first line therapy (NCT02436668) [226]. Ibrutinib is also being evaluated in combination with durvalumab, a human IgG1 monoclonal antibody that binds PD-L1 and inhibits its interaction with CD80, in a phase Ib/II multicenter study in patients with relapsed or refractory mPDA (NCT02403271) [227]. Both of these studies have completed enrollment and are ongoing; however, no results have been published as of this writing.

Limitations to Precision Therapy in PDA

Molecular profiling has changed the approach to therapy in many cancers, including PDA. NGS and other novel technologies are now becoming routinely incorporated in the care of some patients. However, data on genetic analyses are only useful if patients can take advantage of targeted therapy, whether on- or off-label or in clinical trials, in addition to standard treatment.

It is evident that in PDA, there is a necessity to not only develop better therapies, but to also continue to expand our understanding of the genetic make-up of PDA.

Moreover, there is a need for technologies, such as NGS, to provide actionable data in a timely manner so that it becomes routinely incorporated in clinical practice. The results of the IMPaCT trial, which evaluated the feasibility of providing sequencing data to facilitate treatment with targeted therapy, underscore the need to move genomic and molecular information into routine clinical care in order to propel precision medicine as a standard of care treatment strategy in patients with PDA. This will require continued financial support of agencies behind clinical trials that embrace this approach.

With continued improvements in modeling systems, such as patient-derived organoids, there will be an increased understanding of the genetic and nongenetic landscapes of PDAs. The ability to capture the genetic variability that is present in each PDA in these model systems provides a unique research opportunity that could have a significant return in regards to patient treatment. The ultimate goal would be to recapitulate the genetic diversity seen in individual PDAs into the organoid models in an effort to further identify specific drivers of each PDA that will reveal optimal therapeutic opportunities. Model systems, such as the organoids, allow for drug screens, gene editing, and other manipulations that can improve our understanding of the significance of individual gene mutation events. For instance, at the present time, though a number of low-frequency mutations and pathways disrupted in PDA have been identified, the contribution that these mutations have to driving PDA or if they will be susceptible to the current arsenal of available therapies is not yet something that has been elucidated. Understanding the functional implications of these low-frequency pathway disruptions will be integral in guiding drug discovery and efficient clinical trial design. Ultimately, improvements in the preclinical models in PDA will be helpful to study the clinical relevance of targeting dysregulated pathways or genetic mutations and will most likely result in novel insights moving towards precision therapy for PDA.

Future Directions

Discoveries that underlie the genetic drivers in PDA have been identified in patient samples and established in GEMMs and ex vivo models. This has been incrementally translated into innovative, successful therapeutic approaches that hope to improve patient outcomes. Though at the present time there is a paucity of FDA approved targeted therapies for patients with PDA, the number of trials that are ongoing that utilize this approach is impressive. NGS has given researchers and clinicians an insight into the genetic diversity of PDA. This technology spans the spectrum – its utilization in research laboratories is increasingly becoming translated to use in the clinic. Though targeting of low-frequency mutations will most likely not yield a significant clinical benefit to many patients with PDA, it will hopefully result in an increased understanding of the tumorigenesis of this disease and, importantly, aid a subset of patients. In fact, the field has accepted that targeting 5–10% of patients at a time might be a logical approach to improving outcomes. This strategy has been descriptively termed as the "pie approach" to treating the disease (i.e., if about 10% of patients are matched with

the correct therapeutic strategy, it can lead to significant changes in overall patient outcomes). This can, in turn, be supported by next generation ex vivo models, which will lead to a better understanding of the PDA biology and hopefully will result in higher throughput of drug testing for each patient.

At the present time, in order to make meaningful impact in PDA, researchers, clinicians, and surgeons need to have realistic goals in order to change the current trend in PDA. Ultimately, surgical resection is the only therapeutic option that gives patients a chance for long-term survival. However, since only a minority of patients can benefit from surgery, there need to be improvements in screening, diagnostic, and therapeutic strategies in order to allow more patients an avenue to surgical resection. A schematic for a futuristic clinical trial that employs such a realistic goal for patients in the metastatic setting is presented in Fig. 2. At the time of diagnosis, all patients with metastatic disease should have tumor sampling of both the primary tumor and

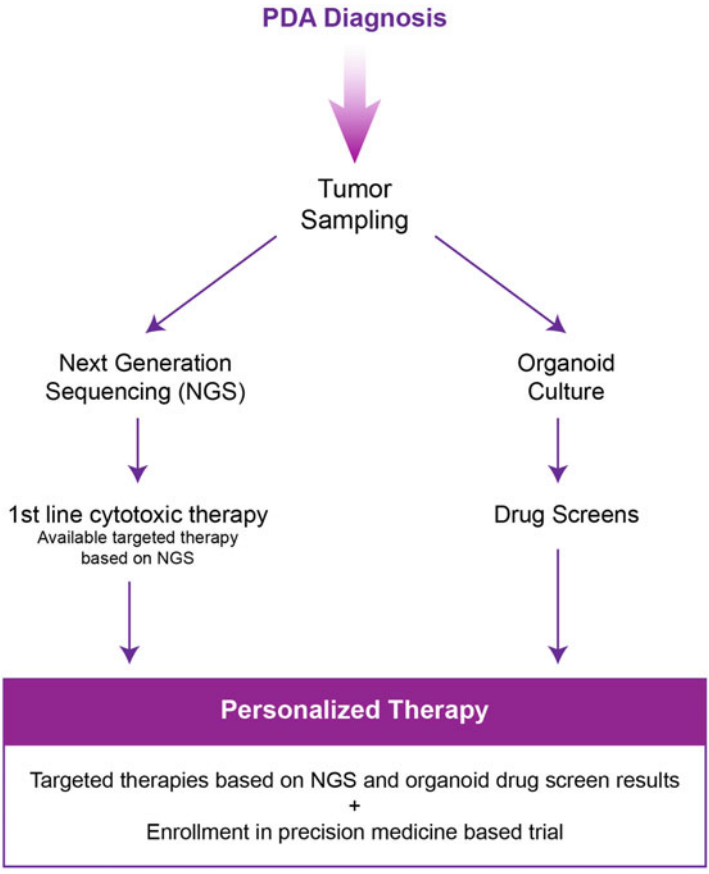

Fig. 2 Proposed clinical trial schema to optimize the use of precision medicine-based therapies

metastatic lesions. Both tumors should be sequenced and provided to a research laboratory for propagation into organoid cultures. The patient should be offered initial cytotoxic-based therapy followed by targeted therapy based on the sequencing results. Simultaneously, large-scale drug screens should be undertaken for both cytotoxic and targeted therapy while utilizing an organoid-like system. Based on these results from the preclinical model, patients should be advised which therapy they should pursue, whether on- or off-label, or as part of a clinical trial.

As a matter of fact, this similar approach can be employed in patients with all stages of PDA. For patients with resectable or locally advanced disease, tumor samples can be obtained, sequenced using whole-genome NGS, and propagated into organoid cultures. The goal should be to have sequencing and organoid drug screening results available to patients and clinicians in a clinically relevant timeline so that this information can be used for better informed clinical decision making. Moreover, utilizing preclinical data for predictive purposes (i.e., high cytoplasmic HuR and drug resistance) will allow clinicians to personalize the treatment approach to each patient. Ultimately, the power of combining NGS, preclinical modeling, such as organoids, and predictive markers will only be fully realized once the use of these technologies become validated.

Conclusion

The research community's understanding of the molecular drivers of PDA has increased over the past decade, with more and more studies delineating the genetic alterations found in this deadly disease. Despite these monumental strides, unlike in other cancers, this progress has been incremental, yet meaningful, in PDA. Our understanding of the implications of genetic aberrations, the role of the tumor microenvironment, metabolic alterations, epigenetic modification, and mechanisms of gene regulation in PDA will continue to increase. However, it is imperative that this is matched with equivalent progress of drug development that results in therapeutic options that can be used in the clinic. Maximizing the results of NGS will require aligning basic research with representative preclinical models. Ex vivo modeling that is done in parallel with NGS at the time of a patient's diagnosis will help support drug-screening that is based in the fundamental principles of targeted therapy. This strategy will also provide the backbone for well-designed clinical trials in order to produce results that lead to the realization of success in the domain of precision medicine (i.e., better treatment options and improved overall outcomes in patients with PDA).

