This work is dedicated to our wives Linda, Gwen, Marie, and Hedi and to our patients and their relatives

Foreword

We have seen remarkable advances in the understanding of the epidemiologic, cellular, and molecular pathogenesis of pancreatic cancer since the First Edition of *Pancreatic Cancer* in 2010. Yet pancreatic cancer is still one of the most common causes of cancer-related death among men and women in the USA and many other parts of the world, and the incidence is increasing relentlessly. The more we seem to know, the bigger the challenge becomes. We said in 2010 "how do we get to the next level?" That next level has now arrived.

In 2010, we were just introduced to FOLFIRINOX, a highly active chemotherapy regimen. That was soon followed by the finding that gemcitabine and albumin-bound paclitaxel is also very effective. As we have advanced these therapies from metastatic to locally advanced to even resectable/borderline resectable disease, we see the overall survival inching up. A small triumph perhaps, but worth noting. Our challenge now is how to insert more targeted agents and to position immuno-oncology into the arsenal against this very "cold" tumor.

Because of more effective therapy, more and more patients are undergoing resection even in settings where, previously, surgery would not be attempted. Despite the greater complexity of the surgical techniques, the operations themselves remain safe. We are also seeing remarkable advances in laparoscopic and robotic surgeries for selected cases with shorter hospital stay, allowing more patients to be eligible for adjuvant treatment.

Gene testing is now recommended for patients in whom we suspect mutations based on family history, but germline testing for inherited cancer susceptibility seems to be gaining more traction. Recently, researchers at Johns Hopkins found the incidence of these mutations in patients with unremarkable family histories was around 4% and much higher than anyone would have anticipated. They sequenced 32 genes in 854 patients and found 33 with a deleterious germline mutation, including BRCA2 (12 patients), ATM (10 patients), BRCA1 (3 patients), PALB2 (2 patients), MLH1 (2 patients), CDKN2A (1 patient), TP53 (1 patient), BUB1B (1 patient), and BUB3 (1 patient). Some of these susceptibility gene mutations would be missed if current family history guidelines for gene testing were to be applied. Although the proportion of affected individuals was small, the potential treatment impact on these individuals and screening implications for family members are both massive. Patients with germline mutations in DNA repair pathways enjoy exquisite

responses to gemcitabine and cisplatin. PARP inhibitors can benefit patients with BRCA1/2 mutations, and pembrolizumab is effective for patients with microsatellite instability-high (MSI-H) cancer. In addition, we can use knowledge of germline mutations to avoid certain treatments, such as radiation, for those with ATM or TP53 mutations.

The Cancer Genome Atlas Research Network has also just recently performed an integrated genomic, transcriptomic, and proteomic profiling of 150 pancreatic ductal adenocarcinomas. Deep whole exome sequencing revealed recurrent somatic mutations in KRAS, TP53, CDKN2A, SMAD4, RNF43, ARID1A, TGFβR2, GNAS, RREB1, and PBRM1. Interestingly, KRAS wild-type tumors harbored alterations in other oncogenic drivers, including GNAS, BRAF, CTNNB1, and additional RAS pathway genes. A subset of tumors was found to have multiple KRAS mutations, with some showing evidence of biallelic mutations. Going onto protein profiling a favorable prognosis subset was identified with low epithelial-mesenchymal transition and high MTOR pathway activation. Associations of noncoding RNAs with tumor-specific mRNA subtypes were also identified. This is one of the key steps providing a roadmap for precision medicine.

This Second Edition textbook, *Pancreatic Cancer*, has maintained the momentum of a carefully composed compendium of state-of-the-art science in all aspects of research of pancreatic cancer. The experts who were selected to provide contributions are the best in their fields. The content is contemporary and comprehensive. This text is a necessary reference for anyone already doing research in pancreatic cancer.

Again I can only reiterate that I am truly grateful to my colleagues around the world who have worked so hard and so tirelessly to create this reference. Disseminating the scientific breakthroughs that we know now will accelerate the progress that will change the lives of more and more of our patients.

University of California, San Francisco Margaret A. Tempero, M.D.

Preface

Pancreatic cancer has become an even greater challenge today than it was in 2010 while paradoxically seeing exciting progress in its understanding with unforeseen advances in its diagnosis and treatment. The First Edition proved to be a major success with over 30,000 downloads: it was up to date, evincing a deep but manageable exposition of the relevant basic and translational science, complexed within a clinically relevant purpose. The forward momentum meant that a Second Edition became an inevitability, but this has not simply meant just updating the same elemental threads but a reworking of the perspective.

The incidence of pancreas cancer is rising around the world and is predicted to become the second commonest cause of death within a few years. Yet survival is beginning to improve and in the case of potentially curable cases the 5-year survival rates are 30% with postoperative adjuvant combination chemotherapy. By 2012 the estimated global incidence was 337,872 cases per year resulting in 330,391 deaths, and in Europe pancreatic cancer accounted for 103,773 new cases and 104,481 deaths each year. In the USA in 2016, there were around 53,070 new cases of pancreatic cancer diagnosed with 41,780 deaths. The American Cancer Society's estimates for pancreatic cancer in the USA for 2017 were 53,670 (27,970 men and 25,700 women) new cases with 43,090 (22,300 men and 20,790 women) deaths. Pancreatic cancer accounts for about 3% of all cancers in the USA and about 7% of all cancer deaths. The 1-year survival rate of people with pancreatic cancer who do not have surgery has risen from around 10% to 30%, and the overall 5-year survival rate has risen from 5% to 7%. In resected cases, the 5-year survival rates have increased from 8% with surgery alone to 30% with combination adjuvant chemotherapy using gemcitabine and capecitabine.

Advances in surgical techniques now enable many more patients to be operated, and the application of neoadjuvant therapies may also render borderline and locally advanced pancreatic cancers more amenable to resection. But much is still needed to understand the biology of the cancer and how the microenvironment of both the pancreatic primary and its metastases influence this. We have expanded sections on stromal inflammatory cells in pancreatic cancer and tumor-stromal interactions in invasion and metastases. There is enhanced discussion on the management of preneoplastic cystic neoplasms of the pancreas, including the controversial area of intraductal papillary mucinous neoplasms. Advanced technologies for diagnosis and

treatment now encompass cancer exosomes, liquid biopsies and circulating tumor cells, and vaccine therapy and immunotherapy.

The application of pancreatic cancer genetics has been progressed into precision medicine based on next-generation sequencing and master controllers. Other novel therapeutic areas are now expounded in considerable depth including defining pancreatic cancer phenotypes via metabolomics, treatments based on the metabolism of pancreatic cancer, epigenetic pharmacology, differential therapy based on tumor heterogeneity, and multiparameter modalities applied in the setting of individualized medicine.

By drawing on many of the world's recognized scientific authorities and practical clinicians, we hope to inspire the current and future generations of active researchers to make clever and bold decisions on how we can successfully continue the fight against pancreatic cancer.

John P. Neoptolemos
Raul Urrutia
James L. Abbruzzese
Markus W. Büchler

Acknowledgments

The Editors would like to dedicate their work to all the pancreatic cancer patients and their families.

The Editors wish to acknowledge the significant support offered by our individual editorial assistants, who provided the day-to-day contacts, oversights, and management of manuscripts that were submitted in each international office.

We specifically wish to thank the assistance of Thilo Hackert in the office of Professor Büchler (Heidelberg, Germany) who made a great contribution as well as Mia Rothwell in the office of Professor James Abbruzzese (Duke Cancer Institute, USA), and Dr. Gwen Lomberk in the office of Professor Raul Urrutia (Mayo Clinic, USA).

All of these people provided an invaluable service that is appreciated highly by the Editors and allowed Springer to publish in a timely and organized fashion.

The Editors would also like to thank the assistance and organizational skills, and the extraordinary attention and diligence of Springer's Saskia Ellis and Barbara Wolf.

About the Editors

Professor **John P. Neoptolemos** was trained at the University of Cambridge with a double degree in Natural Sciences and Philosophy followed by clinical training at Guy's Hospital in London. He is Professor of Surgery at the University of Heidelberg moving from Liverpool University where he held the Chair of Surgery from 1996 until 2017. As Chairman of ESPAC he successfully led the ESPAC-1, 3, and 4 trials, the results of which have been adopted as guidelines for the treatment of potentially curable pancreatic cancer around the world. As Director, he received the Freedom of the City of Liverpool in 2011 for the Liverpool Cancer Research UK Centre. In 2007, he established the NIHR Liverpool Pancreas Biomedical Research Unit (Scientific Director), the NIHR and Cancer Research UK, Liverpool Experimental Cancer Medicine Centre (Deputy Director), and the Liverpool Clinical Trials and Cancer Research UK Cancer Trials Units (Director). In 2012, he was made an Honorary Member of the German Society of Surgery. In 2013, the Pancreas Unit won the Acute Services Sector Health Services Journal National Award. In 2013, he received a Lifetime Achievement Award from the European Pancreatic Club at its 45th Meeting in Zurich. In 2014, he was made an Honorary Member of the Hungary Society of Surgery and also an Honorary Professor of Nanjing Medical University. He was awarded Hirschberg Award for Pancreatic Cancer, American Pancreatic Association in 2005, and the Ruth Brufsky Award for Pancreas Cancer Research in 2017. Presently, he is on the Medical Advisory Board for Pancreas Cancer UK. He was elected Fellow of the Academy of Medical Sciences in 2007 and NIHR Senior Investigator in 2011.

Dr. Raul Urrutia, M.D., was appointed as Director of the Genomic Sciences and Precision Medicine Center (GSPMC), the Warren P. Knowles Endowed Chair of Genomic Sciences and Precision Medicine, and Professor of Surgery at the Medical College of Wisconsin (MCW) from July 1, 2017. He remains Emeritus Professor at the Mayo Clinic, Rochester, MN, where he previously served as Professor in the Departments of Biochemistry and Molecular Biology, Biophysics and Medicine at the Mayo Clinic College of Medicine in Rochester, MN, and Director of Epigenomics Education and Academic Relationships in the Epigenomics Program, Mayo Clinic Center for Individualized Medicine. Dr. Urrutia was also consultant for the Division of Gastroenterology and Hepatology, Department of Internal Medicine, and consultant (joint appointment) for the Department of Physiology and Biomedical Engineering.

Dr. Urrutia received his M.D. degree from the University of Cordoba Medical School in Cordoba, Argentina, in 1987. During medical school he undertook research in the Cell Biology Institute there, where he published studies on diet-induced genomic changes during the development of pancreatic cancer. From 1987 to 1992, Dr. Urrutia held numerous positions at the National Institutes of Health (NIH), including guest researcher, visiting fellow, visiting associate, and tenure-track visiting scientist, during which he trained in the fields of cell biology, molecular biophysics, protein chemistry, and recombinant DNA techniques.

Dr. Urrutia's career and activities combine interests and expertise in the areas of genomics, epigenomics, and individualized medicine. Since joining the faculty at the Mayo Clinic College of Medicine in 1992, Dr. Urrutia has served as Director of the GI Unit, Director of the Ph.D. Program in Tumor Biology, Associate Director for Genomics at the Mayo Clinic General Clinical Research Center, and Director of the GI Cancer Research Program at the Mayo Cancer Center. Also at Mayo, Dr. Urrutia established the first laboratory dedicated to epigenetics and chromatin dynamics in normal cell populations and in diseases, such as diabetes and pancreatic cancer. His laboratory has discovered diabetes-causing genes such as KLF11, for which its alterations are responsible for juvenile (MODY VII) and neonatal diseases, as well as KLF14 for insulin

resistance metabolic syndrome. Dr. Urrutia's laboratory has made fundamental contributions by identifying members and helping to put together the family of KLF proteins, which are critical regulators of biology, pathobiology, and epigenetic reprogramming. In the area of chromatin and epigenetics, the Urrutia laboratory has discovered new histone deacetylase (HDAC), histone acetyltransferase (HAT), and histone methyltransferase (HMT) epigenetic pathways. His work also led to the discovery of histone-proteins associated subcodes, which helps to interpret epigenomic codes. All of these complexes are associated with the development of cancer, as well as many other diseases, and are currently being explored as an extremely promising area in experimental therapeutics. His work has been continuously funded by the NIH since the early 1990s.

Dr. Urrutia has been past Chair for the Pancreatic Diseases Section for the American Gastroenterological Association (2005–2006), past President for the American Pancreatic Association (2007), and a former member of the board of the International Association of Pancreatology.

James L. Abbruzzese, M.D., is the Chief of the Duke Division of Medical Oncology and serves as the Associate Director for Clinical Research and Training for the Duke Cancer Institute (DCI). Dr. Abbruzzese is a leading expert in the clinical study and treatment of pancreatic cancer, and his management experience and vision for clinical research and the division will substantially support cancer care and research at Duke. Before moving to Duke, he held the Waun Ki Hong Distinguished Chair in Translational Oncology, and he was Chairman of the Department of Gastrointestinal Medical Oncology and Digestive Diseases at the University of Texas M.D. Anderson Cancer Center in Houston.

He earned his medical degree with honors from the University of Chicago, Pritzker School of Medicine, and completed his residency in Internal Medicine at Johns Hopkins Hospital. He also completed clinical fellowships in Infectious Diseases at the Johns Hopkins and in Medical Oncology and Medical Oncology Research Laboratory of Neoplastic Disease Mechanisms at the Dana-Farber Cancer Institute of Harvard Medical

School. Before his recruitment to Duke University he spent most of his professional career at M.D. Anderson, where he progressed through the ranks to assume leadership positions as Chairman of the Department of Gastrointestinal Medical Oncology and Associate Vice-Provost for Clinical Research.

Among his many accomplishments, Dr. Abbruzzese is a Fellow of the American College of Physicians and Fellow of the American Society of Clinical Oncology. He has coauthored more than 400 research publications and is the immediate past Chair of the Clinical Trials and Translational Research Advisory Committee of the National Cancer Institute. He currently serves as the Chair of the NCI Pancreatic Ductal Adenocarcinoma Progress Working Group.

Professor **Markus W. Büchler** is the Executive Director and Professor of Surgery at the Department of Surgery at Heidelberg University. After studying medicine in Heidelberg and Berlin, he started his surgical training at the University of Ulm where he became Deputy Clinical Director in 1987. In 1993, he became Professor of Surgery and Clinical Director of General Surgery at the University of Bern, Switzerland. In 2001, he returned to Germany to start leading the surgical department in Heidelberg. Today, he additionally heads the surgical departments at the Salem Hospital in Heidelberg and at the general hospitals of Sinsheim, Eberbach, and Heppenheim. He is an internationally respected expert in the field of oncologic surgery, especially in the field of pancreatic surgery. Professor Büchler has published more than 2000 scientific papers mainly focused on the translational features of GI cancer and pancreatic diseases as well as clinical surgical problems. Among others he has been President of the German Surgical Society, the European Pancreas Club, and the International Hepato-Pancreato-Biliary Association. He is a member of the German Academy of Sciences Leopoldina and he is an Honorary Member of the American Surgical Association, the American College of Surgeons, and the Royal Colleges of Surgeons of England and Scotland among many other societies. Professor Büchler has received multiple scientific awards, and he is a member of the editorial boards of many well-known scientific journals.

Part I

The Nature of Pancreatic Cancer

Epidemiology and Prospects for Prevention of Pancreatic Cancer

Patrick Maisonneuve and Albert Lowenfels

Contents

Abstract

Pancreatic cancer, although infrequent, has a very poor prognosis, making it currently one of the fourth or fifth most common causes of cancer mortality in developed countries. Its incidence varies greatly across regions, which suggests that lifestyle factors play an important role in its etiology. Because pancreatic cancer is strongly age dependent, increasing population longevity and aging will lead to an increase of the global burden of pancreatic cancer in the coming decades. In fact, pancreatic cancer is anticipated to move from the fourth to the second leading cause of cancer death in the United States by 2020, despite stable age-specific and age-standardized incidence rates. The increase in pancreatic

cancer incidence and mortality rates reported in some countries could be largely ascribed to improvement in the diagnosis and ascertainment of the disease, particularly in elderly subjects. The etiology of pancreatic cancer has been extensively studied and has been the subject of numerous meta-analyses and pooled analyses. Using a comprehensive strategy, one can retrieve more than 170 meta-analytical or pooled reports dealing with the association between more than 50 specific risk factors and pancreatic cancer risk. About two-thirds of the major risk factors associated with pancreatic cancer are potentially modifiable, affording a unique opportunity for preventing one of our deadliest cancers: Abstaining from smoking, limiting alcohol intake, adopting a healthy diet, rich in fruits and vegetables, limiting red meat consumption and being physically active in everyday life could reduce pancreas cancer risk by 30 percent.

Burden of Pancreatic Cancer

Before providing information on pancreatic cancer burden, time trends, or risk factors, it is important to recognize that the term "pancreatic cancer" encompasses distinct types of cancer that are often amalgamated in epidemiological studies [1][i]. Pancreatic cancer can arise either from exocrine or endocrine cells. Exocrine cells produce enzymes such as lipase and amylase and bicarbonate that are secreted into the small intestine to help in digesting foods, while endocrine cells, or islets of Langerhans, produce hormones such as insulin and glucagon to maintain the proper level of sugar in the blood. Tumors of the exocrine pancreas represent more than 95% of all pancreatic cancers and comprise themselves different histological subtypes, adenocarcinomas representing by far the largest group. Endocrine tumors could be benign or malignant and functional (producing hormones) or nonfunctional (producing no hormones) and generally have a better prognosis than exocrine tumors [2]. Because all pancreatic cancer subtypes are regrouped under the same main topographic code of the International Classification of the Diseases (i.e., ICD-9157), it is uncommon to obtain epidemiological data for specific subtypes. Descriptive statistics for pancreatic cancer are however largely driven by adenocarcinomas of the exocrine pancreas, which represent the vast majority of the tumors.

Worldwide, pancreatic cancer could be considered as a rare form of cancer, ranking as the twelfth most common form of cancer, with about 330,000 new cases estimated for both sexes combined in 2012 [3]. Because of its very poor prognosis, approximately the same number of deaths was expected in 2012, placing pancreatic cancer as the seventh most common form of cancer-related death worldwide, both in men and in women. Pancreatic cancer incidence and mortality vary significantly across major world areas. In developing countries, pancreatic cancer

represents a rare disease, ranking respectively as the eighth and tenth most common cause of cancer-related death in men and in women. This lower incidence could be largely attributed to the short life expectancy observed in these countries and to poor diagnostic assessment. In fact, we will see in the following sections that pancreatic cancer is very strongly related to age and that its accurate diagnosis relies on modern technologies not often available in low-income countries. In contrast, in developed countries, pancreatic cancer is an appreciable form of cancer, representing about 3% of all cancer cases and 6% of all cancer-related deaths. In some westernized countries such as the United States of America [4], pancreatic cancer ranks as the fourth most common cause of cancer-related death both in men after lung, prostate, and colorectal cancer and in women after lung, breast, and colorectal cancer.

Overall more than a fivefold difference in age-standardized rates is observed between low- and high-incidence countries (Fig. 1). Age-standardized (world standard population) incidence rates in less-developed countries were estimated as 3.3 per 100,000 in men and 2.4 per 100,000 in women for 2012 [3]. For the same year, the country with the highest estimated incidence of pancreatic cancer was the Czech Republic with an age-adjusted rate of 11.9 per 100,000 in men and 7.9 per 100,000 in women. Most of the other countries with high incidence rates are located in Central or Eastern Europe for both sexes and in Scandinavia for women (Table 1). High rates are also recorded in Japan in contrast with those of other countries from Asia.

Time Trends and Related Factors

Variations in cancer incidence may result from several factors well described in a paper by Weir et al. [5]. These factors could be regrouped in three different large categories: (1) change in cancer risk or diagnostic practice, (2) population growth, and (3) population aging. While population growth is more directly related to the variation in the absolute number of cancer diagnosed in a country and is specific to that country, the two other factors are particularly pertinent to pancreatic cancer. Change in cancer risk may a priori be considered as the most obvious factor: A good example is the dramatic change in lung cancer incidence that parallels the epidemic of tobacco consumption [6]. But, unlike lung cancer which is largely caused by exposure to tobacco smoke, pancreatic cancer is a multifactorial disease. Many of its risk factors have been identified (see following section), but altogether they explain only a fraction of all the cases [7]. Since exposure to these risk factors often varies in different ways (i.e., decreasing smoking consumption offset by an increasing prevalence of obesity or diabetes), it is unlikely that changes in the prevalence of a single risk factor could alone explain variations in pancreatic cancer incidence within or across countries.

Change in Diagnostic Practice

On the contrary, change in diagnostic practice is or has been in the past, an important factor. Pancreatic cancer is in fact very difficult to diagnose. Most patients remain

Bulgaria	686	10.4	Austria	800	6.9
Romania	1,692	10.3	Japan	15,886	6.7

free of symptoms until the disease has reached an advance stage. Its location is difficult to access, and the advanced age of the patients at diagnosis also contributes to the limited proportion of those amenable to resection. Palliative treatment remains the only option in many cases and frequently no histological confirmation of the cancer is available. In the absence of surgical specimen, an accurate diagnosis of pancreatic cancer relies on fairly modern and expensive imaging instrumentations and demanding procedures including endoscopic retrograde cholangiopancreatography (ERCP) introduced in the late 1960s, computed tomography (CT) in the mid-1970s [ii], endoscopic ultrasound (EUS) in early 1980s, magnetic resonance cholangiopancreatography (MRCP) [iii], or endoscopic ultrasound fine needle aspiration (EUS-FNA) in the early 1990s [8][iv]. Without these diagnostic tools, many pancreatic cancer cases in the past or even at present in low-income countries, particularly those presenting as diffuse metastatic disease or in elderly or debilitated people, might have been improperly diagnosed or reported. Registration of cancer incidence and mortality also depends upon coding instruments such as the International Classification of Disease (ICD) of the World Health Organization (WHO) [9, 10][v]. This classification has itself evolved overtime, and several alternative specifications to "Malignant neoplasm of pancreas" could have been used to account for imprecision or uncertainty of the diagnosis including "Malignant neoplasm of other and ill-defined sites within the digestive organs," "Malignant neoplasm of other and ill-defined sites," "Secondary malignant neoplasm of digestive systems," "Malignant neoplasm without specification of site," or even "Neoplasm of unspecified nature" (Table 2). Part of the increase in cancer incidence and mortality observed until the 1990s in westernized countries, still ongoing in developing countries or in the older age groups could be ascribed to change in diagnostic practice. This is further supported by data showing increase of the percentage of pancreas cancers that were staged and diagnosed histologically in the last decades in parallel with data

showing decrease of the number of cases recorded as "cancer of unknown primary" [11, 12]. Analysis of time trends after the introduction and diffusion of appropriate diagnostic tools and excluding people in the older age groups which are subject to less intensive diagnostic work-up should provide more accurate information on the real variation of pancreatic cancer incidence over time.

Population Aging

Aging of the population represents another major factor responsible for the increase of the number of cancer cases diagnosed in developed countries [13]. This is

particularly true for pancreatic cancer which is strongly age dependent, being exceptionally diagnosed before age 40 and uncommon before age 50. In an aging country like Italy, nowadays no more than 10% of all pancreatic cancer cases are diagnosed before age 60, approximately 55% between age 60 and 80, and remarkably 35% (still increasing) in elderly people aged 80 years or more. This is a consequence of the astonishing increase in life expectancy that occurred in Italy, or in other westernized countries, over the last century, jumping from 35 years in the late 1800s to over 80 years currently. With the continuing decline of mortality from the big killers (cardiovascular disease and major forms of cancer) [14], the proportion of patients reaching an age at which pancreatic cancer is more frequent will continue to increase.

Time Trends

Analysis of long-time series such as data available from 1930 for the United States shows a modest increase of age-adjusted pancreatic cancer death rates over time in both sexes, contrasting with the clear reduction of mortality from the major forms of cancer such as stomach, uterine cervix, colorectal, prostate, breast, and more recently lung cancer. This rising trend is common to many countries worldwide, but the extent of the increase varies from country to country: Higher increases are seen for countries with historically low mortality rates of pancreatic cancer such as Spain, Italy, Greece, or Japan, while the increase is less important for countries with historically high mortality rates such as the United States, the United Kingdom, Sweden, or Norway (Fig. 2). This points to an ostensible globalization of pancreatic cancer mortality rates, more evident in men than in women, which could in part result from the standardization of diagnostic and coding practice. Since the analysis is based on age-standardized rates, aging of the population is unlikely to explain any of the variation observed.

The pattern is somewhat different when focusing on age-adjusted incidence or mortality rates recorded in the last two decades in countries with large access to modern diagnostic technology. During this more recent period, no significant trends are generally observed in men or in women (National cancer registry of Ireland, Cancer Research UK, US SEER). An analysis of time trends based on age-specific rates instead of age-adjusted rates reveals that pancreatic cancer rates are stable over time in all 5-year age groups below age 70 or 75, but an increase is observed in older age groups particularly in those aged 80 or more. The residual increase in older age groups could again be attributed to change in diagnostic practice among elderly as well as to the reduction of competing cause of death from other forms of cancer and cardiovascular disease. This pattern is present in many countries including the United States or Italy but is particularly evident for Japan, with a drastic increase of age-specific pancreatic cancer mortality rates for all age groups from 1955 until the mid-1980s that stabilized afterward except for elderly subjects for whom a slight increase is still apparent (Fig. 3).

Despite stable age-adjusted rates, the number of pancreatic cancer cases and deaths is drastically increasing in most westernized countries. In 2014, Rahib et al. [15]

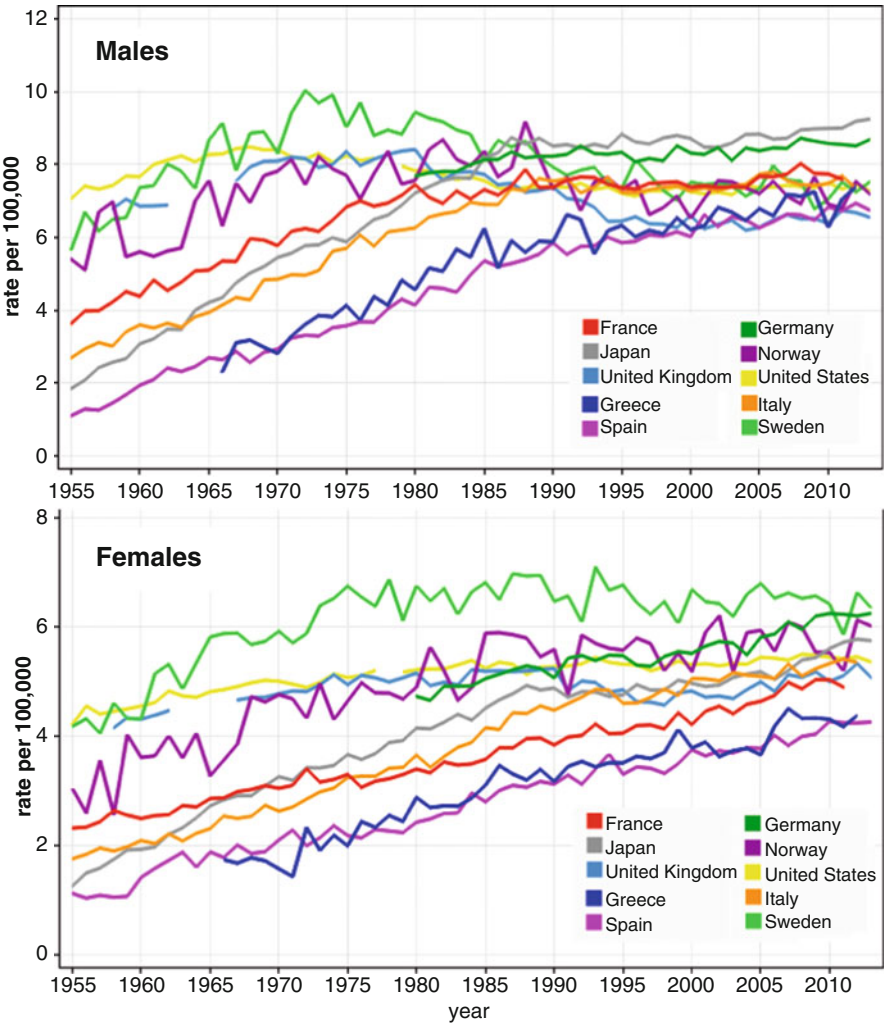

Fig. 2 Trends in age-adjusted (world standard population) pancreatic cancer death rates in selected countries worldwide (Source: International Agency for Research on Cancer (Lyon, France))

published projections of cancer incidence and deaths to 2030 in the United States. They found an "unexpected" burden of pancreas cancers which are anticipated to move from the fourth to the second leading cause of cancer-related death in the United States by 2020. Likewise, Ferlay et al. [16] estimated that by the year 2017, more deaths from pancreatic cancer will occur than breast cancer in the European Union and that pancreatic cancer may become the third leading cause of death from cancer in the EU after lung and colorectal cancers. This increase of the absolute number of cases and deaths is a direct consequence of aging of the population. From a simple projection, applying pancreatic cancer age-specific rates reported for Italy in 2010 to the projected

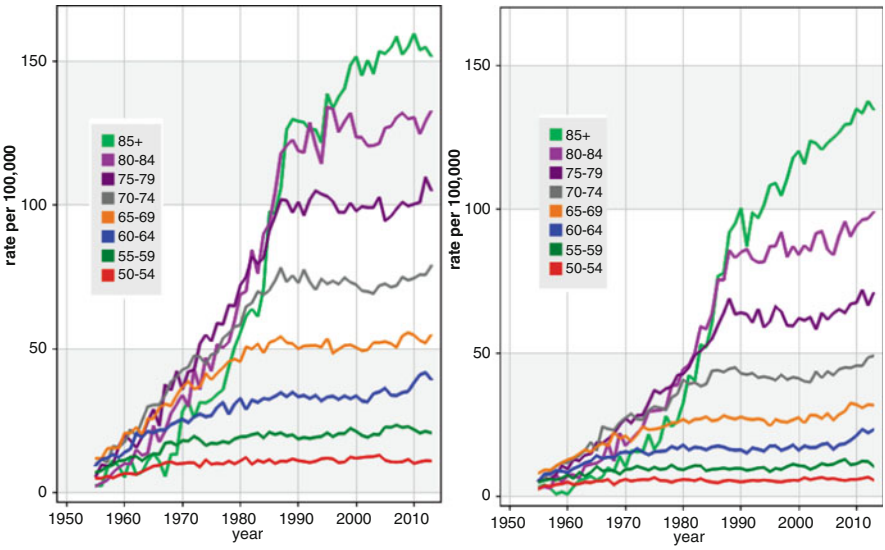

Fig. 3 Trends in age-specific pancreatic cancer death rates in Japan (Source: International Agency for Research on Cancer (Lyon, France))

Table 3 Projection of pancreatic cancer deaths in Italy

Italian population obtained from the Population Division of the United Nations, the number of pancreatic cancer cases in Italian subjects aged 70 or more is predicted to increase from ~7,200 in 2010 to ~8,800 (+22%) in 2020 and >10,400 (+44%) in 2030, while the number of cases aged less than 70 will be about constant and this despite fixed age-specific incidence rates (Table 3).

Risk Factors

The list of suspected risk factors for pancreatic cancer is very long and has been subject of a dedicated chapter in the previous edition of this book [17]. Unlike lung or uterine cervix cancers which are mostly caused by exposure to a single risk factor (respectively, tobacco smoke and human papilloma virus infection), pancreatic

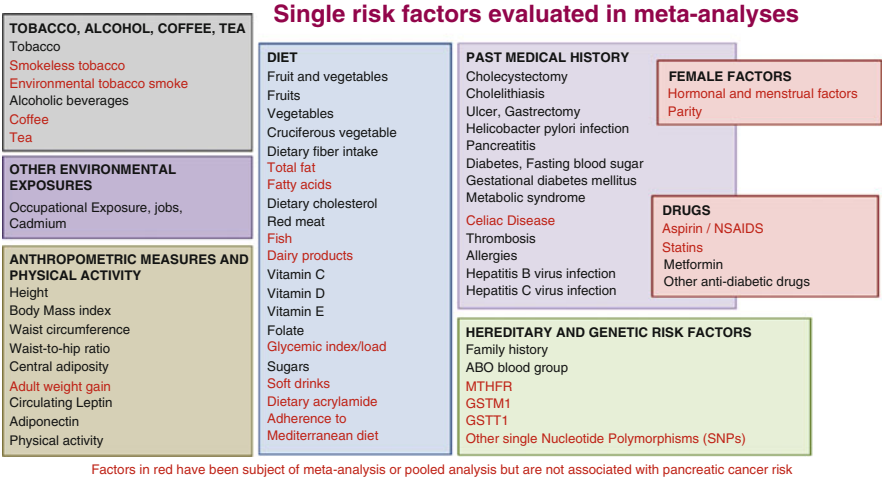

Fig. 4 Single risk factors evaluated in meta-analyses. Factors in *red* have been subject of meta-analysis or pooled analysis but are not associated with pancreatic cancer risk

cancer has been associated with numerous risk factors involved in several distinct pathways [7]. The recent proliferation of systematic reviews, meta-analyses, and pooled analyses of results or individual data from published reports had allowed to identify, quantify, and summarize the association between a series of uncommon or modest risk factors that could not have been possible in a single observational study. A preliminary summary review based on results from 117 meta-analyses or pooled analyses was a comprehensive strategy; one can 1 year later retrieve more than 170 meta-analytical or pooled reports dealing with the association between more than 50 specific risk factors and pancreatic cancer risk (Fig. 4). For many of the risk factors, a statistically significant association has been established, while for a series of other studied risk factors, the results from meta-analyses ascertain the lack of an association with pancreatic cancer.

Hereditary and genetic factors are responsible for a small proportion of pancreatic cancer cases [18]. A family history of pancreatic cancers approximately double the risk of pancreatic cancer, and it is estimated that 5–10% of patients with pancreatic cancer have an underlying germline disorder [19]. Having a non-O blood group, another inherited characteristic, has also been steadily associated with an increased risk of pancreatic cancer [20][vi]. Tobacco smoking is the most important and established lifestyle-related risk factor, being responsible for approximately 20% of all pancreatic tumors [21]. Although a common cause of pancreatitis, heavy alcohol intake is associated only with a modest increased risk of pancreatic cancer [22]. Many factors associated with the metabolic syndrome, including overweight and obesity [23], impaired glucose tolerance [24], and long-standing diabetes [25] also increase the risk disease, while atopic allergy [26] and use of metformin [27] as a treatment for diabetes have been associated with a reduced risk of pancreatic

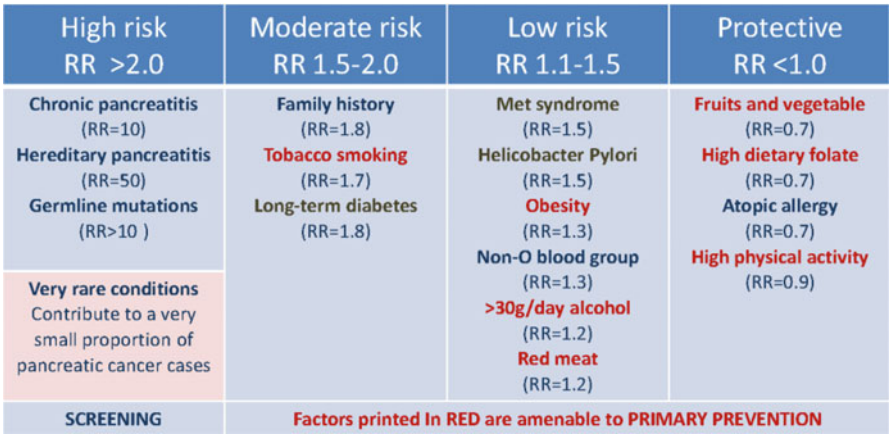

Fig. 5 Major risk factors for pancreatic cancer

cancer. Other medical conditions such as a history of chronic pancreatitis [28] or cholecystectomy [29], infection with *Helicobacter pylori* [30], hepatitis B [31], or hepatitis C [32] virus also increase the risk of developing pancreas cancer. There is only limited evidence of an association between diet and pancreatic cancer risk, with an apparent modest increased risk with increasing red meat [33] and processed meat [34] consumption and risk reduction with increasing consumption of fruits and vegetables [35] and folate [36]. Several meta-analyses confirmed no association with either coffee or tea consumption [37], with total fat [38], dairy products [39], dietary acrylamide [40], or fish intake [41], with glycemic index or glycemic load [42], with exposure to smokeless tobacco [43] or environmental tobacco smoke [44].

Only very few of these risk factors are associated with relative risks greater than two and could be used for identifying individuals who could benefit from screening. These include individuals with a strong family history of pancreatic cancer, with a history of chronic or hereditary pancreatitis, or who have another genetic predisposition for developing this disease (Fig. 5). Although tobacco smoking and long-standing diabetes are among the most established risk factor, the magnitude of the association is only moderate, being comprised between 1.5 and 2.0. Most of the remaining risk factors could be considered "low risk" with summary relative risk never exceeding 1.5.

Prospects for Prevention

The increasing number of pancreatic cancer cases, the difficulty to diagnose the tumor at an early stage, and the lack of effective treatment make primary prevention one of the best options to reduce burden of the disease. Many of the identified risk factors for pancreatic cancer are definitely amenable to primary prevention, but the

magnitude of their association is only low or moderate (Fig. 5). Tobacco smoking alone is probably responsible for 20–30% of all pancreatic cancer cases [7, 45–46]. Because heavy alcohol consumption is associated with a modest 20% increased risk of pancreatic cancer and because the prevalence of heavy (>30 g/day) drinkers is low in the general population, alcohol is thought to be responsible for less than 10% of all pancreatic cancer cases [47]. Depending of the country, the attributable fraction of obesity varies from 3% to as optimistic as 27% for the US population [48]. Again the attributable fraction of high meat or low fruit intake is small [7]. Parkin et al. [49] estimated that 36% of pancreatic cancers were attributable to lifestyle and environmental factors in the United Kingdom in 2010.

It is remarkable that most of the preventable risk factors for pancreatic cancer are also associated with other forms of cancer or with other non-neoplastic diseases. This is the case for tobacco smoking, excessive body weight, lack of physical activity, unhealthy diet, or excessive alcohol consumption. Therefore, the general recommendations already in place for cancer prevention apply particularly well to pancreatic cancer. For instance, the top 6 of the 12 recommendations of the European Code against Cancer have a direct impact on pancreatic cancer [50]. These recommendations are:

1. *Do not smoke. Do not use any form of tobacco.*
2. *Make your home smoke-free. Support smoke-free policies in your workplace.*
3. *Take action to be a healthy body weight.*
4. *Be physically active in everyday life. Limit the time you spend sitting.*
5. *Have a healthy diet:*
   - *Eat plenty of whole grains, pulses, vegetables, and fruits.*
   - *Limit high-calorie foods (foods high in sugar or fat) and avoid sugary drinks.*
   - *Avoid processed meat; limit red meat and foods high in salt.*
6. *If you drink alcohol of any type, limit your intake. Not drinking alcohol is better for cancer prevention.*

It is difficult to quantify how many pancreatic cancer cases the adoption of these measures could prevent, but a study based on data from the prospective National Institutes of Health-AARP Diet and Health Study provides exciting information [51]. This study followed about 450,000 participants aged 50–71 years and 1,057 incidental pancreatic cancer cases were observed during follow-up. Participants were retrospectively scored on five modifiable lifestyle factors as healthy or unhealthy, receiving 1 point for each respective lifestyle factor: nonsmoking, limited alcohol use, adherence to the Mediterranean dietary pattern, body mass index ($\geq$18 and <25), or regular physical activity. The authors estimated that as much as 30% of pancreatic cancer cases in this study were attributable to low healthy lifestyle scores (0–3) and could have been prevented. Because action for tobacco control, for the limitation of alcohol consumption, and for weight control and action plan for healthy diet and exercise are difficult to perform and reach only limited success, a much lower proportion of pancreatic cancer could however be prevented in the real life.

Conclusion

Pancreatic cancer represents a major cause of cancer-related deaths. Part of the increase seen in the past could be ascribed to change in diagnostic and coding practices, while aging of the population is at large responsible for the increase of the number of cases and deaths observed today particularly among elderly individuals. Pancreatic cancer is a multifactorial disease: Hereditary and genetic factors are associated with high risks of developing cancer but are responsible for a small fraction of the cases. Many of the environmental and lifestyle risk factors for pancreatic cancer are common risk factors to other forms of cancer and non-neoplastic diseases and are preventable. Adoption of a healthy lifestyle could substantially reduce pancreatic cancer burden.

Abstract

Cancer is a disease of uncontrolled cell proliferation. Sequencing of the pancreatic cancer genome revealed frequent gene alterations that lead to constitutive proliferation signals and loss of the breaking systems. Cancer cells also display defects in the DNA repair systems, which suggest that compromised genome integrity contributes to the tumorigenesis process. These observations explain many of the abnormal behaviors of cancer cells, yet stopping proliferation of cancer cells remains a difficult task.

This chapter will describe misregulation of the cell-cycle machinery in pancreatic cancer and therapeutic options to stop abnormal proliferation. The basic concept of the normal cell cycle will be outlined first, and the mechanisms of DNA repair will be introduced. Next, alterations of the cell cycle and DNA repair systems in pancreatic cancer will be described. Finally, therapeutic opportunities to target the specific alterations in the cell cycle and DNA repair systems in pancreatic cancer will be discussed.