Abstract

Pancreatic adenocarcinoma is one of the most lethal cancers but has limited therapeutic options necessitating continued investigation of new therapeutic agents. Recently, improved overall survival has been achieved with cytotoxic drug combinations including 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX) and gemcitabine/nab-paclitaxel, but the success has been modest at best. More targeted approaches focusing on EGFR and MAPK signaling have also enjoyed marginal success. Accumulating evidence suggests that pancreatic tumors have increased dependence on metabolic pathways through both KRAS and KRAS-independent mechanisms and are broadly resistant to drug therapy due to stromal remodeling. Genetic and epigenetic vulnerabilities, such as inactivating aberrations in DNA damage repair, chromatin remodeling, and microRNA dysregulation, may reveal exploitable weaknesses. Modern approaches to drug development tailored to molecularly defined subsets of patients likely to respond to targeted therapies are needed to achieve more substantial progress in this disease in an era of precision medicine.

Introduction

Pancreatic adenocarcinoma (PDAC) has very limited treatment options. The best benefit has been achieved with newer combinations of cytotoxic agents such as 5-fluorouracil, leucovorin, irinotecan, oxaliplatin (FOLFIRINOX) and gemcitabine/nab-paclitaxel, but with only modest overall survival benefits over single agent gemcitabine. Unfortunately, these therapies are associated with increased toxicity, and only the most functional patients can tolerate these regimens. Currently, the only targeted agent FDA approved for the treatment of PDAC is the epidermal growth factor receptor (EGFR) inhibitor erlotinib, which provides a minimal survival benefit measured in weeks. Identifying new therapies in pancreatic continues to be a major challenge. In this chapter, potential strategies for emerging therapeutics are discussed, including new approaches to KRAS signaling and suggested development of targets aimed at exploiting metabolic derangements, DNA damage repair, epigenetic modulation, and the tumor microenvironment.

MAPK Targeting

In pancreatic cancer, oncogenic KRAS serves as a necessary critical event in tumor initiation and growth maintenance [1]. Despite understanding the dependency of PDAC on the mitogen-activated protein kinase (MAPK) pathway through constitutive KRAS signaling, targeting RAS and its downstream effectors in PDAC has been unsuccessful. RAF and MEK inhibitors have largely been ineffective in KRAS-mutant tumors. In part, the failure of these agents has been thought due to redundancy in downstream signaling through MAPK (e.g., compensatory ERK reactivation) and the PI3K/mTOR pathways or loss of KRAS "addiction" with neoplastic progression [2].

Multiple mechanisms of resistance RAS and MEK inhibitors have been proposed. Treatment of KRAS-mutant tumors in particular has been challenging due to difficulty in selective targeting of the RAS GTPase, compensatory upregulation of ERK signaling, RAF dimerization, and formation of RAS-MEK complexes. Targeting of these mechanisms, likely in combination, may represent alternative approaches to circumventing poor responses to MEK inhibitors.

Lito et al. demonstrated that treatment of KRAS-mutant pancreatic cancer cells with MEK inhibitors resulted in a reduced ability to sustain prolonged ERK inhibition mediated through rebound ERK phosphorylation [3]. This rebound effect was found to be dependent on the release of feedback inhibition on the CRAF isoform. Two processes mediated rebound phosphorylation of ERK: relief of CRAF inhibition and formation of MEK-RAF kinase complexes. While activated ERK feedback typically inhibits RAF/MEK/ERK signaling by phosphorylating CRAF kinase, treatment with MEK inhibitors relieved the negative feedback signal by ERK on CRAF. Reactivation of CRAF resulted in downstream MEK phosphorylation and ERK rebound phosphorylation. In addition, MEK inhibitors induced complex formation of MEK with RAF kinases in KRAS-mutant cells but not BRAF-mutant cells. Increased association of MEK with RAF resulted in a subsequent increase in active phosphorylated MEK. This increased complex formation combined with increased active CRAF was shown to result in resistance to MEK inhibition. This study suggests that targeting the MAPK pathway will require rationally designed small molecule inhibitors or antibodies to block MEK-RAS complex formation while also inhibiting CRAF kinase activity.

Metabolic Pathways

Metabolic adaptation to changing environmental conditions is a critical component of tumorigenesis. In 1924, Otto Warburg described the ability of tumors to generate adenosine 5′-triphosphate (ATP) by fermentative metabolism through glycolysis, even in the presence of oxygen, rather than prioritization through mitochondrial oxidative pathways as occurs in normal cell metabolism. This seemingly inefficient method of ATP production is thought to benefit cancer cells since glucose and glutamine can be shunted toward synthesis of the necessary building blocks to

maintain rapid cell growth and division [4]. Glucose and glutamine can be diverted into pathways for production of the macromolecular precursors for the synthesis of fatty acids (e.g., acetyl-CoA), nonessential amino acids, and nucleotides (e.g. ribose) (Fig. 1).

In most mammalian cells, since nutrient supply is not typically restricted, nutrient uptake and utilization is tightly controlled to prevent excessive proliferation unless a growth factor is present to stimulate cell growth and division. Through the acquisition of oncogenic mutations, cancer cells circumvent growth factor dependence by altering signaling pathways to promote cell growth and survival. Key to the maintenance of proliferative capacity, the "Warburg effect" has now been linked to a number of oncogenic pathways, including KRAS, AKT, and MYC, and glucose deprivation itself has been implicated as a driving force in the acquisition of KRAS mutations [5].

Recently, a renewed interest in exploiting metabolic pathways in pancreatic cancer has been seen based on advances in transcriptome and metabolomic research. The impact of KRAS in exerting control over numerous metabolic pathways has been shown in a number of studies to be critical in carcinogenesis and maintenance of pancreatic cancer, thus presenting potential opportunities for therapeutic targeting. Metabolic pathways that have been implicated in KRAS-mediated tumorigenesis include glycolysis, the pentose phosphate pathway (PPP), and the tricarboxylic acid (TCA) cycle [1].

The impact of metabolic reprogramming on tumorigenesis is particularly intriguing given evidence that PDAC tumor cell lines were shown to exhibit distinct metabolic profiles [6]. Metabolomic and transcriptomic analysis of 38 pancreatic cancer cell lines identified three metabolic subtypes: slow proliferating, glycolytic, and lipogenic. Glucose and glutamine dependence and utilization either favored growth through glycolytic or lipid synthesis pathways leading to specific metabolic vulnerabilities that could be potentially exploited with pathway-specific metabolic inhibitors. Interestingly, even within the confines of in vitro experiments, some tumor cell lines also exhibited the ability to switch phenotypes based on metabolic stressors and highlight the difficulty in stratifying tumors into a one-size-fits-all therapeutic strategy.

The dependency of PDAC maintenance on KRAS-mediated metabolic changes was eloquently demonstrated in a pancreas-specific doxycycline-inducible $KRAS^{G12D}$ transgenic murine model, dubbed the *iKras* model [1]. As in the LSL-$KRAS^{G12D}$ model, this model required additional crossing with conditional *p53* knockout ($p53^{L}$) to a *iKras p53* mutant (*iKras* $p53^{L/+}$ or *iKras* $p53^{L/L}$) to recapitulate full malignant progression through invasive PDAC. Withdrawal of doxycycline induction resulted in extinction of KRAS expression and allowed analysis of transcriptional and metabolic changes with removal of oncogenic $KRAS^{G12D}$. Importantly, extinction of KRAS expression did not affect flux of glycolytic metabolites through the TCA cycle. The PI3K-AKT pathway and HIF1α also did not have significant impact on tumor metabolic signaling.