Keywords

Cell cycle · CDK · Cyclin · pRB · DNA damage · Checkpoint · p53 · DNA repair · BRCA

Phases of the Cell Cycle

The cell cycle is a process of cell duplication and division, in which two daughter cells are produced from one mother cell. The very essence of the cell cycle is duplication and segregation of the genetic information, which is stored as a form of DNA sequence in the genome. Complementary pairing of the bases in DNA duplexes underlies the copying mechanism of the genome (i.e., DNA replication), in which two identical duplexes are reproduced using each strand of unwound DNA duplex as a template. Duplication of the genome is followed by mitosis, where two copies of the genetic information are segregated into separate daughter cells. Thus, the cell cycle is alternating cycles of the DNA synthesis phase (S phase) and the mitotic phase (M phase) (Fig. 1). The gap between M and S phase is called G1 phase, whereas the gap between S and M phase is called G2

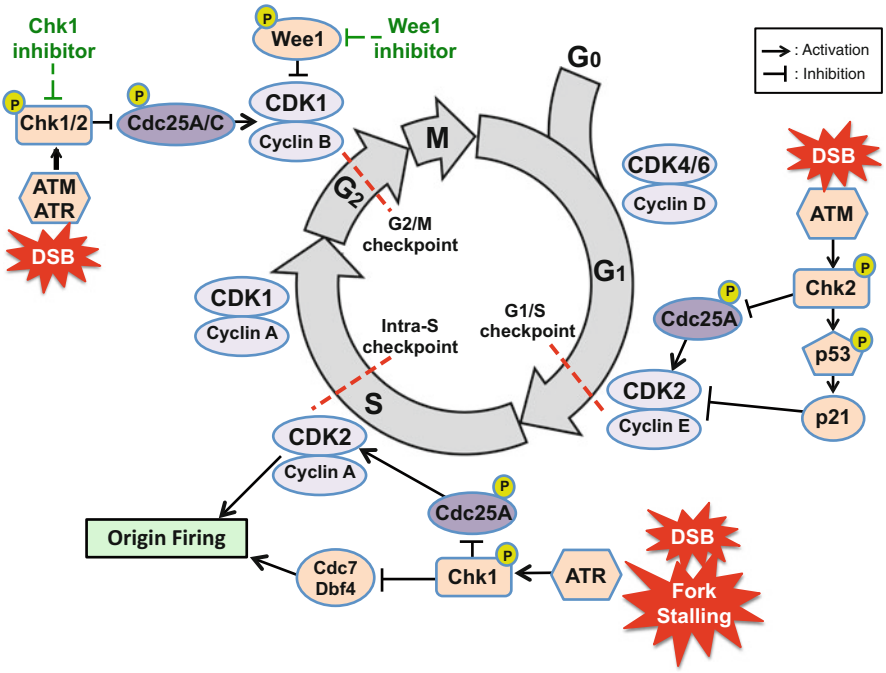

Fig. 1 The cell cycle and DNA damage checkpoints. The cell cycle, which comprises four phases, G1, S, G2, and M, is primarily driven by cyclin-dependent kinases (CDKs) and its binding partners, cyclins. Cdc25 phosphatases remove inhibitory phosphorylation from CDKs and promote cell-cycle progression. In response to DNA damage, cells rely on three major cell-cycle checkpoints: G1/S, intra-S, and G2/M. In response to double strand breaks (DSBs) in G1 phase, activated ATM phosphorylates and activates the downstream kinase Chk2, which in turn phosphorylates Cdc25A and inhibits Cdc25A-mediated activation of CDK2-cyclin E, leading to G1 arrest. Activated ATM and Chk2 also promote stabilization of p53, which in turn induces transcriptional induction of $p21^{Cip1}$, which inhibits CDK2 and prevents S-phase entry. The intra-S checkpoint is primarily mediated by the ATR kinase and is activated by replication fork stalling and resected DSBs, both of which generate single-strand DNA. Activated ATR phosphorylates and activates Chk1, which in turn phosphorylates Cdc25A and inhibits Cdc25A-mediated activation of CDK2. Chk1 also inhibits the Cdc7-Dbf4 kinase. The inhibition of Cdc7-Dbf4 and CDK2, which are required for origin firing, leads to S-phase arrest. When DSBs occur in late S or G2 phase, activated ATM/ATR activate Chk2/Chk1, which in turn phosphorylate and inhibit Cdc25A/Cdc25C-mediated activation of CDK1-cyclin B, leading to G2 arrest. Chk1-mediated phosphorylation stabilizes Wee1, which also contributes to G2/M arrest by maintaining the inhibitory phosphorylation on CDK1. Potential therapeutic drugs (Chk1 and Wee1 inhibitors) are also indicated. *P* phosphorylation

phase. After mitosis, cells make a decision in G1 phase as to whether they continue to proliferate, or exit the cell cycle and enter a quiescence state termed G0 phase. The decision depends on whether the cell receives mitogenic or differentiation signals in G1 phase.

G1 Phase

DNA replication requires sequential assembly of the replication machinery on chromosomes [1]. This process starts in G1 phase with the loading of two hexametric rings of MCM2-7, a replicative helicase, at origins of replication. This is achieved in a concerted action of origin recognition complexes (ORCs), CDC6 and CDT1, which are thought to work as an ATP-dependent clamp loader. The complex containing ORCs, CDC6, CDT1, and MCM2-7 is termed prereplicative complexes (pre-RCs) and marks potential sites of replication initiation. Pre-RC formation in G1 phase also licenses origins for replication initiation in the subsequent S phase. The double hexamer of MCM2-7 complexes remain inactive as a helicase until S phase because they lack cofactors.

S Phase

Upon S-phase entry, the replicative helicases are activated via loading of CDC45 and GINS on MCM2-7 [1]. Resulting is two active CMG (*C*DC45, *M*CM2-7, *G*INS) helicases that encircle each single-strand DNA (ssDNA) and unwind DNA duplexes in the 3′–5′ direction. Once origins are fired and DNA duplex unwound, exposed ssDNA is coated with ssDNA-binding proteins RPAs, and the DNA polymerase α (Pol α)-primase complexes synthesize RNA/DNA hybrid primers. The primer synthesis allows loading of PCNA, a processivity factor for replicative polymerases Pol δ or Pol ε, by the RFC clamp loader composed of RFC1-5. PCNA loading at the primer-template junctions allows polymerase switching from Pol α to replicative polymerase Pol δ or Pol ε. Because DNA duplex is antiparallel, DNA synthesis is continuous on one strand (leading strand), while discontinuous on the other strand (lagging strand). The discontinuous DNA segments in the lagging strand, called Okazaki fragments, are joined together by DNA ligase to form a continuous DNA strand.

While chromosomes are replicated, a pair of replicated chromosomes (called sister chromatids) is held together with cohesin, a ring-shaped protein complex that encircles DNA, until two sister chromatids are separated in mitosis [2]. The loading of cohesin in S phase is performed by the RFC CTF18 lamp loader, which has the same subunits as the PCNA clamp loader RFC except the RFC1 subunit is replaced with CTF18.

G2 Phase

Faithful chromosome segregation in mitosis is dependent on successful completion of DNA replication. In G2 phase, cells ensure that DNA replication is finished throughout the genome, and block the onset of mitosis if there are unreplicated DNA segments (see Sect. 4.2.3). Because sister chromatids can become entangled after DNA replication, cells start decatenating sister chromatids in G2 phase by using

topoisomerase II, which cuts DNA duplex and passing another through the break in an ATP-dependent manner.

M Phase

Mitosis can be described as five distinctive phases: prophase, prometaphase, metaphase, anaphase, and telophase. In prophase, chromosome condensation is initiated with condensin II, which promote loop formation of chromosomes [3]. Concomitantly, cohesin rings dissociate from chromatin, except for at the centromere, where cohesins remain on chromatin until anaphase [2]. Two centrosomes begin to move apart and spindle microtubules are formed. In prometaphase, the nuclear envelope is broken down and, condensin I, another type of condensin that is cytoplasmic in the interphase, gains access to the chromosomes. Condensin I compacts chromosomes further into well-defined rod-shaped structures. In addition, spindle microtubules are attached to sister chromatids at the centromeric structure called kinetochore. In metaphase, all sister chromatids are aligned at the midpoint of the two centrosomes. At the onset of anaphase, ubiquitin E3 ligase APC/C^{Cdc20} promotes degradation of securin, an inhibitor of cysteine protease called separase [4]. Upon securin degradation, activated separase cleaves cohesins remaining at the kinetochore, allowing movement of each sister chromatid toward the opposite spindle poles. Finally in telophase, spindles are disassembled and chromosomes are decondensed. At the same time, new nuclear envelopes are formed around segregated chromosomes in two future daughter cells, and cytokinesis is completed with the division of the cytoplasm.

Successful segregation of sister chromatids requires the attachment of all kinetochores to microtubules and formation of bipolar spindles. Cells ensure these by a mechanism called spindle checkpoint, which monitors proper attachment of microtubules to the kinetochore [4]. In prometaphase and metaphase, kinetochores without microtubule attachment generate diffusible signals of a protein called Mad2 to prevent activation of APC/C^{Cdc20}. Because one unattached kinetochore is sufficient to generate a signal to block APC/C activation, progression to anaphase is prevented essentially until all kinetochores have attached spindles.

Regulation of CDKs

The cell cycle is driven by a signaling cascade of protein phosphorylation. The major driving force is a family of enzymes called cyclin-dependent kinases (CDKs). CDKs require interaction with regulatory subunits, called cyclins, to become active. Levels of most cyclin proteins fluctuate in the cell cycle, and that is reflected in the oscillation of CDK activity in the cell cycle. In addition to cyclin binding, CDKs undergo regulation by phosphorylation and interaction with CDK inhibitors, which

help establish switch-like activation mechanisms, or stop cell-cycle progression if necessary.

Phosphorylation by CDKs has wide variety of effects on substrates, including activation or inhibition of enzymes and induction of protein-protein interactions. CDKs phosphorylate a large number of substrates that are directly involved in duplication and segregation of chromosomes. CDKs also phosphorylate many regulators of cell-cycle events, thereby acting as master regulators of the cell cycle.

CDKs and Cyclins

CDKs

CDKs are serine/threonine kinases that play a central role in cell-cycle progression. There are four major CDKs involved in the cell-cycle regulation. CDK4 and CDK6 are the G1 CDKs that are necessary to enter the cell cycle from the quiescent state. CDK2 is responsible for S-phase entry and promoting DNA replication, whereas CDK1 is the mitotic CDK that drives mitosis in M phase.

CDKs are proline-directed kinases that phosphorylate serine or threonine residue followed by proline in the context of [S/T]PX[K/R], where S/T indicates the serine or threonine residue that is phosphorylated by CDKs, PX indicates proline followed by any amino acids, and K/R indicates lysine or arginine residues. The levels of CDK proteins are mostly stable in the cell cycle, so the regulation of the activity comes in part from the changes in the abundance of the regulatory partner, the cyclin proteins.

The active site of CDKs is located in a cleft where ATP is bound deep inside. In monomeric CDKs, the catalytic cleft is blocked by a segment called the T loop. To achieve full activation, CDKs require cyclin-binding and phosphorylation of the T loop by CDK-activating kinases (CAKs).

Cyclins

Distinct types of cyclins are expressed in different phases of the cell cycle, and they can be classified into four types based on the phases they function in (Fig. 1). Cyclin D is the G1 cyclin that partners with CDK4 or CDK6 to promote cell-cycle entry. Cyclin D gene transcription reflects the mitogenic stimuli and transmits the growth signal to the cell-cycle machinery by inducing cyclin E and cyclin A transcription. Cyclin E is the G1/S cyclin that triggers S-phase entry together with CDK2, while cyclin A is the S cyclin that forms a complex with either CDK2 in S phase or CDK1 in G2/M phase. DNA replication in S phase is driven by CDK2-cyclin E and CDK2-cyclin A. Finally, cyclin B is the M cyclin that is responsible for driving mitotic events in M phase.

Except for the D-type cyclins, the levels of cyclin proteins fluctuate during the cell cycle due to their degradation at specific phases of the cell cycle. Cyclin E is degraded in S phase after phosphorylation by CDK2-cyclin A, which generates binding site for the E3 ubiquitin ligase SCF^{Fbw7}. In contrast, cyclin A and cyclin B

contains a motif called destruction box, which can be recognized by another ubiquitin E3 ligase APC/C^{Cdc20} [5]. In early mitosis, CDK1-cyclin A phosphorylates APC/C subunits and promotes Cdc20 binding with APC/C, thereby inducing its own degradation. Cyclin B is degraded in anaphase after spindle checkpoint has confirmed that microtubules are attachment to all the kinetochores [4].

Regulation of cyclin proteins by proteolysis has several advantages over regulation at the transcriptional level. One is the ability to rapidly shut off CDK activity. This cannot be achieved easily by transcriptional regulation, because proteins will remain even after transcription is turned off. Another advantage is the irreversible nature of protein degradation. By the rapid destruction of the regulatory subunits, cells achieve tight control of CDK activity and ensure that the cell cycle does not move backwards.

Activation Mechanisms of CDKs

Binding with Cyclins

Cyclins interact with specific CDK partners through its conserved cyclin box. Interaction with cyclins induces a structural change of CDKs and promotes a shift to an active conformation. Upon cyclin-binding, the T loop, which is located at the entrance of the catalytic cleft, is moved away from the substrate-binding site. The ATP-binding site in the cleft also undergoes conformational changes, in which the active site residues are realigned and ATP is correctly oriented.

Cyclins also provide substrate specificity to the CDK partner. For example, in the case of CDK2-cyclin E and CDK2-cyclin A, cyclins directly bind to substrates via the Cy (or RXL) motif, which interacts with the hydrophobic patch of the cyclin proteins. Together with the consensus sequence of phosphorylation site ([S/T]PX[K/R]), the Cy motif constitutes a bipartite substrate recognition motif for CDK2-cyclin E and CDK2-cyclin A.

T-Loop Phosphorylation of CDKs

Full activation of CDKs requires phosphorylation of the T loop by CAK. In the case of CDK2, the phosphorylation site is Thr160. The phosphate group on this residue is bound by three Arg residues coming from different parts of CDK2 and induces conformational changes that result in increased substrate binding.

The ternary complex containing CDK7, cyclin H and Mat1 is the CAK for all the cell-cycle CDKs [6]. CDK4 and CDK6 appear to require cyclin binding prior to CAK-dependent T loop phosphorylation, while CAK acts on monomeric CDK2 before cyclin binding. In the case of CDK1, cyclin binding and T loop phosphorylation are interdependent.

The phosphorylated T loop of CDK2 and CDK1 is protected from phosphatases, so that CAK is only necessary to establish active CDK2 and CDK1. On the contrary, the phosphate group on the T loop of CDK4 and CDK6 is unprotected, so that continuous CAK activity is necessary to maintain active CDK4 and CDK6. This indicates that CDK4 and CDK6 are more likely to reflect the changes in CAK

activity. At the G0-G1 transition, CDK7 activation coincides with CDK4 T loop phosphorylation and CDK4 activation. Thus, CAK-mediated T loop phosphorylation appears to play a regulatory role in CDK4 and CDK6 activation, transmitting changes in mitogenic signals to the cell-cycle machinery.

Inhibitory Phosphorylation of CDKs

CDK1 and CDK2 can be inhibited by phosphorylation at Tyr15 by the Wee1 kinase. The mechanism of CDK inhibition by the modification is through the blockade of substrate peptide binding and the induction of nonproductive conformation of the γ-phosphate group of ATP in the catalytic cleft. The phosphate group at Tyr15 is removed by phosphatases in the Cdc25 family; therefore, CDK activity can be influenced by the balance between inhibitory phosphorylation and activating dephosphorylation. There are three Cdc25 phosphatases (Cdc25A, Cdc25B and Cdc25C). Cdc25A acts at both G1/S and G2/M transition whereas Cdc25B and Cdc25C play roles in S and G2/M phases [7].

CDK regulation by the inhibitory phosphorylation has two biological implications. One is generation of a switch-like CDK activation mechanism. Wee1 and Cdc25 are both phosphorylated by CDKs, where Wee1 is inhibited while Cdc25 is activated by CDKs. Thus, there is a positive feedback mechanism built in the CDK activation: initial activation of a small fraction of CDK leads to activation of Cdc25 and inhibition of Wee1, tipping the balance between the inhibitory phosphorylation and the activating dephosphorylation. Another biological significance of the Tyr15 phosphorylation is to inhibit CDKs in the checkpoints in response to DNA damage (see Sect. 4.2).

CDK4 and CDK6 also contain a tyrosine residue equivalent to the Tyr15 residue of CDK2 and CDK1 (CDK4 Tyr17 and CDK6 Tyr24). It has been reported that TGF-β treatment causes CDK6 inhibition through increased Tyr24 phosphorylation via Cdc25A down-regulation. Similarly, ultraviolet radiation causes G1 arrest in a manner dependent on tyrosine phosphorylation of CDK4. The Tyr kinases responsible for these effects are unknown, but it is unlikely Wee1 because Wee1 lacks kinase activity toward cyclin D-associated CDKs in vitro.

CDK Inhibitors

The Cip/Kip Family

$p21^{Cip1}$, $p27^{Kip1}$ and $p57^{Kip2}$ belong to the Cip/Kip family of CDK inhibitors, which mainly inhibit CDK4, CDK6 and CDK2. These inhibitors share a conserved N-terminal region where they interact with both CDK and cyclins. The crystal structure of $p27^{Kip1}$ bound to CDK2-cyclin A revealed several mechanisms of CDK inhibition by CDK inhibitors. First, $p27^{Kip1}$ binding with cyclin A blocks the interaction of substrates with cyclins. The same Cy motif (RXL motif) that is utilized in the substrate recognition by cyclins is also present in $p21^{Cip1}$, $p27^{Kip1}$, and

$p57^{Kip2}$, therefore preventing substrate interactions competitively. Second, $p27^{Kip1}$ inserts the inhibitory 3_{10} helix into the catalytic cleft of CDKs, preventing ATP binding. Third, in the case of CDK4/6, $p27^{Kip1}$ blocks the access of CAK to the T-loop, thereby inhibiting CDK activation indirectly.

Paradoxically, the Cip/Kip family proteins can assist complex formation of CDK4/6 and cyclin D under certain circumstances and promote cell-cycle entry. Mechanistically, mitogenic signals induce $p27^{Kip1}$ phosphorylation at Tyr88 (and weakly Tyr89) by tyrosine kinases and displace the inhibitory 3_{10} helix from the catalytic cleft. $p27^{Kip1}$ phosphorylation by Tyr kinases, therefore, neutralizes its inhibitory effects on CDK4/6 and converts $p27^{Kip1}$ to an assembly factor for CDK4/6-cyclin D. A similar mechanism has been proposed for $p21^{Cip1}$-dependent assembly of the CDK4-cyclin D complexes. Therefore, the Cip/Kip family proteins play opposite roles in quiescent and cycling cells: they inhibit residual CDK4/6 activities in G0 cells, while they switch to activators of CDK4/6 when mitogenic stimuli trigger tyrosine phosphorylation. In addition, the noninhibitory binding of $p21^{Cip1}$ and $p27^{Kip1}$ with CDK4/6-cyclin D sequesters the CDK inhibitors from CDK2-cyclin E/A, facilitating their activation following the cell-cycle entry.

Each Cip/Kip family inhibitor has its own regulatory mechanisms and plays distinct roles in the cell-cycle regulation. $p21^{Cip1}$ is induced at the transcriptional level by the tumor suppressor p53 in response to DNA damage (see Sect. 4.2.1). $p21^{Cip1}$ protein levels are regulated in the cell cycle as well. Phosphorylation of $p21^{Cip1}$ by CDK2-cyclin E at the G1/S transition induces its recognition and ubiquitination by the E3 ubiquitin ligase SCF^{Skp2} followed by proteasome-mediated degradation. $p21^{Cip1}$ also binds PCNA, a sliding clamp for DNA polymerases, through the PCNA-interacting peptide motif in the C-terminus, and inhibits DNA replication in G1 phase. Once cells enter S phase, $p21^{Cip1}$ is ubiquitinated on PCNA by the E3 ubiquitin ligase $CRL4^{CDT2}$ and degraded by the proteasome.

$p27^{Kip1}$ is regulated by transcription, protein stability, and cellular localization. In cycling cells, Thr187 phosphorylation of $p27^{Kip1}$ by CDK2-cyclin E induces recognition and ubiquitination by the E3 ubiquitin ligase SCF^{Skp2}, causing more activation of CDK2-cyclin E. This positive feedback mechanism contributes to the switch-like activation of CDK2-cyclin E at the G1/S transition. In quiescent cells, on the other hand, $p27^{Kip1}$ proteins accumulate in nuclei due to down-regulation of Skp2 and inhibit residual CDK activity. Upon cell-cycle entry, mitogenic stimuli promote $p27^{Kip1}$ inactivation by a number of mechanisms. First, Ser10 phosphorylation of $p27^{Kip1}$ by Akt and other kinases promotes nuclear export of $p27^{Kip1}$ in G1 phase by creating a binding site for exportin-1. Second, phosphorylation at Thr157 by Akt, and Thr198 by Akt and p90 ribosomal S6 kinase enhances retention of $p27^{Kip1}$ in cytoplasm by creating binding site for 14-3-3, which blocks nuclear import of $p27^{Kip1}$. Third, this pool of $p27^{Kip1}$ proteins in the cytosol is ubiquitinated by the E3 ubiquitin ligase KPC and degraded by the proteasome.

$p57^{Kip2}$ is mainly involved in embryogenesis and shows tissue-specific expression patterns. Its expression can be induced by epigenetic modulation to block pancreatic cancer proliferation [8] (see Sect. 6.2).

The INK4 Family

The INK4 family of CDK inhibitors consists of $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$. The family members share a similar domain structure of multiple ankylin repeats and function as inhibitors of CDK4 and CDK6. Unlike the Cip/Kip family members, INK4 proteins interact with monomeric CDKs. Structural studies of $p16^{INK4a}$ and $p19^{INK4d}$ bound to CDK6 suggest that INK4 proteins bind CDK6 opposite to the cyclin D binding site. Binding with the INK4 family inhibitors induces conformational changes that make CDK6 incompatible to cyclin D binding. It also distorts the catalytic cleft and interferes with ATP binding to the active site. INK4 family inhibitors also block the access of $p27^{Kip2}$ to CDK6, thereby causing redistribution of the Cip/Kip family inhibitors to CDK2.

Among the INK4 family members, $p16^{INK4a}$ and $p15^{INK4b}$ are clearly linked to tumor suppressor functions. $p16^{INK4a}$ can be induced by oncogenic RAS signaling, which leads to phosphorylation-dependent activation of the ETS family transcription factors. On the other hand, $p15^{INK4b}$ is induced by antimitogen TGF-β, through SMAD proteins.

Regulation of Cell-Cycle Entry

Signals from extracellular growth factors promote cell proliferation by driving cell-cycle entry at G0/G1 phase. The entry point of the mitogenic signals to the cell cycle is the promoters of *CCND1*, *CCND2,* and *CCND3*, which encode cyclin D1, D2, and D3, respectively. Each cyclin D gene is transcriptionally activated in response to different mitogenic stimuli. The key target of CDK4/6-cyclin D-mediated phosphorylation is the tumor suppressor protein pRB. pRB and its family members, p107 and p130, are repressors of the E2F transcription factors, which bind the promoters of genes that are necessary for S phase and M phase. Phosphorylation of pRB by CDK4/6-cyclin D induces dissociation of pRB from E2F and trigger transcriptional activation of downstream genes. Among the targets activated by E2F are the genes encoding cyclin E and cyclin A. CDK4/6-cyclin D activation in response to mitogenic stimulation, therefore, starts the autonomous signaling cascade of CDK activation, which becomes independent of growth stimuli after passing the restriction point (R-point) in G1 phase (Fig. 2).

E2F Transcription Factors

E2Fs are a family of transcription factors consisting of E2F1 to E2F8 [9]. E2F1 to E2F6 contain a single DNA-binding domain and form a dimer with DP1 or DP2 proteins to bind DNA. In contrast, E2F7 and E2F8 contain two DNA-binding domains and act without forming a heterodimer with DP1 and DP2. There is a third DP family protein, DP4, which has been shown to forms a dimer with E2F but lacks the DNA binding ability. E2F-DP dimers bind the consensus sequence, TTTCCCGC, with slight variations. A large number of genes that are involved in

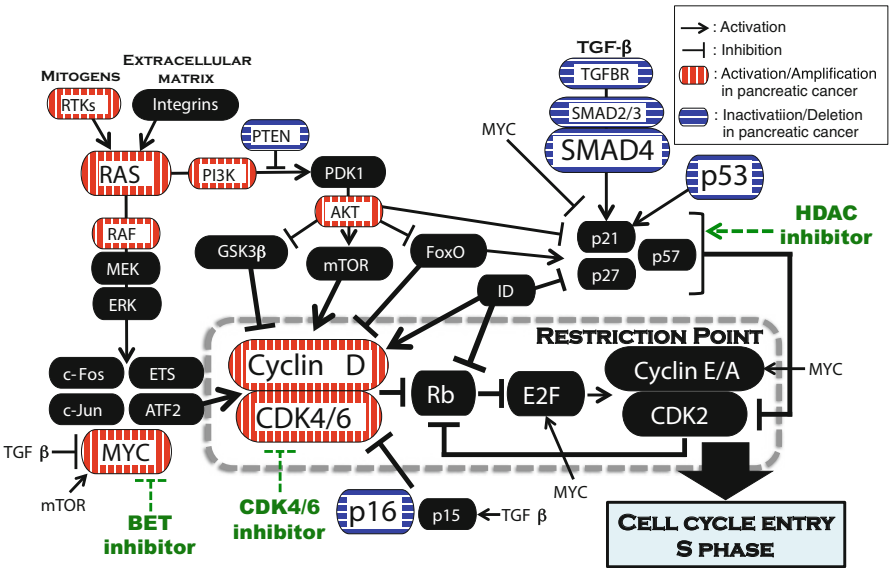

Fig. 2 Cell-cycle entry and its dysregulation. Mitogens interact with receptor tyrosine kinases (RTKs) and trigger RAS activation. RAS activates the RAF-MEK-ERK pathway, resulting in activation of transcription factors (c-Fos, c-Jun, ATF2, ETS, and MYC) to induce expression of cyclin D proteins. RAS also activates the PI3K-AKT pathway, which is antagonized by PTEN. Activated AKT regulates its effectors ($p21^{Cip1}$, $p27^{Kip1}$, GSK3β, FoxO, and mTOR) and promotes cell-cycle entry. ID proteins also promote cell-cycle entry by inhibiting bHLH/Zip transcription factors and pRb. Once cyclin D proteins are expressed, CDK4/6-cyclin D phosphorylates and inactivates pRb, resulting in derepression of E2F. Derepressed E2F induces expression of cyclin E, and CDK2-cyclin E phosphorylates pRb further to induce cyclin A expression for S phase. In various conditions, CDK inhibitors ($p21^{Cip1}$, $p27^{Kip1}$, $p57^{Kip2}$, $p16^{INK4a}$, and $p15^{INK4b}$) are induced to stop the cell cycle. The canonical TGF-β signaling pathway can stop the cell cycle at G1 phase through down-regulation of MYC and induction of CDK inhibitors ($p15^{INK4b}$ and $p21^{Cip1}$). Frequent mutations observed in pancreatic cancer are indicated by vertical stripes (activation or amplification) and horizontal stripes (inactivation and deletion). *KRAS* (>95%), *CDKN2A* (>80%), *TP53* (>80%), and *SMAD4* (55%) are among the most common mutations. In addition, genetic alterations (mutations, deletions, and amplifications) are found in genes encoding RTKs (*MET* and *ERBB2*), proliferation signaling components (*MYC*, *AKT2*, *PTEN*, *PI3KCA,* and *PI3KR3*), CDK-cyclins (*CCND1*, *CDK6,* and *CDK4*), and TGF-β signaling components (*TGFBR1*, *TGFBR2,* and *SMAD3*). Potential therapeutic drugs (CDK4/6 inhibitors, HDAC inhibitors, and BET inhibitors) are also indicated

G1/S transition, DNA replication and mitosis carry the E2F binding motifs at their promoter and are coregulated during the cell cycle.

E2F1 to E2F3 are transcriptional activators and their transactivation can be repressed by pRB binding. In contrast, E2F4 and E2F5 are generally considered transcriptional repressors and they operate in cooperation with p107 and p130. E2F6 to E2F8 are also transcriptional repressors, but they repress transcription independently of pRB family proteins.

Regulation of E2F by pRB Family Proteins

pRB family proteins, pRB, p107, and p130, are transcriptional repressors of E2F transcription factors [10] (Fig. 2). In G0 phase, repressor E2Fs (E2F4 and E2F5) in conjunction with p107 or p130 repress E2F target genes, which include genes encoding activator E2Fs. Upon cell-cycle entry, E2F4 is removed from the nuclei through active nuclear export. Activator E2Fs (E2F1-E2F3) in turn occupy the E2F binding sequences; however, they are repressed by pRB until CDK4/6-cyclin D becomes active.

Several mechanisms contribute to the repression of E2Fs by the pRB family members [11]. Recruitment of a histone deacetylases (HDAC) by pRB family proteins reduces histone acetylation levels and makes chromatin more closed. In addition, the ATP-dependent chromatin remodeling complex, SWI/SNF, remodels chromatin into repressed state. Binding with pRB also physically blocks the access of transcriptional activators to E2Fs.

When CDK4/6-cyclin D is activated in G1 phase, it phosphorylates pRB and releases HDAC from pRB, relieving the repression of the Cyclin E gene at the G1/S transition. SWI/SNF remains on pRB and it is sufficient to suppress the cyclin A gene. pRB phosphorylation by CDK4/6-cyclin D also derepresses activator E2Fs at the promoter of the *E2F1* gene itself, thereby accelerating E2F1 production through a positive feedback. Next, activated CDK2-cyclin E phosphorylates additional sites on pRB and relieves E2Fs from pRB-mediated repression at the cyclin A gene. Activated CDK2-cyclin A in turn maintains pRB phosphorylation during S phase.

Activation of CDK2-cyclin A also initiates a program that down-regulates E2F transactivation. CDK2-cyclin A interacts with activator E2Fs and phosphorylates the DP subunit. This phosphorylation inhibits DNA binding of the E2F1-DP1 dimer. In addition, E2F1 is ubiquitinated by SCF^{Skp2} and degraded by the proteasome in S phase.

DNA Damage Response

Genome integrity is constantly threatened by both extrinsic and intrinsic sources of DNA damage. Although DNA damage is normally repaired by specific mechanisms, unrepaired DNA damage can cause mutations and genome instability, which are hallmarks of cancer. To avoid such adverse consequences, cells have evolved a network of cellular processes called DNA-damage response (DDR). Double-strand DNA breaks (DSBs) directly activate DDR, while other types of damages, such as base loss or modifications, do not activate DDR until they stall DNA replication forks. DNA replication, therefore, works as a sensor for DDR activation for many types of DNA damage. DDR has two major functions: (1) cell-cycle arrest through a process called cell-cycle checkpoint and (2) activation of DSB repair or stabilization of stalled replication forks. If the damage is irreparable, DDR signals cells to undergo senescence (permanent cell-cycle arrest) or programmed cell death (apoptosis). Defects in the DDR pathways have been associated with various

diseases and cancer-predisposition syndromes, illustrating its significance in human health [12].

DNA Damage Signaling

DDR pathways comprise a multitude of proteins that detect DNA damage and transduce the signals to downstream effectors. These effectors execute cellular responses such as cell-cycle arrest, DNA repair, and/or apoptosis. The key upstream components in the DNA damage signaling cascades are the serine/threonine protein kinases in the phosphatidylinositol-3-kinase related kinase (PIKK) family: ataxia-telangiectasia mutated (ATM) and ataxia-telangiectasia and Rad3-related (ATR). ATM and ATR phosphorylate numerous proteins, working as the master transducers of DDR signaling. ATM responds primarily to DSBs, while ATR can be activated by single-stranded DNA (ssDNA) that is indirectly generated after DNA replication is stalled at the DNA lesions.

ATM-Mediated Signaling in Response to DSBs

DSBs are first recognized by the sensor called Mre11-Rad50-Nbs1 (MRN) complexes. This promotes rapid localization and activation of the transducer kinase ATM, which responds to DSBs throughout the cell cycle. One well-known target of ATM is the histone variant H2AX, which is phosphorylated at Ser139 by ATM in response to DSBs. The phosphorylation of H2AX (**γ**H2AX) creates a direct binding site for MDC1, which in turn amplifies the local ATM signaling, leading to spreading of activated ATM and **γ**H2AX along chromatin. This amplification of ATM activity in turn promotes the recruitment and retention of additional mediator proteins such as BRCA1 and 53BP1 at the damage sites, which further promote recruitment of other repair factors.

ATR-Mediated Signaling in Response to Single-Stranded DNA

Many types of DNA damage activate DDR indirectly by blocking DNA replication. Replication-blocking lesions generate ssDNA at stalled replication forks because DNA helicase uncoupled from DNA synthesis continues to unwind double-stranded DNA (dsDNA). In addition, ssDNA can also be generated from DSBs following its end resection during the DSB repair in S and G2 phases (see Sects. 4.2.2 and 4.3.2). ssDNA is a rather unusual structure in cells and generates a signal for ATR-dependent DDR activation.

Cell-Cycle Checkpoints

To stop the cell cycle in response to DDR activation, cells rely on three major cell-cycle checkpoints: G1/S, intra-S, and G2/M (Fig. 1). These checkpoints block the cell cycle by inhibiting CDK, the driving force of the cell cycle.

G1/S Checkpoint

When DSBs occur during G1 phase, the G1/S checkpoint is activated to prevent cells from entering into S phase. The ATM kinase activated by DSBs initiates the G1/S checkpoint by phosphorylating the downstream kinase Chk2 at Thr68. Activated Chk2 in turn phosphorylates Cdc25A, a phosphatase that removes inhibitory phosphorylation of CDK2, causing its ubiquitin-dependent degradation (see Sect. 2.3). As a result, activation of CDK2-cyclin E and CDK2-cyclin A is blocked and cells arrest in G1 phase.

The G1/S checkpoint is also highly dependent on the p53 protein, a tumor suppressor that functions primarily as a transcription factor and plays a role in cell-cycle arrest and apoptosis. In response to DSBs, ATM, and Chk2 phosphorylate p53 and prevent the binding with its negative regulator Mdm2, the ubiquitin ligase that promotes p53 degradation, thereby leading to p53 stabilization and activation. This in turn promotes the transcriptional activation of p53-target genes, including the CDK inhibitor $p21^{Cip1}$, which inhibits CDK2 and prevents S-phase entry.

Intra-S Checkpoint

The intra-S checkpoint can be activated either by DSBs or stalled DNA replication. In the case of DSBs, activated ATM promotes resection of the 5′ end of DSBs for homologous recombination (HR), which is a preferred DSB repair pathway in S and G2 phases (see Sect. 4.3.2). The resection of the 5′ DNA ends creates stretches of ssDNA and activates the ATR-mediated checkpoint, enabling transition of the DDR signaling from ATM to ATR. Stalled DNA replication, on the other hand, results in the formation of ssDNA due to uncoupling between the replicative helicase and the replicative polymerase.

The exposed ssDNA is rapidly coated with ssDNA-binding protein RPA. RPA-bound ssDNA recruits the ATR-ATRIP complex and promotes ATR autophosphorylation *in trans* at Thr1989 [13, 14]. RPA-bound ssDNA also signals for the recruitment of the Rad17-RFC2-5 clamp loader at the junction of RPA-ssDNA and dsDNA, which in turn loads the heterotrimeric ring-shaped Rad9, Hus1, and Rad1 (9-1-1) complex onto chromatin. The phosphorylation of Rad9 in the 9-1-1 complex facilitates the recruitment of TopBP1, which then interacts with ATR-ATRIP complex on RPA-coated ssDNA through the Thr1989 phosphorylation site on ATR. This interaction between TopBP1 and ATR-ATRIP further stimulates ATR kinase activity and/or facilitates its substrate recognition [15, 16].

Once fully activated, ATR phosphorylates and activates its downstream effector kinase Chk1 on Ser317 and Ser345 with the help of several mediator proteins such as Claspin and Tim/Tipin. Activated Chk1 transduces the signal for intra-S-phase arrest by preventing late origin firing or replication initiation until the damage is repaired [17]. Mechanistically, Chk1-mediated phosphorylation of Cdc25A promotes its proteasomal degradation, leading to CDK2 inactivation. Chk1 may also inhibit the Cdc7-Dbf4 kinase activity [18, 19]. Since CDK2 and Cdc7-Dbf4 are necessary for activation of the replicative helicase, inhibition of the two kinases block further origin firing, causing intra-S-phase arrest [17].

G2/M Checkpoint

G2/M checkpoint is activated to prevent cells with damaged DNA or incompletely replicated DNA from entering into mitosis, while providing time to repair the damage. Under normal circumstances, the CDK1-cyclin B complex promotes the entry into mitosis and therefore is the critical target of the G2/M checkpoint. In the presence of DNA damage in G2 phase, activated ATR and Chk1 kinases phosphorylate Cdc25A or Cdc25C, causing their inactivation by ubiquitin-mediated proteolysis (Cdc25A) or cytoplasmic sequestration through a binding to 14-3-3 proteins (Cdc25C) [20]. Since these phosphatases are necessary for CDK1-cyclin B activation through the removal of inhibitory Tyr15 phosphorylation on CDK1 (see Sect. 2.3), inactivation of Cdc25A and Cdc25C by the checkpoint leads to cell-cycle arrest in G2 phase. ATM-Chk2 also plays an important role in the initiation of the G2 arrest after DSBs, although ATR/Chk1 mediated signaling are required for the maintenance of G2/M checkpoint [21].

The G2/M arrest is also maintained though stabilization of the Wee1 kinase induced by Chk1-mediated phosphorylation [20, 22]. Wee1 stabilization enhances the inhibitory Tyr15 phosphorylation on CDK1 and promotes its inactivation (see Sect. 2.3).

G2/M checkpoint is the last resort for cells to ensure that damaged DNA or under-replicated DNA is not carried over to mitosis. If the cells containing unrepaired DNA or under-replicated DNA are forced to progress into mitosis, it leads to mitotic catastrophe, a mechanism that causes cells to die either in M phase or undergo cell death or senescence in the subsequent G1 phase [23].

DNA Repair

DNA Repair Pathways

Besides signaling for the cell-cycle arrest, ATM/ATR kinases also signal for efficient repair of damaged DNA through phosphorylation and recruitment of multiple repair factors to the damage sites. Given the diversity of DNA lesions, cells have evolved different types of lesion specific repair pathways, which are briefly described below.

- Base excision repair (BER): BER repairs small chemical changes or nonhelix distorting adducts of DNA bases such as oxidized bases through removal of the damaged base. DNA single-strand breaks (SSBs) that can arise from direct attack by reactive oxygen species or other reactive metabolites are repaired by the BER pathway with an involvement of a key enzyme called PARP-1 (see Sect. 6.3).
- Nucleotide excision repair (NER): More complex or helix distorting bulky lesions such as intrastrand crosslinks (covalent crosslinks between bases on the same DNA strand) are repaired by NER. NER involves excision of oligonucleotides containing the damaged bases.

- Mismatch repair (MMR): MMR repairs mispaired or misincorporated nucleotides arising from errors of DNA polymerases by replacing them with correct nucleotides.
- Fanconi anemia (FA) pathway: The FA pathway repairs DNA interstrand crosslinks (covalent crosslinks between the two DNA strands) that can be generated by chemotherapeutic agents as well as by endogenous metabolic products. The FA pathway involves cooperation of different repair pathways, including NER, HR, and translesion synthesis.
- Homologous recombination (HR) and nonhomologous end joining (NHEJ): HR or NHEJ repairs DSBs that can arise from exposure to ionizing radiation (IR), chemotherapeutic drugs or intrinsic fork collapse.

This chapter will focus on DSBs repair mechanisms because of the deficiencies in this pathway in some pancreatic cancer.

DNA Double-Strand Break Repair

DSBs are toxic DNA lesions as it can result in extensive loss of chromosomal content, gross chromosomal rearrangements, and/or mutations, leading to cell death or cancer. Human cells rely on two major mechanisms for DSBs repair: NHEJ and HR (Fig. 3). NHEJ is the predominant DSB repair pathway in G0/G1 phase, while HR is used in S and G2 phases, in which sister chromatids are available as a recombination template.

NHEJ NHEJ favors direct ligation of broken DNA ends. NHEJ begins with binding of the Ku70-Ku80 heterodimer to the broken DNA ends. Ku70-Ku80 serves as a scaffold for recruiting and activating DNA-PKcs, a PIKK family kinase. This further recruits end-processing factors such as the nuclease Artemis, which trims and prepares DNA ends for ligation by the DNA ligase IV/XRCC4/XLF complex. Although NHEJ is highly efficient, they are error-prone due to the trimming-ligation approach of this process. DSBs are channeled to NHEJ in G1 phase by 53BP1. 53BP1 not only promotes the recruitment of NHEJ-promoting factor RIF1 but also inhibits the accumulation of HR-promoting protein, BRCA1, to DSB sites [24].

HR HR, unlike NHEJ, is a high-fidelity process as it uses a homologous sister chromatid as a template to identically replace the genetic information on the broken DNA. HR occurs primarily in S and G2 phases as the sister chromatid is readily available as a repair template. HR repair is initiated with the resection of the 5′ ends of DSBs by several nucleases in a BRCA1-dependent manner. The MRN complex and the CtIP nuclease initiate limited resection of the 5′ broken ends. This is followed by extensive resection by EXO1 and BLM-DNA2 that results in the formation of longer stretches of 3′ ssDNA on either side of the DSB. DSBs are channeled to HR rather than NHEJ by BRCA1, which not only promotes efficient 5′ end resection required for HR but also inhibits the recruitment of NHEJ-promoting RIF1 to DSB sites [24].

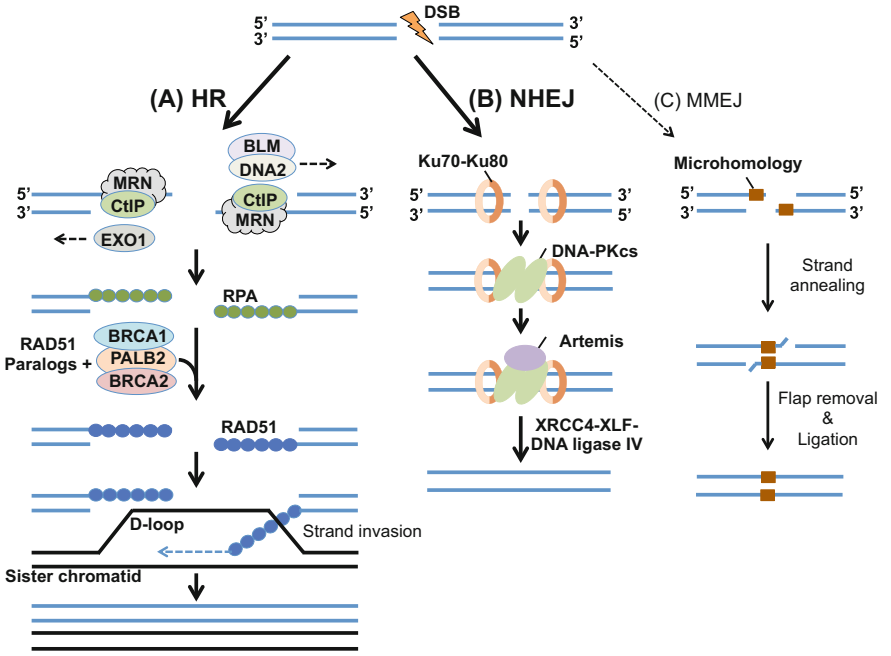

Fig. 3 Double-strand DNA breaks repair pathways. Double-strand DNA breaks (DSBs) are repaired predominantly by (**a**) homologous recombination (HR) or (**b**) error-prone nonhomologous end joining (NHEJ). (**a**) HR initiates with MRN-CtIP complex-mediated 5′ end resection of the broken DNA ends, followed by extensive resection by EXO1 and BLM-DNA2 nucleases. The resulting long stretch of 3′ single-strand DNA (ssDNA) is coated with RPA, which is next displaced by Rad51 in a process dependent on BRCA1-PALB2-BRCA2 and Rad51 paralogs. The Rad51-ssDNA filament performs homologous sequence search and promotes strand invasion into an undamaged sister chromatid, forming a displacement loop (D-loop). Following DNA synthesis at the resected strand, the resulting intermediate structures are resolved to complete the repair. (**b**) NHEJ initiates with the binding of Ku70–80 to the broken DNA, where it prevents end resection. This in turn promotes recruitment of several downstream factors including DNA-PKcs and Artemis, which process the broken DNA ends for ligation by the XRCC4-XLF-DNA ligase IV complex. (**c**) DSBs can also be repaired by alternative-NHEJ, also known as microhomology-mediated end joining (MMEJ), in a less-efficient manner. MMEJ initiates with short resection of the broken DNA, where it exposes microhomology sequences near the broken DNA ends. After the microhomology sequences at the ssDNA are annealed, the flaps are removed and the DNA ends are ligated

The stretches of ssDNA formed after resections are rapidly coated by RPA to inhibit the formation of secondary DNA structures and to facilitate the loading of the recombinase Rad51. The formation of RPA-coated ssDNA also activates ATR-mediated signaling (see Sect. 4.2.2). RPA is then displaced by Rad51 to generate Rad51-ssDNA nucleoprotein filament in a manner dependent on BRCA1, PALB2, BRCA2, and Rad51 paralogs. In particular, BRCA1 promotes the recruitment of BRCA2 to DSBs through the interaction with PALB2, which acts a bridge between BRCA1 and BRCA2. The BRCA1-PALB2-BRCA2 complex together with

Rad51 paralogs assists in the loading of Rad51 onto ssDNA to generate the Rad51-ssDNA recombinase filament. This filament promotes homology search and strand invasion into an undamaged homologous duplex or sister chromatid through formation of a displacement loop (D-loop). DNA synthesis is carried out at the resected strand using the undamaged homologous strand as a template. The resulting intermediate structure formed as a consequence is resolved by resolvases to complete the repair process.

Alternative NHEJ Although regarded more as a less-efficient back up process, DSBs can also be repaired by alternative NHEJ, also known as microhomology-mediated end joining (MMEJ) [25] (Fig. 3). This process involves joining of DSBs using microhomologous sequences flanking the DSB to align the ends for repair. MMEJ causes deletions at the break sites and therefore is a mutagenic repair process.

Cell-Cycle Alterations in Pancreatic Cancer

Cell-cycle entry is tightly regulated and normal cells proliferate only when stimulated by mitogenic signals. In cancer cells, however, cell-cycle entry is constantly driven by dysregulated mitogenic signals, resulting in aberrant proliferation, which is a hallmark of cancer. Recent studies using whole genome sequencing have revealed frequent mutations that influence cell-cycle entry in pancreatic cancer cells [26–30]. Among the most commonly mutated genes are *KRAS*, *CDKN2A*, *TP53,* and *SMAD4*. In general, *KRAS* mutations are observed in early lesions (PanIN-1) followed by *CDKN2A* mutations (PanIN-2), whereas *TP53* and *SMAD4* mutations (PanIN-3) drive tumorigenesis further, eventually resulting in advanced pancreatic cancer. This section will describe how major mutations in pancreatic cancer dysregulate cell-cycle entry, and how they lead to aberrant proliferation in pancreatic cancer.

Constitutive Activation of KRAS

Proliferation signaling pathways play a crucial role in tissue homeostasis; however, their overactivation can cause uncontrolled proliferation in cancer. Activating mutations in the *KRAS* gene are seen in most pancreatic cancers (>95%), in which substitution of glycine 12 (G12D or G12 V) is the major type of mutation. Activity of RAS proteins, which belong to the small GTPase family, is regulated by the binding of guanosine triphosphate (GTP) or guanosine diphosphate (GDP). When cells receive mitogenic signals from receptor tyrosine kinases (RTKs) and integrins, RAS proteins become an active form (RAS-GTP), which binds to its effectors and activates the downstream pathways (Fig. 2). Wild-type RAS proteins hydrolyze GTP to GDP by intrinsic GTPase activity, and this leads to inactivation of RAS proteins (RAS-GDP). Mutations in *RAS* genes usually impair this GTPase activity. Due to the

lack of GTPase activity, mutant RAS is unable to terminate the active state, thereby activating its downstream targets constitutively.

The RAF-MEK-ERK pathway is one of the major downstream pathways of RAS and strongly promotes the cell-cycle entry. RAF, MEK, and ERK are kinases, and they transmit the proliferation signal by phosphorylation. Once active RAS interacts with its effector RAF, RAF phosphorylates and activates MEK. Activated MEK also phosphorylates and activates ERK. Eventually, activated ERK can induce cyclin D1 and cyclin D2 through the activation of transcription factors, such as AP-1 family (c-FOS, c-JUN, ATF2), ETS family, and MYC transcription factors.

The PI3K-AKT pathway is another important downstream pathway of RAS to promote the cell-cycle entry. RAS activates the lipid kinase PI3K, which converts phosphatidylinositol diphosphate (PIP2) to phosphatidylinositol triphosphate (PIP3). This reaction can be reversed by a tumor suppressor protein PTEN. PIP3 provides a docking site for the kinases, AKT and PDK1, at the cellular membrane, where PDK1 activates AKT. Activated AKT promotes cell-cycle entry by several mechanisms. First, AKT-mediated phosphorylation inactivates CDK inhibitors $p21^{Cip1}$ and $p27^{Kip1}$. Phosphorylation of $p21^{Cip1}$ by AKT inhibits its activity to bind CDK2 as well as PCNA, while phosphorylation of $p27^{Kip1}$ causes its cytoplasmic accumulation (see Sect. 2.4.1). Second, AKT phosphorylates GSK3β and inhibits its activity. This results in stabilization of cyclin D1, which is targeted for degradation upon phosphorylation by GSK3β. Third, AKT inhibits FOXO family transcription factors by inhibitory phosphorylation. This leads to changes in FOXO-regulated genes: down-regulation of $p27^{Kip1}$ and up-regulation of cyclin D1 and D2. Lastly, AKT activates the mTOR pathway. The mTOR pathway increases Cyclin D1 and MYC protein synthesis and thereby promotes cell-cycle entry. Taken together, constitutively active KRAS enhances proliferation signals and promotes cell-cycle entry by up-regulating cyclin D and inhibiting CDK inhibitors.

Inactivation of the TGF-β Signaling

Transforming growth factor-β (TGF-β) regulates a wide variety of biological processes including cell proliferation, differentiation, migration, and apoptosis. Binding of TGF-β to the receptors (TGFBR1/2) causes phosphorylation of the transcription factor SMAD2 or SMAD3 by the serine/threonine kinase in the intracellular domain of the receptors. This phosphorylation triggers oligomerization of SMAD2/3 with SMAD4 and its translocation to the nucleus, where it regulates their target gene expression with cofactors. The effects of TGF-β can be either tumor-suppressive or oncogenic. TGF-β induces cell-cycle arrest and apoptosis (tumor-suppressive), while it promotes epithelial-mesenchymal transition (EMT) and changes tumor microenvironment (oncogenic). The SMAD-dependent canonical signaling induces cell-cycle arrest in G1 phase through down-regulation of MYC and induction of CDK inhibitors $p15^{INK4b}$ and $p21^{Cip1}$ (Fig. 2). Numerous studies have found that the canonical TGF-β signaling is impaired in several types of cancers. In pancreatic cancer, inactivating mutations are found in the genes encoding SMAD4 (55%),

TGFBR1/2 (5–10%), and SMAD3 (<5%) [30]. These mutations render cancer cells insensitive to the cytostatic effects of TGF-β. Taken together, inactivation of the canonical TGF-β signaling allows pancreatic cancer cells escape from the tumor suppressive effects of TGF-β, while they exploit its oncogenic power.

Inactivation of $p16^{INK4a}$

More than 80% of pancreatic cancers exhibit aberrations in the *CDKN2A* locus [31]. The *CDKN2A* gene is usually inactivated by homozygous deletions or loss of heterozygosity (LOH) involving point mutations that result in frame shifts, premature stop codons or aberrant splicing. In addition, gene silencing by promoter methylation was also observed and, if these are included, nearly 100% of the *CDKN2A* genes may be inactivated in pancreatic cancer [32].

CDKN2A encodes two different proteins, $p16^{INK4a}$ and $p14^{Arf}$, which are important for the cell cycle and apoptosis. $p16^{INK4a}$ binds to CDK4/6 and inhibits its activity (see Sect. 2.4.2 and Fig. 2) while $p14^{Arf}$ binds to MDM2, an E3 ubiquitin ligase for p53, and stabilizes p53. Interestingly, mutations in pancreatic cancer tend to specifically target $p16^{INK4a}$, although both $p16^{INK4a}$ and $p14^{Arf}$ can be inactivated. This indicates a specific role of $p16^{INK4a}$ inactivation in the development of pancreatic cancer, strongly suggesting that elevated CDK4/6-cyclin D activity is an important driver of pancreatic cancer. Consistent with this notion, amplification of genes encoding cyclin D1 (9%), CDK4 (6%), and CDK6 (7%) are also found in pancreatic cancer [26, 28].

Overexpression of MYC

MYC proto-oncogene encodes a basic helix-loop-helix/leucine zipper (bHLH/Zip) family transcription factor, and its function is associated with many biological processes such as cell cycle, metabolism, and cell stemness. Up-regulation of *MYC* is often seen in many types of cancer including pancreatic cancer, and it contributes to a variety of cancer phenotypes including increased cell proliferation, cancer stem cells, drug resistance, and metastasis. In pancreatic cancer, MYC is often overexpressed by gene amplification (15–30%) and other mechanisms such as activation of RTK-RAS-ERK, WNT/β-catenin signaling, and inactivation of TGF-β signaling [26, 33]. It was recently shown that the squamous type pancreatic cancer, which is characterized by MYC pathway activation, is strongly associated with poor prognosis [29]. MYC can strongly promote the cell cycle by activating and suppressing transcription of target genes (Fig. 2). MYC activates genes encoding cell-cycle positive regulators such as cyclin D2, cyclin E1, CDK4, Cdc25A, and E2F1, while repressing negative regulators including CDK inhibitors ($p21^{Cip1}$ and $p27^{Kip1}$) and miRNAs that target critical cell-cycle regulators (let-7 family, miR-15a/16-1, miR-26a, and miR-34a). Taken together, overexpression of MYC drives cell-cycle progression by regulating its target genes related to the cell cycle.

Overexpression of ID Proteins

Inhibitors of DNA binding (ID) proteins (ID1-3) are often overexpressed in pancreatic cancer [34–36]. ID proteins form a heterodimer with bHLH transcription factors and inhibit its DNA binding. In general, bHLH transcription factors can induce cell differentiation and the cell-cycle arrest, therefore, the elevated ID proteins is associated with the dedifferentiation and the high cell proliferation in cancer. Mechanistically, inhibition of bHLH transcription factors by overexpressed ID proteins results in down-regulation of cell-cycle inhibitors such as $p21^{Cip1}$, $p27^{Kip1}$, $p57^{Kip2}$, and $p16^{INK4}$ and up-regulation of cyclin D1 and cyclin E (Fig. 2). Indeed, it was shown that the ID3 overexpression was sufficient to induce cell-cycle entry in human pancreatic cells [36]. Besides bHLH transcription factors, ID2 can directly bind pRB proteins and promote proliferation. The mechanism of ID overexpression in pancreatic cancer is not completely understood. Because many oncogenic pathways such as MYC, RAS, and Notch can induce ID proteins, it is possible that ID protein overexpression might be a consequence of other oncogenic events.

Inactivation of p53

The *TP53* gene is altered in more than 80% of pancreatic cancers [37]. Missense mutations in the DNA binding domain are observed most frequently, while other mutations such as frame shift mutations and deletions, complete absence of the protein without any mutations are also found. p53 protects cells from oncogenic stresses, such as DNA damage and impairment of ribosome biogenesis. Once p53 is activated by these stresses, it induces target gene expression as a transcription factor and causes cell-cycle arrest and apoptosis depending on the degree of the stress. The most well-studied target of p53 is the CDK inhibitor $p21^{Cip1}$, which inhibits CDK2-cyclin E activity and causes G1 arrest as a part of the G1/S checkpoint mechanism (see Sect. 4.2.1 and Figs. 1 and 2). Defective p53 allows cell-cycle entry even under stress conditions, thereby disrupting the barrier to tumorigenesis.

However, evidence is also accumulating that some of the mutant p53 proteins found in cancer might be more than just inactive p53: they instead acquire new functions (gain-of-function). For example, p53 with point mutations in the DNA binding domain, such as R175H and R273H, exhibit aberrant transcriptional activity. In response to DNA damage, mutant p53 proteins recruit histone acetyltransferase to the promoters of the genes for cyclin A2, cyclin B1, CDK1, and Cdc25C for their activation, while wild-type p53 recruits histone deacetylase HDAC1 for repression [38]. Gain-of-function of mutant p53 has also been demonstrated using pancreatic cancer mouse models. Mutant p53 causes dysregulation of genes related to proliferation and cell migration, and it is necessary for the metastatic phenotype of pancreatic cancer [39, 40]. In summary, mutant p53 proteins lose its canonical functions in the cell-cycle checkpoint, while some of the point mutants may gain new functions that promote pancreatic cancer.

Mutations in the BRCA Pathway

Germline mutations in the BRCA pathway genes, *BRCA1, BRCA2,* and *PALB2* (encoding BRCA2-interacting protein essential for HR), have been associated with increased susceptibility to pancreatic cancer [41–44] (Fig. 3). In addition, somatic mutations in *BRCA1* and *BRCA2* have been identified in pancreatic ductal adenocarcinoma (PDAC). These mutations are particularly associated with a subtype of PDAC (14%) that is characterized by a large number of abnormal chromosome structures such as duplication, deletions, and inversions and marked genome instability [28]. The majority of the tumors in this PDAC subtype exhibit characteristic mutational signatures, which is characterized by equal representation of all possible base substitution. These tumors also have large deletions harboring microhomology at breakpoint junctions, indicating that alternative NHEJ, rather than error-free HR, was used to repair DSBs. This signature is also found in ovarian and breast cancer with *BRCA1* and *BRCA2* mutations [28, 45].

Recent studies using genetically engineered mouse models provided insights in the roles of BRCA mutations in the PDAC development. The BRCA1 protein comprises multiple domains, including the N-terminal RING domain important for its E3 ligase activity and two BRCA C-terminal (BRCT) domains that mediate protein–protein interactions with other DDR proteins. Shakya et al. 2011 found that the mutations in the BRCT domain of BRCA1 accelerate oncogenic Kras-driven PDAC, whereas the mutation affecting the E3 ligase activity of BRCA1 does not affect PDAC pathogenesis [46]. This suggests the importance of BRCT domains, which are vital for its HR repair function, in BRCA1-mediated suppression of PDAC formation.

In accordance with the importance of the BRCA pathway in PDAC suppression, *Brca2* inactivation also promotes oncogenic Kras-driven PDAC in a mouse model [47]. Interestingly, contrary to the current view that loss of heterozygosity (somatic deletion of the wild-type allele) is required to stimulate the tissue-specific cancer in carriers with inherited heterozygous *BRCA2* mutations, germline heterozygous *Brca2* mutation was enough in promoting Kras-driven PDAC in this mouse model [47]. These tumors retained the wild-type *Brca2* allele and tumor-derived cell lines exhibited partial HR function [47]. These results suggest that *Brca2* may act as a haplo-insufficient tumor suppressor gene in the case of Kras-induced PDAC [48].

Therapeutic Opportunities

Pancreatic cancer has a poor prognosis with 5-year survival of around 5%. Standard initial chemotherapies for this disease have been antimetabolites, such as 5-fluorouracil (5-FU) and gemcitabine. Active metabolites of these drugs inhibit nucleoside synthesis and/or DNA replication, causing DNA damage and eventually cell death. Combination therapies such as FOLFIRINOX (5-FU, folinic acid, irinotecan, and oxaliplatin) and nab-paclitaxel plus gemcitabine are now first-line therapies for patients with metastatic pancreatic cancer and have shown improved

patient survival [49–52]. However, these drugs simply target highly proliferating cells, and they do not necessarily target the abnormal proliferation signals driving tumor formation. A number of new drugs have been proposed based on the features of pancreatic cancer including its genetic background and dysregulated pathways as described in the previous section. This section will introduce potential drug targets related to the cell cycle and the DNA repair pathways.

Inhibition of CDK4/6

As described in the previous section, major mutations and other dysregulated pathways in pancreatic cancer promote cell-cycle entry through up-regulation of cyclin D and the loss of $p16^{INK4a}$. Direct inhibition of CDK4/6-cyclin D is, therefore, an attractive strategy to stop aberrant proliferation of pancreatic cancer [53, 54] (Fig. 2). PD-0332991 (also known as Palbociclib) is a highly specific and orally-available CDK4/6 inhibitor. As expected, *CDKN2A* (encoding the CDK4/6 inhibitor $p16^{INK4a}$) mutant cancer cells are more sensitive to PD-0332991 as shown in a large scale drug sensitivity screen [55]. This drug, however, requires intact pRB, which represses E2F activity and stops the cell cycle upon CDK4/6 inhibition. Taking these points into consideration, pancreatic cancer might be sensitive to CDK4/6 inhibitors, because most of pancreatic cancers have intact pRB and inactivated *CDKN2A*.

Several groups, however, reported that a single-agent treatment of pancreatic cancer cell lines with PD-0332991 often showed a modest effect and development of resistance despite the initial response [56–58]. It turned out that the PI3K-AKT-mTOR pathway was up-regulated after the CDK4/6 inhibition, and expression of cyclin D1 and cyclin E1 were elevated consequently [57, 59]. Therefore, it appears that cancer cells overcame the CDK4/6 inhibition by enhanced proliferation signals and G1 cyclin overexpression. This raises a possibility of using a combination of drugs that inhibit CDK4/6 and bypassing pathways. Indeed, it was reported that inhibition of the PI3K-AKT-mTOR pathway by PI3K/mTOR inhibitors or insulin-like growth factor 1 receptor (IGF1R) inhibitor (IGF1R is one of the upstream RTKs of PI3K-AKT-mTOR pathway), or inhibition of RAF-MEK-ERK pathway by MEK1/2 inhibitor, synergized with the CDK4/6 inhibitor in vitro and xenograft models [56, 57]. Additional CDK4/6 inhibitors are in the pipeline (LY-2835219, abemaciclib; LEE011, ribociclib), and combination therapies of LY-2835219 and a PI3K/mTOR dual inhibitor are in phase II clinical trials for advanced pancreatic cancer. Thus, CDK4/6 inhibitors combined with other agents may be promising mechanism-based therapies on the horizon for pancreatic cancer.

Cell-Cycle Inhibition by Epigenetic Drugs

Aberrant transcription plays a major role in cancer. Epigenetic drugs, which inhibit writers, erasers, and readers of histone modifications, have been explored as therapeutic agents against pancreatic cancer [60]. While epigenetic drugs generally have

pleiotropic effects on cancer cells, induction of cell-cycle arrest is one of the key tumor suppression mechanisms. In pancreatic cancer, a number of studies have shown that treatment with histone deacetylase (HDAC) inhibitors induces cell growth arrest accompanied by up-regulation of the CDK inhibitors ($p21^{Cip1}$, $p27^{Kip1}$, $p57^{Kip2}$, and $p19^{INK4d}$ [61]) (Fig. 2). Given that genes encoding CDK inhibitors are often silenced by aberrant histone deacetylation in cancer, derepression of CDK inhibitors by HDAC inhibitors might be a viable strategy to block cell proliferation.

A bromodomain and extraterminal (BET) family member protein BRD4 is another epigenetic factor that can be targeted therapeutically (Fig. 2). BRD4 binds acetylated histones via its BET domains at super enhancers and up-regulate transcription by promoting transcriptional elongation. BET inhibitors block the interaction of BRD4 with acetylated histones, thereby inhibiting transactivation of the target genes. A study using patient-xenograft model of pancreatic cancer showed inhibition of tumor growth by the BET inhibitor JQ1, accompanied by marked reduction of *CDC25B* expression [62]. In another study, a combinational treatment with JQ1 and the HDAC inhibitor SAHA synergistically suppressed tumor growth through induction of cell-cycle arrest and apoptosis in pancreatic cancer mouse models [8]. Suggested mechanisms of tumor suppression by JQ1 plus SAHA include *MYC* down-regulation and $p57^{Kip2}$ induction. Although the exact mechanism of the synergy between BET and HDAC inhibitors is not clear, combination therapies of epigenetic drugs could lead to improved treatment for pancreatic cancer.

PARP Inhibitors for BRCA Mutant Pancreatic Cancer

PARP (poly [ADP-ribose] polymerase) is an enzyme that is best known for its role in DNA repair, particularly in the repair of SSBs through the BER. The PARP family is composed of 17 enzymes that are involved in a variety of cellular processes including DDR, gene transcription, mitosis, and cell death. Among them, PARP-1 is the most abundant and well-defined protein involved in DNA repair. PARP-1 senses and binds SSBs, and creates poly(ADP-ribose) chains on itself and protein around the DNA damage. This creates a scaffold for other proteins that facilitate SSBs repair. The extensive auto-poly ADP ribosylation of PARP1 also results in its dissociation from the DNA, which is important for the completion of SSBs repair [63].

PARP inhibitors (PARPi) have shown encouraging results against HR defective-*BRCA1/BRCA2* mutant cancers, including ovarian and breast cancer. PARPi are thought to work by inducing accumulation of unrepaired SSBs, which eventually develop into DSBs after collision with DNA replication forks [64, 65]. PARPi may also inhibit dissociation of PARPs from SSBs, covalently trapping PARP to DNA damage sites [66]. Stabilized PARP-DNA complexes can block the DNA replication machinery and cause fork collapse and DSB formation. While normal cells with wild-type BRCA proteins utilize HR to repair these DSBs (Fig. 3), cancer cells with *BRCA1/BRCA2* mutations accumulate toxic DSBs and eventually undergo cell

death. Due to the selective toxicity of PARPi in *BRCA1/BRCA2* mutant cells, PARPi is an attractive agent for treating cancer associated with deleterious BRCA mutations.

Given that germline *BRCA* mutations have been linked to a higher risk of PDAC, PARPi (alone or in combination with other DNA damaging agent such as radiation or chemotherapy) could be an effective agent for treating *BRCA* mutated-pancreatic cancer. However, a study using a PDAC mouse model with a heterozygous *Brca2* mutation showed that loss of the wild-type *Brca2* allele is not necessary for PDAC development [47]. This suggests a possibility that not all PDAC in *BRCA2* mutation carriers loose the HR function. Consistent with this, *Brca2* heterozygote tumors in the mouse model were more resistant to a PARP inhibitor than *Brca2* null tumor cells [47]. These data, therefore, suggest that PARPi should be used to treat PDAC in *BRCA2* mutation carriers only after loss of the wild-type allele has been confirmed.

Because BRCA-associated pancreatic cancer is rare, there is limited data regarding the use of PARPi in pancreatic cancer. However, several investigations of PARPi in *BRCA1*/*BRCA2*-mutated pancreatic cancer patients have been instigated with encouraging partial response [67–69], and several clinical trials are ongoing.

Checkpoint Inhibitors

In response to DNA damage, normal cells undergo cell-cycle arrest at G1/S, intra-S, or G2/M. However, cancer cells often have inactive G1/S checkpoint due to *TP53* mutations (see Sect. 4.2.1). They are therefore highly dependent on the G2/M checkpoint for preventing mitotic entry with damaged DNA. As such, DNA damaging agents or replication inhibitors in combination with G2/M checkpoint inhibitors have been explored as therapeutic options for *TP53* mutant cancer. The G2/M checkpoint can be inactivated by inhibitors of the checkpoint kinase Chk1 or Wee1 (the kinase that phosphorylates and inactivates CDK1 in the G2/M checkpoint) (Fig. 1). The defective G2/M checkpoint will force cancer cells to enter mitosis with damaged DNA or incomplete DNA replication, causing mitotic catastrophe and cell death (see Sect. 4.2.3).

One study showed that the combination of chemotherapeutic agent gemcitabine and Wee1 inhibitor MK-1775 showed a synergistic antitumor effect in p53-deficient pancreatic cancer xenografts [70]. In another study, MK-1775 in combination with the PARP inhibitor olaparib and ionizing radiation showed an enhanced antitumor effect in pancreatic cancer [71]. However, it was recently shown that pancreatic cancer cell lines with deficiency in DNA repair genes (*BRCA2*, *FANCC,* and *FANCG*) were less sensitive to MK-1775 compared to DNA repair-proficient cells, suggesting that DNA repair proficiency of tumor cells is a critical factor for this therapy [72]. Similarly, the Chk1 inhibitor MK8776 was also shown to sensitize pancreatic cancer cells to a combination of gemcitabine and radiation, although the sensitization was specific to HR-proficient cells [73]. Taken together, although it requires intact DDR, chemotherapeutic agents in combination with inhibition of the

G2/M checkpoint can induce mitotic catastrophe and cell death in *TP53*-mutant pancreatic cancer.

Conclusion

The cell cycle is strictly controlled by multiple layers of regulation, yet findings from countless studies of cancer cells have uncovered its vulnerabilities. Many of the abnormalities in pancreatic cancer drive cell-cycle entry through elevated CDK4/6 activity. Loss of checkpoint functions and DNA repair defects are also common. The next challenge is to translate these findings to new therapeutic strategies for pancreatic cancer. Monotherapies promote drug resistance in cancer cells; therefore, combination therapies might be a more promising approach to this deadly disease.

by tubular units, cysts, and papilla or mucin formation and expression of mucin-related glycoproteins and oncoproteins. There are also genetic and molecular alterations that are fairly tumor specific.

Invasive ductal adenocarcinoma (DA) constitutes the vast majority (>85%) of carcinomas of ductal lineage. DA is characterized by insidious infiltration and rapid dissemination, despite its relatively well-differentiated histologic appearance. Presumed precursors include microscopic intraductal proliferative changes now termed pancreatic intraepithelial neoplasia (PanIN). PanINs represent neoplastic transformation ranging from early mucinous change (low-grade PanIN) to frank carcinoma in situ (high-grade PanIN). A similar neoplastic spectrum characterizes intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs), cystic ductal-mucinous tumors with papillae formation, which may be associated with DA. As such, these are regarded as mass-forming preinvasive neoplasia. Some IPMNs are associated with colloid-type invasive carcinoma, a clinicopathologically distinct indolent tumor.

Although most ductal pancreatic neoplasia show some degree of mucin formation, serous tumors, of which serous cystadenoma is the sole example, lack mucin formation, presumably because they recapitulate centroacinar ducts.

Among non-ductal pancreatic tumors, neuroendocrine neoplasms are the most common. The vast majority are well-differentiated, low-/intermediate-grade malignancies characterized by protracted clinical course. In contrast, poorly differentiated neuroendocrine carcinomas (small or large cell type) are exceedingly uncommon and highly aggressive. Pancreatic acinar lineage tumors, namely, acinar cell carcinomas and pancreatoblastomas – the latter mostly a childhood malignancy – are uncommon and are associated with aggressive clinical course, though not as dismal as DA. Solid pseudopapillary neoplasm is a female-predominant pancreatic tumor of undetermined lineage that follows a predominantly indolent course.

Ductal · Intraductal · Mucinous · Colloid · Acinar · Pancreatoblastoma · Solid pseudopapillary · Neuroendocrine

Introduction

Since the days of Galen of Ephesus, the “physician of physicians” (200 AD) had concluded that the pancreas was merely a fat pad serving as a protective cushion to the major vessels lying behind; the pancreas has remained an enigmatic organ, largely neglected by the medical field throughout the history. In the nineteenth century, it began to be appreciated as an organ, the failure of which leads to dire consequences. More importantly, it is now widely known that cancer arising from

the ductal system of this organ is one of the deadliest of all cancers and has recently become the fourth leading cause of cancer deaths in the USA [1]. This has led the medical field to analyze pancreatic neoplasia more carefully, and consequently, in the past two decades, various important developments have taken place in the pathologic classification, terminology, and our understanding of various pancreatic tumor types [2, 3].

Pathologic Classification of Pancreatic Neoplasia

Pancreatic neoplasms are classified according to which normal cell type of this organ they recapitulate, because the clinicopathologic and biologic characteristics of tumors are determined or manifested mostly by their cellular lineage.

The cell types that constitute the pancreas form three functionally distinct units:

1. Exocrine pancreas is responsible for the production and delivery of the digestive enzymes such as trypsin, chymotrypsin, amylase, and lipase to the duodenum. These enzymes are produced and stored in *acinar cells*. While acinar cells constitute the vast majority of pancreatic tissue (Fig. 1), neoplasms of acinar lineage are exceedingly uncommon. The second component of the exocrine pancreas is the ducts, the mere function of which is to transport the acinar enzymes to the duodenum. The ductal system begins with the *centroacinar cells* and continues with intralobar and interlobular ductules and, through the main pancreatic duct, ultimately opens into the ampulla of Vater. Although the ductal component is not a complex structure when compared with the other components, it is the main source of the vast majority of neoplasms in the pancreas [4]. This propensity for neoplastic transformation may not be very surprising as the ductal system is the only component in the pancreas that is exposed to the outside world (mutagens).
2. The second major and physiologically distinct component of this organ is the neuroendocrine, which is represented by widely scattered islands of neuroendocrine cells referred to as islets of Langerhans, distributed throughout the pancreas in forms of small, distinct nests amidst the acinar tissue (Fig. 1). The islets are responsible for producing a variety of hormones but mostly insulin, glucagon, and somatostatin, which play a key regulatory role not only in glucose metabolism but also other systemic metabolic processes as well. Unlike the exocrine component, which releases enzymes locally to the duodenum, the hormones produced by the neuroendocrine component are secreted to a rich capillary network that penetrates into the islets. Neuroendocrine tumors are not uncommon and form an important category, although they occur far less frequently than ductal neoplasia.
3. As in any other organs, there is also supportive tissue including fibroblasts, vessels, nerves, and immune cells in the pancreas, and these also, on occasion, give rise to pancreatic neoplasia [2–4].

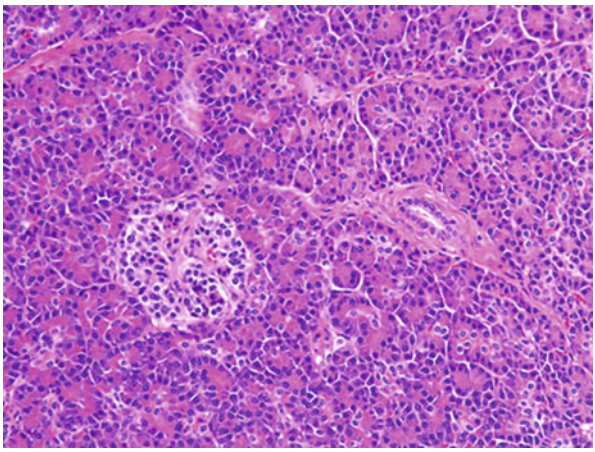

Fig. 1 Normal pancreatic tissue. Acinar cells arranged in lobules constitute the majority of the parenchyma. These cells have apical lightly eosinophilic cytoplasm due to the presence of zymogen granules and basophilia in the basal aspect of the cytoplasm. To aid in their secretory activity, the nuclei are polarized to the periphery and the cells are arranged in round units creating the *acinus*. In the *left middle part* of the field, an islet of Langerhans consisting of round collection of endocrine cells is represented. Endocrine cells have moderate amphophilic cytoplasm and nuclei with finely stippled chromatin pattern. In the *right upper part* of the field, an intralobular duct lined by cuboidal – low columnar – epithelium is seen

There are also tumors in the pancreas that are of undetermined origin and lineage. In the ensuing text, an overview of the clinicopathologic characteristics of pancreatic neoplasia will be discussed based on their lineage. Emphasis will be given to those that are more common ones.

Ductal Neoplasia

In order to transport the acinar enzymes to the duodenum, the ductal cells are organized in luminated structures and produce protective and lubricative glycoproteins (the mucins). Neoplasia of pancreatic ductal lineage recapitulates these characteristics at a variable degree. Tubular (lumen-forming) units, cysts (mega versions of these tubules), and papilla (fingerlike projections of the mucosa lining these ducts/cysts) are hallmarks of ductal differentiation in this organ and are also incorporated to the names of some of the tumors as well [2–4]. There are also certain genes, molecules, and mutations that are fairly specific to ductal neoplasia. Mucin-related glycoproteins and oncoproteins such as CA19-9, CEA, DUPAN, and MUC1 are typically detectable by immunohistochemistry in mucinous ductal tumors. Expression of certain subsets of cytokeratin such as CK19 and mutations in *KRAS* and *SMAD4/DPC4* genes are also fairly specific [5–7] and are typically lacking in acinar or neuroendocrine tumors with a few exceptions. Moreover, even though rare

scattered neuroendocrine cells can be seen in almost any ductal tumor; evidence of acinar differentiation such as enzyme activity is exceedingly uncommon.

Invasive Ductal Adenocarcinoma

More than 85% of pancreatic tumors are invasive ductal adenocarcinomas (DAs), also named as pancreatobiliary type, scirrhous, tubular, or usual ductal adenocarcinoma [4, 8]. Because it is by far the most common and most important tumor type in the pancreas, DA has become synonymous with "pancreatic cancer," which sometimes leads to erroneous interpretations due to inappropriate inclusion or exclusion of other cancers that occur in this organ but have different clinical, pathologic, and behavioral characteristics as discussed below. Patients with DA are usually between 60 and 80 years old (mean age: 63), and it is very uncommon to see this tumor in patients younger than 40 years old.

DAs grow rapidly, and regardless of the size of the tumor, metastasis to lymph nodes and liver ultimately ensue. They also have very insidious growth pattern, and in fact, along with ovarian cancer, DA is the most common cause of "intra-abdominal carcinomatosis," the formation of numerous small tumor nodules throughout the abdomen. It is also one of the most common sources of carcinomas of unknown primary. Only 20% of the cases with DA are resectable at the time of diagnosis.

Because of these features (rapid growth, insidious infiltration, and early dissemination), the cure rate of DA is extremely low, with a 5-year survival still 3–5% [1]. In fact, most 5-year survivors of "pancreatic cancer" prove to be a tumor type other than ordinary DA after careful reexamination of microscopic features [9].

The diagnosis of invasive DA can be very problematic, both at clinical and microscopic levels. This tumor type is typically associated with abundant host tissue stroma referred as *desmoplastic stroma* (Fig. 2). This creates a "scirrhous" (scar-like) appearance that can be very difficult to distinguish from true scarring inflammatory lesions of this organ, in particular, autoimmune and paraduodenal types of chronic pancreatitis. This difficulty in the differential diagnosis is also valid for microscopic examination. Injured native ducts of the pancreas can show substantial cytologic atypia that can closely imitate that of carcinoma, and conversely, most DAs form well-differentiated glandular units that resemble benign ducts [10, 11] (Fig. 3) or cause ductal obstruction and eventually lead to chronic pancreatitis. Consequently, the distinction of DA from pancreatitis is considered one of the most, if not the most, challenging differential diagnosis in diagnostic pathology.