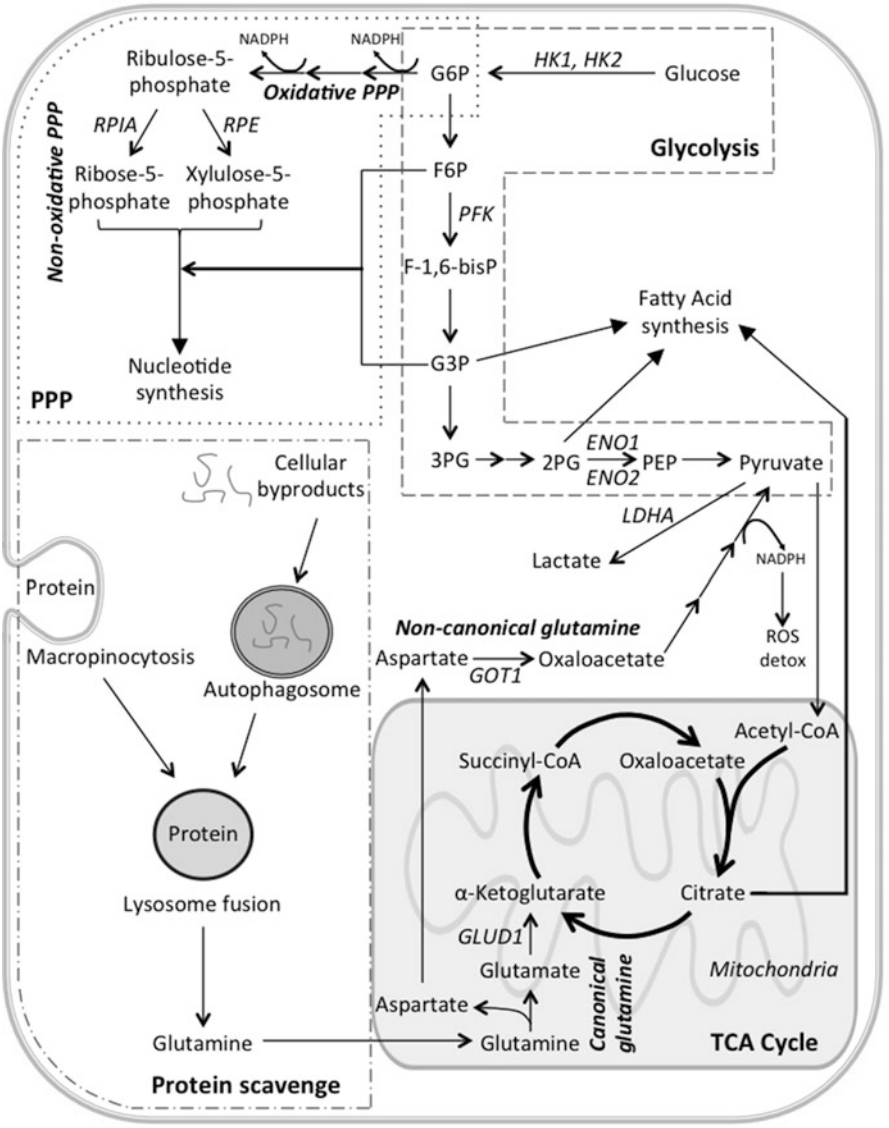

Fig. 1 Metabolic pathways involved in PDAC. *Abbreviations* (alphabetical order): *2PG* 2-phosphoglycerate, *3PG* 3-phosphoglycerate, *ENO1* enolase 1, *ENO2* enolase 2, *F-1,6-bisP* fructose-1,6-bisphosphonate, *F6P* fructose-6-phosphate, *G6P* glucose-6-phosphate, *GLUD1* glutamate dehydrogenase 1, *G3P* glyceraldehyde-3-phosphate, *GOT1* glutamic-oxaloacetic transaminase 1, *LDHA* lactate dehydrogenase A, *NADPH* nicotinamide adenine dinucleotide phosphate (reduced), *PPP* pentose phosphate pathway, *PEP* phosphoenolpyruvate, *PFK* phosphofructokinase, *RPE* ribulose-5-phosphate 3-epimerase, *RPIA* ribose-5-phosphate isomerase A, *ROS* reactive oxygen species, *TCA* tricarboxylic acid

Glycolysis

In line with the Warburg effect hypothesis, the i*Kras*/p53 study showed $KRAS^{G12D}$ was a major regulator of channeling glucose metabolites into synthesis of macromolecular molecules, including nucleotide and lipid synthesis pathways. KRAS itself appeared to drive glucose flux by upregulating uptake and shunting of glucose through glycolysis [1]. Glucose metabolic changes that were found to be dependent on $KRAS^{G12D}$ included regulation of multiple rate-limiting glycolytic enzymes (HK1, HK2, ENO1, and PFK1) and the glucose transporter GLUT1. These findings support the hypothesis that diversion of glycolytic intermediates into biosynthetic pathways promotes tumor proliferation and suggests PDAC reliance glycolytic processes can be exploited for therapeutic targeting.

KRAS-mediated regulation of ENO1, which regulates conversion of 2-phosphoglycerate (2-PG) to phosphoenolpyruvate (PEP), may be of particular interest given enolases have been implicated in promoting tumor cell extracellular matrix degradation, migration, and proliferation [7]. In pancreatic cancer, ENO1 is upregulated, and expression promotes invasiveness and metastasis and mediates an immunoregulatory role in infiltrating T-cell effector function [8–10]. Interestingly, Daemen et al. identified ENO2 as one of the most differentially expressed genes in glycolytic cell lines compared to lipogenic cells [6]. This observation may lend support to a metabolomic approach to personalized treatment of pancreatic cancer by assessing tumor metabolic profiles with subsequent targeting of glycolytic enzymes, such as ENO1 or ENO2.

Lactic Dehydrogenase A

Also regulated by $KRAS^{G12D}$, lactic dehydrogenase A (LDHA) represents a particularly interesting target given its role in reduction-oxidation (redox) reactions with nicotinamide adenine dinucleotide (NAD) and NADH for both glycolytic and TCA cycles [11]. The two isoforms of LDH are expressed in tissue-specific distributions: LDHA in skeletal tissue and liver and LDHB in myocardium. Tumor tissue, including pancreatic adenocarcinoma, frequently demonstrates elevated levels of LDHA compared to normal tissue and has been implicated in tumor initiation, maintenance, progression, and aggressiveness and is associated with poor prognosis [11–13]. Increased metabolic demands of tumor growth and the hypoxic tumor environment drive up lactate levels. These processes have been shown to be regulated at the transcriptional and posttranslational level by c-MYC, HIF1α, and forkhead box protein M1 (FOXM1) [4, 14]. In pancreatic, lymphoma, and $KRAS^{G12D}$-driven lung mouse models, lactic dehydrogenase reduction delayed tumor xenograft progression due to increased oxidative stress from ROS production through enhanced pyruvate flux into the mitochondria. Such an approach may be potentially useful in PDAC tumors [12, 15].

Pentose Phosphate Pathway

Glucose flux into anabolic pathways for nucleotide synthesis was demonstrated to be significantly regulated by $KRAS^{G12D}$ with specific channeling of glucose metabolites through the non-oxidative arm of the pentose phosphate pathway (PPP) [1]. The PPP generates NADPH as well as ribose-5-phosphate for nucleotide synthesis. NADPH provides the reducing equivalents needed for macromolecular biosynthesis (e.g., fatty acids) and also relieves oxidative stress caused by mitochondrial ROS production, which is critical for KRAS-mediated tumorigenicity [16]. Comprised of the oxidative arm and the non-oxidative arm, this pathway is thought to be key to maintenance of the reducing equivalents needed for ROS detoxification.

The non-oxidative arm primarily generates ribose-5-phosphate (R5P) for DNA/RNA biosynthesis. RPIA and RPE, enzymes that regulate carbon metabolism in the non-oxidative PPP arm, were found to be significantly decreased with $KRAS^{G12D}$ extinction. The functional importance of this pathway in maintenance of PDAC was confirmed with knockdown of either or both RPIA and RPE, resulting in inhibition of xenograft tumor growth. These findings may suggest that KRAS-mutant PDAC have an exploitable reliance on this pathway to generate nucleotides for continued proliferation.

TCA and Glutamine Addiction

Consistent with the Warburg effect hypothesis, studies have also demonstrated that KRAS-driven oncogenesis requires glutamine diversion and catabolism into the TCA cycle for tumorigenesis [16, 17]. Fatty acid synthesis relies primarily on glutamine conversion in the mitochondrial tricarboxylic acid (TCA) cycle. Glutaminase, along with alanine aminotransferase, catabolizes glutamine to the alpha-ketoglutarate intermediate substrate of the TCA cycle. RAS-, MYC-, and AKT-dependent tumor cells have previously been suggested to require glutamine for mitochondrial metabolism [16].

Myc and Glutamine

MYC-overexpressing tumor cells have previously been shown to rely on glutamine for cellular proliferation. Promoter analysis and MYC knockdown studies suggest that MYC mediates $KRAS^{G12D}$-dependent transcriptional control of PDAC metabolic reprogramming [18]. As a byproduct of glutamine catabolism by the TCA cycle and further enhanced by oncogenic KRAS, mitochondrial reactive oxygen species have been shown to be potential regulators of cell cycle progression. This supports a distinct role for MYC as a regulator of metabolic intermediates primarily through control of glutamine entry into the mitochondrial TCA cycle. Given that a subset of PDAC tumors may have increased dependence on lipid synthesis pathways, blockade of glutamine diversion or generation of TCA cycle intermediates through MYC-mediated pathways may represent new avenues for therapeutic intervention.

Glutamine Scavenging

Targeting glutamine metabolism may be another novel approach to therapy and include specific enzyme targeting or inhibition of salvage of amino acids from proteins. PDAC tumors have been demonstrated to have increased reliance on a noncanonical glutamine metabolism. While normal cells typically utilize glutamate dehydrogenase 1 (GLUD1) to convert glutamate into α-ketoglutarate in the mitochondria, PDAC cells support the TCA cycle through glutamic-oxaloacetic transaminase1 (GOT1)-dependent conversion of aspartate to oxaloacetate, and ultimately pyruvate, through an oncogenic KRAS-mediated mechanism. Inhibition of enzymatic components of this pathway led to PDAC tumor growth inhibition through sensitization to ROS [17]. Other suggested mechanisms that support glutamine supply in PDAC also include glutamine from proteolytic degradation of extracellular protein, scavenged through an oncogenic RAS-mediated mechanism of macropinocytosis or through autophagy [19–21].

Methionine Salvage

The tumor suppressor gene CDKN2A on chromosome 9p21 is inactivated in more than 90% of pancreatic adenocarcinomas either through homozygous deletion, mutation, or hypermethylation [22, 23]. Deletion of CDKN2A occurs in roughly 40% of PDAC tumors. Because it is located about 100 kilobases telomeric from the CDKN2A gene, methylthioadenosine phosphorylase (MTAP) is frequently co-deleted with CDKN2A and is absent in 26–31% of pancreatic adenocarcinomas [23–25]. MTAP normally cleaves methylthioadenosine (MTA) to adenine and 5-methylthioribose-1-phosphate, which are essential for recycling AMP and generating methionine for adenine and methionine salvage pathways. In MTAP deficiency, neither adenine nor methionine can be salvaged. Cells are completely reliant on de novo purine synthesis for AMP production leading to sensitivity to inhibitors of de novo methionine synthesis and methionine starvation. Attempts at targeting MTAP-deficient tumors either through targeting of de novo synthesis or methionine depletion have been under investigation since the 1980s, but while successful in experimental models, a Phase II clinical trial aimed at inhibiting de novo methionine synthesis with *L*-alanosine was not successful [26, 27].

Recent analyses by Kryukov et al. and Mavrakis et al. demonstrated that MTAP loss resulted in a passenger vulnerability to protein arginine methyltransferase 5 (PRMT5) inhibition [23, 28]. Arginine methyltransferases transfer a methyl group from *S*-adenosylmethionine to arginine to produce methylarginine and *S*-adenosylhomocysteine (SAH). PRMT5 has been implicated in tumorigenesis through epigenetic regulation of cell cycle progression, promotion of EMT, and posttranslational modification of proteins, including p53 [29, 30]. In a pooled shRNA screen from 216 cancer cell lines, cell lines with loss of MTAP had marked differential expression of PRMT5 ($P = 1.64 \times 10^{-25}$) [23]. In in vitro and in vivo studies, MTAP-deficient pancreatic cancer cell lines with concomitant loss of CDKN2A and MTAP resulted

in markedly decreased tumor growth with PRMT5 knockdown that could be rescued with MTAP reconstitution. The same effect was not seen with CDKN2A deletion alone. MTAP passenger deletion, therefore, unmasked a dependence on PRMT5 in MTAP-deficient pancreatic cancer cells.

Importantly, the mechanism for PRMT5 sensitivity was found to be due to MTA accumulation from loss of MTAP [23, 28]. MTA competes with PRMT5 substrate *S*-adenosylmethionine (SAM). Increased MTA levels resulted in an MTA-bound form of PRMT5, whose catalytic domain became conformationally inactivated. Thus, the mechanism for sensitivity to PRMT5 inhibition is possibly due to impaired methyl group transfer functions downstream from PRMT5. In a separate study, MTAP-deficient tumors were also sensitive to knockdown of methionine adenosyltransferase II alpha (MAT2A), which converts ATP and methionine into SAM. MTAP-deficient cells were also sensitive to loss of PRMT5 and the PRMT5 co-complex factor RIO kinase 1 (RIOK1) [31]. Upstream and downstream mediators of PRMT5 signaling in methionine metabolism could therefore suggest exploitable vulnerabilities in the subset of pancreatic cancers with co-deleted CDKN2A/MTAP. The significance of PRMT5 with regard to chromatin remodeling should also be noted (see section "Chromatin Remodeling").

DNA Repair Genes

The DNA damage response (DDR) can play seemingly opposing roles when it is defective or intact, depending on the cellular context. A defective DNA damage response in tumor cells promotes genomic instability and tumorigenesis, but conversely, increased signaling of an intact DDR may also enhance resistance to therapies by repairing the induced genotoxic stress and preventing cell death [32]. The most common inherited genetic aberration in familial pancreatic cancers is BRCA1 and BRCA2 germline mutations, accounting for up to 17% of patients [33]. The presence of BRCA1/BRCA2 mutations increases the risk of pancreatic cancer up to sevenfold compared to the general population [34]. BRCA pathway mutational signatures are the most frequently identified genes associated with genomically unstable PDAC tumors [35, 36]. Of these BRCA pathway (BRCA1/2, ATM, or PALB2; Fig. 2) aberrations, 5% were germline and 12% were somatic mutations [36]. With deficiency of one component of the DDR, cancer cells may become reliant on other DNA repair mechanisms that would increase their susceptibility to additional DDR targeting, termed synthetic lethality. Stabilization of replication fork dynamics actually imparts a mechanism of chemoresistance in BRCA deficiency by rescuing cells from synthetic lethality. While PARP inhibitors in BRCA-associated pancreatic cancers are under investigation (NCT02042378, NCT02184195), other DNA repair defects may expand the therapeutic options to include combinations with radiation therapy [37]. Given that specific mutations in DDR pathways each represent a very small proportion of PDAC patients, this approach would likely require patient selection based on genetic analysis using a