However, DA has some morphologic characteristics that are fairly unique and not seen as much in other common organ cancers. First, despite its highly aggressive behavior, the vast majority of invasive DAs are "well or moderately differentiated" (Figs. 3 and 4), i.e., recapitulate the normal ducts extremely well. They also show a remarkable affinity to spread through the nerves and vessels. Nearly 80% of these cases show *perineural invasion* (Fig. 5) by microscopic examination, although if the entire tumor is examined, this ratio will probably be higher. This feature is thought to be the reason of back pain, one of the more common symptoms of this tumor. *Vascular invasion* is also very common and pancreatic carcinoma cells have this unique ability to form well-formed glandular elements in vascular spaces [12, 13]

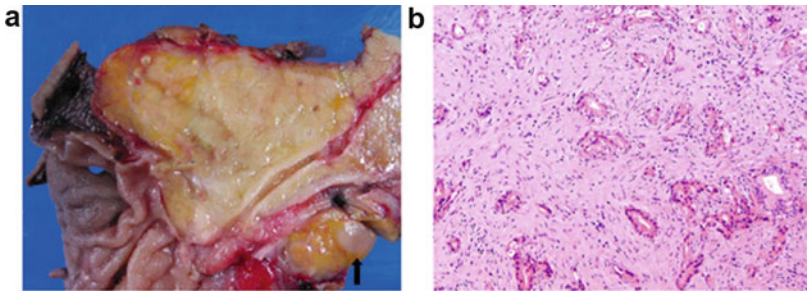

Fig. 2 (**a**) **Invasive ductal adenocarcinoma, macroscopic findings**. A firm, sclerotic, poorly defined mass is seen in the head of the pancreas. The rounded pale structure adjacent to the right lower border of the specimen represents a lymph node enlarged by metastatic adenocarcinoma. (**b**). **Invasive ductal adenocarcinoma** is characterized (and defined) by infiltrating tubular units embedded in **desmoplastic stroma**

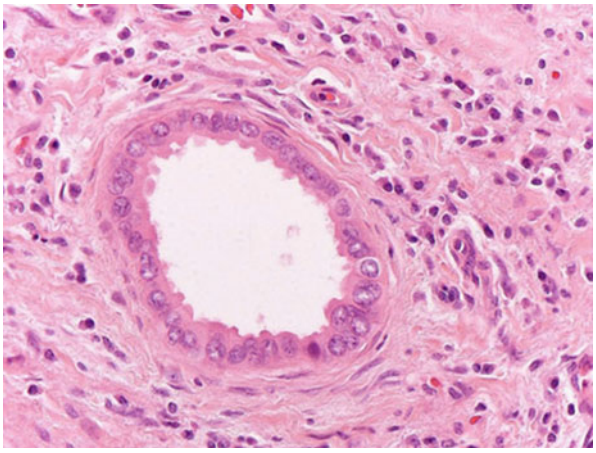

Fig. 3 Invasive ductal adenocarcinoma, well differentiated. Well-formed glandular structures lined by cuboidal cells closely mimic the nonneoplastic ducts

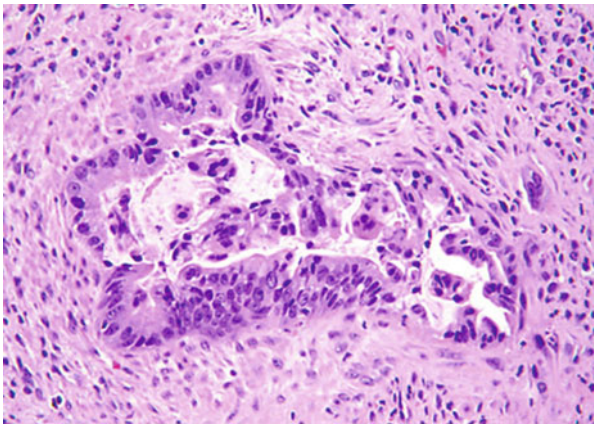

Fig. 4 Invasive ductal adenocarcinoma, moderately differentiated. There is a greater degree of cytologic and nuclear atypia. Loss of polarity can be seen as well

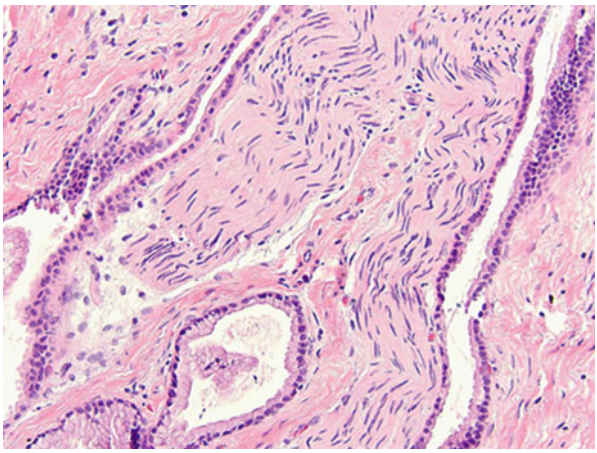

Fig. 5 Invasive ductal adenocarcinoma showing perineural invasion

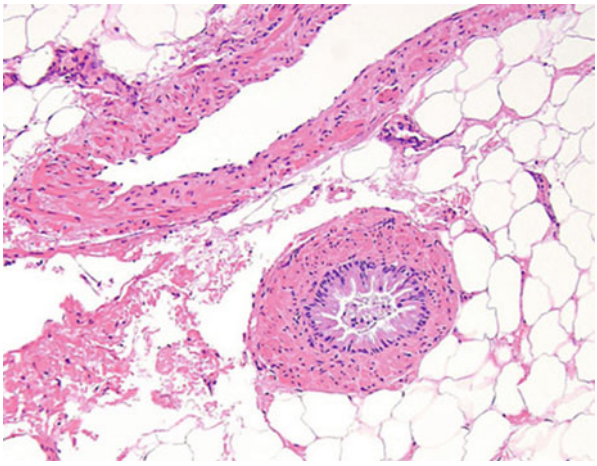

Fig. 6 Vascular invasion of infiltrating ductal adenocarcinoma. Carcinoma cells line the luminal surface of vascular walls in such an organized and polarized fashion that they form a well-structured duct-like unit virtually indistinguishable from normal ducts or PanINs

(Fig. 6). What referred to as *isolated solitary ducts*, which are microscopic (grossly invisible) invasive units located away from the main tumor lying individually in peripancreatic fat tissue, is a very common finding (Fig. 7) and may be responsible for the high recurrence rate of seemingly margin-negative resections [13].

The cells in DA are typically cuboidal shaped with variable amount of cytoplasm that contains mucin and mucin-related glycoproteins and may occasionally demonstrate predominance of a specific organelle creating distinctive patterns such as "foamy-gland" pattern with swollen, altered mucin, "clear-cell" pattern with abundant glycogen [14], and "oncocytoid" or "hepatoid" variants with prominent mitochondria or lysosomes, respectively [2, 3].

As discussed earlier, abundant *desmoplastic stroma* (Fig. 2) of variable cellularity is a very important feature of this tumor type. Carcinoma cells are somewhat diluted in this desmoplastic stroma, and this dilution phenomenon creates major problems

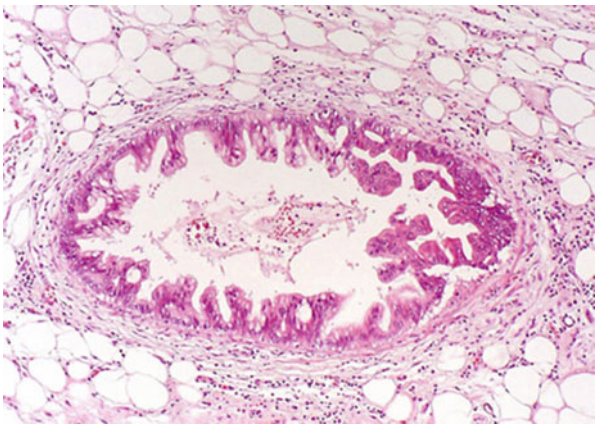

Fig. 7 Isolated solitary ducts surrounded entirely by adipocytes without any accompanying islets, acini, or other ducts are indicative of invasive carcinoma. This phenomenon of renegade ducts away from the main tumor is a peculiar manifestation of the insidious spread of pancreatic adenocarcinoma

for both diagnosticians and researchers. This is an important pitfall, in particular, for studies that utilize "global" arrays, which do not discriminate between the different cellular compartments of the specimen and analyze all pancreatic tissues together. If the intent is to analyze the carcinoma cells, it should be kept in mind that most of the tumor tissue is in fact composed of this desmoplastic stroma, not the cancer cells, and further complicating the analysis, the normal pancreas is also composed mostly of acini with no relevance to ductal carcinogenesis. Therefore, if a comparison of normal ducts and ductal adenocarcinoma is intended, normal ducts and carcinoma cells need to be dissected out from the background tissue, or alternatively, visual-aided methods of analysis such as immunohistochemistry or in situ hybridization are ought to be utilized by experts who can distinguish between the nonneoplastic and neoplastic elements.

Other Invasive Carcinomas of Ductal Lineage

Various uncommon types of invasive carcinomas of also ductal lineage, classified separately from the conventional DA, have been recognized [2, 3].

Colloid Carcinoma

Colloid carcinoma has been a well-established tumor type in other exocrine organs such as the breast where pure examples of this entity are associated with an excellent prognosis. In the pancreas, this tumor type has come to attention only after the delineation of IPMN (discussed below) as a distinct entity in the mid-1990s, because colloid carcinomas are seen in association with these tumors. It is characterized by extensive extracellular mucin deposition [15], which is responsible for its grossly soft, gelatinous appearance. By microscopic examination, there are mucin lakes that contain scanty clusters of carcinoma cells floating within this mucin (Fig. 8).

The prevailing theory is such that the mucin of colloid carcinoma is biochemically and biologically different than the mucins of other ductal cancers, made up of the "gel-forming mucin," the MUC2 glycoprotein [16]. It is speculated that, with its tumor suppressor properties and its physical distribution around the cells, this mucin

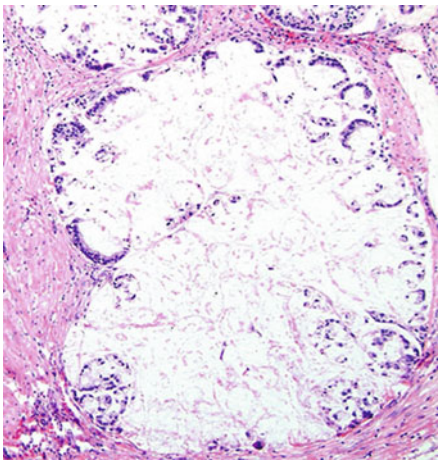

Fig. 8 **Colloid carcinoma** characterized by large amounts of mucin pools. Detached fragments of tumor cells can be observed in these pools

acts as a containing factor, limiting the growth and thus culminating in the more protracted clinical course observed in many studies [17].

Recent studies have also shown that molecular features of colloid carcinoma are different that those of DA. Colloid carcinoma, and its intestinal-type preinvasive precursor (intestinal-type IPMN), is associated with high frequencies of *GNAS* mutations [18].

Adenosquamous and Squamous Carcinoma

In the pancreas, squamous cells are found only rarely in injured ductal epithelium as a result of a metaplastic process. Same metaplastic phenomenon also seems to take place focally in some examples of DA. When this finding is prominent (arbitrarily defined as >25% of the tumor), the tumor is classified as adenosquamous carcinoma, and if the tumor is exclusively squamous, then squamous cell carcinoma. One may observe keratinization in various degrees in these tumors [19]. They constitute <2% of all invasive cancers of the pancreas and appear to be even more aggressive than ordinary DAs [20].

Medullary Carcinoma

This is an exceedingly uncommon tumor type as a primary in the pancreas [21], although it can occur in the periampullary region. The term medullary is adopted from similar tumors that occur in the GI tract. These tumors are often associated with a defect in DNA mismatch repair genes (genes that are responsible for correcting the mismatches that occur routinely in the DNA), which in turn leads to microsatellite instability [21]. Medullary carcinomas are characterized by nodular pattern and sheetlike growth of poorly differentiated epithelioid cells without any intervening stroma, as opposed to ordinary DAs, which have widely scattered well-formed tubular units with abundant stroma. In addition, there is often dense lymphoplasmacytic immune cell participation associated with medullary carcinomas.

Signet Ring Cell Carcinoma

Signet ring cell carcinoma is a tumor type that is well characterized in the stomach and is featured by a distinctive infiltration pattern referred to as "diffuse infiltrative." The carcinoma cells form small cords or chains of cells or invade as individual cells without any tubule formation. Commonly, this pattern is also associated with abundant intracytoplasmic mucin accumulation that pushes the nucleus to the periphery of the cell, which in turn creates the signet ringlike morphology [3].

Defined as such, signet ring cell carcinoma with all these characteristics is exceedingly uncommon in the pancreas. Many authors believe that those that are reported in the pancreas may very well represent secondary invasion from the stomach. Focal signet ringlike formations do occur in otherwise classical DAs of the pancreas; however, most authors feel that these should not be classified as signet ring carcinomas. Similarly, signet ring morphology may also be seen in colloid carcinomas of the pancreas, but in the absence of other characteristic features, these are not classified as signet ring carcinomas.

Undifferentiated Carcinoma

In some ductal carcinomas of the pancreas, the hallmarks of ductal differentiation, namely, the tubule formation, mucin production, and others, may be lacking. Such cases are classified as "undifferentiated carcinoma." Some can be so undifferentiated that only after adjunct studies such as immunohistochemical studies for keratins or mutation analysis for *KRAS* oncogene, the epithelial and ductal nature of the tumor can be elucidated. In some, epithelial-to-mesenchymal transition can be so complete that the tumor cells may be mostly spindle shaped and resemble sarcomas (i.e., sarcomatoid carcinoma). In fact, some may even show bone and cartilage formation. In others, the undifferentiated cells may form bizarre giant cells. These can be difficult to distinguish from high-grade malignancies like lymphomas or melanomas. Undifferentiated carcinomas are rare and their demographics do not seem to differ from ordinary DA [3].

Undifferentiated Carcinoma with Osteoclast-Like Giant Cells

Some sarcomatoid carcinomas of the pancreas have a peculiar predilection to attract osteoclastic-type giant cells of histiocytic/macrophagic origin [22], normally responsible for bone resorption. Often, osteoclastic cells are so abundant that they dominate the picture, and the tumor is referred to as "osteoclastic giant cell carcinoma." Recent molecular studies confirmed what is suspected by morphologic observations that these osteoclasts are in fact reactive in nature and that the malignant cells are actually the smaller, ovoid to spindle cells in the background (Fig. 9). Once inspected carefully, a more conventional adenocarcinoma component composed of invasive tubular elements is identified in most cases. Despite the impression in the literature, undifferentiated carcinoma with osteoclast-like giant cells appears to have a significantly better prognosis compared to DAs [22].

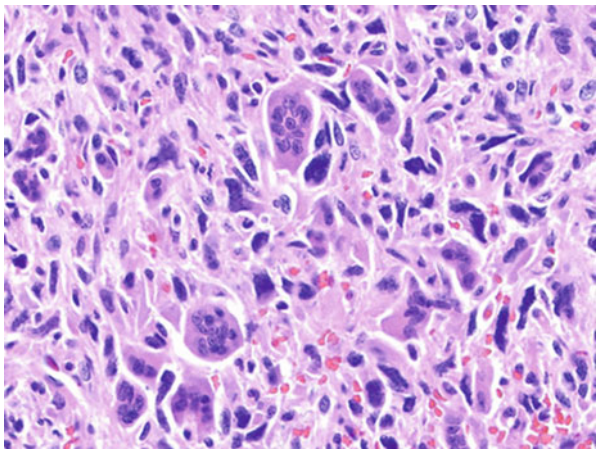

Fig. 9 Undifferentiated carcinoma with osteoclast-like giant cells. Nonneoplastic multinucleated giant cells (osteoclastic cells) of histiocytic origin are mixed with neoplastic mononuclear spindle-shaped/epithelioid cells. The mononuclear cells have hyperchromatic, occasionally bizarre nuclei

Noninvasive (Preinvasive) Ductal Neoplasia

Pancreatic Intraepithelial Neoplasia

It has long been recognized that there are abnormal *intraductal* proliferations that often accompany invasive DAs and may occasionally also be seen in the absence of DA. For decades, these were termed variably as hyperplasia, metaplasia, or dysplasia. In 1999, a group of pathologists interested in pancreatic neoplasia were brought together by the National Cancer Institute in a Think Tank that took place in Park City, Utah, and during that meeting, it was proposed to refer these lesions as *pancreatic intraepithelial neoplasia (PanIN)* [23]. Included in this neoplastic category as low-grade PanIN were changes that used to be called mucinous hypertrophy or mucinous metaplasia, based on the fact that although these mucinous changes seem perfectly innocuous and do not show classical morphologic attributes of neoplasia, they nevertheless exhibit some molecular alterations that are considered hallmarks of neoplastic change such mutation in *KRAS* oncogene. It has been shown that starting with these earliest forms of neoplastic transformation, the process advances to accumulate more genetic abnormalities including *p53* gene mutations [6, 24]. These genetic abnormalities are manifested microscopically as nuclear enlargement and hyperchromasia (deposition of abnormal nuclear material). Altered cellular metabolism leads to accumulation of different types of glycoproteins (mucins) as well as disorganization of cells, manifested as loss of polarity of the cells. Furthermore, loss of "guardians of genetic stability" leads to uncontrolled cellular proliferation that is reflected as increased mitotic activity. The spectrum of changes was previously graded as PanIN-1A, PanIN-1B, PanIN-2, and PanIN-3 [23]. However, recently, to improve concordance and to align with practical consequences, a two-tiered system (low grade vs. high grade) is proposed for all precursor lesions including PanINs, with the provision that PanIN-2 now be categorized as low grade [25]. High-grade PanIN is also regarded as synonymous to *carcinoma* in situ (Fig. 10), the last step before invasive cancer develops.

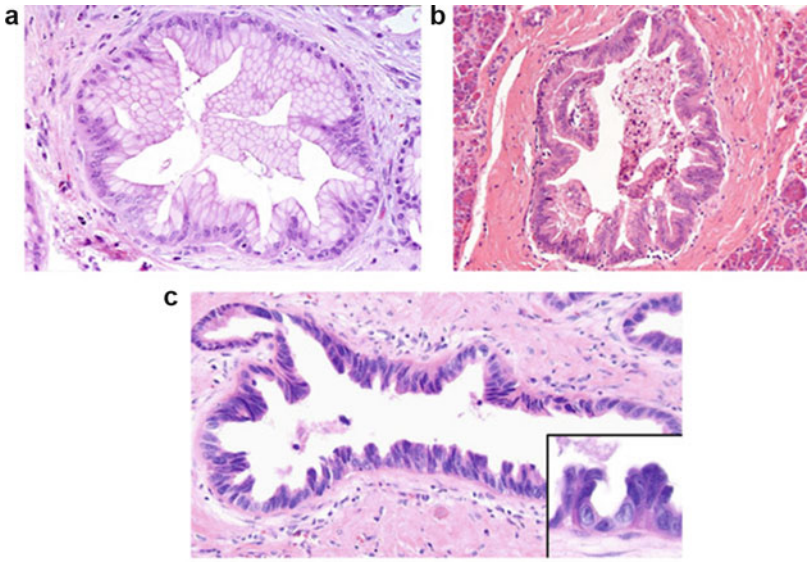

Fig. 10 (**a**, **b**) **Low-grade PanIN**, the normal cuboidal to low columnar ductal epithelial cells, is replaced by tall columnar cells containing abundant apical mucin. The nuclei are basally located. The epithelium can be relatively flat or papillary (**a**) in low-grade PanIN. Pseudostratification, loss of polarity, and mildly enlarged nuclei (**b**) may also be seen. (**c**) High-grade PanIN is characterized by severe cytologic atypia that is seen in full-blown carcinoma. Loss of polarity, nuclear irregularities, and prominent (macro) nucleoli (*inset*) and mitoses, which may occasionally be abnormal, are usually prominent

Mass-Forming Preinvasive Neoplasia

These lesions are in some ways similar to PanIN in the sense that they arise from the ductal system, and they are noninvasive neoplasia with potential for cancerous transformation. Unlike PanINs, however, they themselves present clinically with mass formation, usually as a cystic tumor [26–29], and this obviously raises the possibility of curative intervention. There are essentially three tumor types that can be included in this category of mass-forming preinvasive neoplasia: *intraductal papillary mucinous neoplasms* (*IPMNs*), *intraductal tubulopapillary neoplasms* (*ITPNs*), *and mucinous cystic neoplasms* (*MCNs*) [28].

These lesions are being encountered with increasing frequency and constitute up to 20% of pancreatic resections in some institutions [30], especially because they are often resectable tumors. The incidence of invasive carcinoma in these tumors is about 30%. Conversely, the estimated ratio for invasive pancreatic adenocarcinomas to arise in association with these lesions is about 1%. Even though there are controversies regarding their management, it is certain that these tumors are potentially curable, and because of this, the differential features of the lesions under this category and recognizing their clinicopathologic characteristics are important [28, 30].

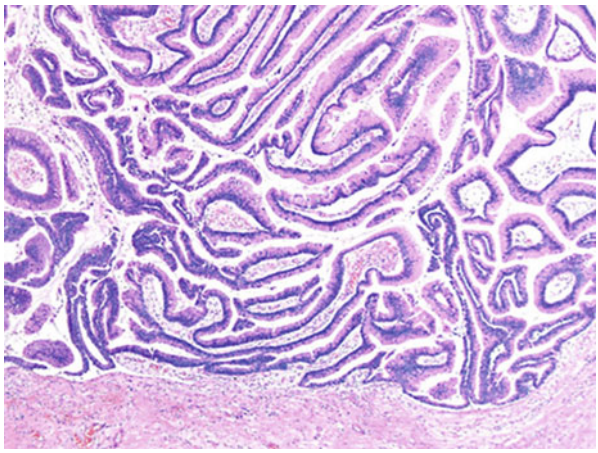

Fig. 11 Intraductal papillary mucinous neoplasia (IPMN). Tall, exuberant papillary structures lined by columnar cells with abundant mucin and cigar-shaped nuclei filling and dilating the ducts (cystic transformation). The overall picture of the process is highly similar to that of villous adenomas of the colon

Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasms (IPMNs) are characterized by intraductal proliferation of mucin-producing neoplastic cells that often form papillary configuration and lead to cystic dilatation of the ducts [25, 26, 29, 31–33] (Fig. 11). This process is reflected in imaging studies as dilatation of the ductal system with cyst formation and thus used to be called "ductectatic mucinous cystic neoplasm," and endoscopically, they are often associated with mucin extrusion from the ampulla of Vater, thus the previous name, "mucin-producing tumor."

IPMNs differ in the cell type that composes the papillary epithelium, allowing their stratification into intestinal, pancreatobiliary, gastric, and oncocytic subtypes [26, 34]. Although "oncocytic subtype" of IPMN was originally described as a separate variant of pancreatic intraductal neoplasms [35], the current (2010) WHO designated this neoplasm as a subtype of IPMN due to its overlapping features with other subtypes of IPMN [28].

There is also a spectrum of neoplastic transformation in IPMNs representing *adenoma-carcinoma sequence*, accompanied by an increasing number of molecular alterations [36]. Those with mild cytoarchitectural atypia are classified by the current (2010) WHO as low grade [28]. These are composed of relatively simple papillary units lined by well-polarized, tall columnar cells with basally oriented non-atypical nuclei and abundant apical cytoplasm with mucin. As the neoplasm progresses, with accumulation of other molecular-genetic alterations, the cells begin to show hyperchromatism and pleomorphism (variably sized and shaped nuclei), along with loss of organization and rapid proliferation of cells which lead to complex papillary elements, irregular clustering of cells, and cytologic atypia, altogether reflecting cancerous transformation, i.e., high-grade dysplasia or carcinoma in situ [23, 33]. The lesions in between the *low grade* and *high grade* were previously graded as *intermediate grade*. However, recently, a two-tiered system (low grade vs. high grade) is proposed for all precursor lesions to improve concordance and to align with practical consequences. In this two-tiered system, lesions with aforementioned

intermediate-grade dysplasia are categorized as low grade [25]. Accordingly, the term high grade is reserved only for the uppermost end of the spectrum.

The cancerous transformation within an IPMN culminates in invasive carcinoma in many patients. There are two types of invasive carcinomas that occur: (1) ductal (tubular) type [31, 32], which is virtually indistinguishable from conventional DA of the pancreas discussed previously and often behaves like one as well (with rapid recurrences, metastasis, and fatality) [37], and (2) colloid type [15], characterized by abundant extracellular mucin in which the carcinoma cells "float" (Fig. 8). Presumably, due to the containing effect of this stromal mucin, the spread of colloid carcinoma cells is much slower, and prognosis is significantly better than that of the ductal type [17].

Despite the earlier concerns and contentions, it has become clear in the past few years that if these tumors are carefully evaluated by experts and the possibility of high-grade dysplasia and invasive carcinoma is excluded definitively, this classification of IPMNs as low grade, high grade, or invasive is highly predictive of clinical outcome [37]. The important issue is that it is difficult to ascertain the absence of carcinoma without thorough pathologic examination of the tumors because foci of carcinoma can be focal and well hidden, not only from the eyes of the imagers on radiologic/endoscopic examination but even naked eyes inspecting the resected tumors in the pathology gross rooms, thus the mandate for complete microscopic examination of these lesions [29]. There are, however, surrogate findings that seem to be very helpful in preoperative classification of most (unfortunately not all) patients with IPMN. Most IPMNs confined to the branch ducts in the uncinate process tend to be small and less complex and prove to be low grade (i.e., without carcinoma) by pathologic examination [38]. The cell type of these *branch-duct-type* IPMNs also tends to be of gastric type [34]. Studies have shown that if a branch-duct IPMN is asymptomatic, smaller than 3 cm, and without mural nodularities (lack of complex papillary nodules) and EUS-guided cytologic examination fails to show any suspicious cells, the case can be managed conservatively because most of these prove to be low grade [30]. In contrast, branch-duct IPMNs that are larger and more complex with suspicious findings have a higher incidence of high-grade dysplasia and invasive carcinoma, which appears to justify surgery. IPMNs that also involve the main duct are referred to as *main duct type*. These have a high propensity to contain or evolve into invasive carcinoma and for this reason they typically warrant resection [30, 39]. Interestingly, these commonly show intestinal differentiation virtually indistinguishable from colonic villous adenomas [26, 34, 40]; in fact, some were previously reported as villous adenoma of Wirsung duct. This intestinal differentiation, which is also reflected at molecular level by expression of markers of intestinal programming, namely, MUC2 and CDX2 [34], as well as by recurrent mutations of *GNAS* [41, 42], is an intriguing and unique aspect of IPMNs. The problem is that these main duct IPMNs are also often diffuse, involving a large portion of or the entire pancreas; thus, their complete removal often means total pancreatectomy, which is an operation with relatively high complication rate, and it is difficult to balance the risk-benefit ratio in such patients, especially considering most IPMN patients

are relatively old (mean age: 68) with other comorbid conditions. Of note, many patients with IPMNs also have other neoplasms [32].

Intraductal Tubulopapillary Neoplasm

This is a recently recognized entity [43], first reported by Tajiri et al. under the heading of intraductal tubular carcinoma in 2004 [44, 45]. The entity is now being named *intraductal tubulopapillary neoplasm* [28], although papilla formation is seen only in a minority and in a very limited fashion in our experience.

The clinical findings are often indistinguishable from those of IPMNs. It occurs predominantly in the head but may involve any part of the gland [43, 46].

Microscopically, ITPNs are typically composed of multiple smooth-contoured nodules intervened with fibrotic stroma that may contain scattered pancreatic elements. The nodules are typically cellular but punctuated by numerous tubules, which are prominent in most cases. The overall pattern closely mimics intraductal variant of acinar cell carcinoma. Therefore, the absence of acinar markers is crucial to the diagnosis.

A third of the cases were reported to have invasive carcinoma of tubular type; however, distinguishing invasive carcinoma in ITPNs is a great challenge because of the complexity of the intraductal process and its striking ability to extend to atrophic lobules, creating a pseudoinvasive appearance [43]. Nevertheless, even if there is an associated invasive carcinoma, limited follow-up suggests these are indolent neoplasms with a protracted clinical course similar to IPMNs [43, 46].

Of note, genetic findings of ITPNs seem to be different than those of IPMNs. *KRAS* and *GNAS* mutations are very rarely, if ever, present in ITPNs, in contrast with IPMNs that frequently show these alterations [47–49].

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms (MCNs) are seen almost exclusively in perimenopausal women (mean age: 48, >95% of the patients are female). They typically form a thick-walled multilocular cyst in the body or the tail of the pancreas [50–53]. Some examples may become infected and mimic pseudocysts. MCNs do not have obvious communication with the ductal system, which distinguishes MCNs from IPMNs. Cyst fluid is often rich in mucin-related glycoproteins and oncoproteins such as CEA, which may help differentiate these tumors from serous adenomas (see below) preoperatively. The cysts are lined by a mucinous epithelium, which may exhibit various degrees of cytologic and architectural atypias that have been classified as low, intermediate, and high grade [4]. However, recently, a two-tiered system (low grade vs. high grade) is proposed for all precursor lesions in the pancreas, including MCNs. In this two-tiered system, lesions with aforementioned intermediate-grade dysplasia are categorized as low grade [25]. Typically, small (<3 cm) and less complex lesions tend to be low grade, whereas larger, more complex lesions with abundant intracystic papillary nodules may harbor high-grade dysplasia or invasive carcinoma. As happened for IPMNs, it has become evident that if these tumors are examined thoroughly and the presence of high-grade dysplasia or invasive carcinoma is excluded, the grade does accurately predict the clinical outcome [50, 52] and

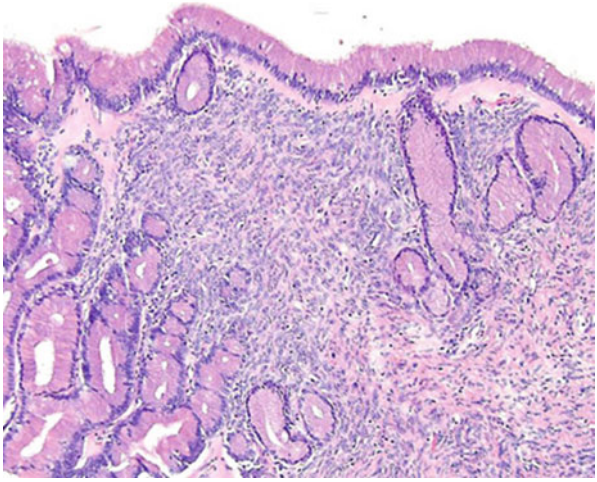

Fig. 12 Mucinous cystadenoma (MCN). The cyst lining is composed of tall columnar mucinous epithelium, surrounded by a cuff of distinctive hypercellular stroma on the wall which shows all the characteristics of ovarian stroma

that the cases classified as low-grade dysplasia are typically cured by complete removal. One caveat, however, is that invasive carcinoma may be very focal and easily missed if the tumor is not thoroughly examined, and for this reason, most authors advocate the total submission of these tumors for microscopic evaluation.

A microscopic feature that has become a requirement for the diagnosis of MCN is the presence of an "ovarian-type" stroma (Fig. 12) [25, 30, 39]. This stroma is not only similar to that of the ovarian cortex but also expresses estrogen and progesterone receptors that are detectable by immunohistochemistry, suggesting that hormones may have a role on initiation and progression of these tumors. This distinctive mesenchyme also helps distinguish MCN from other similar neoplasms, especially IPMNs.

Invasive carcinoma is seen in approximately 15% of the MCNs resected and is predominantly of the tubular type [53]. Interestingly, none of the cases have pure colloid-type invasion, which is the predominant type of invasion in IPMNs [53]. It appears that if there is established invasive carcinoma, the prognosis is often very poor [53].

Non-mucinous Ductal Neoplasia

Serous Cystadenoma

Serous cystadenomas (*SCA*), also called glycogen-rich or microcystic adenomas, are seen predominantly in older females (mean age: 58, F:M = 3:1) [54]. They appear to recapitulate centroacinar cells, and although they are of ductal lineage, they lack the features of mucinous differentiation. Grossly, they form well-demarcated, relatively large lesions (mean size: 4 cm; some up to 18 cm) with a central satellite scar [54]. *Microcystic* SCAs are typically composed of innumerable small cysts each measuring a few millimeters, which leads to the characteristic spongy appearance of the lesion by macroscopic examination, thus the name microcystic adenoma.

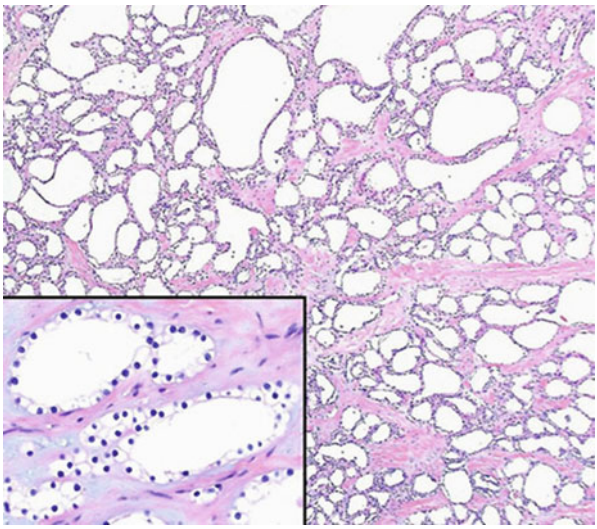

Fig. 13 Serous cystadenoma. Typical honeycomb (microcystic) pattern due to innumerable cysts of various sizes. Inset illustrates the lining of these cysts composed of low cuboidal epithelial cells with clear (glycogen-rich) cytoplasm showing distinctive, uniform, round, small nuclei with homogenous, dense chromatin

Macrocystic (unilocular or multilocular) and *solid* variants have also been described but are uncommon [54].

Microscopically, the microcysts correspond to variably sized gland-like structures lined by a single layer of non-mucinous cuboidal epithelium that contains intracytoplasmic glycogen that is responsible for the distinctive clear cytoplasm in the tumor cells (Fig. 13). The cysts contain watery, clear fluid that is devoid of mucin-related glycoproteins and oncoproteins in contrast with mucinous ductal tumors described above. This feature may be helpful in preoperative diagnosis. Multilocular macrocystic variant is characterized by a limited number of locules (typically <10), with each locule measuring in centimeters, creating a megacystic pattern, previously also called "oligocystic." Tumors with a singular locule are classified as unilocular macrocystic variant, and tumors with uniform, small, evenly shaped and sized nests or tubules with minimal or no lumen formation creating a solid, well-demarcated nodule on macroscopic examination constitute solid variant [54].

Of note, serous lesions may be observed in von Hippel-Lindau (VHL) disease [55] and some SCAs show *VHL* gene alterations [56]. Concurrent ductal adenocarcinomas, pancreatic neuroendocrine tumors, and congenital pathologic conditions may also be observed in association with SCAs [54].

Even though SCAs are invariably benign, it appears that a subset has a rapid doubling rate [57], which may be responsible for their large size in some patients. Also, larger serous neoplasms (>11.0 cm) with inflammation and hemorrhage may show localized adhesion and/or penetration of neighboring organs, including lymph

nodes, spleen, stomach, and colon, which does not seem to be an indicator of malignant behavior. There are only a few serous cystadenocarcinomas of dubious nature reported in the literature [58–60]. The majority of these are histologically identical to their benign counterparts. The only difference reported is that they recur, metastasize, or show angioinvasive growth. For those that are reported to recur or metastasize, the question of multifocality rather than true metastatic spread has been raised. Therefore, for serous neoplasms occurring in the liver, the possibility of synchronous-independent tumors may have to be considered before concluding metastasis.

Neuroendocrine Neoplasia

Aberrant neuroendocrine differentiation (the presence of scattered neuroendocrine cells or a small neuroendocrine component) is not uncommon in tumors with ductal differentiation (discussed above) and in acinar tumors (discussed later). However, if a tumor is predominantly composed of cells with neuroendocrine lineage, it is classified as "neuroendocrine."

Well-Differentiated Pancreatic Neuroendocrine Tumor

Well-differentiated pancreatic neuroendocrine tumors (PanNETs, previously referred to as "islet cell tumors" and "endocrine tumors") are the majority of the neuroendocrine neoplasms in the pancreas. They recapitulate the islets of Langerhans to variable degrees. Those that are associated with increased serum levels of hormones and lead to corresponding symptoms are referred to as "functional." These constitute nearly half of the PanNETs and are named according to which hormone they secrete (insulinoma, glucagonoma, gastrinoma, somatostatinoma, VIPoma, and others). Depending on the type and level of hormone secreted, the patients may suffer from a variety of symptoms or "syndromes." For example, insulinoma patients may present with symptoms related to excessive and erratic insulin secretion by the tumor that leads to "Whipple triad": (1) symptoms of hypoglycemia including confusion, convulsion, fatigue, and weakness, (2) serum fasting glucose level <50 mg/dL, and (3) relief of symptoms after intravenous glucose administration. Patients with "glucagonoma syndrome" have weight loss, diabetes mellitus, anemia, painful glossitis (sore and red tongue), venous thrombosis, and necrolytic migratory erythema. Excessive gastrin production may lead to Zollinger-Ellison syndrome characterized by multiple gastric and duodenal ulcers. Interestingly, the amount of hormone detected immunohistochemically in the tumor cells does not necessarily correlate with the functionality status [3].

In general, PanNETs form solid, circumscribed, fleshy lesions that appear significantly different than the scirrhous ductal adenocarcinomas. They can sometimes be multinodular. Microscopically, patterns suggesting a neuroendocrine differentiation are the result of a well-organized relationship of the neoplastic cells to numerous small blood vessels and the tendency of most cells to be rather uniform in appearance. The cells are usually rounded or polygonal, and in the

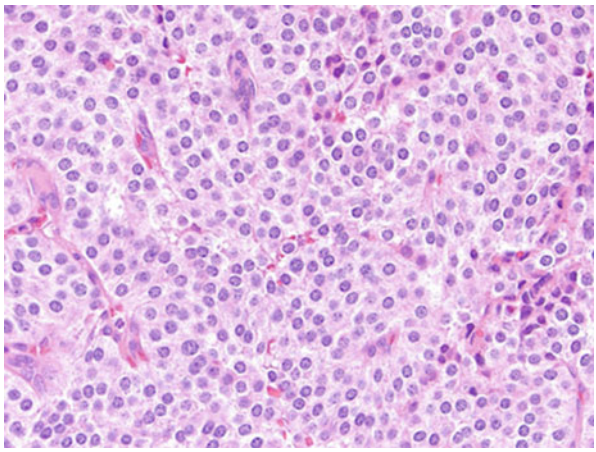

Fig. 14 Well-differentiated pancreatic neuroendocrine tumor. Uniform cells are arranged in nests, and nuclear features show the characteristic clumped, "salt and pepper" chromatin pattern

majority of cases, they are similar to one another in size and shape. The nuclei often resemble those of normal islet cells, often showing the distinctive "salt-and-pepper" chromatin pattern (with tiny clumps of dense heterochromatin scattered through the nuclei) (Fig. 14) [3].

In the current (2010) World Health Organization (WHO) classification system, pancreatic as well as gastrointestinal system neuroendocrine neoplasms are classified as *well-differentiated* neuroendocrine tumor (NET) (Grade 1 or Grade 2) and *poorly differentiated* neuroendocrine carcinoma (NEC) (Grade 3); see poorly differentiated neuroendocrine carcinomas section for the latter. This grading is performed on the basis of morphologic criteria and the assessment of proliferation fraction: [1] mitotic count and [2] Ki-67-labeling index (using the MIB1 antibody). Grade 1 NETs are defined as having a Ki-67 index of <3% and <2 mitoses/10 high-power fields (HPF). Grade 2 NETs have a Ki-67 index of 3–20% or 2–20 mitoses/10 HPFs [61]. For grade-discordant cases (based on differences in mitotic count and ki-67 index), the higher grade should be used [61].

Well-differentiated PanNETs (Grade 1 or 2) are low-grade malignancies. Those that are diagnosed at an early stage are often (but not always) curable, and even those that are advanced with metastases may have a relatively protracted clinical course that may stretch up to decades. Additionally, insulinomas also often follow a benign course since they are highly symptomatic even when they are small, thus detected in an early phase. PanNETs associated with multiple endocrine neoplasia, type 1 (MEN1), tend to be less aggressive as well. However, it should be kept in mind that a group of *well-differentiated* PanNETs have comparatively high Ki-67-labeling indices of more than 20% (usually between 20% and 50%) [62]. As per the current (2010) WHO guidelines, these *well-differentiated* PanNETs with an elevated proliferative rate are classified as NEC – Grade 3 – along with full-blown *poorly differentiated* NECs. However, preliminary studies have shown that even though their outcome is worse than that of ordinary *well-differentiated* PanNETs, it is still significantly better than that of the *poorly differentiated* NECs [62, 63]. Therefore, it

is becoming clear that the current Grade 3 group defined as >20% will have to be split into two separate categories in the future in order to distinguish the *well-differentiated* Grade 3 PanNETs (Ki-67, 20–50%) from the full-blown *poorly differentiated* NECs [62, 64].

Poorly Differentiated Neuroendocrine Carcinomas

As mentioned above, in the current (2010) WHO classification system, poorly differentiated pancreatic neuroendocrine carcinomas (NECs) are included in the Grade 3 category along with well-differentiated PanNETs that have more than 20 mitoses per 10 HPFs or a Ki-67 index greater than 20% [61]. This system suggests that poorly differentiated pancreatic NECs are part of a continuum with well-differentiated PanNETs, and therefore the two entities are closely related and that the grade should be based entirely on proliferation rate. However, evolving evidence strongly suggests that morphologic differentiation is also relevant and that poorly differentiated pancreatic NECs should be regarded as a separate entity [62, 63, 65].

Primary pancreatic poorly differentiated NECs are extremely rare, accounting less than 1% of all pancreatic [66] and at most 2–3% of all pancreatic neuroendocrine neoplasms [4]. Most patients are in their late 50s and there is a slight male predilection. In contrast to well-differentiated PanNETs, the poorly differentiated pancreatic NECs are not associated with hereditary syndromes and are usually clinically nonfunctional [65, 67].

Poorly differentiated pancreatic NECs are more common in the head of the pancreas and present as a large (median tumor size of 4 cm), relatively circumscribed, tan-yellow, fleshy mass. Microscopically, these carcinomas are subdivided into small and large cell variants, based on cell size. The small cell variant (small cell carcinoma) is characterized by small to intermediate cells with finely granular chromatin, high nucleus-to-cytoplasm ratio, inconspicuous nucleoli, prominent nuclear molding, and crush artifact [65]. The large cell variant (large cell NEC) is more common and characterized by large cells with prominent nucleoli and variable amounts of cytoplasm. Apoptotic cells and mitotic figures are abundant, but mitotic figures in the large cell NECs are usually not as numerous as in the small cell carcinomas [65]. In cases with the typical cytologic features of small cell carcinoma, it is not necessary to document neuroendocrine differentiation by immunohistochemistry. However, for large cell NECs, positive immunohistochemical staining for chromogranin or synaptophysin should be obtained to confirm the diagnosis [4, 61, 68].

Recently, pancreatic small cell carcinomas and large cell NECs were shown to be genetically related but distinct from well-differentiated PanNETs: The genetic changes frequently seen in these poorly differentiated pancreatic NECs, such as inactivation of the TP53 and the retinoblastoma/p16 pathways [69], are rarely observed in well-differentiated PanNETs [70]. Conversely, approximately 45% of sporadic well-differentiated PanNETs harbor mutually exclusive mutations in either *DAXX* (death domain-associated protein) or *ATRX* (α-thalassemia/mental retardation syndrome X-linked) genes [70]. *DAXX* and *ATRX* encode nuclear proteins, which form a chromatin-remolding complex and are involved in chromatin remolding at

telomeric and pericentromeric regions. Mutations of these genes are associated with loss of DAXX/ATRX protein expression.