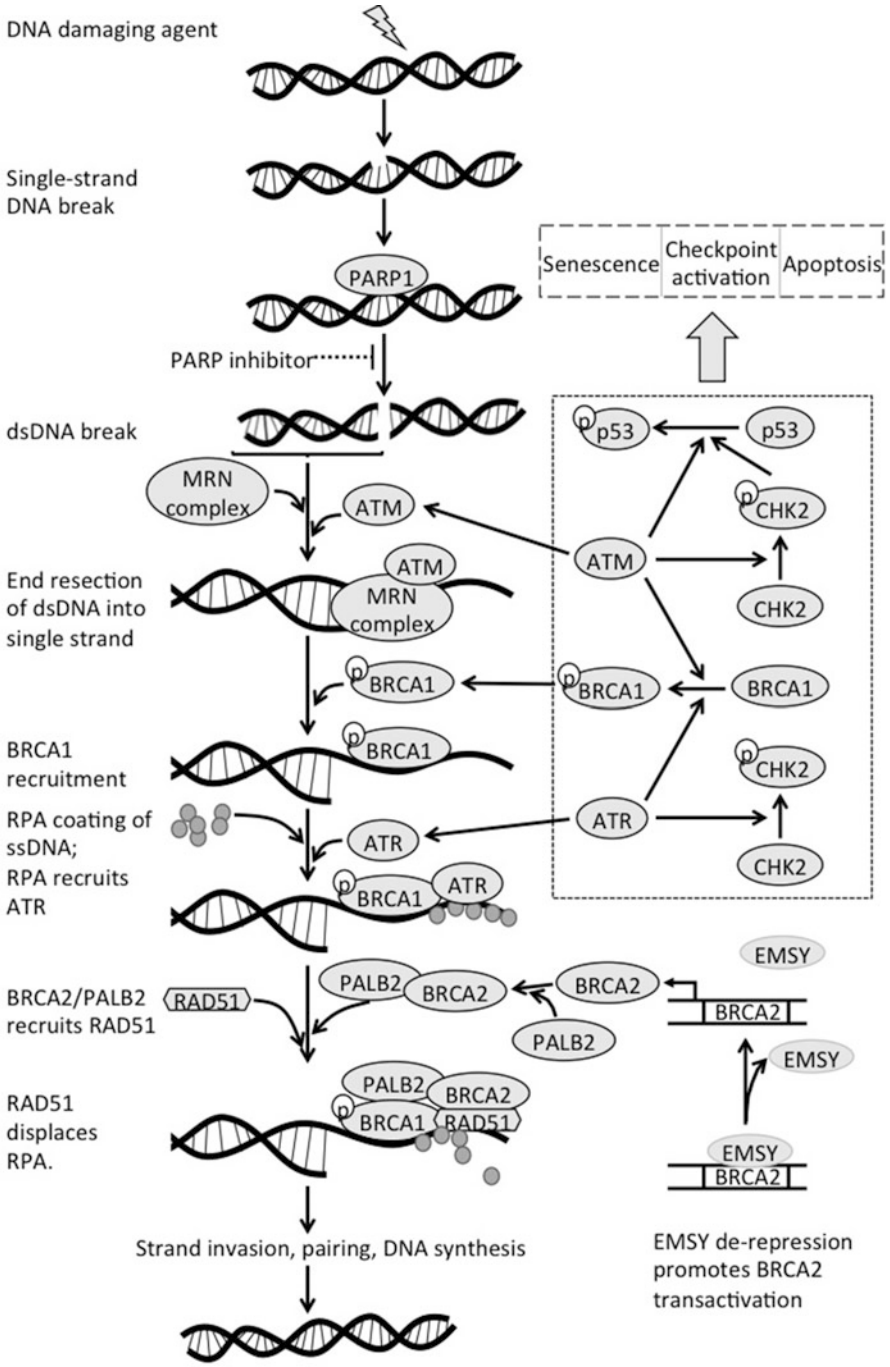

Fig. 2 (continued)

precision-medicine approach to enrich for pancreatic cancer subpopulations that may benefit. Below, potentially exploitable DDR genetic aberrations that may confer increased susceptibility to DNA damage repair inhibition are addressed.

PALB2

A nuclear binding partner of BRCA2, PALB2 facilitates BRCA2-mediated response by promoting its nuclear localization and stabilization for double-strand DNA (dsDNA) repair and homologous recombination. Disruption of PALB2's binding interaction with BRCA2 impairs repair of dsDNA breaks. Congruent with this, exomic sequencing analysis identified PALB2 as a pancreatic susceptibility gene in familial pancreatic cancer [38]. Germline deletions as well as truncating PALB2 mutations have been found in 3–4% of familial cases of pancreatic cancer [35, 36, 38, 39]. Included among these genetic alterations, a 6.7 kb germline deletion of PALB2 of exons 12 and 13 would notably interfere with PALB2's binding domain to BRCA2 [39].

ATM

Found on chromosome 11q, ATM is a serine/threonine kinase involved in the repair of double-strand DNA breaks as well as integration of signaling networks in response to genotoxic stress and cellular homeostasis. ATM aberrations are one of the most common genetic alterations and have been identified in up to 8% of pancreatic cancers [40, 41]. An immunohistochemical analysis of 57 patients also identified low ATM protein expression in 66% of pancreatic tumor samples compared to 8% of normal pancreatic tissues with decreased protein expression correlating to a more aggressive PDAC phenotype (less differentiated, more nodal metastases) [42]. In support of this, PDAC $ATM^{-/-}$, $KRAS^{G12D/+}$, and $p48^{Cre/+}$murine models suggest that ATM loss results in increased EMT and cancer cell stemness to promote PDAC progression and aggressiveness that further enhanced the effects of oncogenic KRAS. ATM loss additionally contributes to promotion of ROS production [43].

The synthetic lethal approach may also be effective in ATM-deficient PDAC tumors. Given that PARP inhibitors have shown potential for efficacy for prostate cancer, they may also hold promise in ATM-mutant pancreatic tumors [44]. Inhibition of the CHK1 pathway either through upstream ATR (ataxia telangiectasia and

Fig. 2 Homologous recombination DNA repair. *Abbreviations* (alphabetical order): *ATM* ataxia-telangiectasia mutated, *ATR* ataxia-telangiectasia and Rad3-related protein, *BRCA1* breast cancer 1, *BRCA2* breast cancer 2, *CHK1* checkpoint kinase 1, *CHK2* checkpoint kinase 2, *EMSY* BRCA2-interacting transcriptional repressor, *MRN complex* Mre11-Rad50-Nbs1, *PALB2* partner and localizer of BRCA2, *RAD51* RAD51 recombinase

Rad3 related) inhibition or direct CHK1 blockade may also be effective in ATM-deficient cancers. Preclinical evidence suggests that blockade of this pathway in multiple tumor types, including pancreatic cancer, may sensitize cells to DNA-damaging chemotherapy or radiation [45]. Direct small molecule inhibitors of ATM and ATR are under development for treatment of tumors with DDR deficiencies [46].

BUB1B

BUB1B (budding uninhibited by benzimidazoles) is a kinetochore protein that is critical to the mitotic spindle checkpoint that is activated by ATM and has been associated with genomic instability [47]. Less frequent than BRCA, PALB2, or ATM alterations, deleterious mutations in BUB1B were found in 1 of 39 familial pancreatic cancer patients [40]. However, bioinformatic analysis based on function and protein-protein networks suggested that BUB1B was one of the most differentially expressed gene hubs compared to normal pancreas [48]. Interestingly, PDAC tumors that bypassed KRAS dependency through a YAP1-dependent mechanism also consistently upregulated BUB1B suggesting it deserves further investigation as a possible mechanism for KRAS escape (see section "Epithelial to Mesenchymal Transition (EMT)") [49].

Chromatin Remodeling

Rapid modulation of gene expression is regulated at multiple levels beyond the simple gene coding sequence. Variable gene expression is further defined by cooperative epigenetic mechanisms such as histone modification, DNA methylation, and microRNAs to control cellular functions. Deregulation of epigenetic phenomena leads to aberrant signaling promoting PDAC development and progression.

SWI/SNF Complex

Multiple inactivating mutations in chromatin remodeling have been identified through genomic analysis [35]. Genetic mutations have been reported in PDAC in up to 14–34% of genes encoding components of the SWItch/sucrose non-fermentable (SWI/SNF) multiprotein complex, which modulates transcription by disrupting the DNA-to-histone contact in the nucleosome through ATP hydrolysis [36, 50]. The SWI/SNF complex is comprised of 15 subunits in various combinatorial assemblies. Mutations in the various subunits of the complex have been identified with clear tumor suppressor function [50, 51].

Encoding the BAF250a subunit of the SWI/SNF complex, ARID1A represents one of the most commonly mutated genes involved in chromatin remodeling and is a marker of poor prognosis in PDAC [52]. Depletion of ARID1B decreased the

viability of ARID1A-deficient pancreatic cancer cells compared to ARID1A-proficient cells, suggesting that a synthetic lethal approach to ARID1A-mutant PDAC tumors may be exploited [52, 53].

In a study by Shain et al., ARID1B deletions were found in 77% of 48 patient-derived xenografts and 22 PDAC cell lines [50]. Fifty-two of these deletions were single copy deletions indicating that typically only one subunit component of the complex would be affected. Two cell lines (PANC1 and MIAPaCa2) had loss at two separate subunits. Notably, on an individual level, each subunit harbored inactivating gene alterations in 2–10% of samples. Functional studies have suggested a possible tumor suppressive role for components of the complex. While promising, given the combinatorial complexity of the SWI/SNF complex, the impact of the stoichiometric distribution of subunits with loss of individual or multiple subunits on oncogenesis is likely to be complex and will require further investigation to develop viable therapeutic options [50].

KMD6A

Inactivating genetic aberrations of the histone demethylase KMD6A has been found in 18% of pancreatic cancers [35]. As a negative modulator of DICER transcription, KMD6A inhibition promotes EMT transformation through miR-200-mediated derepression of zinc finger E-box binding homeobox 1 (ZEB1) expression [54]. Limited preclinical data is available in pancreatic cancer. Significantly though, a relationship between KMD6A may exist with SWI/SNF complexes, PRMT5, and PRC2 (polycomb repressive complex 2). PRC2's catalytic subunit EZH2 (enhancer of zeste homolog 2) is a methylating enzyme known to have pro-oncogenic function in multiple tumor types, including PDAC, and EZH2 inhibitors are currently under Phase I investigation (NCT01897571, NCT02082977) [55–57].