The clinical course of poorly differentiated pancreatic NECs is worse than that of morphologically well-differentiated PanNETs that would be classified as (2010) WHO Grade 3 on the basis of proliferation rate [62]. Most cases are rapidly fatal with widespread metastases involving the regional and distant lymph node as well as intra- and extra-abdominal organs such as the liver and lung [63, 65]. Cisplatin- and etoposide-based regimens have shown some promise in controlling their growth; however, their overall prognosis remains grim [63, 71, 72] with a median survival of 11 months [65].

Acinar Neoplasia

Focal acinar differentiation can occasionally be observed as a small component of PanNETs and is also present as an important constituent of pancreatoblastomas (see below); however, most pancreatic tumors with predominant acinar differentiation are acinar cell carcinomas. With the exception of the recently described acinar cell cystadenoma, which is probably not a neoplasm (also called cystic acinar transformation [73], acinar differentiation is seen essentially only in malignant neoplasms in this organ.

Acinar Cell Carcinoma

Acinar cell carcinomas (ACCs) are rare neoplasms constituting <1% of all pancreatic carcinomas [74]. Occasionally, the neoplastic cells may secrete lipase and other digestive enzymes to the serum which may lead to the so-called lipase hypersecretion syndrome characterized by fat necrosis, polyarthropathy, occasional eosinophilia, and nonbacterial thrombotic endocarditis. Elevated levels of AFP in serum may also be observed.

Most ACCs are large (mean size: 8 cm) at diagnosis, and patients often present with early metastasis to the liver and lymph nodes. Macroscopically, they form a well-delineated, nodular, fleshy, yellow-tan tumor. Dense fibrotic appearance created by desmoplastic stroma characteristic of DAs is not a feature of ACCs [75]. Predominantly, intraductal growth of acinar cell carcinoma is uncommon but has been reported [76, 77]. Such cases can be mistaken as other intraductal neoplasias including intraductal papillary mucinous neoplasms or intraductal tubular carcinomas. On occasion, ACCs may present as cystic tumors.

Microscopically, ACCs are highly cellular tumors with solid sheets of cells that may form nests or rosette-like (acinar) patterns (Fig. 15). Many examples maintain production of digestive enzymes, which is represented as a distinctive eosinophilic granularity in the apical portions of their cytoplasms. These zymogenic granules are positive immunohistochemically by antibodies targeting specific enzymes such as trypsin, chymotrypsin, and BCL10 [74, 75, 78, 79]. Nuclei of ACCs are fairly round and relatively uniform. The most distinctive histologic feature of this tumor type is the presence of single prominent eosinophilic nucleolus (Fig. 15), recapitulating the

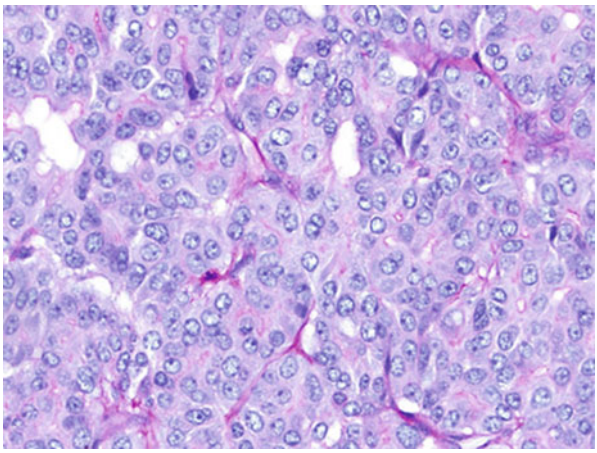

Fig. 15 Acinar cell carcinoma. The tumor cells are highly atypical but at the same time fairly monotonous and round. They display markedly chromopholic cytoplasm, mostly reflecting the enzymatic granules and cytoplasmic organelles involved in their production, which imparts this tumor its characteristic appearance. Single prominent nucleoli are also among the most distinctive histologic feature of this tumor type

normal acinar cells. Of note, aberrant and mixed differentiation, especially neuroendocrine, is quite common in acinar tumors (see below) [80].

In contrast to DAs, mutations in *KRAS*, *TP53*, and *SMAD4* are uncommon in ACCs [81]. However, molecular alterations in the APC-β-catenin pathway have been repeatedly reported in approximately 20% of ACCs, including inactivating mutations in *APC* and activating mutations in *CTNNB1* [82]. Recent whole exome sequencing and more targeted broad-spectrum sequencing studies have revealed a high degree of genomic instability in acinar neoplasms. Many different genes were mutated across the tumors studied, with no single gene being mutated in more than 30% of cases. The lack of common alterations in DA (*KRAS*, *SMAD4*, *TP53*, and *CDKN2A*), cystic neoplasm (*GNAS* and *RNF43*), and NET (*MEN1*, *DAXX*, and *ATRX*) genes was confirmed. Also confirmed were the alterations in *APC* and *CTNNB1* described previously. Additional recurrently altered genes include a variety of potential therapeutic targets, such as *JAK1*, *BRAF*, and genes of the mTOR and DNA repair pathways [83, 84]. An additional molecular alteration of potential therapeutic significance is the finding of *BRAF* fusions in 23% of acinar neoplasms [84]. The fusions are functional, leading to activation of the MAPK pathway, sensitive in vitro to MEK inhibitors. A rapid FISH assay to identify *BRAF* fusions in pancreatic acinar neoplasms has also been developed [85].

ACCs are fairly aggressive neoplasms. Liver metastases are seen in more than half of the cases and are mostly present at the time of diagnosis. Another 25% develop them subsequently [74]. Metastatic disease usually affects the lymph nodes and liver; even late in the course of disease, extrahepatic metastases are uncommon. However, rare cases present with ovarian metastases [86]. Nevertheless, the overall prognosis seems to be better than that of DA. Recent data have shown an even more favorable prognosis, presumably due to earlier detection and some responses to chemotherapy [87]. An overall 5-year survival rate of 43% (72% for patients undergoing resection, 22% for those with unresectable disease) and a median survival of 57 months for resectable disease and 20 months for those with metastases

are now reported [87]. However, most patients ultimately succumb to their disease. Prognostic factors include only staging features (primary tumor size, lymph node status, and presence of metastases) [75]. There is no predictive grading scheme for ACC.

Neoplasms with Multiple Lineages (Pancreatoblastoma and Mixed Acinar-Neuroendocrine Carcinoma)

Aberrant differentiation is exceedingly rare in the DAs, whereas it is rather common in non-ductal tumors.

Pancreatoblastoma is the principal example of the tumors with polyphenotypic differentiation; all three main constituents of normal pancreas, namely, acinar, ductal, and neuroendocrine, are represented in pancreatoblastomas, the acinar elements being the most consistent. In many ways, pancreatoblastoma can be regarded as pancreatic counterpart of other childhood "blastic" tumors such as Wilms (nephroblastoma), which is also a multi-lineage neoplasm. Pancreatoblastomas are very rare; however, they are the most frequent pancreatic tumor of the early childhood (mean age: 4). There appears to be a second peak in adults of 30's [88]. Elevated serum levels of AFP can be observed [89], and the tumors might be associated with Beckwith-Wiedemann [90] or familial adenomatous polyposis (FAP) syndromes [91].

Grossly these form large (7–18 cm), well-demarcated, solitary, solid, multilobulated tumors that can extend outside of the pancreas. Microscopically, solid sheets, nests, trabecula, and strands of neoplastic cells are divided by variable amounts of stroma, which on occasion may contain heterologous elements such as osteoid. Necrosis may be present. Squamoid corpuscles composed of large, spindled squamoid cells that form small morular arrangements, occasionally with keratinization, are a pathognomonic finding of pancreatoblastoma (Fig. 16), not seen in other tumor types of the pancreas [88, 92]. Acinar, ductal, and neuroendocrine elements can be highlighted by the markers discussed in the corresponding sections. The squamoid nests do not seem to reflect a particular cell lineage. Interestingly, they also show nuclear labeling for β-catenin, which is implicated in the molecular histogenesis of acinar neoplasms, but the acinar components of the tumors retain normal membranous labeling for β-catenin [93]. Genetic alterations are similar to those of ACCs and starkly different from the ones seen in DAs [78].

Pancreatoblastomas can behave aggressively, but like pediatric ACCs, they are less aggressive in children than in adults. Patients without metastases at presentation may be cured, and favorable responses to chemotherapy have been documented [79, 88, 94].

In addition to pancreatoblastoma, prominent multi-lineage differentiation is also seen in tumors that are classified as "mixed" [95]. While ACCs often show focal aberrant neuroendocrine differentiation in forms of microfoci or scattered individual cells, in some cases, there is a well-established, prominent neuroendocrine component. If this component constitutes more than 25% of the tumor, the designation of

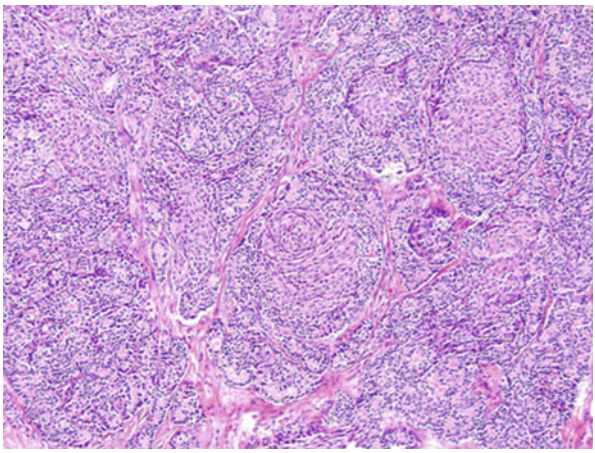

Fig. 16 Pancreatoblastoma. The acinar component predominates in most pancreatoblastomas as seen here. The most distinctive and characteristic finding in this tumor type are the *squamoid corpuscles*, which are well-defined nests of plump to spindle-shaped cells that form a vague fascicular or whorled pattern highly similar to the "morules" seen in other malignant tumors that are also related to beta-catenin pathway alterations

"mixed acinar- neuroendocrine" carcinoma is given [4]. Similarly, on occasion, ACCs may have a significant ductal component, and if this component is >25% of the tumor, the diagnosis of "mixed acinar-ductal" carcinoma is rendered. It may be important to note that in these "mixed" carcinomas, invariably the dominant component is acinar. Mixed carcinomas are very rare; thus, their clinical behavior is difficult to ascertain, but most appear to behave like ACCs (discussed above) [4].

Neoplasms of Uncertain Histogenesis

Solid Pseudopapillary Neoplasm

Solid pseudopapillary neoplasm (SPN) is a peculiar tumor of indeterminate lineage. This is reflected in the various descriptive names previously used for this tumor: "papillary cystic," "cystic and papillary," "solid and cystic," and "solid and papillary" [96]. It is also known as Frantz or Hamoudi tumor, crediting the observers that recognized this as a distinct category.

Clinically, SPNs are significantly more common in women. In a recent series, 84% of the patients have been reported to be females [97]. They have been described in all age groups, but the mean age is 33 [97, 98]. Symptoms are nonspecific, and some cases are detected incidentally following trauma or during gynecologic or obstetrical exams. As experience with these relatively uncommon tumors developed, it became clear that these are essentially solid tumors, which often undergo cystic degeneration [98, 99]. Unlike in other cystic tumors, the cysts are not lined by an epithelium. Grossly, their appearances vary from beige-tan to brown-hemorrhagic

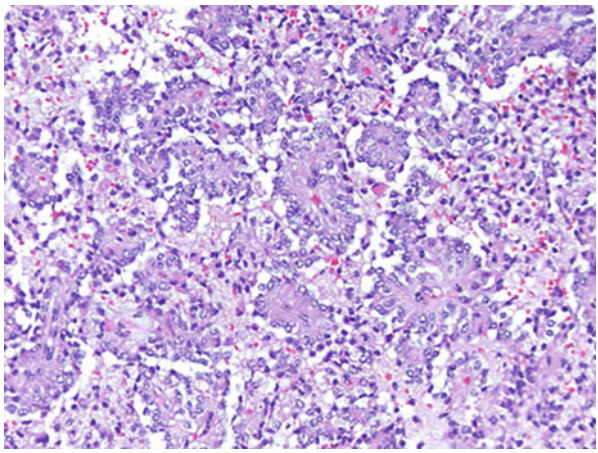

Fig. 17 Solid pseudopapillary neoplasm. Prominent pseudopapillary growth pattern is seen in most cases and is a characteristic feature of this enigmatic tumor

depending on the degree of hemorrhage and degeneration. Histomorphologically, SPNs typically show diffuse cellular proliferation of relatively bland-appearing cells admixed with variable degree of stroma ranging from dense collagen to myxoid to hemorrhagic (Fig. 17). The cells can also be arranged in vague nests, intervened by fairly dense but relatively inconspicuous microvasculature. The preferential dyscohesiveness of the cells away from the microvasculature, presumably related to the alterations in cell adhesion molecules (catenins and cadherins) [99, 100], leads to the highly distinctive arrangement of cells that is referred to as "pseudopapillary," which was recently incorporated to the name of this entity, although it is not present in all cases. Other characteristic and rather specific findings include nuclear grooves and the eosinophilic cytoplasmic globules.

Despite intensive study, the line of differentiation of these neoplasms remains uncertain [98]. Although some cases appear to exhibit some less specific neuroendocrine differentiation markers such as synaptophysin or CD56, chromogranin is never expressed. Both acinar and ductal markers are also consistently negative. In fact, the weak expression of keratin casts doubt on even the epithelial nature of these tumors, although some authors classify them as "carcinoma." There are various markers expressed by this neoplasm that were thought could be helpful in its diagnosis and also in establishing its lineage; however, none are specific. These include vimentin, alpha-1-antitrypsin, progesterone receptors, beta-catenin, and CD10. Among these, beta-catenin expression appears to be most helpful because it is not seen in neuroendocrine tumors, which is the main differential. This pattern of labeling is secondary to constitutive activation of Wnt pathway in SPN that caused point mutations within exon 3 of the *CTNNB1* gene (reported in more than 90% of SPNs) [42]. Recent molecular studies have also shown the absence of abnormalities in *KRAS*, *TP53*, or *SMAD4* genes observed in DA and support also that SPN is distinct from all other pancreatic neoplasms [6]. However, it should be noticed that genetic/mutations in the beta-catenin/APC pathway are seen in up to 80% and 50% of pancreatoblastomas and ACCs, respectively [42, 82].

SPNs are considered malignant, but metastases occur in only 10–15% of cases [98, 101]. In almost every instance, metastases are either in the liver or peritoneum; nodal metastases are rare. Interestingly, even patients with metastatic disease often survive for many years (even decades) with few symptoms [97, 102, 103]. In fact, only rare deaths have been attributed to direct effects of SPNs [97]. None of the pathologic findings, with the exception of anaplastic/sarcomatoid differentiation, have been proven of value in determining which rare cases will have metastasis [101].

Miscellaneous Cystic Pancreatic Lesions

In contrast to the ones seen in salivary glands, *lymphoepithelial cysts* (LEC) of the pancreas [104] do not show any association with immune-suppressive, autoimmune, or malignant diseases. They are mainly seen in adult men (mean age: 52, M/F = 3/1) [104, 105] and usually are asymptomatic and incidental lesions, which can be located within the pancreas or protrude from the pancreas and present as a peripancreatic mass. Gross examination reveals a well-demarcated, often encapsulated, uni-/multilocular cystic lesion with semisolid, caseous, keratinaceous, or sometimes watery luminal contents. Histologically, the cysts lined by mature stratified squamous epithelium with variable keratinization are surrounded by a band of dense lymphoid tissue, which may show lymphoid follicle formation. Lymphoepithelial islands can also be seen in some cases. Leakage of the cyst content might cause inflammatory reaction and granuloma formation in the surrounding tissue. Cholesterol clefts and fat necrosis can be seen as well. LEC-like epidermoid cysts may evolve in intrapancreatic accessory spleens [2, 3].

Other entities that may form cystic lesions are the following: *Dermoid cysts* [104, 105] are similar to LECs but lack lymphoid tissue and have skin adnexal elements including sebaceous glands. *Lymphangiomas* [106] are seen in young females (mean age: 29, M/F = 1/3) and form endothelial-lined cysts surrounded by a rim of lymphoid tissue. *Squamoid cyst of pancreatic ducts* is a recently described entity that is probably reactive in nature but may produce high CEA levels [107]. *Congenital cysts* and *intestinal duplications* may also form cystic lesions in the vicinity of the pancreas and periampullary region. These may have variable lining including respiratory type, intestinal, squamous, or transitional [3].

Mesenchymal Tumors

Mesenchymal tumors including fibromatosis (desmoid tumor), solitary fibrous tumor, leiomyoma, schwannoma, primary sarcomas such as primitive neuroectodermal tumor, synovial sarcoma, desmoplastic small round cell tumor, leiomyosarcoma, malignant fibrous histiocytoma, and others may rarely arise primarily in the pancreas [108].

Pseudotumors

In the pancreas, a variety of nonneoplastic conditions may form solid masses that may mimic cancer. Up to 5% of pancreatectomies performed with the preoperative clinical diagnosis of carcinoma prove to be nonneoplastic by pathologic examination, although this figure has been on a steep decline in the past few years with improved preoperative diagnostic modalities and the experience in their usage [109]. Chronic inflammatory lesions are the leading cause of pseudotumor formation, and among these, two entities remain highly problematic as close mimickers of cancer [2–4]:

1. Autoimmune pancreatitis (AIP), a relatively recently defined distinct form of pancreatitis, has been divided into two types – type 1 and type 2 – which share certain clinical similarities but are vastly different in terms of pathology and extrapancreatic features [3].
   (a) Type 1 (previously known as *lymphoplasmacytic sclerosing*) autoimmune pancreatitis is characterized by a pseudotumor composed of dense lymphoplasmacytic infiltrates, in particular IgG4-positive plasma cells, which concentrate around the ducts ("duct-centric pancreatitis") as well as medium-sized venules (periphlebitis) and is associated with fibrosis. The process may be associated with diffuse enlargement of pancreatic tissue or may form a localized lesion. The pancreas was the first organ in which IgG4-related disease was identified, but the disease has now been described in virtually every organ system: the biliary tree, meninges, orbital tissues, salivary glands, thyroid gland, lungs, etc. [3]. The serum IgG4 concentration is elevated (>135 mg/dL) in many patients, which can be very helpful in distinguishing it from carcinoma [109–111], but it may be normal in up to 40% of patients with biopsy-proven AIP type 1 [112]. On immunohistochemistry, the majority of plasma cells are positive for IgG4. The finding of more than 50 IgG4 (+) plasma cells/HPF is considered highly specific for AIP type 1. To identify the full spectrum of changes occurring in AIP, one must recognize its five cardinal features (the Mayo Clinic's HISORt criteria): suggestive **h**istology showing lymphoplasmacytic infiltrate with storiform fibrosis, **i**maging showing a diffusely enlarged pancreas, **s**erology showing elevated IgG4 levels, or evidence of **o**ther organ involvement and **r**esponse to steroid therapy [113, 114].
   (b) AIP type 2 seems to be a pancreas-specific disorder. It is not associated with either other organ involvement or with serum IgG4 elevation typically seen in AIP type 1. However, the lack of other organ involvement or absence of serologic abnormalities in patients with AIP does not necessarily imply the diagnosis of type 2, as type 1 also can be without other organ involvement and seronegative. The most distinctive feature of the AIP type 2 is a dense periductal lymphoplasmacytic inflammation accompanied by neutrophilic microabscesses within the lumen, the so-called granulocytic epithelial lesion

(GEL), involving medium-sized and small ducts, as well as in acini [110, 115–118]. AIP type 2 cases have none or very few (<10 cells/HPF) IgG4 (+) plasma cells [115].

Regardless of subtype, it is important to recognize AIP because it is considered a reversible pancreatitis. The pancreatic (and extrapancreatic) manifestations respond to steroid therapy within an interval of a few months [119]. Although relapses are common, especially in AIP type 1 [120], retreatment with steroids remained effective at inducing remission [116, 119].

2. Paraduodenal pancreatitis, also referred to as cystic dystrophy of heterotopic pancreas, paraduodenal wall cyst, or groove pancreatitis, typically forms thickening, nodularities, and stricture of duodenal wall at the region of accessory ampulla and resembles periampullary cancers [121]. The lesion is characterized by dense myoid proliferation of stroma admixed with pancreatic ducts, rounded acinar lobules, extravasated acinar secretions that illicit stromal and inflammatory reaction rich in eosinophils, as well as Brunner's gland hyperplasia. Most patients are middle aged and have history of alcohol abuse. It is hypothesized that paraduodenal pancreatitis forms as a result of localized alcoholic pancreatitis differentially involving the region drained by the accessory duct [11, 109].

Other lesions that may form pseudotumor and mimic cancer are the following [109]: *Adenomyomatous hyperplasia of ampulla of Vater* is a subtle lesion that is difficult to define; larger examples (>5 mm) have been found to be the cause of obstructive jaundice. *Accessory (heterotopic) spleen* may also form a well-defined nodule within the tail of the pancreas and is typically mistaken for neuroendocrine neoplasm.

Lipomatous hypertrophy is the replacement of pancreatic tissue with mature adipose tissue that occasionally leads to moderate to marked enlargement of the pancreas [122]. *Hamartomas* are very rare if the entity is defined strictly. They are characterized by irregularly arranged mature pancreatic elements admixed with stromal tissue. A cellular, spindle-cell variant with c-kit (CD117) expression is recognized.

*Pseudolymphoma*s form well-defined nodules composed of hyperplastic lymphoid tissue. Rarely, foreign body deposits, granulomatous inflammations (such as sarcoidosis or tuberculosis), and congenital lesions may form tumoral lesions [4].

Secondary Tumors

Secondary tumors involving the pancreas can be listed according to the decreased frequency as pulmonary tumors, lymphomas, gastrointestinal tract carcinomas, renal cell carcinomas, and breast carcinomas [123]. The majority are detected only at

autopsy [124]. Tumors arising in the retroperitoneum, nearby lymph nodes, or gastrointestinal system may also show direct extension to the pancreas. Lymphomas and renal cell carcinomas involving the pancreas are more prone to mimic primary cancers [123]. Renal cell carcinomas may even form polypoid ampullary lesions and may grow within ducts.

Conclusion

The vast majority of pancreatic neoplasms are of ductal lineage rather than neuroendocrine or acinar; thus most research focuses on the ductal tumors. Consequently, significant developments have taken place in the classification and in our understanding of ductal neoplasia in the recent years.

A major recent development was the more unified terminology and grading of precursor lesions, namely, pancreatic intraepithelial neoplasia (PanIN) comprising a neoplastic transformation ranging from early mucinous change (low-grade PanIN) to frank carcinoma in situ (high-grade PanIN).

Also, it is now well known that even the different types of ductal neoplasia vary greatly in their clinicopathologic characteristics and prognoses. Although invasive ductal adenocarcinoma, the most common carcinoma occurring in the pancreas, is one of the deadliest of all cancers, cystic lesions are often either benign or low-grade indolent neoplasia. Better characterization of cystic ductal tumors such as intraductal papillary mucinous neoplasms and mucinous cystic neoplasms has been a major step not only from the standpoint of patient care but also for cancer researchers, because they serve as an interesting model of carcinogenesis. They have well-established malignant potential, representing an *adenoma-carcinoma sequence* that often culminates in invasive carcinoma. Invasive carcinomas in intraductal papillary mucinous neoplasms are predominantly colloid type, which is now regarded as clinicopathologically distinct type of pancreatic cancer with indolent behavior.

Among non-ductal tumors of the pancreas, neuroendocrine neoplasms are by far the most common and form an important category. The majority of these are low-intermediate grade malignancies, and their behavior is far better than that of invasive ductal adenocarcinoma. Those that are treated at an early stage are even considered "benign." However, it should be noted that poorly differentiated neuroendocrine carcinomas are highly aggressive and rapidly fatal tumors.

Key Points

- Pancreatic neoplasms are classified according to which normal cell type of this organ they recapitulate (ductal, acinar, endocrine), because the clinicopathologic and biologic characteristics of tumors are determined or manifested mostly by their cellular lineage.

- Most pancreatic neoplasms are of ductal lineage. Invasive ductal adenocarcinoma (DA) constitutes the vast majority (>85%) of carcinomas of ductal lineage. These are rapidly progressive and highly aggressive solid tumors despite their relatively well-differentiated appearance. They have a tendency to illicit abundant desmoplastic stroma and high propensity for perineural invasion and vascular spread.
- In contrast with solid tumors, cystic lesions of the pancreas are often either benign or low-grade indolent neoplasia. However, those that are mucinous, namely, intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs), constitute an important category, because they have well-established malignant potential, representing an *adenoma-carcinoma sequence*. Approximately 30% of resected IPMNs and 20% of all MCNs have an associated invasive carcinoma. Invasive carcinoma in IPMNs is predominantly colloid type, and those associated with MCNs are almost exclusively of the ordinary ductal type.
- Among non-ductal tumors, well-differentiated pancreatic neuroendocrine tumors (PanNETs) are by far the most common. These are much more indolent tumors than DA and can be associated with multiple endocrine neoplasia, type 1 (MEN1). They form solid, circumscribed, fleshy lesions. Microscopically the tumor cells mimic the islet cells.

Future Scientific Directions

- Most of the DA tissue is composed of desmoplastic stroma and not the cancer cells. Therefore, if the intent is to analyze the carcinoma cells, carcinoma cells need to be dissected out from the background tissue, or alternatively, visual-aided methods of analysis such as immunohistochemistry or in situ hybridization are ought to be utilized.
- *Preinvasive* neoplasms (PanINs, IPMNs, ITPNs, and MCNs) constitute a very important category not only because they are early cancers and thus catching in an early stage often leads to cure, but also they offer an invaluable model of carcinogenesis to analyze. They all show a spectrum of cytoarchitectural atypia. It is now known that starting with the earliest forms of neoplastic transformation, the process advances to accumulate genetic abnormalities. Some of these abnormalities are well documented in the literature, but a lot more awaits to be elucidated.
- On the cyst wall and septa of MCNs, a distinctive ovarian-type stroma that regularly expresses progesterone receptors and sometimes estrogen receptors is seen. This stroma is an entity-defining feature of these neoplasms, to an extent that it has become a requirement for the diagnosis. Moreover, some MCNs are reported to be associated with ovarian thecomas. Efforts should be made to further elucidate the nature of this stroma and hormone influence in the pathogenesis of these neoplasms.

- Despite intensive study, the line of differentiation of solid pseudopapillary neoplasm remains uncertain.
- Currently, it is difficult to determine which well-differentiated pancreatic neuroendocrine tumors will have recurrences and metastases. More studies are needed to more accurately estimate the malignant potential of a given well-differentiated pancreatic neuroendocrine tumors.

Clinical Implications

- Invasive ductal adenocarcinoma cases have highly insidious infiltrative patterns, and often the carcinoma cells are spread far beyond the seemingly confines of the main tumor. Perineural invasion is common and is thought to be the reason of back pain, one of the more common symptoms of this tumor.
- It has become clear in the past few years that if IPMNs are carefully evaluated and the possibility of high-grade dysplasia (*carcinoma* in situ*)* and associated invasive carcinoma is excluded definitively, the classification of IPMNs as low-grade, high-grade, or with an associated invasive carcinoma is highly predictive of clinical outcome. This is also valid for MCNs.
- There are surrogate findings that seem to be very helpful in preoperative classification of most patients with IPMN. Most IPMNs confined to the *branch ducts* in the uncinate process tend to be small and less complex and prove to be adenomas by pathologic examination. In contrast, IPMNs involving main ducts are usually larger and more complex with suspicious findings and have a higher incidence of malignancy.
- Well-differentiated pancreatic neuroendocrine tumors are low- or intermediate-grade malignancies. Those that are diagnosed at an early stage are often curable. Even those that are advanced with metastases may have a relatively protracted clinical course. It should be noted here though that poorly differentiated neuroendocrine carcinomas are highly aggressive and rapidly fatal tumors.
- Nearly half of the well-differentiated pancreatic neuroendocrine tumors are associated with increased serum levels of hormones and are named according to which hormone they secrete (insulinoma, glucagonoma, gastrinoma, somatostatinoma, VIPoma, etc.). Depending on the type and level of hormone secreted, the patients may suffer from a variety of symptoms or "syndromes."

Developmental Molecular Biology of the Pancreas

L. Charles Murtaugh, Ondine Cleaver, and Raymond J. MacDonald

Contents

Abstract

Pancreatic organogenesis is a complex and coordinated process that generates a compound gland of exocrine tissue composed of acini and ducts and endocrine tissue organized in islets of Langerhans. Both tissues originate from the same early endodermal epithelium through cell-cell signaling exchanges with adjacent tissues, including associated mesenchyme that directs a cascade of transcriptional

regulatory events. Current research is aimed at elucidating the formation of pancreatic cell types and the molecular mechanisms that shape the anatomy and physiology of the pancreas. Insights into these questions come from a combination of mouse and human genetics and, increasingly, pluripotent stem cell-based models of organogenesis. These studies have identified both intrinsic factors, such as transcriptional regulators, and extrinsic signaling factors, such as secreted growth factors, morphogens, and cell-surface ligands, as determinants of cellular fate decisions, proliferation, or differentiation. The interplay between organ-restricted intrinsic factors and widely used extrinsic factors guides the stepwise process of pancreatic development from early endodermal patterning and specification of the initial pancreatic field to expansion of pools of progenitors, resolution of individual cell types, and the differentiation of mature exocrine and endocrine cells. A better understanding of pancreatic development is proving useful for comprehending the regulatory defects that drive pancreatic carcinogenesis and for devising effective therapies to correct those defects.

Overview of Pancreatic Development

The mammalian pancreas is a compound gland of exocrine and endocrine epithelia. In adults, the exocrine compartment is composed of ducts and acini and comprises ~90% of the mass of the gland. The endocrine compartment is organized as islets of Langerhans and comprises ~2% [2]. These two tissues serve two distinct functions: (1) the production of digestive enzymes, which are secreted from the acinar cells and channeled to the duodenum via the ducts and (2) the regulation of blood sugar levels by the endocrine cells of the islets of Langerhans via the islet vasculature. A description of the embryonic formation of the pancreas must include the genesis of both exocrine and endocrine tissues, as well as the mechanisms that distinguish these two developmental programs and balance the proportion of precursor cells committed to each. The organogenesis of the pancreas has been well characterized for mouse, rat, rabbit, and chicken. Although pancreas development has been less well studied in the human embryo in situ, it is increasingly amenable to modeling in vitro with human pluripotent stem cells (PSCs). The genetic toolkit of the mouse embryo, including gene knockout (germline or tissue specific) and lineage tracing techniques [3], has kept this species at the forefront of pancreas development studies in the past several decades. Much of our review will therefore focus on mouse development, although we will also discuss insights gained from human embryology and PSC modeling and identify similarities or differences between mouse and human pancreatic development.

The exocrine and endocrine tissues of the pancreas derive from common precursor cells that arise from a dorsal and a ventral domain along the posterior foregut

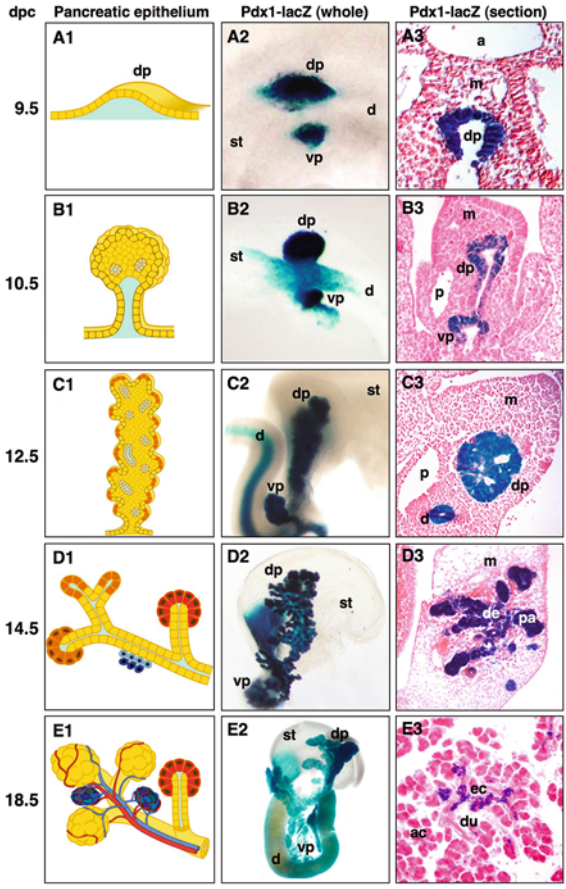

Fig. 1 Overview of pancreatic organogenesis. Schematics and photographs of embryonic pancreas depict development at stages indicated, from (**a**) bud evagination from the endoderm, (**b**) initiation of stratification or branching, (**c**) onset of the secondary transition, (**d**) exocrine and endocrine differentiation, and (**e**) the maturing anatomy of acinar, ductal, and endocrine tissues and associated vasculature just prior to birth. *Left* panels depict the pancreatic epithelium at each stage (mesenchyme not shown). Note the alternative models for dense branching (*left*) versus stratification and microlumen formation (*right*) of the epithelium at 10.5 (B1) and 12.5 dpc (C1). *Yellow*, pancreatic epithelium; *orange*, multipotent precursor cells (MPCs); *red*, differentiating acini; *light blue*, newly emerged endocrine cells; *dark blue*, maturing endocrine cells. *Middle panels* show whole mount views of Pdx1-expressing (*blue stain*) dorsal and ventral pancreatic buds. At 12.5–15.5 dpc, the pancreas is associated with the underlying stomach and duodenum. *Right panels* show sections through Pdx1-expressing epithelium (*blue stain*) surrounded by pancreatic mesenchyme (*pink eosin staining*). *a* aorta, *ac* acini, *d* duodenum, *dp* dorsal pancreas, *du* duct, *ec* endocrine cord, *m* mesenchyme, *p* portal vein, *pa* proacinus, *st* stomach, *te* tubular precursor epithelium, *vp* ventral pancreas

endoderm at the end of gastrulation. The endoderm evaginates (Fig. 1A1–2) at these two sites to form two epithelial buds encased in mesenchyme (Fig. 1A3; mouse 9.5–10 days post-coitum [dpc]; human 25–30 dpc) [4, 5]. The dorsal bud receives important inductive signals, first from the overlying notochord, then from the dorsal

aorta, and finally from the surrounding mesoderm. The ventral bud receives signals from adjacent splanchnic and procardial mesoderm, as well as from the septum transversum. All epithelial tissues of the pancreas derive from these two endodermal buds, which develop further via a dynamic signaling dialogue between the epithelium and the overlying mesenchymes. The dorsal bud generates the gastric and splenic lobes of the murine pancreas, while the ventral bud forms the extensive lobe that runs along the proximal duodenum. In the more compact human pancreas, the dorsal bud forms the head, body, and tail, and the ventral bud forms the uncinate process and inferior part of the head.

Shortly after budding (about 10.5 dpc), the pancreatic epithelium initiates dramatic morphogenetic changes including epithelial stratification and formation of microlumina [5–8] (Fig. 1B1–2). In rodents (but not in humans), the first differentiated endocrine cells appear at this time in the early dorsal bud. The period of bud formation with this early wave of endocrine cells in the rodent pancreas (9.5–10.5 dpc) has been termed the "primary transition" [8]. Slightly later, around 11.5 dpc (35–37 dpc human), both buds have grown and extended, the gut tube turns, and the organ primordia along its axis change their positions relative to each other. At this time, the ventral bud migrates with the bile duct dorsally around the duodenum, resulting in the fusion of the ducts of the dorsal and ventral buds. Whereas the dorsal and ventral pancreases of rodents retain their major ducts, the principal ducts in humans generally fuse to form a main pancreatic duct (of Wirsung) that connects through the ventral pancreas to the common bile duct, while a vestigial accessory duct (of Santorini) maintains its connection to the duodenum through the dorsal pancreas.

By embryonic day 12.5 (40–45 dpc human), cell proliferation has created a densely packed epithelium (Fig. 1C1–3) containing mostly progenitor cells for the islets, acini, and ducts. The number of progenitor cells in the epithelium at this stage determines the eventual size of the mature pancreas [9]. The microlumina have fused to generate a dynamic tubular plexus [10, 11] with second-wave endocrine cell production in the core and acinar cell formation, beginning around the periphery in nascent elongating epithelial tips [10] (Fig. 1C1). The onset of this new striking phase of morphogenesis is termed the "secondary transition" [8]. Subsequently, islet cells arise from regions of the epithelial "trunk" and acinar cells from replicating epithelial cells as the organ continues to expand (Fig. 1D1–3). Pancreatic acini have their own peculiar morphogenesis that is unique among mammalian exocrine glands. The simple tips of the growing epithelium thicken, enlarge, then engulf, and extend over the ends of the tubules, which become intra-acinar intercalated ducts (Fig. 1D1). Consequently, the termini of intercalated ducts extend into the center of the mature acinus [12]. These intra-acinar intercalated duct cells have been called centroacinar cells and have been postulated to possess stem or progenitor cell-like qualities [13].

Select cells within the interior plexus epithelium commit to islet-cell fate and then escape through a process similar to an epithelial-to-mesenchymal-like transition (EMT) [14]. The new islet precursor cells associate along the main pancreatic ducts and in close association with the major pancreatic blood

vessels. Thus, whereas acini and ducts remain within the topological integrity of the tubular epithelium, individual islet precursor cells delaminate from the epithelium (Fig. 1D1). After a short migration and likely still in contact with the underlying epithelium, these islet precursors coalesce into small amorphous cell clusters, reform epithelial contacts, and differentiate into one of five major cell types, each of which express one of the major pancreatic polypeptide hormones (insulin, glucagon, somatostatin, pancreatic polypeptide, or ghrelin).

Prenatal development continues the expansion of the tree-like ductal and acinar tissues and the maturation of islets **(**Fig. 1E1–3**)**. After the secondary transition (in mouse, after ~15.5 dpc), expansion of acinar tissue is predominately through acinar cell replication rather than de novo formation of acini. Extensive acinar cell cytodifferentiation occurs during this period and is marked by the polarization of cells with basal nuclei surrounded by extensive rough endoplasmic reticulum, a highly active Golgi apparatus, and the accumulation of dense secretory (zymogen) granules that fill the entire apical region of the cells. mRNAs encoding approximately 30 digestive enzymes and cofactors rise to very high levels and dominate the total mRNA population [15].

Maturation of the islet cell clusters of rodents occurs progressively, starting with the genesis of endocrine cells at the secondary transition, the gradual coalescence endocrine cells into cords, and the resolution of individual islets during late gestation and in the weeks after birth. The development of mouse islets is characterized by the formation of an α-(glucagon) cell mantle with interspersed δ-(somatostatin), ε-(ghrelin), and PP-(pancreatic polypeptide) cells surrounding a predominately β-(insulin) cell core. Prenatal replication of differentiated endocrine cells is infrequent, and the increase of endocrine tissue during embryogenesis is due almost exclusively to de novo formation from precursor cells in the tubules [11, 16, 17].

Postnatal growth and tissue maintenance occurs principally through proliferation of differentiated endocrine and exocrine cells. Replication of insulin-expressing β-cells begins shortly after birth and gradually decreases. Dividing β-cells are subsequently uncommon but sufficient to maintain β-cell mass [18, 19]. Similarly, acinar cell proliferation decreases postnatally [20, 21] but appears to be the sole source of acinar cell replacement in mature animals [22].

The common origin of islets, ducts, and acini from the duct-like epithelium of the embryonic pancreas underlies an intimate relationship between islets, ducts, and acini in the mature gland [23]. A greater understanding of the development of the endocrine and exocrine compartments, including their structural and physiologic relationships and the principal intrinsic and extrinsic molecular regulators that drive their formation, is important to our growing understanding of the origin and nature of diseases that affect them. Other recent comprehensive reviews: [5, 24, 25]. Here we address current research in the field of pancreatic developmental biology, as these fundamental processes often go awry in pathological conditions such as pancreatic cancer. Key developmental parameters are outlined below in Box 1.

Box 1 Key Research Points

- The acinar, ductal, and endocrine cells of the pancreas derive from a common progenitor cell population that evaginates from the posterior foregut endoderm.
- The budding pancreatic epithelium, encased in mesenchyme, first stratifies, then transforms into a tubular plexus of sufficient early progenitor cells to sustain subsequent development, and establish the final size of the pancreas.
- These multipotent progenitor cells initiate a secondary developmental that generates the acini, ducts, and islets.
- Cell proliferation propels epithelial growth outward, leaving behind precursors for duct and islet cells and forming acini at epithelial tips.
- Islet precursor cells delaminate from central regions of the epithelium, begin endocrine differentiation, and progressively aggregate to form islets.
- The pancreatic program of organogenesis is coordinated by a repeating interplay between extrinsic signals and intrinsic transcriptional regulators.
- Hedgehog, FGF, retinoic acid, Wnt, TGFb, BMP4, Notch, and Hippo cell-cell signaling pathways all contribute to the extrinsic control of pancreatic development.
- Extracellular matrix (ECM), cell adhesion, and integrin-mediated signaling are required for the 3D architecture of the pancreatic epithelium, which is in turn required for proper cell fate acquisition.
- Known pancreas-restricted transcription factors, in intrinsic regulatory networks, specify a pancreatic response to the widely used extrinsic signals.
- In turn, temporal changes in extracellular signals reformulate the transcription factor network in a stepwise manner to resolve cell lineages and control lineage-specific differentiation programs.

Overview of Extrinsic and Intrinsic Developmental Factors

The embryonic formation of all organs is regulated through the stepwise interplay between extracellular developmental signals (generally diffusible extrinsic growth factors, acting as inducers and morphogens) and intracellular mediators of developmental programs (e.g., transcription factors that bind and control specific target genes in a developmental program). Extrinsic factors (EFs) alter the interacting gene regulatory network of intrinsic transcription factors (TFs), which in turn adjusts the developmental state of a cell by changing the pattern of gene expression (Box 2). The induction of new regulatory proteins and the loss of others determine the developmental potential of the cell and its response to subsequent signals. Successive signals during a developmental program transform the transcriptional network of precursor cells in a stepwise manner, increasing cellular differentiation and limiting the developmental options in response to later signals. The program-specific response of a certain cell type to a common signal is

dictated by the nature of the signal and the developmental history of the cell – i.e., its lineage. The record of a cell's lineage is embodied in a particular collection of TFs, the interacting network they create, and their influence on chromatin architecture (Box 3). The network establishes the competence of the cell to respond to a signal and the nature of the response elicited. This chapter will focus on the nature of the extrinsic (intercellular signals) and intrinsic (mostly transcriptional regulatory proteins) factors for pancreatic organogenesis and the developmental processes they control.

Box 2 Extrinsic Developmental Factors (EFs): Cell-Cell Signaling Molecules

Cells and tissues send signals across extracellular space via extrinsic factors. The principal signaling pathways that control organogenesis include TGFbeta/BMP, Notch, Wnt, Hedgehog, receptor tyrosine kinase (FGF, EGF, IGF, and Eph) signaling, nuclear hormone, and JAK/STAT (Fig. 2). Each pathway regulates developmental decisions through the binding of an extracellular factor to a transmembrane receptor on a recipient cell. Binding to the receptor transduces an intracellular response into the recipient cell. The response is propagated as an intracellular signaling event that activates pathway-specific TFs to change gene expression patterns by binding and altering the transcription of a battery of target genes. Myriad extrinsic factors have been demonstrated to control developmental programs. Many of these cell-cell signaling factors have been termed "morphogens," which are secreted into the extracellular space and transmit their developmental effects to nearby cells in a concentration-dependent manner. Cells near a source are exposed to high levels of the morphogen and respond in one way, while cells farther away are exposed to lower levels and may respond differently. Extrinsic developmental factors can also act in a "relay" fashion. For example, a cell that secretes an extrinsic factor may induce a transcriptional response in a nearby responding cell, which reacts by secreting a second extrinsic factor that influences other neighboring cells or the initiating cell, and so on, in a signaling dialogue that alters either the fate of responding cells or their own signaling potential.

Other extrinsic signaling factors are molecules that are tethered to the cell surface and transduce signaling via direct cell-cell or cell-ECM communication. The former category includes cell adhesion molecules, such as adherens junction and tight junction components, which mediate cell-cell adhesion; the latter category includes a wide range of ECM-binding molecules including integrins. A common feature of adhesion modulators is that they are generally tethered to the cytoskeleton and have the ability to transduce a range of signals, from ligand-based to mechanical stimuli.

Extracellular (or extrinsic) signaling molecules are "cell non-autonomous" factors. In other words, they generally regulate genes/responses in recipient cells, rather than in the cells that produce them. "Cell non-autonomy" is a genetic designation indicating the effect of mutations in a gene affects neighboring cells rather than the cells that produce the gene product.

Box 3 Intrinsic Developmental Factors: DNA-Binding Transcription Factors (TFs)
Gene regulatory proteins with the ability to recognize and bind short DNA sequences play the central role in controlling the spatial and temporal transcription of developmentally regulated genes. Once bound to a regulatory site in a promoter or enhancer, these proteins recruit chromatin-modifying enzyme complexes or additional TF complexes that initiate or maintain transcription or, in some instances, do both of these in a stepwise fashion. TFs are often composed of discrete structural domains with specialized functions. A simple DNA-binding TF usually contains a discrete DNA-binding domain, a dimerization domain (TFs often function as homo- or heterodimers), and a transactivation domain (which interacts with the general transcriptional machinery). Approximately 1,300 genes in a typical mammalian genome encode DNA-binding TFs, classified by structural homologies into approximately 30 families of factors. The major families are classified as zinc finger (ZF), basic helix-loop-helix (bHLH), homeodomain (HD), basic leucine zipper (bZip), nuclear receptor (NHR), high-mobility group (HMG-box), Tbox, ETS/IRF, and Forkhead factors. Members of each of these families play prominent regulatory roles in organ development through the genes they bind and control. Many establish the developmental status of cells and determine temporal and stage-specific changes in gene expression in response to extrinsic signaling molecules. Others are the transcriptional effectors of extrinsic signaling pathways.

Remarkably, the genesis of the great diversity of cell types, their integration into distinct complex tissues, and the assembly of tissues into unique organs are directed by a few signaling pathways, each of which is used in the formation of most, if not all, organs. Usually, a single DNA-binding TF (although sometimes a few related factors) specific to a pathway binds target gene promoters and alters their activity in response to the activation of that pathway. There are seven principal developmental signaling pathways, each with their specific transcriptional mediators (Fig. 2).

1. The transforming growth factor-β family (TGFβ/activin/BMP/GDF) pathway with Smad TFs. The TGFβ pathway is generally subdivided TGFβ/activin/Nodal, which use Smads 2 and 3, and BMPs, which use Smads 1, 5, and 8. (Note: the names for genes and proteins are distinguished with italics for genes.)
2. The Hedgehog (HH) pathway with Gli TFs.
3. The Wnt pathway with Lef/Tcf TFs.
4. The Notch pathway with Rbpj.
5. Nuclear hormones with intracellular hybrid receptors.
6. Receptor tyrosine kinase (RTK) pathways with a wide variety of extracellular ligand families (such as fibroblast growth factors (FGFs), epidermal growth factor (EGF), Eph-ephrins, and many more) and downstream transcriptional mediators.

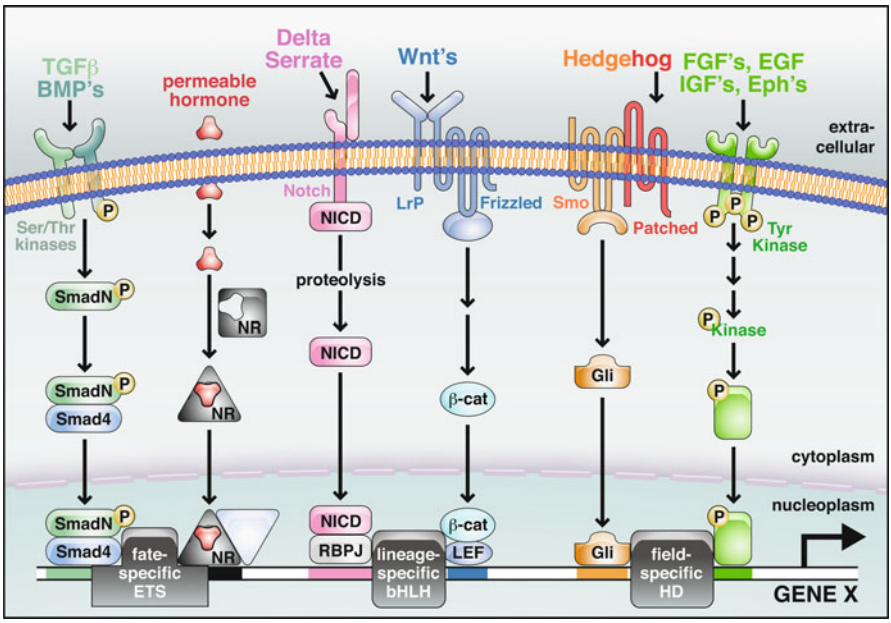

Fig. 2 Major developmental signaling pathways. Pathways from *left* to *right*: TGFβ/BMP, nuclear hormone receptor (with permeable hormones), Notch, Wnt, Hedgehog, and tyrosine kinase receptors for fibroblast growth factors (FGFs), epidermal growth factor (EGF), insulin-like growth factors (IGFs), and Eph/Ephrins. The key to a unique cell-specific outcome (e.g., activation of Gene X) of signaling by a commonly used pathway lies in the developmental history of the responding cell, which is embodied in a specific collection of lineage-specific and spatially restricted transcription factors, such as members of the ETS, bHLH, and homeodomain transcription factor families. Although all pathways discussed in the text are shown, all are not likely to act on the promoter of a single gene

7. The Hippo-Warts pathway, which includes kinases Mst1/Mst2 (hippo) and Lats1/Lats2 (warts) upstream of the transcriptional coactivators Yap and Taz (yorkie orthologues), which bind the transcription factors Tead1/Tead2.

Each of these pathways is critical to proper pancreatic development.

Extrinsic Factors: Cell-Cell Signals

Extrinsic signaling cues regulate multiple aspects of pancreatic organogenesis [26]. These signals are usually transient, are sequential, and frequently have opposing effects at different developmental stages. In particular, several prominent signaling pathways have inhibitory effects on the primary transition and must be kept in check for the pancreatic primordia to be specified [27]. Not only has this phenomenon been observed by experimental embryologists but it is increasingly translated

in efforts to direct the differentiation of PSCs toward pancreatic fates, the protocols for which include application of several pathway inhibitors [28]. Understanding the molecular basis of EF action in the pancreas is a challenge, particularly given the potential for redundancy, the changing responses with age and differentiation state, and the overall cellular complexity of an organ in which multiple cell types engage in paracrine and autocrine interactions. Knowledge of the roles of EFs is important not only for efforts to program pancreatic fates in PSCs but also for understanding pancreatic neoplasia, as most cancers of the pancreas are associated with the dysregulation of these bioactive molecules [29–34].

Here, we introduce those EF signaling pathways known to regulate pancreatic organogenesis. We briefly describe the molecular components that constitute the canonical pathways leading to transcriptional changes in responding cells (Figs. 2 and 4) and provide a specific example for each pathway in pancreatic development.

- Transforming growth factor-β (TGFβ) signaling is based on the binding of secreted extracellular ligands to single-pass transmembrane serine/threonine kinase receptors on responding cells [35]. Ligands in this large family include subfamilies of TGFβs, activins, bone morphogenetic proteins (BMPs), and growth and differentiation factors (GDFs). Ligand-binding induces the heterodimerization of type I and type II receptors. Upon heterodimer formation, the type II receptor phosphorylates and activates the type I receptor, which then transduces the signal by phosphorylating a member of the Smad family of transcription factors. Three types of Smad proteins mediate the transcriptional effects of TGFβ signaling within the responding cell: the receptor-regulated Smads (R-Smads), the common mediator Smads (co-Smads), and the inhibitory Smads (I-Smads). The early specification of the definitive endoderm, from which the pancreas and other gut organs arise, is driven by activin/Nodal-family signaling during gastrulation [36, 37], and PSC differentiation to pancreatic fates requires early exposure to these ligands [28, 38].
- Hedgehogs (HHs) compose a family of secreted signaling proteins that include Sonic (Shh), Indian (Ihh), and Desert (Dhh) hedgehogs, all of which bind a 12-pass receptor subunit called Patched 1 (Ptc 1) [39]. The binding relieves Ptc1-mediated repression of Smoothened (Smo), which is a G-protein-like membrane-associated signaling molecule that transduces intracellular signaling to the nucleus via the Gli family of TFs. Among the earliest detectable steps of pancreas development is downregulation of Shh specifically in the prepancreatic endoderm, induced in the dorsal pancreas by signals from the overlying notochord [40–42]. Loss of Ptc1, resulting in constitutive HH signaling, abolishes pancreas specification. Consistent with a critical role for HH inhibition in early pancreas development, inclusion of the Smo antagonist cyclopamine is essential for directed differentiation of mouse and human PSCs to pancreatic fates [28, 43].
- The Wnts (Wingless/int) are a family of secreted glycoproteins that control cell proliferation, asymmetric cell division, and cell fate [44, 45]. Wnts transduce signaling to responsive cells by binding Frizzled receptors and a variety of co-receptors, such as LRP5/LRP6, RORs1/RORs2, or Ryks. Signaling

downstream of the receptor is transduced via two alternative pathways, roughly categorized as either "canonical" or "noncanonical." The latter includes both the Ca^{2+} signaling pathway (Ca/G-protein/PKC pathway) and the planar cell polarity (or PCP) pathway (frizzled/Rho/JNK). For the canonical pathway, binding of Wnts to a Frizzled/LRP complex leads to stabilization of cytoplasmic β-catenin, which activates target genes by interaction with LEF/TCF family transcription factors. In unstimulated cells, β-catenin levels are kept in check by a cytoplasmic "destruction complex" that includes the proteins APC, Axin, and the serine/threonine kinase GSK3; Wnt binding to Frizzled and LRP5/LRP6 induces inhibition of this complex, allowing accumulation of signaling-competent β-catenin protein. Wnt/β-catenin provides a striking example of the context-dependent actions of EFs in the pancreas, whereas this pathway must be inhibited early; to allow pancreas specification during the primary transition [46, 47], it acts during the secondary transition and after to promote progenitor and acinar cell expansion [47–51].

- The Notch family of receptors mediate juxtacrine signaling, i.e., between immediately adjacent cells [52, 53]. The extremely short range of Notch signaling activity is dictated by an idiosyncrasy of the pathway: both the receptors (Notches) and ligands (Deltas and Jaggeds) are single-pass transmembrane proteins, and activation of the receptor requires active "pulling" by the ligand-producing cell. Intracellular signal transduction is very simple (Fig. 2): after ligand binding and pulling, the Notch receptor is cleaved to release an intracellular portion that enters the nucleus, binds the transcription factor Rbpj, and converts it from a repressor to an activator by recruiting cofactors of the Mastermind-like (MAML) family. Key target genes include the Hes subfamily of bHLH repressor factors, which bind and suppress the transcription of pro-differentiation genes. Notch signaling acts as a binary switch to control two general functions critical to many developmental programs [53]. In some instances, it promotes the expansion of a progenitor cell population by suppressing the decision to begin differentiation; in others, it controls the decision of cells in a population to choose one cell fate at the expense of others. During pancreatic development, Notch signaling performs both developmental functions: it promotes expansion of the progenitor population prior to the secondary transition, while during the secondary transition, it acts in a stepwise fashion to divert cells away from acinar and endocrine fates and toward duct differentiation [54–58].
- Retinoic acid (RA), the active metabolite of vitamin A, binds two types of nuclear receptors, the retinoic acid receptors (RARs) and the retinoid X receptors (RXRs) or co-receptors, which form heterodimers that translocate to the nucleus to control the transcription of genes containing RA responsive elements (RAREs) [59]. RA is the simplest signaling pathway; its receptor is also the DNA-binding TF that mediates transcriptional control. RA is synthesized from circulating retinol (vitamin A), via an enzymatic pathway including retinaldehyde dehydrogenases (Raldh). Raldh2 is present early and widely during embryonic development [60] and is absolutely required for specification of the dorsal pancreas [61, 62].

Not surprisingly, treatment with RA is a critical step in directed differentiation of PSCs to pancreas [28, 43].

- Receptor tyrosine kinases (RTKs) mediate signaling from numerous families of growth factors, such as FGFs, EGFs, insulin-like growth factors (IGFs), vascular endothelial growth factors (VEGFs), platelet-derived growth factor (PDGF), ephrins, and many others [63]. The cellular outcomes of RTK signaling span a wide range of cell behaviors, including cell proliferation, migration, morphogenesis, cell fate choices, and cell survival. RTKs are single-pass transmembrane receptors, which often hetero- or homodimerize, usually cross phosphorylate each other, and then transduce signaling within the responding cell via multiple pathways, the most prominent of which is the RAS/RAF/extracellular signal-regulated kinase (ERK) cascade. The RTK ligand Fgf10 is particularly critical for pancreas development, being required for proliferation of pancreatic epithelial progenitor cells and maintenance of their organ identity [64, 65].
- The Hippo-Warts signaling pathway controls organ size and is highly conserved from flies to mammals. Key components of this pathway include a kinase signaling cascade, composed of the MST1/MST12 (Hippo orthologues) and LATS1/LATS2 kinases (Warts orthologues), as well as their downstream transcriptional co-activators yes-associated protein (YAP) and its paralog TAZ [66]. Upon phosphorylation, YAP and TAZ are retained in the cytoplasm; however, in the absence of phosphorylation, they are translocated to the nucleus where they interact with the Tea-domain (TEAD) family of transcription factors. Together, YAP/TAZ and TEAD factors stimulate cell proliferation and survival [67]. Deletion of *Mst1/Mst2* in the developing mouse pancreas results in reduced organ mass resulting from postnatal de-differentiation of acinar cells [68]. Ectopic expression of YAP similarly blocks differentiation. Together these findings underline an important role for this family of regulators during pancreas morphogenesis and cell fate lineage allocation.

These extrinsic factors play critical roles in the development of most embryonic organs, including the pancreas, although the effects of any given EF will depend on the developmental status of the recipient cell and may not be consistent throughout organogenesis. As we discuss the different stages of pancreas development in detail, we will review experimental evidence elucidating the diverse roles of the above EFs, including examples where the same factor has seemingly opposite effects.

Intrinsic Factors: DNA-Binding Transcription Factors

The key transcription factors (TFs) that pattern the endoderm, specify and maintain pancreatic fate, and resolve the individual pancreatic cell lineages are known. A model for the pancreatic lineage with associated TFs is shown in Fig. 3. For example, the Forkhead box A2 factor (Foxa2/Hnf3b) controls the formation of the anterior endoderm during gastrulation, the HD protein Mnx1/Hlxb9 participates in endoderm patterning and cell-lineage specification within the pancreatic domain, the

bHLH factor Neurogenin3 (Ngn3) specifies endocrine cell identity, and the bZip proteins MafA and MafB control the final stages of β-cell differentiation. It is important to note that some of these intrinsic factors play critical roles at more than one developmental stage.

In this regard, four TFs merit special mention. The HD factors hepatocyte nuclear factor 1 beta (Hnf1b) and pancreas duodenal homeobox (Pdx1), the bHLH protein pancreas transcription factor 1a (Ptf1a), and the HMG factor Sry-box9 (Sox9) perform distinct regulatory functions at early, middle, and late stages of development. Hnf1b is crucial for essentially every step of pancreas development, including specification of the pre-pancreatic endoderm, growth and branching of the precursor epithelium, development of duct and acinar cells, and initiation of the islet cell genesis [69, 70]. Mouse embryos and human fetuses homozygous deficient for *Pdx1* [71–73] or *Ptf1a* [74–76] do not form a pancreas. Although neither Pdx1 nor Ptf1a is required for the formation of the initial pancreatic buds at 9.5 dpc, both are necessary for the growth, branching morphogenesis, and the transition to the protodifferentiated state. Pdx1 controls the formation and growth of the protodifferentiated cell population; is required at the secondary transition for the formation of the acinar, ductal, and islet cell lineages; and later controls the differentiation and maintenance of β-cells [77–79]. Ptf1a maintains pancreatic identity in the nascent buds, sustains precursor cell growth of the early epithelium, defines the multipotent precursor population that initiates the secondary transition, and later controls the differentiation of acinar cells and maintenance of the mature acinar phenotype [74, 79–82]. Sox9 induces and maintains pancreas identity during organ specification, maintains the undifferentiated state of precursor cells during the primary and secondary transition, and is necessary for proper duct and endocrine cell development [65, 83–86]. As we will discuss, the ability of each of these factors to exert such diverse effects reflects their ability to act in collaboration with additional stage- or cell-specific TFs.

The TFs at the ends of signal transduction pathways (Fig. 2) are the intrinsic mediators of transcriptional control by extrinsic signaling factors. The signaling pathway TFs are thought to collaborate with stage- and lineage-specific TFs in two ways. One is by binding and activating the promoter of a gene encoding a stage- or lineage-specific TF to produce that factor at a specific time and place. The other way is to cooperate with stage- and lineage-specific factors by binding together on the promoter or transcriptional enhancer of a developmentally regulated gene (Fig. 2).

The cooperation of lineage-specific and signaling pathway TFs is the basis for the ability of a signal for a widely used transduction pathway to activate a particular gene in a unique developmental context (Box 4). In general, gene enhancers and promoters require the binding and cooperation of several DNA-binding TFs to be activated. The binding of the transcriptional mediator of a signaling pathway alone is insufficient for activation. This makes sense; otherwise activation of a pathway would induce in a cell the expression of all possible genes regulated by that pathway for all developmental programs. In a complementary fashion, the binding of stage-/lineage-specific transcriptional activators alone is also insufficient. Otherwise, developmental programs would initiate and continue in the absence of extrinsic control

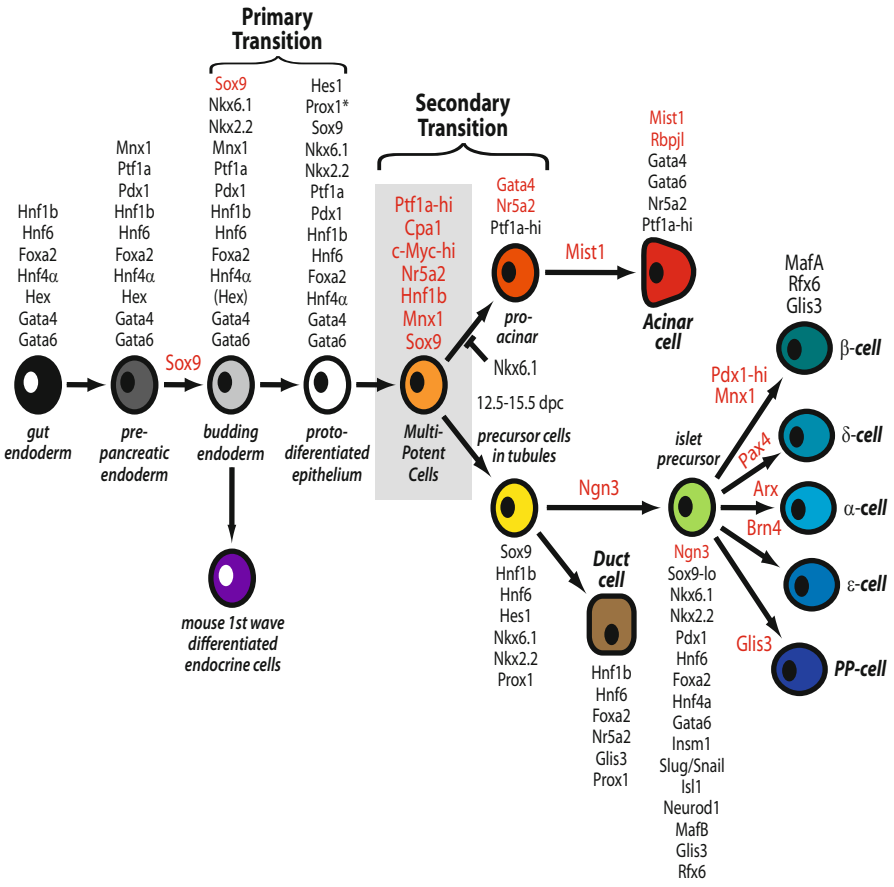

Fig. 3 Primary transcriptional regulators of pancreatic development. Regulatory TFs discussed in the text are listed in association with the progression of cellular commitment and differentiation. Key TFs that appear at a particular stage and likely control the transition to that stage are in *red*. The multipotent precursor cell (MPC) state is highlighted with a *gray* background. The composition of TFs for the first-wave endocrine cells is not listed but is similar to those for the second-wave α- and β-cells. The list of factors is not comprehensive; for example, not all the TFs that distinguish the islet cell types are listed, and some assignments to intermediate cell types are tentative and need confirmation. Prox1*: transient affect on progenitor cells

without regard to correct timing and position in the embryo. Thus, to activate a particular developmentally regulated gene properly, a cell must have the correct history embodied in the presence of the signaling pathway receptor, chromatin markings from a pioneer factor, *and* the appropriate stage-/lineage-specific TFs. The cell also must be in the correct position to receive an effective concentration of the extrinsic signaling molecule released from nearby cells. In turn, for proper regulation, a gene must have a promoter or enhancer with a pre-activation chromatin mark from a pioneer factor and the nucleotide sequences for binding both the

transcriptional mediator of the signaling pathway(s) as well as appropriate stage-/lineage-specific TFs of that developmental program.

Box 4 Extrinsic and Intrinsic Developmental Pathways Converge at the Promoters and Enhancers of Developmentally Regulated Genes

Many, but not all, effects of extrinsic factors on responding cells are transcriptional changes of target genes. The effectors of transcriptional change are the intrinsic, pathway-specific TFs at the end of signaling pathways for extrinsic factors. In many instances, the absence of signaling maintains the pathway-specific TF as a repressor, which keeps target genes firmly off, by recruiting a corepressor [1]. Receipt of a signal converts the transcription factor into an activator, which initiates target gene transcription. For example, in the absence of Wnt ligands, the pathway transcription factor Lef/Tcf is bound to target gene promoters and recruits corepressor proteins that repress transcription. Binding of a Wnt to Frizzled diminishes the destruction of a cytoplasmic structural protein, β-catenin, which then accumulates to a higher level. The increased pool of β-catenin causes some of it to relocate to the nucleus, where it binds Lef/Tcf and either displaces the corepressor or overcomes its action by recruiting coactivators. The change from repression to activation establishes rigorous ON/OFF transcriptional control of target genes necessary for dramatic changes in gene expression.

However, the activation of a pathway-specific TF, such as Lef/Tcf, alone is generally not sufficient to initiate transcription of a developmentally regulated gene. Other TFs already assembled at the promoter are necessary to complement the action of the pathway factor. In this context, the intrinsic lineage- or stage-specific TFs alone are also insufficient to activate transcription. Thus, gene enhancers and promoters with gene-specific combinations of binding sites for pathway-specific and lineage-specific factors act as genetic microprocessors to control developmentally regulated genes (Fig. 2). Thus, the spectrum of genes activated in response to a signal depends on the lineage history of the recipient cell, which is manifested in its set of stage/lineage-specific TFs.

The Roles of Extrinsic and Intrinsic Factors During Pancreatic Development

Here we divide embryonic pancreatic development into four temporal stages and review the roles of extrinsic and intrinsic factors in distinct cellular or morphogenetic events that occur during these stages:

1. Specification of endodermal domains to pancreatic fate (mouse 6.5–9 dpc; human 22–31 days)

2. Initial growth of pancreatic buds and the primary developmental transition (mouse, 9–12 dpc; human, 30–45 days)
3. Onset of acinar, ductal, and islet development by the secondary developmental transition (mouse, 12.5–15.5 dpc; human, 8–18 weeks)
4. Perinatal growth and differentiation (mouse, 16 dpc to neonate; human 20 weeks to neonate)

Specification of Endodermal Domains to Pancreatic Fate

Early Endoderm and Gut Tube Formation

The pancreas forms from the embryonic definitive endoderm, one of three germ layers that emerge during gastrulation (the ectoderm and mesoderm are the others). The ectoderm gives rise to the nervous system and the epidermis; the mesoderm to the muscle, heart, kidney, blood, vasculature, and gut mesenchyme; and the endoderm to the lining of the entire gastrointestinal system, including most organs along its length, such as the pharynx, thyroid, lungs, liver, stomach, pancreas, and intestine. The mouse endoderm emerges from the primitive streak and forms a single epithelial sheet of approximately 500–1,000 cells [87]. As the embryo takes shape, the epithelial sheet rolls up into a primitive gut tube, which runs along the anterior to posterior axis of the embryo. A thick layer of splanchnic mesoderm adheres to the gut tube endoderm during this early phase of morphogenesis, inducing and supporting endodermal proliferation, morphogenesis, and differentiation.

Broad patterning of the definitive endoderm begins as it forms during gastrulation and is based on the timing of the movement of the pre-endodermal epiblast cells through the primitive streak [88, 89]. The first presumptive endodermal cells exiting the primitive streak become the most-anterior and most-posterior endoderm, followed by cells that form the middle endoderm and the rest of the posterior endoderm. During the passage of cells through the primitive streak, signaling by Nodal (a member of the extended TGFβ/BMP family of morphogens) preferentially establishes the anterior foregut endoderm in part through the induction of Foxa2, a Forkhead TF also important for subsequent endodermal organogenesis [90]. Embryos deficient in Smad2, a TF mediator specific to the TGFβ/activin/nodal subfamily of extrinsic signals, fail to generate endoderm properly [36]. This pathway of definitive endoderm induction was first described in fish and frog [91], and its deep conservation across vertebrates is highlighted by the fact that induction of definitive endoderm from human pluripotent stem cells (PSCs) requires treatment with Nodal or the related Smad2-/Smad3-activating ligand activin [28].

Anteroposterior Patterning of the Endoderm

The broad developmental domains of the early definitive endoderm resolve progressively to form the pharynx, esophagus, stomach, intestine and colon, and the glands that bud off the gut tube during organogenesis (the submandibular and sublingual glands, thyroid, parathyroid, trachea, lungs, liver, and pancreas). Although the early

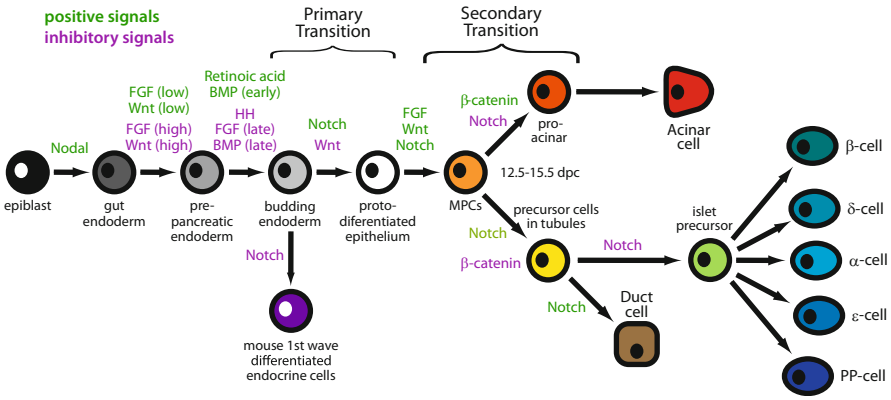

Fig. 4 Cell-cell signaling during pancreatic development. The lineages of the developing pancreas are depicted as in Fig. 3. Key signaling factors that control specific developmental transitions are indicated in *green* or *purple*, according to whether they promote or inhibit those transitions. Notably, the direction of a given signal can change dramatically at different times and with different concentrations. For example, canonical Wnt signaling is required at low levels for the specification of the pre-pancreatic endoderm but inhibitory at high levels. Wnt must thereafter be downregulated to allow the primary transition to occur but then is reactivated to promote proliferation of MPCs

endoderm appears morphologically homogeneous prior to the onset of organogenesis, it is in fact patterned along its anteroposterior axis.

How is the broad anteroposterior regionalization of the nascent endoderm refined? The regional expression of lineage-specific intrinsic factors is established through complex, extrinsic signaling from the mesoderm to the underlying endoderm and back again [91]. For example, the endoderm is patterned in a concentration-dependent manner by FGF and Wnt signals produced by adjacent mesoderm (Fig. 4). In experiments with mouse and chick embryos, using explant culture and bead implantation, exposure to high levels of FGF4 promotes posterior (intestinal/hindgut) fate, whereas lower levels allow more anterior cell fates including *Pdx1*-expressing pancreas [92, 93]. This extrinsic FGF signal acts directly on cells of the endoderm (rather than indirectly via the mesoderm), as expression of a constitutively active FGF receptor (FGFR1) in the endoderm also leads to the same anterior expansion of *Pdx1* expression. The posterior mesoderm also appears to be a source of Wnt ligands that promote intestinal (hindgut) development while repressing foregut fates including pancreas and liver. This is revealed in knockdown and overexpression experiments targeting the canonical β-catenin pathway in zebra fish and frog [94, 95]. Interestingly, directed differentiation experiments in human PSCs indicate that the effects of Wnts on endoderm patterning, similar to those of FGF, are concentration dependent, with low levels actually enhancing pancreas fate specification while high levels inhibit it [96].

Several transcription factors with restricted expression cooperate with developmental signaling to control regional identity along the endoderm. The foregut

endoderm expresses regulators of anterior developmental programs not found in posterior endoderm, such as the HMG-box factor Sox2 and the HD proteins Six, Nkx2.1, and Hex. Six and its coactivator Eya1 pattern a subregion of the pharyngeal endoderm for thyroid and parathyroid formation [97]. Sox2 and the HD factor Nkx2.1 play reciprocal roles in resolving the esophagus and trachea: Sox2-deficient esophageal endoderm acquires a tracheal phenotype including ectopic *Nkx2.1* expression, and Nkx2.1-deficient tracheal endoderm initiates a partial esophageal developmental program, including ectopic *Sox2* expression [98, 99]. The HD factor Pdx1 is first restricted to the initial domains of the prepancreatic buds and then expands to include the proximal duodenum and the distal stomach [72]. The HD factors Cdx1 and Cdx2 establish the intestinal region of the gut tube distinct from the stomach and more anterior regions and are excluded from the pancreatic domain [100, 101].

Initiation of Pancreatic Fate and Morphogenesis

Soon after early endodermal gut tube formation, the first morphological sign of pancreatic development is a local thickening and evagination of the dorsal midline endoderm at about E8.75 in the mouse and during the fourth week of gestation in humans. Cells within the thickening epithelium change from cuboidal to columnar, which drives the growth of a small fin-like evagination. Approximately 12 h later, as the anterior intestinal portal closes over the pancreatic domain, the ventral pancreatic evagination becomes evident. The dorsal pancreatic bud emerges just caudal to the developing stomach, and the ventral bud appears just caudal to the developing liver, near the base of the primordium of the common bile duct. Some mammals are thought to form a single ventral bud (rat and human), whereas others have two clear ventral buds (frogs and chick). In mouse, a second ventral bud is present transiently [40, 102].

These morphological changes are prefigured by changes in gene expression, in particular the downregulation of *Shh* and upregulation of *Pdx1* within the future dorsal and ventral pancreatic buds [40, 42, 103, 104]. Although *Pdx1* itself is required for the outgrowth of the pancreatic epithelium after budding, rather than budding itself [72], its early expression provides a convenient marker for the process of pancreas specification. Several TFs and EFs have been found to be essential for the initial events of pancreas specification, in several cases acting differently between the dorsal and ventral primordia. The SRY-box TF *Sox17* and the homeodomain TF *Hnf1b* are required for both pancreatic buds, with defects manifesting at the initial stages of *Pdx1* expression [105, 106]. By contrast, the homeodomain TF *Mnx1/Hlxb9* and the Zn-finger TF *Gata4* are required selectively for specification of the dorsal and ventral pancreata, respectively [107, 108]. Similarly, the earliest requirement for the bHLH TF *Ptf1a*, which plays multiple roles in pancreas development, appears to be the determination of ventral *Pdx1*+ endodermal cells to a pancreatic fate; in its absence, these cells are respecified to the duodenum and bile duct, "next-door neighbor" organs relative to the ventral pancreas [74, 79]. Reciprocally, misexpression of *Ptf1a* is sufficient to induce *Pdx1* expression, and

ectopic pancreas development, from endodermal tissue outside the normal pancreatic domain [80, 109].

While it is not yet clear why different TFs are required for initiation of the dorsal and ventral buds, it is possible that these factors act in collaboration with extrinsic factors whose activity differs between dorsal and ventral endoderm. For example, chick and mouse studies have identified the notochord and dorsal aorta as providing critical early cues for dorsal, but not ventral, pancreas specification [40, 41, 110, 111]. Shortly after these interactions, the lateral plate mesoderm migrates around the endoderm to provide additional signals for dorsal bud formation. Among these is retinoic acid, synthesized by mesodermal Raldh2 and required for dorsal, but not ventral, bud development [61, 62]. Interestingly, retinoic acid treatment is an essential step in the directed pancreatic differentiation of human pluripotent stem cells, indicating that this process may model dorsal bud development specifically [28, 43]. Dorsal pancreas agenesis is also observed in *Isl1* mutant mice, reflecting a cell non-autonomous requirement for this TF in the lateral plate mesoderm [112]. By contrast, initiation of the ventral, but not dorsal, pancreas depends on signaling through Smad4, mediating a narrow window of pro-pancreatic BMP signaling [113].

In addition to positive signals that promote its development, the pre-pancreatic endoderm is vulnerable to an array of inhibitory signals that must be evaded for specification to occur. Prominent among these is the HH pathway, downregulation of which is obligatory for pancreas development in vivo [41], as well as elaboration of pancreatic cell types from human PSCs in vitro [28, 43]. BMP and FGF signaling, which have positive roles in pancreas specification as noted above, are also major negative regulators of ventral pancreas specification. Emanating from the precardiac mesoderm and septum transversum, these signals promote liver development at the expense of pancreas [114, 115]. If cells fated to the ventral pancreas are unable to move away from these influences, as occurs in mice lacking the endodermal TF *Hex*, they are diverted to a liver fate [116]. The remarkable changes in the endodermal response to FGF and BMP signaling [113] are not unique to these pathways, or to early specification; as we will see, analogously variable response to Wnt and Notch signaling is observed at later stages of pancreas development. Indeed, a great deal of current efforts in the field of pancreatic studies involves elucidating the sequential exposure of pancreatic progenitors to extrinsic positive and negative cues, including WNT, FGF, and Notch signaling and their influence on cell lineage allocation (Fig. 4).

Initial Growth of Pancreatic Buds and the Primary Developmental Transition (9–12 dpc)

The early phase of pancreatic development, or the "primary transition" (Fig. 5), involves growth of the epithelium, the appearance of a few differentiated "first-wave" endocrine cells in rodents, and the formation of a lumen. The nascent bud first forms a complex, stratified epithelium containing a pool of progenitor cells of

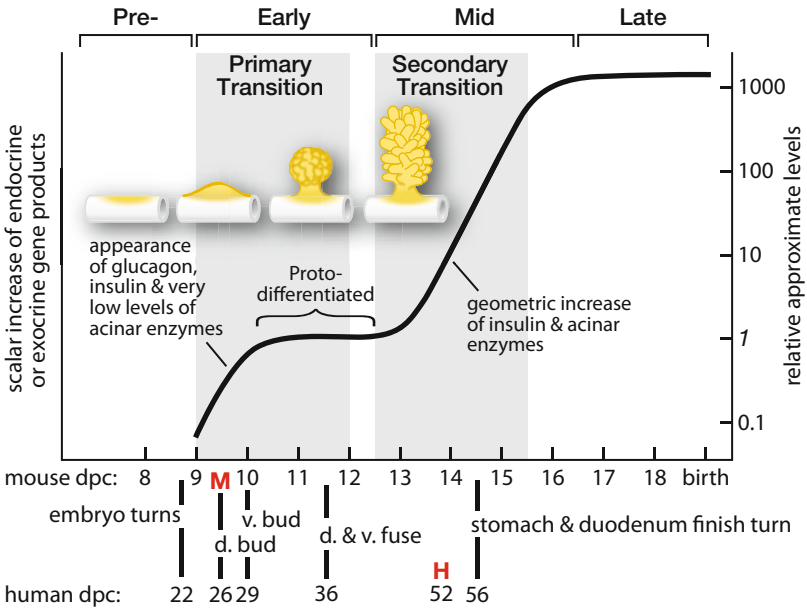

Fig. 5 The primary and secondary transitions of pancreatic development. The primary and secondary transitions were originally defined by William Rutter, Raymond Pictet, and their colleagues on morphologic criteria [8] and biochemical quantification of the products made by differentiated endocrine and exocrine cells [157, 267, 268]. The primary developmental transition marks the appearance of very low levels of acinar digestive enzymes (principally Cpa1) and the first-wave glucagon-gene, and subsequently insulin-gene, expressing cells. The secondary developmental transition spans the geometric increase of acinar digestive enzymes and insulin. Human pancreatic development has a primary transition that forms a protodifferentiated epithelium, but not first-wave endocrine cells. Human development also has a secondary transition stage, but it does not begin at the same time in all regions of the larger pancreatic rudiment and so appears much less concerted than the rodent transition [269]. The first endocrine cells appear in the primary transition at 9 dpc in mouse embryos (*red* M) and at about 50 dpc during the extended secondary transition in human fetuses (*red* H)

sufficient size to allow the proper transformation of the pancreas into a tubular tree-like organ at the "secondary transition," with its array of islet, ductal, and acinar tissues. Here, we describe the cellular events that define the developmental progression of the dorsal pancreatic epithelium during the primary transition. Interestingly, within the last half decade, improved imaging and immunofluorescent techniques have significantly advanced our understanding of pancreatic morphology and development, allowing unprecedented elucidation of cellular events during pancreatic bud ontogeny.

Epithelial Microlumen Formation

Prior to budding, the endoderm destined for dorsal pancreas transforms from a flat, thin, and simple cuboidal epithelium (Fig. 1a) to a thickened columnar epithelium that begins to acquire multiple layers [10]. It is this localized growth that initiates

budding of the epithelium into a fin-like structure. As growth continues, the neck of the bud constricts and the bud takes on a fist-like appearance, containing a compact epithelium surrounded by mesenchyme. During this externally visible bud development, dramatic changes are occurring within the epithelium. Indeed, it was noted over a decade ago that small isolated lumens, termed microlumens, opened between cell layers, which were proposed to constitute an initial event in the formation of branches [7]. This epithelial mechanism for tubular network formation is also found in the development of the exocrine pancreas of zebra fish [6]. In this species, the branched ductal epithelium arises from the formation of microlumens within a stratified epithelium, and their subsequent fusion creates the branching ductal tree. Recent studies have now demonstrated that microlumen fusion initiates pancreatic branching in mammals as well [10, 11, 117].