SWI/SNF complexes have been found in association with PRMT5 (see section "Metabolic Pathways") and PRC2 to downregulate tumor suppressor gene transcription of suppressor of tumorigenicity 7 (ST7), nonmetastatic 23 (NM23), retinoblastoma-like protein 2 (RBL2) message [58]. Bromodomain protein 7 (BRD7), a SWI/SNF-associated protein that recognizes acetylated histones, recruits not only PRMT5 and PRC2 but also KMD6Ato the same tumor suppressor gene sites as PRMT5 and PRC2 [59]. KMD6A acts as an activating transcriptional regulator, suggesting a counter-regulatory role for KMD6A to PRMT5 and PRC2.

With loss of KMD6A in a significant proportion of PDAC tumors, PRMT5 and PRC2 hypermethylation could conceivably be unchecked in KMD6A-deficient PDAC tumors that leads to repressed expression of multiple tumor suppressor genes. Enriched selection of PDAC patients who have deficiency of KMD6A in combination with CDKN2A/MTAP co-deletion and/or EZH2 overexpression may identify patients who may derive added benefit from broader derepression of tumor suppressor genes through treatment with inhibitors of PRMT5, EZH2, BRD7, histone deacetylases, or methyltransferases.

Transcription Factors

EMSY

EMSY encodes a protein that abrogates BRCA2-mediated effects through transcriptional repression of BRCA2 and disruption of BRCA2 binding to RAD51, a protein interaction critical to homologous recombination repair of double-strand DNA breaks. In sporadic pancreatic cancers, EMSY gene amplification was found in 13.6% (8 of 59) tumor samples and mRNA overexpressed in 45% (9 of 20) pancreatic cancer cell lines [60]. Increased expression of EMSY results in inefficient homologous recombination repair of double-strand breaks and genomic instability, simulating BRCA2, PALB2, or ATM deficiency. Most current strategies that induce synthetic lethality rely on loss of DDR mechanisms. As an alternative approach, directly inhibiting pathways whose expression mimics deficient DDR mechanisms may represent a broader synthetic lethality approach. EMSY has also been implicated in chromatin remodeling through protein complex formations and promoter regulation of histone lysine demethylase KDM5A and the histone deacetylases HDAC1 and HDAC2 [61]. The role of EMSY in epigenetic modulation is particularly interesting given the expression of HDACs and the high frequency of hypermethylated genes in PDAC [62, 63]. Given EMSY's frequent gene amplification and overexpression in PDAC, its roles in mimicking BRCA2 deficiency and modulating epigenetic regulation, strategies to directly inhibit EMSY, or its downstream effectors may represent viable avenues for therapeutic intervention [62].

The p63 Family

Recent evidence suggests that the p63 family may be involved in DNA damage repair and EMT to increase tumorigenesis, metastatic potential, and chemoresistance and thus may be of therapeutic interest [64]. The p63 family additionally interacts with Wnt, mTOR, Notch, and sonic hedgehog pathways [64–66]. Unlike its p53 homologue, which is mutated in 60–70% of PDAC, p63 is rarely mutated. However, genetic loci variants have been linked to increased risk of pancreatic adenocarcinoma [67]. While the TP63 gene encodes for multiple isoforms, the two main variants TP63ΔN and TAp63 have opposing effects to regulate cellular function. The full-length transactivating isoform, TAp63, is transcribed from the promoter upstream from exon 1 of chromosome 3p27 and mediates tumor suppressor effects. In contrast, TP63ΔN (NP63) is pro-oncogenic and is transcribed from an alternate promoter in intron 3 as a truncated isoform missing the N-terminal transactivation domain.

The TAp63 isoform acts as a tumor suppressor by inducing cellular senescence and inhibiting metastasis through transcriptional activation of microRNA processing enzyme DICER1 and microRNA miR-130B [68]. Loss of TAp63 also results in defective fatty acid oxidation, mitochondrial function, and glucose uptake, making it particularly interesting in the context of the significant metabolic derangements found in PDAC tumors (see section "Metabolic Pathways") [69]. Countering the

function of TAp63, TP63ΔN acts as dominant negative for TAp63 as well as for p53 and p73 by competing for promoter elements or by direct protein inhibition [64]. TP63ΔN and its transcriptional targets were found to be highly expressed in the more aggressive squamous PDAC subtype compared to other subtypes [36]. In pancreatic cancer cell lines, TP63ΔN was the dominant isoform, exerting transcriptional control over EGFR with downstream upregulation of ERK, AKT, and JNK (c-Jun N-terminal kinase) signaling to promote proliferation, migration, and invasion [70]. The 14-3-3σ promoter was also activated by TP63ΔN to increase resistance to cisplatin-induced apoptosis. Although it is likely a balance of TAp63 versus TP63ΔN that directs tumorigenic potential, disruption of TP63ΔN pro-tumorigenic effect may be of particular interest as a therapeutic target.

Epithelial to Mesenchymal Transition (EMT)

Epithelial cells that acquire a more mobile mesenchymal phenotype have increased capacity to migrate, invade, and disseminate systemically in a process of developmental plasticity called epithelial to mesenchymal transition (EMT). Loss of apical-basal polarity and disruption of tumor cell adhesion are modulated by E-cadherin, Twist upregulation, and ZEB1 that are largely coordinated by cross talk among TGFβ, Wnt, and Notch pathways along with miRNAs [71, 72]. TGFβ signaling promotes Snail and ZEB1 expression that, in turn, appears to control a feed-forward mechanism of transcriptional suppression of the pro-epithelial microRNA-200 family [73].

In pancreatic adenocarcinoma, EMT is thought to play a key co-regulatory role with cancer-associated fibroblasts in remodeling stroma. Pancreatic cancer-associated EMT is activated and maintained through TGFβ/TNFα signaling that is associated with sustained activation of RAS/MEK/ERK signaling [74]. Evidence suggests that the relationship between KRAS and epithelial to mesenchymal differentiation may present a therapeutic window for targeting.

KRAS Addiction and EMT

KRAS dependence or "addiction," where tumor cell growth is reliant on continued KRAS signaling, represents a potentially exploitable pathway. A prior study by Singh et al. suggested a link between EMT induction and loss of KRAS dependency [75]. However, KRAS-addicted cells remained sensitive to inhibition of SYK and RON kinases as well as integrin-beta6 with distinctly reduced tumor cell growth and increased caspase-3-mediated apoptosis. Similar inhibitory effects were not seen in KRAS-independent cell lines. Inhibition of SYK, RON kinase, or integrin-beta6 may offer benefit in selected patients with PDAC tumors selected for KRAS dependency.

KRAS Independence and EMT

Although KRAS has been established to play essential roles in initiation and maintenance of PDAC tumors, loss of KRAS addiction allows tumor escape and development of resistance mechanisms that make targeting KRAS signaling more difficult.

Strong evidence supports a role for YAP1 mediating KRAS-independent growth to bypass KRAS dependence. Yes-associated protein 1 (YAP1) is a transcriptional coactivator involved in regulating pancreas development, DNA replication, cell cycle progression with pro-tumorigenic roles in the Hippo kinase cascade, and β-catenin/Wnt signaling [76, 77]. In two key studies, tumorigenic growth from loss of KRAS was rescued by reciprocal YAP1 gain of function [49, 78]. Utilizing the previously described doxy-inducible *iKras* PDAC model, tumor relapse was observed in mice despite extinction of KRAS expression suggesting that KRAS was no longer necessary for tumor growth [1, 49]. In relapsed tumors, PDAC maintenance circumvented dependence on KRAS signaling through acquisition of YAP1 gene amplifications and downstream binding to TEA domain family member 2 (TEAD2) to activate transcription of cell cycle and antiapoptotic genes. In the second study by Shao et al., YAP1 expression rescued previously KRAS-dependent lung cell lines whose KRAS expression was suppressed. Transcriptional activation was found to be mediated through a TEAD-independent mechanism through FOS-mediated transcriptional control of the EMT program. KRAS-independent cells were noted to be enriched with an EMT signature. These two studies suggest that YAP1 represents a potential targetable KRAS resistance mechanism in PDAC tumors.

Stroma

PDAC tumors prominently demonstrate a strong desmoplastic reaction leading to development of a peri-tumoral fibrotic stroma. An increasing volume of literature supports a role for stromal signaling in modulating tumor carcinogenesis, growth, immunosuppression, and chemoresistance [79]. PDAC stroma is composed of mainly dense extracellular matrix (ECM) proteins, activated pancreatic stellate cells (PSCs), cancer-associated fibroblasts (CAFs), and immune cell infiltrates. Under pro-inflammatory conditions of injury and carcinogenesis, autocrine and paracrine cytokine and growth factor signaling in concert with tumor cells activate PSCs and CAFs to secrete ECM components, including collagens, integrins, and fibronectin to form the fibrotic matrix.

The nature of the stroma-tumor interaction is under some debate since studies have conflicted on whether the stroma protects versus inhibits tumors. Early evidence suggested that stroma acted as a physical barrier limiting drug delivery to tumor cells through sonic hedgehog (SHH) signaling or through vascular collapse from increased interstitial fluid pressures [79, 80]. The seminal paper by Olive et al. showed that ablation of stromal CAFs through SHH inhibitor IPI-926 (saridegib) in transgenic KPC mouse model allowed increased intratumor vessel growth and gemcitabine penetration [80]. Follow-up clinical trials showed no benefit and possibly even detriment with sonic hedgehog inhibitors [79]. Recent preclinical studies

have suggested that the stroma actually serves to constrain pancreatic tumor growth and depletion of stroma enables accelerated PDAC growth.

Subsequent strategies to modulate stromal interactions have included targeting of acellular extracellular matrix components in addition to recent literature indicating a significant role for microRNAs. MicroRNAs are discussed in section "MicroRNAs (miRNAs)" of this chapter. Far from being a bystander to cellular signaling, the acellular stromal elements have also been shown to promote carcinogenesis, stromal remodeling, metastasis, chemoresistance, and immunosuppression.

Enzymatic depletion of the matrix polysaccharide hyaluronic acid (HA) demonstrated improved tumor perfusion by decreasing interstitial pressures, increased vascular permeability, and microvascular re-expansion that allowed increased gemcitabine delivery with decreased tumor growth and improved survival [79]. Early phase I/II trials with enzymatic HA depletion with recombinant PH20 hyaluronidase (PEGPH20) demonstrated good tolerability and suggested potential benefit in high HA-expressing tumors. PEGPH20 is now in a randomized, double-blind, placebo-controlled phase III trial with nab-paclitaxel and gemcitabine and in phase I/II trials with other drug combinations (NCT02715804, NCT02241187, NCT01959139).

Additional approaches to depletion of various matrix components may be of benefit. One such strategy may be to target proteins that may be dependent on the metabolic derangements found in PDAC tumors. Pancreatic tumors are known to acquire *O*-linked glycosylation patterns with malignant progression [81]. As are characteristic of adenocarcinomas, mucins are highly expressed on epithelial cell surfaces whose core proteins are also heavily post-translationally modified in both normal and cancer tissue. In pancreatic cancer, mucins MUC-1 and MUC-4 are differentially glycosylated, likely by polypeptide glycosyl transferases, to produce glycoforms that act as tumor-associated carbohydrate antigens (TACA). They contain truncated glycan structures with sialyl Tn (STn, NeuAcα2-6GalNAc) and Tn (GalNAc) antigens that are not found in normal pancreas and are increased with metastatic liver disease [81, 82].

Galectins belong to a family of lectins with a carbohydrate recognition domain that binds extracellular or ECM glycans, such as MUCs, specifically at the N-acetyllactosamine (Galβ(1–4)-GlcNac; LAc-NAc) units [83]. Galectin-1 (GAL1) and galectin-3 (GAL3) are aberrantly overexpressed in epithelial cells and stroma of pancreatic tumors and have well-documented roles in tumorigenesis, migration, invasion, and immunosuppression [8, 83, 84]. Oncogenic RAS signaling appeared to be activated by galectin-3 through direct KRAS binding in an orthotopic PDAC mouse model [85]. Galectins, particularly galectin-1, have been implicated as playing significant roles in mediating tumor-stromal interactions. GAL1 promotes stromal activation and acinar-to-ductal metaplasia through a SHH-dependent mechanism to promote progression and invasion [86]. Its role in immunosuppression was also supported by Gal1 knockout in a transgenic PDAC (*Ela-myc*:Gal1$^{-/-}$) mouse model, where effector immune infiltration was increased and desmoplasia notably was decreased [86, 87].

Pancreatic Neuronal Targeting

The pancreas is richly innervated with a complex network of both extrinsic and intrinsic neural inputs derived during embryonic development from the primitive foregut. Sensory information from the digestive system is conveyed to the central nervous system via an extrinsic system of autonomic afferents mainly distributed along the vagus nerves (parasympathetic) and splanchnic nerve trunks (sympathetic) through celiac and superior mesenteric artery plexi. Aggregates of neural cell bodies, called intrapancreatic ganglia, are distributed throughout parenchymal tissue and act as the intrinsic component of the pancreatic nerve supply.

Perineural invasion occurs in pancreatic adenocarcinoma with a reported incidence of up to 90–100% of PDAC cases and represents one of the most important prognostic factors for poorer survival [88, 89]. A mutual tropism between pancreatic tumor cells and neural tissue has been well documented. Histologic analysis of PDAC tumors has shown tumor cells spread continuously along nerve branches into the extra-pancreatic nerve plexus [90]. Tumor infiltration of neural tissue has been implicated as a major cause of regional recurrence after resection since innervation of lymph nodes provides a direct route for distant tumor cell dissemination through lymphatics.

Increasing evidence also indicates that nociceptive information mediates a reciprocal signaling interaction with neurotrophic factors to promote tumor growth and neural invasion. Preclinical models have consistently shown a role for neuronal modulation of inflammation in chronic pancreatitis, a known precursor to PDAC. Significant increases in immunoreactive neurotransmitters, such as calcitonin gene-related peptide (CGRP), substance P/tachykinins (SP/TK), neuropeptide Y (NPY), or vasoactive intestinal peptide (VIP), were demonstrated in the setting of chronic pancreatic inflammation. The neuropeptides CGRP and SP/TK in particular heavily co-localize with pancreatic nerves supplying pancreatic vasculature [91].

Alterations in neuronal growth factor protein expression, such as protein gene product 9.5 (pgp9.5), myelin P0 protein (MPP), nerve growth factor (NGF), TRKA, and p75, have been associated with glucose dysregulation in PDAC as well as increased perineural invasion [89]. Additionally, PDAC tumors demonstrate multiple aberrantly methylated promoters regulating neuronal growth and differentiation [62]. These data suggest that regulatory neuropeptide signaling plays a significant function in mediating PDAC neuronal invasion and that targeting these signaling pathways may alter the progression of pancreatic cancer.

ROBO/SLIT and Semaphorins

Integrated genomic analysis comparing a clinical cohort of 142 early-stage PDAC (clinical stages I to II) patients, KRAS mouse models, and cell line shRNA knockdowns showed frequent somatic aberrations of potential functional significance in axon signaling pathways [41]. Three axon guidance pathways were enriched: SLIT and roundabout (SLIT/ROBO) pathways, class 3 semaphorins, and ephrins. Up to

15% of patients had focal copy-number losses and 5% harbored mutations in SLIT2 and ROBO2. Amplification of class 3 semaphorins SEMA3A and SEMA3E was present in 18% of patients and mutations found in 3%. Corroborating patient molecular data, transgenic KRAS murine models of pancreatic carcinogenesis showed progressive mRNA expression changes in SLIT/ROBO and semaphorin pathways with transformation from normal pancreas to tumor.

The role of the SLIT/ROBO pathways in endothelial cell guidance is particularly interesting given the interdependent regulation of angiogenesis and neurogenesis [92]. SLIT proteins bind ROBO receptors to mediate repulsive cues in axon growth and inhibit cell migration of neurons as well as vascular sprouting and branching [93, 94]. SLIT2 mRNA expression has been shown to be decreased in PDAC cells. Additionally, restoration of the repellent axonal cues by SLIT2 inhibited unidirectional movement of PDAC tumor cells along contacted neurites [95]. These findings suggest that the absence of key negative regulators of neural migration and vascular growth may allow permissive invasion and dissemination of tumor cells along nerves and vessel tracts. Consistent with this, PDAC tumors also demonstrate epigenetically suppressed SLIT/ROBO pathway signaling through DNA hypermethylation [96]. As such, therapeutics aimed at ROBO/SLIT networks may limit PDAC progression and invasion.