Ductal Plexus Formation

The appearance and interconnection of microlumens within the epithelium rapidly form a three-dimensional network of ductal tubules (Fig. 6). Recent work has shown that this plexus forms in the stratified region of the developing pancreas epithelium, referred to as "trunk" or "body" cells [10, 24, 118]. This region has further been identified as the niche where endocrine progenitors later arise [11]. Disruption of expression of the endocrine progenitor factor Neurog3 or inhibition of Notch signaling results in defects in both ductal plexus remodeling and differentiation of endocrine cells. Interestingly, ablation of *Pdx1*, which has long been known to be

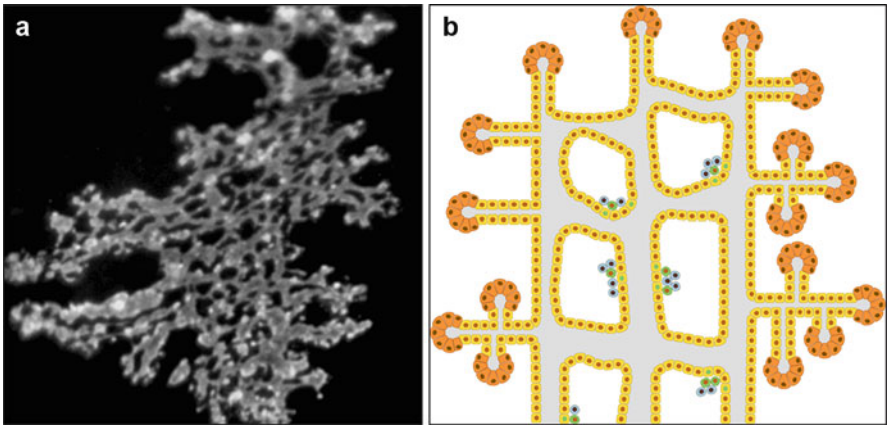

Fig. 6 At the cord of the midgestation embryonic pancreas is a transient ductal plexus, where endocrine cells are generated. Microlumina form within the stratified epithelium of the early pancreatic bud, which then fuse into a 3D ductal plexus. In the core region of this plexus, endocrine progenitor cells express Ngn3 and then delaminate from the epithelium to generate endocrine lineages. *Yellow*, precursors in the tubules for duct and islet cells. *Orange*, pro-acinar tip cells. *Green nuclei,* scattered cells in the tubules initiate *Ngn3* expression. *Green cells* have escaped the epithelium and begun the islet cell developmental program. *Light blue*, differentiating endocrine cells that have initiated the synthesis of an islet hormone. *Gray*, epithelial lumen cavity

required for both acinar and endocrine fate in the pancreas, also results in significant defects in the pancreatic epithelial architecture, with complete failure in the maintenance of the fine plexus of ductal lumens and reduction of E-cadherin levels [119]. Hence, epithelial architecture has been proposed to be intimately linked to differentiation of pancreatic lineages, including both endocrine and exocrine lineages.

Epithelial Reorganization and Regionalization

The defining characteristics of ductal plexus formation are the initiation of regionalized and distinct changes of cell shape and behavior. While microlumens are forming and connecting within the bud core, cells at the periphery, termed "cap cells," acquire a distinctly columnar appearance [10]. The cap cells are both $Sox9^+$ and $Ptf1a^+$ and become allocated to "tip" domains and ultimately an acinar fate. Cells within the trunk-like interior epithelium are $Nkx6.1^+$, $Sox9^+$, and $Hnf1b^+$ and constitute bipotent ducto-endocrine progenitors [120]. Shih and colleagues find that cap cell specification is induced by ECM-integrin activation of FAK/Src signaling, which controls actomyosin and suppresses E-cadherin adhesion [118]. These changes in cell adhesion and morphology result in differential cell behavior and branching of outer versus inner cells. Loss of β1-integrin leads to loss of cap cell segregation and branching morphogenesis. Live imaging of the normal developing pancreatic bud showed that cap cells exhibit mitosis-associated cell dispersal involving release from the epithelium, division, and reinsertion at distant locations. This process has been observed in other epithelial organ systems such as the kidney tubular epithelium and described as "luminal mitosis" [121]. A better understanding of cell shape changes, and motility during the stages of pancreatic morphogenesis will help us characterize the epithelial niche for endocrine cell differentiation.

The Protodifferentiated State

The epithelial cells of the nascent buds are specified to begin the pancreatic program and transition to a committed protodifferentiated state characterized by low level expression of acinar gene products (Fig. 5); a small number of differentiated endocrine cells appear at this stage [8, 122]. Referred to in rodents as the "primary transition," this shift toward a characteristic pancreatic pattern of gene expression reflects the upregulation of a battery of transcription factor genes, including *Pdx1*, *Ptf1a*, *Sox9*, *Nkx6.1*, and *Hnf1b*, that regulate both progenitor and differentiated cell-specific genes. As described below, this phase of pancreatic development is characterized by critical interactions with surrounding mesenchyme that drives both outgrowth and differentiation. It is important to note that pancreatic identity is not irrevocably fixed at these stages, as evidenced by studies in which abnormal signaling or transcriptional processes can cause respecification of the pancreatic buds. For example, hyperactivation of Wnt/β-catenin signaling in Pdx1+ cells induces cystic, gut-like structures devoid of pancreatic gene expression [47]. A very similar phenotype occurs in mice lacking the HD TF Bapx1, which is normally required for separation of the pancreatic and splenic mesenchyme; when the splenic mesenchyme remains adjacent to the dorsal pancreatic bud, it induces respecification

to a gut-like fate [123]. By contrast, loss of the epithelial TF Sox9 causes cells in both the dorsal and ventral pancreata to undergo hepatocyte differentiation, beginning after bud outgrowth [65]. Therefore, although we follow the usual convention of describing distinct phases of pancreas development, it is important to remember that the underlying processes regulating specification, growth, and differentiation are likely to occur in overlapping windows of time.

First Wave Endocrine Cells: Glucagon Cells Bud from the Epithelium

The first endocrine cells in rodents appear during the early stages of bud evagination (9 dpc in mouse), either as single cells integrated in the epithelium or clusters of cells that remain attached to the pancreatic epithelium [124]. Initially, all of these early endocrine cells express the glucagon gene, and as the number increases, a few cells co-express glucagon and insulin, and later some only insulin, although the majority express glucagon only. These observations initially suggested that insulin-expressing cells throughout development might derive from glucagon-expressing cells, through an intermediate co-expressing both hormones. Lineage tracing and ablation studies, however, demonstrated that mature β-cells and α-cells did not develop from precursors with overlapping insulin/glucagon expression [125, 126]. The ultimate fate of these enigmatic "first-wave" endocrine cells remains unproven, and the absence of a homologous population in early human pancreas development [127, 128] makes their relevance to human pancreatic development uncertain. Nonetheless, insulin/glucagon double-positive cells are frequently generated in protocols for directed differentiation of human pluripotent stem cells and are generally regarded as an undesirable, nonfunctional byproduct of these techniques [28].

"Founder Cells" and Early Determination of Organ Size

The majority of cells during the protodifferentiated stage are multipotent progenitor cells (MPCs). These express transcription factors including Pdx1, Ptf1a, and Sox9 that are collectively required to expand the MPC population to the size needed at the secondary transition to generate the proper number of differentiated acinar, ductal, and islet cells. Interestingly, the size of the early MPC population ultimately determines the final size of the organ. This is indicated by experimental ablation studies, in which cell-autonomous expression of a toxic transgene is used to kill a subset of the protodifferentiated cell population [9]. Experimental ablation of a fraction of pancreatic progenitor cells prior to 9.5 dpc has little or no effect on final organ size. By contrast, ablation of progenitors during the phase of protodifferentiated cell expansion (9.5–12.5 dpc) limits the size of the pancreas at birth and in adulthood in proportion to the number of lost progenitors. This reduction in size affects both endocrine and exocrine cells. Thus, pancreatic size is dependent on the number of MPCs established prior to the secondary transition and is largely independent of regulatory influences that might modulate this population during subsequent growth and development. By analogy to "founder effects" in human populations, in which impacts on a small number of ancestors reverberates to their descendants, mutations that cause agenesis or hypoplasia of the mature pancreas are likely to reflect very

early impacts on the establishment, growth, or survival of the protodifferentiated population.

Epithelial-Mesenchymal Crosstalk: Control of the Protodifferentiated State

Growth and differentiation of the pancreatic epithelium requires critical signals from the surrounding mesoderm. This was demonstrated decades ago in elegant embryological recombination experiments [129, 130]. When cultured as an intact rudiment including both endoderm and mesoderm, the protodifferentiated pancreatic bud undergoes growth as well as differentiation, into both endocrine and exocrine cells. Removal of the mesenchyme dramatically impairs epithelial growth and biases differentiation dramatically away from exocrine and toward endocrine cells [130–132]. In vivo, ablation of the mesenchyme by expression of a toxic transgene product causes pancreatic agenesis, likely resulting from defective MPC growth or survival [133]. Although early studies indicated that at least some of the effects of the pancreatic mesenchyme could be recapitulated by a partially purified factor [134], the nature of the signal that emanates from the mesenchyme has yet to be fully resolved, almost certainly because it comprises multiple molecular species that act both separately and in cooperation.

For example, as described above, recent work points toward a key role for extracellular matrix and cell-cell adhesion molecules in partitioning protodifferentiated cells between "cap" and "body" populations [10, 118]. Cap cells are polarized by contact with basement membrane molecules synthesized by surrounding mesenchyme cells, including laminin. Laminin has the intriguing property of being required for exocrine (acinar and duct) development in cultured pancreatic buds, while suppressing endocrine differentiation [117, 135]. These studies indicate that the physical proximity of epithelium and mesenchyme is as important as any diffusible signaling factors transferred between these tissues.

Nonetheless, secreted factors from the mesenchyme are essential for proper pancreatic development, most prominently FGF signals that promote expansion of the protodifferentiated cell population. Mouse embryos lacking the FGF receptor 2b (FGFR2b) or expressing a dominant negative form develop acute hypoplasia affecting both exocrine and endocrine lineages [136, 137]. FGF10, a ligand for FGFR2b, is expressed by pancreatic mesenchyme and required early (10.0–12.5 dpc) for proper pancreatic budding and growth. Loss of *Fgf10* function eliminates the expansion of the progenitor cell pool but not the specification of the first-wave endocrine cells [64]. FGF10 is also required to maintain Sox9 expression in the epithelium and, thereby, prevent respecification of protodifferentiated cells to a hepatic fate [65]. The importance of FGF signaling to pancreas development is also demonstrated by directed differentiation studies in pluripotent stem cells, in which inclusion of FGF10 or the related Fgfr2 ligand FGF7/KGF during pancreas specification steps dramatically enhances the generation of MPC-like cells [43, 138]. As in the earlier stages of specification, FGF signaling has dose-

dependent effects at the protodifferentiated stage: Fgf10 overexpression in the pancreatic endoderm leads to marked hyperplasia, prolonged maintenance of *Pdx1* expression, and suppression of pancreatic endocrine and exocrine differentiation [139, 140]. This effect appears to be partly due to the dysregulation of the Notch pathway.

Notch signaling is known principally for its regulation of binary cell fate decisions, a process referred to as "lateral inhibition" or "lateral specification" in which neighboring cells parse out their respective fates by reciprocal signaling [52, 53]. In this process, a ligand (e.g., Delta or Jagged) produced under the direction of a transcriptional regulator (e.g., Ngn3, in the embryonic pancreas) binds and activates a cell-surface Notch receptor on a neighboring cell, which, in turn, activates a transcriptional response through the downstream transcription factor Rbpj (Fig. 2). The key element of the response is the induction of *Hes1* or related members of the *Hes* gene family within the cell bearing Notch receptors. In mutant mouse embryos lacking the Notch ligand Dll1, the Notch partner TF Rbpj, or the downstream target Hes1 in the pancreatic epithelium, the protodifferentiated cell population is not maintained [55–57, 141, 142]. The Hes TFs are transcriptional repressors that inhibit the expression of pro-endocrine factors such as Ngn3 in receiving cells. In the pancreatic epithelium prior to 12.5 dpc, this suppression of differentiation promotes the expansion of the protodifferentiated cell population. Loss of function of Notch pathway genes at this stage of development leads to the uncontested expression of *Ngn3* and to the premature differentiation of MPCs into glucagon-expressing first-wave endocrine cells [55, 56].

As mentioned above, the maintenance of the protodifferentiated state MPC by Notch signaling is itself affected by extrinsic factors, such as Fgf10, from the mesenchyme. Forced expression of Fgf10 in the early pancreatic epithelium causes the inappropriate high-level expression of the Notch ligands Jagged1 and Jagged2, which leads to the persistent induction of Notch receptors and Hes1 [57, 139, 140]. The superinduction of Hes1 and possibly other Hes family members suppresses differentiation, at least in part, by repressing *Ngn3* expression, and promotes cell proliferation. This cascade of effects suggests that pancreatic mesenchyme normally promotes acinar and beta cell development indirectly by extending the window of epithelial Notch signaling via FGF10, thus allowing the protodifferentiated progenitor pool of the epithelium to expand [64]. Overall, however, the epithelial defects observed in the absence of *Fgf10* mutants are less severe than those caused by complete lack of mesenchyme; for example, exocrine tissue still develops in *Fgf10* mutant pancreata, albeit at reduced overall mass [64]. In addition, the endocrine-suppressive effects of this tissue cannot be recapitulated in vitro by treatment with FGF10 [143], indicating that multiple additional signals must be sent by the mesenchyme to promote MPC expansion.

Within the epithelium itself, as noted, Notch signaling appears to be a major driver of MPC expansion [51, 57]. Emerging evidence implicates the Wnt signaling pathway as another pro-proliferative cue, although its effects on differentiation are more complex. Deletion of β-catenin (*Ctnnb1*), the key mediator of canonical Wnt signaling, causes reduced proliferation of protodifferentiated cells and overall

pancreatic hypoplasia [48, 50]. The epithelium itself abundantly expresses the Wnt ligand *Wnt7b*, deletion of which also causes pancreatic hypoplasia [51]. The *Wnt7b* hypoplasia phenotype is less severe than that of β-catenin knockouts; one explanation for this difference is that other Wnt ligands are expressed and partially redundant with Wnt7b. However, β-catenin mutants also exhibit patterning and differentiation defects not seen in *Wnt7b* mutants, including loss of acinar differentiation (see below); these might reflect Wnt-independent roles of β-catenin in cell-cell adhesion, consistent with recent studies emphasizing the importance of adhesive cues in the early pancreas [118, 119].

These extrinsic factors that promote pancreatic bud outgrowth must act in cooperation with key transcriptional regulators, including Sox9, Pdx1, Ptf1a, and Hnf1b, active in the protodifferentiated epithelium and required for its expansion (Fig. 3). The HMG-box transcription factor Sox9, for example, controls a transcription network [144] that sustains the precursor cell population by deferring differentiation while promoting cell proliferation and survival [85]. Developmental abnormalities in Sox9-haploinsufficient human fetuses are consistent with an inability to sustain a proper pancreatic progenitor population during pancreatic organogenesis [145]. Elimination of Sox9 in the developing pancreas causes failure to maintain the pool of protodifferentiated precursor cells due to decreased cell proliferation, increased apoptosis, diversion of cells to differentiation to the early endocrine lineage of glucagon-expressing cells [85], and fate conversion to the liver lineage [65]. As described above, Sox9 is also involved in FGF signaling within protodifferentiated cells by driving expression of the Fgfr2b receptor, which establishes a reinforcing regulatory circuit that maintains pancreatic progenitor cells as long as Fgf10 is produced by the mesenchyme [65].

Experimental manipulation of embryonic *Pdx1* expression in utero was used to show that *Pdx1* is also required for the expansion of the protodifferentiated epithelium and its subsequent differentiation [77]. Depletion of Pdx1 during the protodifferentiated stage (9.5–12.5 dpc) inhibited cell proliferation (Hale and R.J.M unpublished). Depletion at progressively later developmental times allowed incremental expansion of the protodifferentiated epithelium and thereby further pancreatic growth and development. For example, the depletion of Pdx1 after 12.5 dpc allows some acinar and islet development. The complete absence of *Pdx1* results in pancreatic agenesis in mouse and human, due to arrest and malformation of the pancreas at the protodifferentiated stage [72, 73, 119, 146]; this requirement is recapitulated in human PSCs, in which engineered deletion of *Pdx1* completely blocks genesis of pancreatic cell types [147].

The expression of the bHLH factor Ptf1a begins in the epithelium of the nascent pancreatic bud, expands throughout exocrine and endocrine cell progenitors of the primary transition, slowly wanes during the protodifferentiated state, and is reestablished prior to the secondary transition [74, 79, 148, 149]. Ptf1a is necessary for the formation of the ventral pancreatic bud and for the proper growth and development of the dorsal bud [74, 75, 149]. In the absence of Ptf1a, the protodifferentiated cell population does not expand; consequently, the secondary transition does not occur, and only an incomplete main pancreatic duct forms.

Experiments with both frogs and mice in which *Ptf1a* was inappropriately expressed in the early endoderm demonstrated the potential of *Ptf1a* to specify pancreatic fate at ectopic sites in the embryo [80]. The ectopic expression of *Ptf1a* converted the anterior duodenum, the extrahepatic biliary system, and the glandular stomach to pancreatic tissue, including acini, ducts, and islet-like endocrine cell clusters. Thus, the normally precise expression of *Ptf1a* at specific regions of the endoderm positionally restricts pancreas formation and prevents the disruption of other foregut organs. Interestingly, although mutation of *Ptf1a* in humans causes pancreatic agenesis, its deletion in PSCs does not prevent generation of pancreatic endoderm in tissue culture [76, 147]. This may reflect a role for Ptf1a in inhibiting signals that normally suppress pancreas development in vivo (Fig. 4), which may not be present in vitro.

bHLH transcription factors like Ptf1a generally act as homo- or heterodimers that bind a six-base pair DNA recognition sequence. Ptf1a is the only bHLH factor known that requires a third DNA-binding subunit (either Rbpj or Rbpjl), which extends its functional binding site to 21 base pairs [150, 151]. A single tryptophan-to-alanine substitution near the carboxyl terminus of Ptf1a disrupts the ability of Ptf1a to recruit Rbpj (but not Rbpjl) into the trimeric complex. The extensive developmental defects of *Ptf1a*-null embryos are recapitulated in embryos homozygous for this single amino acid change [149]. Thus, the biochemical form of Ptf1a required for the early stages of pancreatic development is the trimeric complex including Rbpj and called PTF1-J. This developmental role for Rbpj is distinct from its role in Notch signaling. Whereas its function as part of the Notch-pathway is to prolong the protodifferentiated state by preventing cellular differentiation, its function as a subunit of the PTF1 complex is to sustain the developmental program of the early epithelium [149].

Hnf1b is another intrinsic factor required for the protodifferentiated state and the expansion of pancreatic progenitor cells. The results from lineage tracing showed that *Hnf1b*-expressing cells of the early rudiment contribute extensively to all three epithelial lineages [69]. In the absence of Hnf1b, the ventral pancreatic bud does not form; however, the dorsal bud forms, begins normal growth, and then fails to expand the protodifferentiated cell population effectively [105]. The absence of Hnf1b leads to decreased proliferation and increased death within the *Pdx1*-expressing progenitor population [70]. The developmental actions are mediated through Hnf6/Onecut1, Pdx1, and Ptf1a [105, 152]. Indeed, the developmental phenotype is similar to that of *Ptf1a*-deficient embryos [74, 149] and the depletion of Pdx1 after initial pancreatic bud formation [77].

Gata4 and *Gata6* have essential and partly redundant functions in pancreatic development. Whereas the absence of either Gata4 or Gata6 modestly affects the formation of the exocrine compartment (see below), the absence of both leads to early developmental failure of the pancreatic buds [153, 154]. The inactivation of *Gata4/Gata6* at the onset of pancreatic development allows the formation of the initial buds, but *Shh* and other genes of the Hedgehog signaling pathway are activated, and the cells of the dorsal and ventral pancreas convert to lineages of the stomach and intestine, respectively [155].

Onset of Islet and Acinar Development by the Secondary Developmental Transition (12.5–15.5 dpc)

The next stage of pancreatic organogenesis converts the protodifferentiated epithelium of expanding progenitor cells into a dynamic epithelium that generates acinar cells, differentiated ductal cells, and the second (principal) wave of endocrine cells that form the islets. This dramatic and critical conversion period is termed the "secondary transition" (Fig. 5). It was recognized initially by the sudden appearance of large numbers of insulin-producing β-cells [8], the expansion of the glucagon-producing α-cell population [156], and the appearance of pro-acini coincident with a massive increase in the synthesis of acinar digestive enzymes [157]. Highly proliferative cells in epithelial tips around the periphery of the pancreatic rudiment form a domain of rapid outward growth [158]. By the end of the secondary transition, a greatly expanded and highly branched and ramifying tubular epithelium has formed from the protodifferentiated epithelium (Fig. 7). Acini form at the tips of the branches, and islets form near the core of the epithelium, in close apposition to major ducts and associated blood vessels [159, 160]. In this section, we describe the developmental processes that occur during the secondary transition and the extrinsic and intrinsic factors that control these processes.

Pancreatic Bud Lobulation and Branching

Following the initial outgrowth of the early pancreatic epithelium (9–12 dpc), the bud transforms from a small, featureless mass of epithelium to a highly branched gland. As the gut tube undergoes "turning," a process that breaks bilateral symmetry of the alimentary tract and changes the positions of digestive organs relative to one another, the dorsal epithelium extends from an overall "fist-like" to a "bat-like" shape as it begins to extend numerous lateral (90° from the main axis) branches along its proximo-distal axis. Approximately 80% of branching events are lateral, the remaining bifid [161]. Small lobulations form along each lateral branch. Here, we define "lobulation" as the formation of multiple short blunt branches, or "lobules" [162, 163], while we refer to "branching" as the extension of longer, definitive epithelial branches with multiple lobulations and a predictable organization, which generate the main branches of the maturing organ [10]. While it remains unclear what geometrical parameters dictate cell movements that drive branch formation, it is believed that plexus formation, cellular proliferation, and epithelial remodeling are likely drivers of internal bud expansion, rather than simple extension of branch tips. These events set in motion the next phase of pancreatic development: the secondary transition. A better understanding of branching is likely to yield critical insights into pancreatic fate, as architectural changes of the epithelium have been associated with allocation of progenitors to the different pancreatic cell lineages [117, 118, 164].

The Secondary Transition

The secondary transition, as defined by Rutter and colleagues [8, 165], is the period of exponential increased accumulation of islet hormones and acinar digestive enzymes. By these criteria, this corresponds to the developmental window

encompassing the exhaustion of MPCs and the establishment of the bipotent tubular trunk/plexus with ductal and endocrine-restricted progenitor cells and the epithelial tips with committed, proliferation-competent acinar cell progenitors (Fig. 6). In the trunk/plexus domain, committed endocrine cells delaminate, cluster, and remain in close association with the epithelium. At the tips, committed acinar cells begin their final phase of differentiation.

The secondary transition initiates at about 12 dpc from multipotent precursor cells (MPCs) scattered throughout much of the epithelium including the periphery [69, 164, 166]. The MPCs were identified from a combination of several developmental markers with partially restricted expression: Ptf1a at a high level, Pdx1, Hnf1b, low carboxypeptidase A1 (Cpa1), and high c-Myc, consistent with high replication rate of these cells and the requirement for Myc to attain normal acinar cell mass [167]. MPCs also possess and require the TFs Sox9, Hes1, Mnx1, and Nr5a2 [58, 168, 169]. Importantly, other developmental markers are absent: Ngn3, endocrine hormones, Mist1, and acinar digestive enzymes other than Cpa1. Genetic lineage-tracing experiments of cells expressing *Cpa1* at 12.5 dpc showed that acinar, ductal, and islet cells all derive from the MPC population [164].

By about 14 dpc, the MPC population is exhausted [164, 166], converting to two compartments of replicating cells that characterize the secondary transition (Fig. 7). One within the tubular trunk regions produces precursor cells for islets and ducts and the other around the periphery for acinar cells. A high rate of cell proliferation propels the pro-acinar epithelial tips outward, while a slower rate of cell division expands the partly differentiated core epithelium [5]. Branching of epithelial tips is

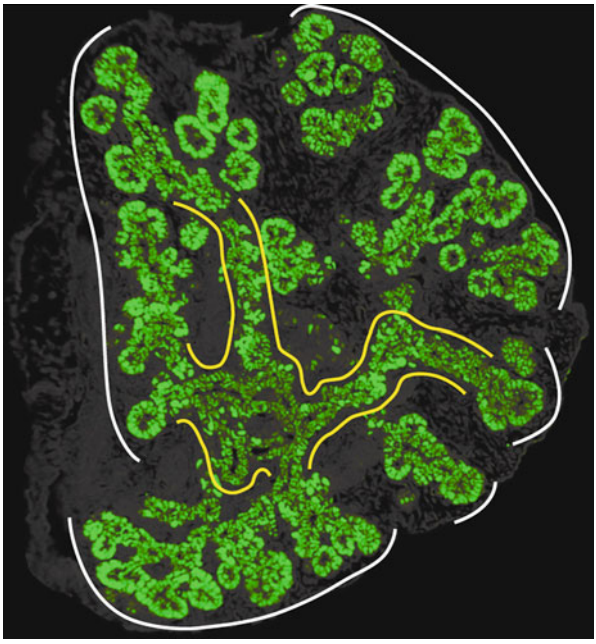

Fig. 7 The branched pancreatic epithelium during the secondary transition of an embryonic mouse pancreas. A section through the dorsal pancreas at late 14.5 dpc with immunolocalization of the transcription factor Pdx1 (*green*) displays the pancreatic epithelium during the secondary transition. At this stage, most of the cells of the epithelial tubules containing islet and ductal precursors (*yellow outlines*) and pro-acini (*white* indicators around the periphery) have nuclear Pdx1

in part driven by the formation of intervening "clefts" of differentiating tubule cells within clusters of tip cells [161, 164]. After 14 dpc, branch tips have committed to become acinar and begun the synthesis of the other secretory digestive enzymes, the core epithelium continues to generate endocrine cells from bipotent protodifferentiated epithelium.

Ductal and islet cells derive from the MPC progeny remaining in the trunk region of the epithelium. MPC daughter cells that enter this developmental compartment initially may be bipotent for the ductal and islet lineages [170]. Differing levels of Ngn3 distinguish three states of commitment: to endocrine development by high Ngn3, endocrine bias by low Ngn3, and ductal bias by the absence of Ngn3. Cells that then initiate expression of the TF Ngn3 to a high level initiate the islet developmental program [7, 124, 171, 172]. To date, an analogous transcriptional regulatory factor that commits precursor cells to the ductal lineage has not been identified. Ductal development may be the default option for the cells of the tubular epithelium that do not activate Ngn3 expression. Alternatively, bipotent MPC progeny may resolve quickly to more stable progenitors specified to either ductal or islet fate, which await further developmental cues. For the islet lineage, this is Notch signaling, which induces Ngn3 gene activation in a controlled temporal and spatial manner leading to the proper formation of committed endocrine cells that coalesce into islets [83].

In sum, the morphogenetic processes of the secondary transition generate a greatly expanded and branched tubular epithelium (Fig. 6) with regions specialized for the formation of islet cells near the center and acinar cell clusters toward the periphery. After this transition, the pancreatic epithelium has undergone three transformations: predifferentiated →1→ protodifferentiated →2→ tubular epithelium of ductal and endocrine progenitor cells with MPCs and differentiating acini at the tips →3→ differentiated ductal epithelium linking acini and separated from the delaminated endocrine cells. We consider next some of the developmental processes, both cellular and molecular, that create the acini, ducts, and islets.

Formation of Acini at Epithelial Tips

As the epithelial expansion of the secondary transition runs its course, MPCs commit to the acinar lineage, continue to replicate, and differentiate to pro-acinar cell clusters. To form acini, the pro-acinar cells at the ends of the precursor tubules may alter their cell-cell contacts and extend back over the tubule to form a cap of acinar cells (Fig. 8) [169]. This process is consistent with a developmental intermediate of a mature acinus with the terminus of the intercalated duct (aka centroacinar cells) inserting deep into the acinus [12].

The resolution of pro-acinar tip cells from the MPCs depends on both intrinsic and extrinsic factors, the interaction between which remains imperfectly understood (Figs. 3 and 4). One of the first signs of tip-trunk separation is the reorganization of Nkx6.1 and Ptf1a expression [173]. These TFs are initially present together in MPCs, but as MPCs generate bipotent trunk and acinar-committed tip cells, Nkx6.1 segregates to the trunk and Ptf1a to the tips (Fig. 8). In *Nkx6.1* mutant embryos at the MPC stage, Ptf1a is present ectopically in the trunk cells, and many

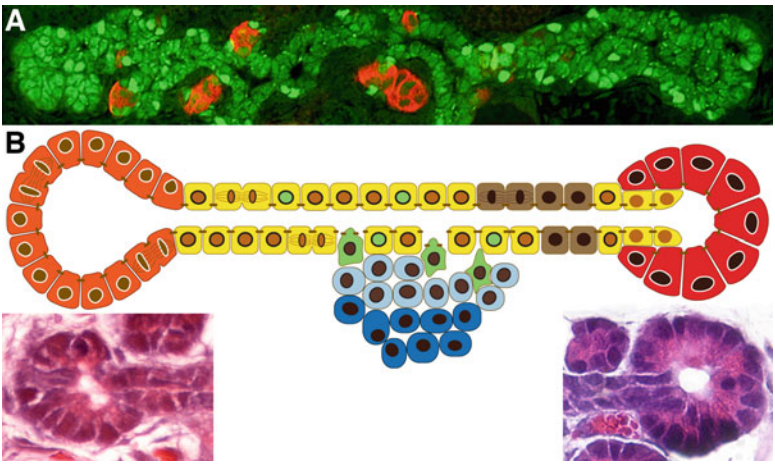

Fig. 8 A stereotypic model for the morphogenetic processes that generate islets centrally and acini peripherally. (**a**) A closeup view of the structure of Pdx1-expressing tubules, peritubular cords, and pro-acini from a section nearby that of Fig. 6. Note the subset of cells located in the cell cords or the tubules in contact with the cords that have very high Pdx1; these may be cells committed selectively to the β-cell differentiation program [270]. *Green*, Pdx1; *red*, glucagon, which marks the majority of the differentiated endocrine cells at this stage (14.5 dpc). (**b**) Diagram of the proposed developmental compartments of the post-MPC epithelium. The disposition of cell-cell junctions is not confirmed. *Yellow*, progenitors of islet and ductal cells retain the capacity for cell proliferation. *Beige*, committed ductal cell precursors. *Burnt orange* (*left*), committed pro-acinar cells retain cell proliferation and continuity with the tubular epithelium and have begun the synthesis of other digestive enzymes in addition to Cpa1. *Red* (*right*), differentiating acinar cells with low cell-replication capacity, ongoing cytodifferentiation, and accumulation of secretory (zymogen) granules. The acinar cells have formed a cap engulfing the tubule end cells, which become the centroacinar cells of the mature acinus. *Green*-to-*blue*, islet precursors initiate the islet program via *Ngn3* expression (*green* nuclei) and release from the tubule epithelium. Pre-endocrine cells in the epithelium break intracellular junctions, acquire transient mesenchymal properties, migrate from the epithelium, congregate in clusters, reestablish epithelial cell properties, and differentiate. *Inset left*: pro-acinus with connecting tubule. *Inset right*: differentiating acinus with cap structure

more acinar cells form. Conversely, forced continuous expression of *Nkx6.1* suppresses *Ptf1a* expression and acinar cell differentiation at this stage. In a complementary fashion, continuous expression of *Ptf1a* suppresses *Nkx6.1* and endocrine cell development. Thus, antagonism between these two fate-determining transcription factors leads to the resolution of the bipotent and acinar lineages through their segregated expression.

Among extrinsic signals, those mediated by β-catenin and the Notch pathway appear particularly critical for establishing the pro-acinar tip population (Fig. 4). Deletion of β-catenin produces an almost acinar-deficient pancreas, due to an accelerated depletion of MPCs into the bipotent duct-endocrine trunk fate at the expense of tip cells [48, 50, 174]. This phenotype correlates with downregulation of *Ptf1a* precisely at the onset of the secondary transition, indicating a key role for β-catenin in maintaining, but not establishing, the expression of this key acinar

determinant [50]. Polarized β-catenin activity, at the tips of the branching epithelium, could therefore serve as a "symmetry-breaking" process to tip the balance of the Ptf1a-Nkx6.1 antagonism described above.

Given that the mesenchyme into which the tip cells branch is known to have acinar-inducing activity, as described above, it is attractive to hypothesize that this tissue serves as a source of Wnt ligands, responsible for activating β-catenin/LEF-TCF-mediated transcription. Several observations argue against this, however. Transgenic reporters of Wnt/β-catenin/LEF-TCF activity exhibit little or no expression in the developing pancreas and no enrichment in MPCs or pro-acinar tips [175]. Pancreatic expression of a dominant-negative Frizzled 8 receptor, competent to block a wide variety of Wnt ligands, inhibits proliferation of progenitor cells but does not impair acinar development [176]. Impaired proliferation is observed in pancreas-specific β-catenin knockouts, as well as in *Wnt7b* knockouts described above, but this appears to be a separate phenomenon from the loss of pro-acinar tips [50, 51]. Given accumulating evidence that cell-cell adhesion cues play important roles in pancreas development, it is increasingly plausible that the functions of β-catenin in MPC patterning and acinar development are mediated by its signaling-independent functions downstream of E-cadherin [118, 119].

The role of β-catenin in acinar development appears to be approximately opposite to those of the Notch signaling pathway, and, indeed, the loss of acinar differentiation in the absence of β-catenin can be partially rescued by inhibition of Notch signaling [50]. In normal development, the expression of the Notch target gene *Hes1* in the precursor epithelium of the secondary transition extends up to, but does not include, the pro-acinar cells [148, 177], suggesting that Notch signaling may control this developmental boundary. Ectopic activation of Notch inhibits acinar development, in part by tipping the Ptf1a-Nkx6.1 balance in favor of the latter TF [173, 177, 178]. Conversely, development of pro-acinar tip cells is enhanced when Notch signaling is inhibited in MPCs, by deletion of *Hes1* or the Notch ligand co-factor *Mib1*, or expression of a dominant negative form of the Notch-Rbpj co-factor Mastermind-like [54, 179]. Thus, Notch signaling plays opposite roles, early and late, in determining acinar cell numbers: the pathway must be active in the primary transition to support progenitor cell expansion and then inactivated for segregation of pro-acinar cells (Fig. 4).

Pro-acinar cells derived from MPCs lose the transcriptional regulators that maintain the progenitor status of the epithelium. Hes1 is not detected in cells expressing amylase, and the TFs Sox9, Mnx1, and Hnf1b rapidly decline in these cells [148, 166, 169, 180]. However, *Ptf1a* expression continues at a high level in pro-acini, whereas it is shut off in the tubules containing the ductal and islet precursors. In this new context, Ptf1a acquires a new developmental function, which is to direct the differentiation of acinar cells. The active form of Ptf1a during early development is the trimeric PTF1-J complex (section "Initial Growth of Pancreatic Buds and the Primary Developmental Transition (9–12 dpc)"), which is necessary to initiate the formation of acini. Ptf1a, as part of the PTF1 complex, and Nr5a2 sit near the top of a transcription factor network that directs acinar development.

An early step in acinar differentiation is the synthesis of Rbpj-like (Rbpjl), the product of an *Rbpj* gene that was duplicated sometime during vertebrate evolution and since diverged. Whereas Rbpj is the transcriptional mediator for Notch, Rbpjl has lost the ability to participate in the Notch signaling pathway [181]. Rbpjl expression is largely limited to acinar cells of the pancreas and discrete regions of the forebrain. Transcription of the *Rbpjl* gene is activated in pro-acinar cells by the PTF1-J complex bound to the *Rbpjl* promoter [149]. As Rbpjl protein accumulates, it replaces the Rbpj subunit in the PTF1 complex. It is the Rbpjl form (PTF1-L) that binds and drives the promoters of most, if not all, the secretory digestive enzymes of differentiated acinar cells [82]. PTF1-L also replaces PTF1-J on the Rbpjl promoter and creates a positive regulatory loop that ensures the continued production of Rbpjl in acinar cells. In a complementary fashion, the Ptf1a gene has a transcriptional enhancer with a PTF1-binding site that requires the presence of a trimeric PTF1 complex for activity [182]. Consequently, the genes for both pancreas-restricted subunits of the complex are auto-activated in acinar cells by PTF1-L. Similar transcriptional positive feedback loops are commonly found near the top of a regulatory hierarchy in developing systems, and serve to first drive development toward a particular state, and then to stabilize that state [183]. It is likely that the PTF1-J complex helps establish the MPC population. The fact that *Rbpj* is required for acinar formation [141, 142] may be due to its role in the PTF1-J complex of the MPCs and not its role in Notch signaling, particularly as other components of the Notch pathway actively inhibit, rather than promote, acinar development. Ensuring the continued transcription of Ptf1a and Rbpjl through their autoregulatory loops drives acinar differentiation to completion.

In the adult, PTF1-L maintains the differentiated phenotype of pancreatic acinar cells. The complex resides on the enhancers or promoters of 34 of the 37 genes encoding the secretory digestive enzymes and is required for their continued transcription [82]. The loss of Ptf1a disrupts acinar cell identity and greatly increases susceptibility to KRAS-induced neoplasia [81].

Nr5a2/Lrh1, a member of the family of nuclear hormone receptors, is required during early embryonic development and subsequently for the formation of the pancreas during organogenesis. The lack of Nr5a2 leads to disruption of the primitive streak and failure of gastrulation [184]. During pancreatic development, it is required for the formation of the MPC population and a proper ductal tree, subsequently for allocation to the acinar lineage, and finally to complete acinar cell differentiation [169]. In the adult, Nr5a2 collaborates with the PTF1 complex to maintain genes for specialized acinar functions and likely controls much the same set of genes during acinar differentiation [185]. The induced loss of Nr5a2 from midgestation confers a heighted sensitivity to neoplastic transformation by oncogenic KRAS [186].

The bHLH TF Mist1 is present selectively in the serous-type secretory cells of many exocrine glands [187] and helps establish high-capacity secretory phenotype of those cells [188]. During pancreatic development, Mist1 is required to establish proper apical-basal cell polarity and complete acinar differentiation [189]. Mist1 acts downstream of Ptf1a, because Mist1-deficient embryos initiate acinar development

normally, but the acinar cells do not acquire proper cytoarchitecture or regulated exocytosis. Indeed, PTF1-L binds the pancreatic transcriptional enhancer of *Mist1* and drives *Mist1* transcription [190]. In the absence of Mist1, acinar cells lose intercellular communication because gap junctions do not form properly [191], have mitochondria with compromised Ca++ uptake and Golgi positioned incorrectly [192], and have defective regulated exocytosis [193]. As a consequence of these defects in gene expression and cellular organization, normal acinar cell polarity is not established, Ca++ signaling is abnormal, packaging the secretory enzymes is defective, intracellular zymogens are activated, and genes characteristic of duct cells are expressed aberrantly [191–193]. Mist1 assists acinar differentiation independently and in collaboration with the PTF1-L complex. In adult acini, Mist1 and PTF1-L together bind and regulate more than 100 downstream genes for specialized acinar cell functions such as secretory protein synthesis and processing, exocytosis, and robust maintenance of endoplasmic reticulum homeostasis [190]. Mist1 also collaborates with Xbp1 to maintain a vigorous unfolded protein response system [194], a critical aspect of the acinar phenotype. Mist1 also limits acinar cell replication by controlling the expression of the cell cycle regulator p21 [195]. Thus, Mist1 controls the final stage of differentiation that establishes the functional and stable acinar cell phenotype.

The zinc-finger TFs Gata4 and Gata6 are present throughout the early pancreatic epithelium [196]. Gata4 becomes restricted in the tips of epithelial branches during the secondary transition and is present exclusively in the acinar cells of the mature gland [196, 197]. In contrast, Gata6 segregates to the ducts and their associated endocrine cell cords. Function follows distribution: at this developmental stage, Gata4 is needed for the proper number and maturation of acinar cells and Gata6 for ducts [153, 198].

The HD protein Prox1 is required for the proper allocation of progenitor cells to the endocrine versus exocrine lineage. *Prox1*-deficient embryos have precocious acinar development and diminished total acinar and islet tissue formation [192]. These developmental defects suggest that Prox1 might help maintain the multipotent progenitor cell population by delaying acinar development. Because Prox1 can interact with and inhibit the transcriptional activity of Nr5a2 in other contexts [199], it might govern the orderly formation of acini by restraining Nr5a2 function during pancreatic development. Indeed, Prox1 and Nr5a2 are expressed in complementary patterns during the secondary transition. Just as eliminating the restraining effects of Notch signaling on Ngn3 activity causes progenitor cell depletion by allowing precocious endocrine development, so too might the absence of Prox1 allow unrestrained Nr5a2 activity and the premature induction of acinar development. Prox1 deficiency retards the early growth of the embryonic pancreas. Before birth, growth restores normal amounts of acinar and islet tissue, and inter- and intralobular ducts acquire larger than normal diameters due to greater numbers of cells [200]. Ductal developmental regulators Sox9, Hnf6, and Hnf1b were unaffected, so that Prox1 appears to affect principally growth, although functional studies of mature ducts were not reported.