MicroRNAs (miRNAs)

MicroRNAs are 19–25-nucleotide noncoding RNAs that regulate gene expression posttranscriptionally. They are transcribed by RNA polymerase II initially as precursor miRNAs, which are then processed into mature miRNAs by Drosha (nucleus) and Dicer (cytoplasm) [97]. The miRNA associates with Argonaute proteins to form the RNA-induced silencing complex (RISC). RISC binds target mRNAs and either blocks translation or initiates degradation of the target mRNA, as determined by complex interactions based on the degree of complementarity to the miRNA. A single miRNA may be able to bind a variety of mRNAs and vice versa, and consequently a single miRNA may affect the expression phenotype of multiple genes, and a single gene expression phenotype may be modified by multiple miRNAs. In cancers, miRNAs may block translation of oncogenes (tumor suppressor miRs) or tumor suppressor genes (onco-miRs). Conceptually, targeting of multiple miRNAs in combination may be possible treatment strategies to affect signaling at multiple regulatory levels by delivering tumor suppressive-miRs while inhibiting onco-miRs.

MicroRNAs act as critical modulators of PDAC pathogenesis, including carcinogenesis and stromal remodeling. At least 500 differentially expressed miRNAs have been identified in PDAC [98]. MicroRNAs with altered expression in pancreatic cancer compared to chronic pancreatitis, such as miR-217 and miR-196a, may offer targets to differentiate stromal changes from tumor. Key among these are miRNAs that interact to promote oncogenic pathways, such as KRAS and NF-κB, and mediate pro-tumorigenic processes such as EMT or stromal expansion.

Translation of KRAS itself is inhibited by multiple tumor suppressor miRNAs, including miR-217, miR-206, miR-145, and let-7 [97]. Let-7 miRNA is also regulated by oncogenic RAS and in PDAC its upregulation reverses EMT. Dysregulation of the miRNAs can lead to KRAS upregulation and layers of downstream miRNA signaling complexities to promote oncogenesis. Here, some of the more promising miRNAs documented in PDAC oncogenesis are discussed.

Tumor Suppressor miRs

miR-200 Family

The miR-200 family (miR-200a through c) promotes mesenchymal to epithelial transition (MET) to limit metastatic potential, invasion, and chemoresistance. Expression of miR-200 correlated with decreased EMT markers E-cadherin and Vimentin through targeting of ZEB1 and ZEB2 [72]. Their role in EMT regulation has implicated the miR-200 family in stromal remodeling as paracrine signaling agents that modulate cytokine signaling in the tumor microenvironment [99]. The miR-141 member of the miR-200 family is expressed at low levels in PDAC relative to normal pancreas tissue and has been associated with worse overall survival and negative clinical-pathologic characteristics such as tumor size, nodal status, and lymphatic invasion [100]. miR-141 inhibits YAP1, previously discussed in section "Transcription Factors" as a possible mediator of escape from KRAS addiction [78, 101]. Additionally, miR-141 has been implicated with roles in decreasing pancreatic tumor cell migration, invasion, and cell cycle progression [97].

miR-34

The miR-34 family is composed of three homologues (miR-34a through miR-34c) with variable tissue-specific expression. Their tumor-suppressive regulation of multiple critical pathways in PDAC oncogenesis suggests miR-34 delivery could be a potential therapeutic agent [97]. miR-34a and miR-34b inhibit tumor growth by inhibiting Bcl-2, Notch, and TGFβ signaling. Apoptosis may also be induced in PDAC cells through both p53-dependent and p53-independent functions. miR-34a additionally inhibited EMT, tumor cell proliferation, and cell cycle progression and reduced stem cell characteristics.

Onco-miRs

miR-155

Overexpressed in PDAC, upregulation of miR-155 is driven by activating KRAS mutations and is associated with poorer survival [102]. Its role in PDAC oncogenesis has been well studied [97]. Its function has been implicated in regulation of multiple signaling pathways key to PDAC pathogenesis, including signal transducer and activator of transcription 3 (STAT3), EGF, MAPK, NF-κB, IL-6, interferon-related

pathways, and inhibition of p53 activation. It has also been implicated in transforming pancreatic fibroblasts into cancer-associated fibroblasts.

miR-21

Signaling through KRAS also upregulates miR-21 expression [97]. In PDAC, miR-21 expression is increased and predicts worse outcome in node-negative disease. Expression of miR-21 correlates with chemoresistance, tumor cell growth, invasion, migration, proliferation, and recruitment of CAFs, as mediated through PI3K-AKT signaling, PTEN inhibition, and upregulation of antiapoptotic molecules, such as Bcl-2.

In Vivo Delivery of Small RNAs

While microRNAs (miRNAs) and other small RNAs such as siRNAs have promising characteristics for manipulation of PDAC signaling, current obstacles in their systemic delivery limit translation into therapeutic agents. In vivo delivery of small RNAs has been hampered by the inability to administer them systemically due to poor tissue penetration, cellular uptake, and rapid clearance due to rapid renal excretion and serum RNase degradation [103]. Naked nucleic acids cannot penetrate cell membranes through passive diffusion due to their hydrophilic nature, large molecular weight, and polyanionic charge and so require molecular modification to enter the cell. Delivery efficiency with intravenous administration has therefore been insufficient to achieve therapeutic benefit. Additionally, off-target gene silencing by siRNAs and immunogenicity of the siRNA duplex are considerations. These combined factors vastly limit the utility of small RNAs as systemic therapeutic agents despite clear in vitro efficacy. Efforts to increase their cell membrane penetration to reach cytoplasmic or nuclear targets and to prolong bioavailability have been heavily investigated. Attempts to improve systemic circulating half-life have focused on nanoparticle encapsulation of the nucleic acids to protect them from nuclease degradation and to improve cellular uptake. These approaches have included encapsulation in carrier systems, such as liposomes, or cationic complex formation with cationic lipids or polymers (e.g., polyethyleneimine [PEI], polyamide amine dendrimers [PAMAM]), but carrier-based strategies have been hindered by systemic toxicity although modifications such as polyethylene glycol (PEG) groups may ameliorate some effects.

Recently, tumor growth inhibition and improved survival were seen in a MYC-induced liver carcinoma mouse model with an intravenously administered dendrimer-encapsulated miRNA [104]. This approach was unique since the selection of the delivery vehicle was based on a novel methodological approach to identify candidate dendrimers from a chemically diversified library followed by progressive chemical modification through multiple in vitro and in vivo steps until a dendrimer was identified with the following features: high cellular penetrance, small RNA delivery efficiency, prolonged extracellular distribution (>6 days), and low toxicity

of the parent and degradation products. As a proof of principle, this degradable dendrimer GA2-SC8 was used to encapsulate tumor suppressor *let*-7g miRNA to form GA2-SC8 nanoparticles (NP) and intravenously injected on a weekly basis. Demonstrating high potency with a 13-fold increase in *let-7g* expression after 48 h, transgenic mice treated with GA2-SC8-*let*-7g NP demonstrated remarkably improved survival ($P = 0.004$) with minimal to no toxicity compared to their untreated and GA2-SC8-control counterparts. The lack of liver toxicity in this hepatocellular carcinoma model is of clinical importance given the high frequency of liver metastasis in PDAC. While it remains to be seen if the success of the GA2-SC8 dendrimer or the dendrimer selection methodology can be translated to effective small RNA delivery in humans, successful translation would open enormous opportunities for highly selective targeting with siRNA and miRNA.

Conclusion

Prior advances in treatment of pancreatic adenocarcinoma have seen modest success through empirical study of cytotoxic chemotherapy or radiation regimens rather than through targeted or rationally designed approaches. As technologies for multilevel genomic and expression-level analysis continue to advance, a refined approach to utilizing patient genetic information combined with PDAC pathway vulnerabilities will be critical to the discovery of new clinically useful therapeutics.

Key Research Points

- Novel pathways demonstrate exciting anticancer targets in preclinical studies.
- Metabolic reprogramming, stromal remodeling, and neuronal signaling pathways in pancreatic cancer offer promising targets for therapy.
- Treatments impacting chromatin remodeling and microRNAs present therapies aimed at altering signaling networks at the epigenetic level.
- Mutations in metabolic genes and DNA damage response may expose synthetic lethal vulnerabilities in pancreatic cancer.

Future Research Directions

- Recent multi-platform analysis of genetic and expression profiles for pancreatic cancer identify the heterogeneity of molecular drivers of disease. Further investigation of agents that exploit somatic mutational events in combination with metabolic vulnerabilities may offer strategies for tailored treatment of pancreatic cancers.
- Studies investigating agents to modulate the tumor microenvironment will inform development of novel treatment approaches and improve the distribution of investigational and standard therapeutic agents.

Clinical Implications

A personalized treatment approach to identifying individual tumor susceptibilities will be increasingly needed to address the heterogeneity in genetic and phenotypic features of pancreatic adenocarcinomas.