Ductal Development

The ductal system of the mature pancreas comprises the two main pancreatic ducts that drain into the intestine, small interlobular ducts that link the lobules to the main drainage, smaller intralobular ducts, and even finer intercalating ducts (IDs) that connect to individual acini [201, 202]. In addition, the pancreas is the only exocrine gland in which the connecting ducts (here intercalated ducts) insert into the acinus. These extensions of the intercalated duct have been designated "centroacinar cells," a term that obscures their function, origin, and relationship with the ductal tree, and we suggest instead the designation intra-acinar duct cells (IAD cells). The ductal nature of the IAD cells is indicated by their expression of the TF Sox9, the intermediate filament cytokeratin-19 (CK19), and the transmembrane protein CD133, all of which becomes duct restricted after the secondary transition [168, 203, 204].

The evidence that the IDs and IADs derive from a developmental program distinct from that of large ducts is severalfold. The two programs can be resolved by the gestational times at which each requires Pdx1 [77]: depleting Pdx1 experimentally just prior to the secondary transition at 12.5 dpc allows the formation of the large ducts, but not IDs or IAD cells. The ductal structure that forms upon Pdx1 depletion at sequential time-points appears to represent incomplete main ducts (one from each bud), primary branches from the main ducts (the interlobular ducts), and the beginning of secondary branches distally (intralobular ducts). In a similar fashion, the directed germline inactivation of *Ptf1a* leads to the formation of the large but not the small ducts [74, 75, 149], while the opposite phenotype is observed in *Hnf6* mutant pancreata [205]. The Notch signaling pathway appears to be a critical determinant of duct cell development: whereas activation of this pathway prior to the secondary transition induces a trunk progenitor-like fate, its activation after the secondary transition induces mature duct cell differentiation [58]. Conversely, targeted disruption of the Notch ligands *Jagged1* and *Jagged2* results in failure of IAD development in later embryogenesis, while deletion of the Notch partner TF *Rbpj* in adult IADs causes their re-specification into acinar cells [203, 204]. The increasing availability of tools to mark and manipulate different classes of duct cells is likely to provide new insights into pancreatic cancer as well, such as the recent appreciation that duct cells give rise to IPMN precursor lesions rather than PanINs [206, 207].

Resolution of the Epithelial Plexus

The transformation of the epithelial plexus into the ramifying ductal network of the exocrine pancreas, with its interspersed islets, has only recently been elucidated. Previously thought to develop by the more conventional mechanisms of bud tip extension and branching, as in the lung, the pancreas is now understood to arise via formation and resolution of a complex plexus [10, 117]. Transiently 3D, the plexus undergoes remodeling and resolution, as rungs of the plexus ladder either regress or enlarge, to yield a tree-like network. However, it remains unclear how this occurs at the cellular level, and the molecular underpinnings of these processes remain unknown. Understanding this process has become of particular interest, since a

recent report has identified this early epithelial plexus as the niche for endocrine progenitors [11]. Indeed, $Sox9^+/Ngn3^+$ progenitors are found primarily within this region, and EdU pulse-chase experiments show that the secondary transition occurs at the height of plexus remodeling. Furthermore, during this burst of endocrine differentiation, progenitors take about 12 h to transit through to delamination and differentiation, as Notch signaling functions to maintain the pool of progenitors. Upon full resolution of the plexus at perinatal stages, ducts and finer branches fully emerge, and progenitors become exhausted. These findings identify the epithelial plexus as the niche for endocrine differentiation in the embryonic pancreas; however, it underscores that our understanding of cell-cell relationships within this microenvironment is still in its infancy.

A number of TFs are critical to formation of the ductal network. Sox9 is one such TF, which is expressed throughout the early epithelial plexus, which is required for ductal as well as endocrine and exocrine lineages [69]. The early epithelium expresses Sox9 widely and secondary transition trunk epithelium contains $Sox9^+$ bipotent ducto-endocrine progenitor cells [69, 168]. During plexus resolution, cells asynchronously flatten and lose Sox9 expression as they acquire ductal fate [208]. Loss of Sox9 results in a cystic pancreas with scattered acini and near total loss of endocrine cells [85]. In addition to being required for endocrine specification, it is also known to be required to maintain pancreatic ductal identity. In the adult pancreas, it is restricted to duct and centroacinar cells and is required to maintain ductal integrity and primary cilia formation [83, 209].

Similarly, Hnf6 and the TFs it controls are critical regulators of ductal development. The absence of Hnf6 causes extensive developmental defects of the pancreas [210]. Whereas the extent and morphology of acinar tissue is near normal and the first-wave endocrine cells form, the second-wave lineage does not appear, and dilated cystic duct structures appear in the epithelium. The cystic ductal phenotype appears at 15 dpc, which may mark the onset of duct-specific differentiation. The cystic ducts express the differentiation marker Muc1 but are devoid of the primary cilia normally present throughout the mature ductal tree [205]. Mutations in the genes for the structural proteins of the cilium cause similar defects in ductal differentiation, but the second-wave endocrine cells form nonetheless [211]. These observations suggest that ductal precursors form in Hnf6-deficient pancreas but do not differentiate properly, in part due to the absence of primary cilia.

Hnf6 controls ductal morphogenesis including ciliogenesis via two additional TFs, Hnf1b, and Glis3. Hnf6 is needed for the expression of Hnf1b during liver and pancreatic development [212], and Hnf1b is known to control the expression of genes for cilium function in the kidney [213]. The absence of Hnf1b in the cells of the cystic ducts of Hnf6-deficient embryonic pancreas [205, 211] indicates that the cilium defect is due directly to the loss of Hnf1b. In turn, Hnf1b binds and controls the transcription of *Glis3*, a Zn-finger TF also necessary for ductal cilia. Glis3 first appears in the bipotent trunk progenitor cells, segregates to ductal, β- and PP cells [214], and functions in each of these three developmental compartments [215]. The pancreas of embryos bearing a functionally impaired *Glis3* forms cystic ducts [215] due to disrupted primary cilia.

Notch signaling is necessary for proper formation of ducts through the induction and maintenance of Sox9 and Hnf1b expression [83, 216]. In this context, Sox9 induces genes directing ductal differentiation and cilia that complement the set of genes controlled by Hnf1b [83]. The level of Notch signal received by bipotent trunk cells affects their decision to remain on the path to duct development or veer off to the islet cell fate (see below).

The Second Wave of Endocrine Cells: Formation of Primitive Islets

A new population of endocrine cells, distinct from the first wave of the early pancreatic bud, arises during the secondary transition from a population of progenitors left behind by the advancing epithelial tips (see Fig. 7). Several excellent reviews describe islet cell specification and development comprehensively [5, 25, 217].

A transient, intense expression of the *Ngn3* in scattered cells of the tubular plexus epithelium commits these cells to cease proliferation [17, 218] and begin the islet developmental program [56, 178, 219]. Notch signaling within the specialized environment of the mid-development epithelial plexus described earlier nurtures pre-endocrine progenitors by sustaining proliferative growth and suppressing differentiation [11]. A recent study indicates that the "bipotent trunk" region has a subpopulation of cells that are biased toward the endocrine fate with *Ngn3* transcription, but low-Ngn3 protein [170]. Two likely fates for those low-Ngn3 cells are proposed: replication to maintain the endocrine-biased progenitor population and derepression of *Ngn3* to high functional levels to initiate endocrine cell development. Studies on *Ngn3*-knockout mice showed without the generation of endocrine cells, transcription of the Ngn3 locus was increased [220], suggesting that differentiating endocrine cells may produce Notch ligands that normally control the balance between the low (suppressed) Ngn3 progenitors and the high (derepressed) Ngn3 precursors specified to endocrine development [11].

The activation of *Ngn3* is promoted directly by the binding of Hnf1b, Hnf6, Glis3, Pdx1, Foxa2, and Sox9 to distal regulatory regions of the *Ngn3* gene [210, 221–224]. These TFs are present throughout the interior region of the precursor epithelium, but high *Ngn3* expression is repressed in all but a few scattered cells at any one instant by Notch signaling [221]. Strong localized Notch signaling favors progenitor status and duct cell formation by maintaining high levels of Hes1, which binds and represses the *Ngn3* promoter [177, 178]. Lower Notch signaling is unable to maintain effective Hes1 levels but still drives transcription of *Sox9*, which in turn drives *Ngn3* transcription, and the balance is tipped toward endocrine development [86]. Limited *Ngn3* expression provides a measured induction of endocrine development without exhausting the progenitor population prematurely and without preempting ductal cell development from the same population. By the time islet precursors become committed and leave the epithelial tubule, *Ngn3* transcription is abruptly shut off by feedback repression of *Sox9* by Ngn3 [86].

Ngn3 initiates a developmental cascade by activating the promoters of genes for TFs with roles in endocrine differentiation (Fig. 3: "islet precursor" set) [217]. Neurod1, Insm1, and Rfx6 are downstream and likely direct targets of Ngn3 [225]. Rfx6 helps establish the common islet lineage [226, 227] and is required

subsequently to maintain the functional identity of β-cells [228]. Insm1 facilitates endocrine cell differentiation by suppressing the endocrine-progenitor program and inducing genes necessary for proper islet cell differentiation [229]. The action of Neurod1 favors the formation of β-cells over α-cells [230].

Genes encoding intrinsic factors that resolve the α, β, δ, ε, and PP sub-lineages of islet cells are among the set of endocrine regulatory genes induced by Ngn3. Transcription factors critical to specifying individual islet cell lineages and their final differentiation include Pdx1, Foxa2, Neurod1, Pax4, Arx, Rfx6, Nkx6.1, Mnx1, Insm1, Glis3, Isl1, Nkx2.2, Pax6, and MafA. More complete descriptions of the TFs that control islet cell differentiation are presented in several excellent reviews [104, 180, 231–233].

Extrinsic factors also regulate the second wave of endocrine differentiation. The control of the commitment to endocrine fate by Notch signaling has been well characterized by experimental manipulation. Driving Notch1-ICD expression in precursors to both endocrine and exocrine lineages prevents the differentiation of both compartments and leaves an incompletely differentiated ductal epithelium [178]. The in vivo overexpression of constitutively active Notch (Notch1-ICD) selectively in the Ngn3+ precursor population also suppresses endocrine differentiation [234].

Formation of Islet Precursor Cells by Delamination

Whereas acini form at the ends of precursor tubules and maintain topological continuity of with the ductal system, islets form from cells that escape the continuum of the epithelial tubules (Fig. 8). The escaped islet precursor cells coalesce into cords that remain intimately associated with and within the basal lamina of the single-cell layer tubules [8]. The endocrine cell cords grow by continued recruitment of precursors from the epithelial tubules, rather than by replication of the differentiating endocrine cells.

The endocrine cell cords are thus endocrine cells early in their differentiation process and can be distinguished from the tubules by the presence of synaptophysin, a component of the microvesicle secretory machinery and an early differentiation marker of neuroendocrine cells [16]. Cord cells with synaptophysin, but without any of the five principal islet hormones, appear to constitute the less differentiated cells most recently released from the tubules. Approximately half of the synaptophysin-expressing cells at 14.5–15.5 dpc are pre-hormone precursors, while the remainders have endocrine hormones and are therefore more differentiated. As the endocrine cords mature, increase in size, and form spherical structures, the basal lamina surrounding the forming islet eventually pinches off near its association with the differentiating duct and thereby separates the extracellular spaces of the endocrine and exocrine tissues.

Cells committed to the islet lineages are released from the pancreatic epithelium by a version of the developmental epithelial-to-mesenchymal transition (EMT) [14]. During EMT, epithelial cells escape their epithelial neighbors by dismantling tight junctions and acquiring modest mesenchymal cell properties [235]. For this process to be a viable option for islet cell derivation, reversion from a transient mesenchymal state back to an epithelial state must occur prior to endocrine differentiation within the endocrine cell cords. The evidence for EMT during the

endocrine development of the secondary transition is threefold: lower levels of E-Cadherin and increased Vimentin in delaminating cells [14] and the appearance of Snail2 (a known inducer of EMT in other contexts) in scattered cells of the tubular precursor epithelium at the appropriate time for initiating EMT shortly after precursor cells commit to endocrine fate [236].

Comparison of First and Secondary Waves of Endocrine Cells

The precise developmental relationship between the first- and second-wave endocrine cells is unknown; however, differences between them suggest that they represent different cellular lineages [237].

- Although both first- and second-wave endocrine cells require *Ngn3* [238], the formation of the first-wave cells does not require *Pdx1* [72, 146] or *Ptf1a* [74], which are critical to the formation of the second-wave lineage. Indeed, only a few of the first wave cells express *Pdx1*.
- Many more β-cells than α-cells are made during the secondary transition. In addition, glucagon and insulin co-expressing endocrine cells are not observed following the secondary transition. The ratio of β- and α-cells seems to be an inherent property of the two lineages, because experimental manipulation by superinduction of Ngn3 to high levels during the primary transition leads to overproduction of glucagon-cells and during the secondary transition leads to overproduction of β-cells [124].
- Clusters of first-wave endocrine cells are invariably connected to the precursor epithelium by a cellular bridge and appear to separate from the protodifferentiated endoderm by a budding process [239], rather than the delamination that occurs during the secondary transition.
- Whereas the α-cells that form during the secondary transition use prohormone convertase 2 (PC2) to process the proglucagon polypeptide precursor to active glucagon, the early cells have PC1/PC3 rather than PC2 and cleave the precursor to GLP1 and GLP2 [240]. Because the glucagon-expressing first-wave cells have PC1/PC3 and produce the GLP peptides, they are not strictly α-cells. If these cells contribute to the α-cell population of neonatal islets, as proposed, they must switch to PC2 from PC1/PC3 to produce glucagon. Processing proglucagon to GLP1 and GLP2 by PC1/PC3 is a characteristic of the enteroendocrine L cells of the intestine and stomach. Thus, the early endocrine cells may be closely related to an enteroendocrine lineage, which also requires Ngn3.

The developmental origins and fates of the first- and second-wave cells are notable in two respects. *First*, the cells of the first wave are not the progenitors of the second [7, 125]. Consequently, two separate endocrine programs occur rather than a single, continuous one. *Second*, an equivalent, predominately glucagon-expressing, first-wave endocrine cell population does not occur during human pancreatic development [4, 127]. Instead, insulin cells appear first and are always prevalent, followed shortly by the appearance of glucagon and somatostatin cells. These earliest human endocrine cells form during a period of morphogenesis that appears related to the murine second

transition, rather than an earlier primary transition. For comparisons with the developmental processes of human islet formation, it is important to distinguish the first and second waves of murine endocrine cells.

Dorsal and Ventral Bud Fusion

As the dorsal and ventral buds grow, branch, and extend, they are brought into contact at the base of their primary ducts by the movements of gut turning. The primary ducts fuse at 11.5 dpc, while their distal portions remain largely separate. In humans, fusion of the dorsal and ventral buds (~35 days) creates a more integrated organ than in rodents. The dorsal bud forms the upper part of the head of the human pancreas, as well as the main body and tail (or splenic portion). The ventral bud forms the lower part of the head of pancreas – the uncinate process. The compositions of the dorsal and ventral portions differ. The dorsal pancreas forms more abundant large islets, with a higher number of β- and α-cells and a smaller number of PP cells. In contrast, the ventral pancreas is interspersed with smaller islets that contain proportionally more PP cells [241]. However, the relative numbers of islets within the two sections of the pancreas are comparable [242].

Perinatal Growth and Differentiation (16 dpc to Neonate)

Following the secondary transition and the acquisition of acinar, ductal, or endocrine cell fates, the pancreas continues growth in parallel with most other embryonic organs. The pancreas expands by cell proliferation with exocrine tissue added at the periphery and endocrine cells coalescing into progressively larger and more mature clusters. The proportion of endocrine cells declines due to the massive expansion of maturing exocrine tissue. During the first few weeks after birth, the first mature islets become distinguishable with the recognizable architecture of a β-cell core surrounded by a mantle of alpha, epsilon, and recently emerged delta and PP cells (which begin to appear at 15.5 dpc).

Isletogenesis

Islet morphogenesis begins at the secondary transition with the endocrine cell precursors released from the tubular pancreatic epithelium. Unlike the first-wave cells, these pre-endocrine cells aggregate into ribbon-like cords that remain in close association with the precursor epithelium. The cells migrate along rather than away from the underlying epithelium, and not far from their origin. Shortly before birth, glucagon-expressing α-cells begin to envelop the β-cell cords [239], initiating the formation of a peripheral mantle in mature islets. The cords of mixed endocrine cells have been proposed to be broken up by the growth of acinar tissue, which intercedes and divides the cords into segments, like beads-on-a-string [7]. Shortly before birth, the forming islets acquire a characteristic spherical

shape, lose their tight association with the ductal epithelium, and organize nearby within the acinar parenchyma [8]. An important aspect of islet morphogenesis is the internal organization of β-cells into tightly bundled and polarized epithelial sheaths, perfused by numerous fine capillaries [243]. The polarity of β-cells around individual blood vessels is dependent on the serine threonine kinase Lkb1 [244]. Similar to mouse, human islets arise primarily in the core region of the pancreatic bud [245] but have a markedly different mature organization, with α-, β-, and δ-cells distributed throughout the islets [246]. Although isletogenesis is readily observed in the developing pancreas, and the term widely used, it has been almost completely ignored by researchers, with only a few exceptions outlined below.

Mutations in a number of key developmental extrinsic and intrinsic factors disrupt the morphogenesis of normal islets. The defects fall into one of two main categories: disruption of intra-islet organization or aberrant islet growth, which have been observed in mouse models of diabetes [247–250]. Loss of function of an intrinsic factor, the GTPase Rac1, leads to impaired migration of endocrine progenitors following delamination, which causes aberrant increase in cadherin-mediated cell-cell adhesion and retention of islets near ducts [251]. Disruption of BMP signaling via deletion of the BMP receptor 1a gene, for instance, disrupts the segregated distribution of α-cells to the mantle and β-cells to the interior and impairs glucose-stimulated insulin secretion [252]. Proper control of the matrix metalloproteinase MMP-2 by TGF-β1 also is required for normal islet morphogenesis [132]. Persistent expression of HNF6 beyond 18.5 dpc causes failure of islet architecture and β-cell dysfunction [253]. When Nkx2.2 is experimentally converted into a repressor (via fusion with the engrailed repressor domain) and expressed in the perinatal endocrine compartment, α-cells form within the islet core, and the affected mice become overtly diabetic after birth [99]. These are only a few of many similar examples of mutations that cause aberrant islet anatomy.

It is likely that much of the control of islet architecture by EF and TF pathways occurs via their regulation of cell-surface adhesion molecules or components of the extracellular matrix, which direct many aspects of tissue morphogenesis. Indeed, integrins and cell adhesion molecules, such as E-cadherin and NCAM, are downstream targets of TF and EF signaling pathways driving pancreatic development, and they have been directly implicated in guiding the migration and organization of endocrine cells into islets.

Conclusion

A complex and dynamic interplay of extrinsic and intrinsic signaling pathways create the cell diversity, anatomy, and finely tuned physiologic functions of the adult pancreas. Because each signaling pathway is used broadly during embryogenesis, pathway defects often cause early embryonic lethality, prior to the onset of

pancreatic organogenesis, and consequently pancreatic defects generally cannot be distinguished. In contrast, because most of the key pancreatic TFs discussed in this review have functions largely restricted to pancreatic development or function, many are directly linked to heritable human pancreatic maladies, including endocrine cell defects in diabetes [254] and exocrine agenesis [73, 76].

Defects in signaling pathways are common in human pancreatic cancers. Aberrations in Notch, TGFβ, Hedgehog, and Wnt pathways occur in adenocarcinoma [255–257] and are discussed in other chapters of this handbook. By contrast, mutations in genes encoding key pancreatic TFs that control acinar development are not commonly associated with human pancreatic cancer. The association of *Nr5a2* with pancreatic adenocarcinoma through a GWAS study [258] is the notable exception. Recent evidence from mouse genetic models of pancreatic adenocarcinoma strongly links acinar cell dedifferentiation with susceptibility to transformation by oncogenic KRAS. [34, 259]. Inactivation of *Mist1*, *Nr5a2*, *Gata6,* or *Ptf1a* leads to acinar dedifferentiation and the acquisition of non-acinar cell characteristics and enhances the pace and extent of transformation by oncogenic KRAS [81, 186, 260–262].

Understanding the complex relationships between these factors and how they influence pancreatic cell growth, proliferation and/or differentiation, will be critical to developing therapeutic approaches to diseases affecting a wide range of conditions from metabolic defects to pancreatic cancer (Box 5). One striking example is the recent demonstration that insulin gene expression can be induced in vivo by directed transdifferentiation of adult acinar cells through the forced expression of just three endocrine transcription factors, Pdx1, Ngn3, and MafA [263, 264], by expression of Pax4 [265] or by reduction of Ptf1a activity [266]. Refinement of this process may lead to a therapeutic approach to replace lost β-cell function in diabetics (Box 6). It is imaginable that similar approaches may someday provide the option of inducing acinar function to reverse exocrine pancreatic insufficiency.

Box 5 Future Directions

- Identify signals from vasculature and mesoderm that control pancreatic growth and differentiation.
- Define the cellular and molecular processes that underlie the formation of islet cell precursors by the delamination of cells from the pancreatic epithelium.
- Understand molecular and cellular consequences of defects in the extrinsic signaling pathways that control pancreatic organogenesis.
- Define the plasticity of exocrine and endocrine cell phenotypes that allow transdifferentiation.
- Delineate the intrinsic and extrinsic factors that maintain acinar cell identity.

Box 6 Clinical Implications

- An understanding of developmental factors involved in growth and differentiation lays the foundation for developing clinically relevant therapies for pancreatic exocrine cancer.
- Potential to translate an understanding of the formation and maintenance of acinar cell identity to mechanisms that resist neoplastic transformation. An emerging understanding of the development of ducts and acini may inform the design of treatments to restore exocrine tissue destroyed by disease.
- Understanding the key developmental factors has already led to the in vitro generation of beta cells for potential replacement therapy for diabetics.

Acknowledgments We thank Chris Wright for the Pdx1-lacZ mice used for Fig. 1. We are indebted to Galvin Swift helpful discussions and invaluable comments, to Jose Cabrera for illustrations, and to Alethia Villasenor, Diana Chong, Ling Shi, and Mike Hale for contributing unpublished data and images. Abstract

It has become evident over the past decade that pancreatic ductal adenocarcinoma (PDAC) does not originate de novo, but rather, through a multistep progression that involves histologically defined precursor lesions. Three major subtypes of precursor lesions of PDAC have been identified to date, including pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasm (IPMN), and mucinous cystic neoplasm (MCN). PanINs constitute by far the most common precursor lesion, and are, by definition, microscopic in nature, while IPMNs and MCNs occur less frequently and are macroscopic (e.g., radiographically detectable) precursor lesions. In addition to the development of consensus histopathological criteria for the identification and classification of PDAC precursors, there has also been considerable progress made in characterizing the genetic alterations underlying these lesions. Elucidating the molecular pathology of precursor lesions has enabled a better understanding of the pathogenesis of early pancreatic neoplasia, and provided a seedbed for developing tools for early detection and chemoprevention of PDAC. The histopathology, molecular genetics as well as clinical implications and possible directions for future research of PanINs, IPMNs, and MCNs will be discussed in this chapter.

Keywords

Pancreatic ductal adenocarcinoma · Precursor neoplasms · Molecular genetics · Early detection · Pathogenesis

Introduction

The first example linking the progression from a noninvasive precursor lesion to invasive cancer with a cumulative sequence of genetic aberrations was established for the adenoma-carcinoma sequence in colon cancer [1]. This concept has since been extrapolated to many solid cancers, including pancreatic cancer or pancreatic ductal adenocarcinoma (PDAC). In fact, there is now increasing evidence to suggest, that almost all of the major epithelial malignancies may be associated with discrete noninvasive precursor lesions, and that histological progression of such lesions is paralleled by an underlying genetic progression. The general concept that PDAC does not arise de novo, but rather originates from tangible noninvasive precursor lesions, was first proposed over a century ago [2]. However, only over the past few decades have the identity of these precursor lesions been solidified through

Table 1 Clinicopathologic features of PanINs, IPMNs, and MCNs

	PanIN	IPMN	MCN
Predominant age	Prevalence increases with age	60–70 years	40–50 years
Female: male ratio	1:1	2:3	20:1
Preferential location	Head > body/tail	Head (80%) > body/tail	Body/tail (90%) > head
Ductal communication	N/A	Yes	No
Cyst contents	N/A	Viscous	Viscous
Stroma	Collagen-rich	Collagen rich	Ovarian type
Multifocal disease	Often	In ~20–30%	Extremely rare
EUS findings	Normal	Ampullary mucin extrusion, dilated pancreatic duct, and filling defects	None
Key genes involved in pathogenesis and progression	*KRAS*, *CDKN2A*, *TP53*, and *SMAD4*	*KRAS*, *GNAS*, *RNF43*, *CDKN2A*, *TP53*, *PIK3CA, PTEN*, and *SMAD4*	*KRAS*, *RNF43*, *CDKN2A*, *TP53*, *PIK3CA, PTEN*, and *SMAD4*

Abbreviations: *IPMN*, intraductal papillary mucinous neoplasm; *MCN*, mucinous cystic neoplasm; *N/A*, not applicable; *PanIN*, pancreatic intraepithelial neoplasia

meticulous histopathological and molecular biological analysis, and through introduction of a consensus nomenclature [3, 4]. Three different types of precursor lesions to PDAC are recognized: pancreatic intraepithelial neoplasia (PanIN), by far the most common, intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs). The key features of these three precursors are listed in Table 1, and each will be discussed independently within the text.

Pancreatic Intraepithelial Neoplasia (PanIN)

Clinical and Histopathological Features of PanINs

PanIN lesions are microscopic noninvasive precursor lesions with varying degrees of architectural and cytologic atypia, and are located in the interlobular ducts of <5 mm in diameter [3]. Based on the degree of both architectural and cytologic atypia, PanINs are divided into two grades: low-grade and high-grade. Low-grade PanINs consist of flat-to-papillary ductal epithelium with abundant supranuclear mucin. The nuclei may be round or elongated and basally oriented or show some loss of polarity, crowding, enlargement, pseudostratification, and hyperchromasia (Fig. 1a). Mitoses are only rarely seen, and when present, are basal and morphologically normal. In contrast, high-grade PanINs are characterized by significant architectural and cytologic atypia. These lesions are usually papillary and, in some instances, demonstrate

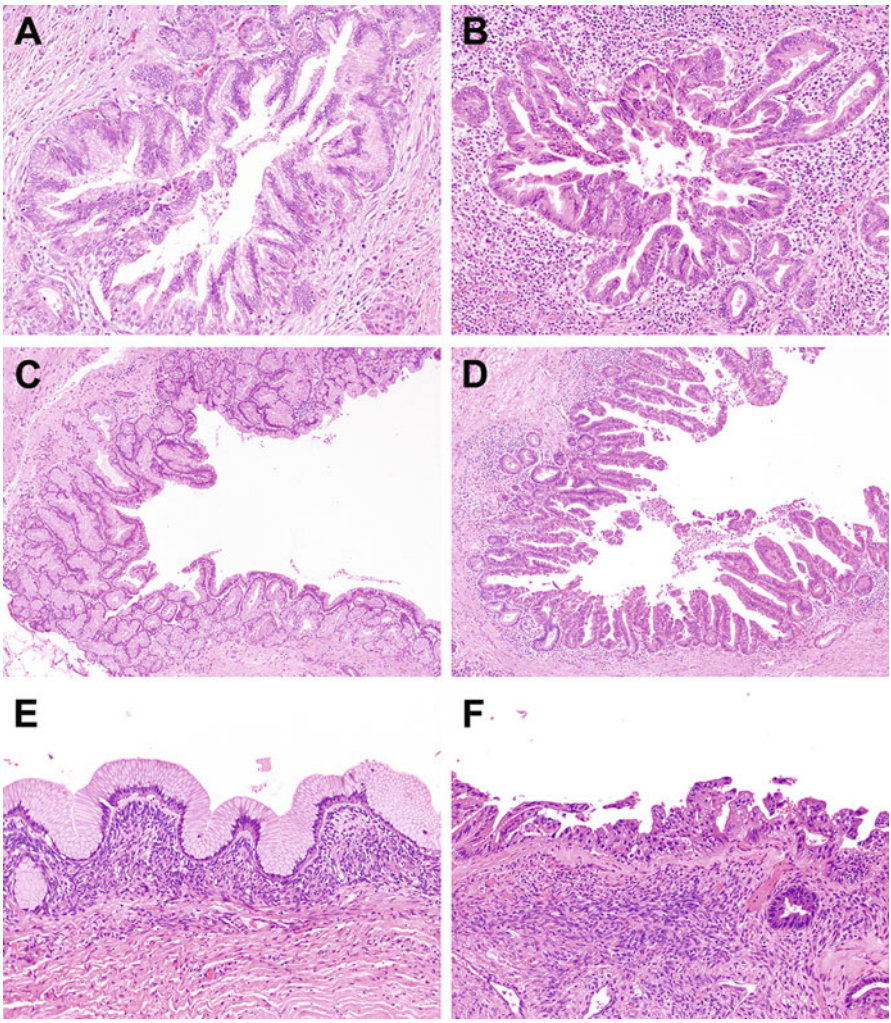

Fig. 1 Representative histologic sections of low-grade (**a**) and high-grade (**b**) PanINs, low-grade (**c**) and high-grade (**d**) IPMNs, and low-grade (**e**) and high-grade (**f**) MCNs. Note the presence of ovarian-type stroma underlying the mucinous epithelium of MCNs (**e**, **f**)

cribriform architecture and luminal necrosis. The nuclei are enlarged, hyperchromatic and show loss of orientation, such that they are no longer perpendicular to the basement membrane (Fig. 1b). Further, the nuclear-to-cytoplasmic ratio is significantly increased. Nucleoli may be prominent, and mitoses, some of which are luminal and atypical, may be present.

The overall prevalence of PanINs increases with age, and low-grade PanINs are found in over half of the population above the age of 65 years [5]. An increased

prevalence of PanINs in not only observed in PDAC, but also in the setting of chronic pancreatitis [6]. In one series, Andea and colleagues found PanIN lesions in 67 of 82 (82%) pancreata from patients with PDAC and in 54 of 86 (63%) of patients with chronic pancreatitis, but only in 10 of 36 (28%) patients with otherwise normal pancreata. Interestingly, PanINs are also frequently found adjacent to other periampullary neoplasms, including ampullary adenomas and adenocarcinomas, acinar cell carcinomas, well-differentiated pancreatic neuroendocrine tumors, serous cystadenomas, and solid-pseudopapillary neoplasms [7, 8].

Molecular Genetics of PanINs

The histological progression of PanIN lesions has been linked to progressive accumulation of genetic aberrations that are shared with PDAC. These aberrations do not occur in a random manner, but rather in a well-described sequence of early and later events (Fig. 2), as depicted in the PanIN progression model ("PanINgram").

Oncogene Mutations in PanIN Lesions

A growing number of oncogenes have been identified that contribute to pancreatic carcinogenesis upon activation, usually through intragenic mutations or copy number alterations. The most commonly observed activating point mutations in PDAC, as well as in PanINs, are found in the *KRAS* oncogene on chromosome 12p. These mutations, which are also among the earliest genetic alterations observed during pancreatic carcinogenesis, can be detected in up to 90% of PDACs and most often occur on codons 12, 13, or 61 [10, 11]. Utilizing pyrosequencing, a highly sensitive DNA sequencing technique, Kanda et al. showed more than 90% of low-grade PanINs harbor *KRAS* mutations, suggesting that this oncogene plays a critical role in PDAC initiation [12]. The importance of constitutively activated *KRAS* in PDAC initiation is further underscored by the development of genetically engineered mouse models of PDAC, wherein a mutant *Kras* allele is sufficient for the development of murine PanIN (mPanIN) lesions [13, 14]. Activating mutations impair the intrinsic GTPase activity of the *KRAS* gene product, leading to constitutive activation of downstream intracellular signaling cascades [15]. Three major downstream Ras effector cascades have been identified that are involved in mediating the oncogenic properties conferred by constitutively active *KRAS*, namely the RAF/MEK/ERK, the PI3K/AKT, and the RalGDS/Ral pathways. Of note, oncogenic Ras signaling seems to be involved in not only PDAC initiation, but also required for tumor maintenance in established cancers [16, 17]. Interestingly, in a proportion of PDAC more than one distinct mutation within the *KRAS* gene can be detected, suggesting that within the same organ, multifocal precursor lesions can develop independently from the one that eventually culminates in PDAC [18].

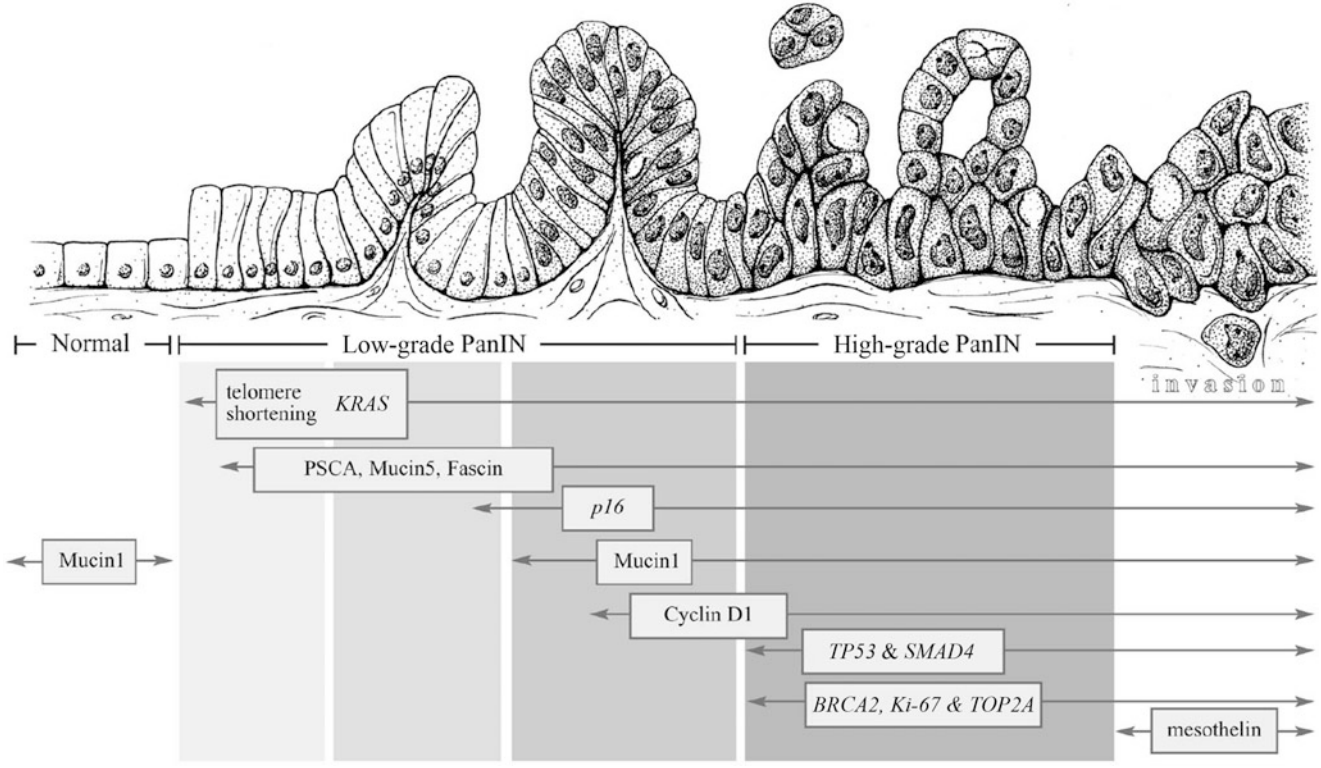

Fig. 2 Schematic illustration of some of the key genetic alterations observed during the multistep progression from the normal duct to PanIN and eventually PDAC in the form of a "PanIN-gram." The alterations shown are not comprehensive and are discussed in detail within the text (Reproduced from Maitra et al. [9] with permission)

Tumor Suppressor Gene Mutations in PanIN Lesions

Three tumor suppressor genes frequently inactivated in PanIN lesions, mirroring their common loss of function in PDAC, are *CDKN2A*, *TP53*, and *SMAD4/DPC4*. The *CDKN2A* gene on chromosome 9p21 encodes for the cell-cycle checkpoint protein p16, which binds to the cyclin-dependent kinases CDK4 and CDK6, and thereby inhibiting cyclin D1-binding and causing cell-cycle arrest in G1-S [19]. The *CDKN2A* gene is inactivated in virtually all PDACs: in approximately 40% of cases, this is due to homozygous deletion; another 40% carry intragenic mutations and show loss of the second allele; and 15% demonstrate epigenetic inactivation [20, 21]. Loss of p16 expression, which can be exploited as surrogate marker of the *CDKN2A* gene status, correlates with PanIN progression and is observed in 30–55% of low-grade PanINs and 71% of high-grade PanINs [22]. Interestingly, the frequencies of *CDKN2A* inactivation appear to be lower in PanIN lesions associated with chronic pancreatitis [23]. In a subset of cases, homozygous deletions of *CDKN2A* at 9p21 can also include homozygous deletion of the *methylthioadenosine phosphorylase* (*MTAP*) gene, whose product is required for the salvage pathway of purine synthesis. Codeletion of *MTAP* and *CDKN2A* is observed in approximately one-third of PDACs, and 10% of high-grade PanINs [24, 25].

The tumor suppressor gene *TP53* on the short arm of chromosome 17 encodes the protein p53, which plays a key role in mediating several important physiological functions, including regulation of the G1/S cell-cycle checkpoint, maintenance of G2/M arrest, and induction of apoptosis. Therefore, the inactivation of p53 in the majority of PDACs affects two major mechanisms controlling cell number: cell proliferation and apoptosis. Moreover, p53 abrogation contributes to genomic instability observed in PDACs [26]. Loss of *TP53* function is observed in 50–75% of PDAC and almost exclusively through intragenic mutations and loss of the second allele [27]. Nuclear accumulation of p53 using immunohistochemistry largely correlates with the mutational status of *TP53* and can therefore be used as a surrogate marker of *TP53* mutations in PanIN lesions. Immunohistochemistry reveals intranuclear p53 accumulation mostly in high-grade PanINs, and, thus, suggesting that *TP53* mutations constitute rather late events in the multistep pancreatic cancer progression cascade [9].

SMAD4 on chromosome 18q is inactivated in approximately 55% of PDACs by homozygous deletion in 30% of cases, or through intragenic mutation and loss of the second allele in another 25% [28]. *SMAD4* encodes the protein Smad4, which is involved in transforming growth factor (TGF)-beta signaling. The activation of the TGF-beta signaling pathway leads to binding of Smad4 to a phosphorylated Smad2/3 protein complex and its translocation to the nucleus, where it binds to specific promoter regions and induces expression of respective target genes [29]. Therefore, the loss of Smad4 function interferes with the intracellular signaling cascade downstream of TGF-beta and leads to reduced growth inhibition through loss of proapoptotic stimuli and inappropriate G1/S transition [30]. A potential alternative mechanism was recently unmasked in an elegant study showing that selective loss of Smad4-dependent signaling in T-cells leads to development of

epithelial cancers of the gastrointestinal tract in mice, while no tumor development was observed in mice with epithelial-specific deletion of *SMAD4*. These observations suggest that in addition to the abovementioned cell functions, Smad4 might also be crucially involved in interactions between cancer cells and the microenvironment and/or modulation of immune surveillance [31]. As described above for p53, immunohistochemical labeling for Smad4 can be used as a surrogate marker of the *SMAD4* mutational status [32]. Loss of Smad4 nuclear expression is observed in about one-third of high-grade PanINs, while it is preserved in normal ducts and low-grade PanINs [9, 33]. Therefore, *SMAD4* mutations, like mutations of *TP53*, represent a relatively late genetic event in the progression model for pancreatic cancer.

Caretaker Gene Mutations in PanIN Lesions

Caretaker genes comprise a third class of cancer-related genes, which are not directly involved in controlling cell growth or apoptosis, but rather help to maintain DNA integrity, e.g., by means of mismatch repair, nucleotide-excision repair, and base-excision repair [34]. By repairing subtle changes in the genomic DNA sequence that occurs due to polymerase errors or as a result of exposure to mutagens, as well as gross chromosomal aberrations, caretaker genes prevent accumulation of mutations within a cell that might provide a selective advantage leading toward a malignant phenotype.

The Fanconi anemia gene family is a group of caretaker genes known to be involved in pancreatic carcinogenesis [35, 36]. The Fanconi anemia gene family is involved in homologous recombination repair in response to DNA damage, e.g., by crosslinking agents or radiation [37]. One member of this family, the breast and ovarian cancer susceptibility gene *BRCA2* on chromosome 13q, is of particular interest in the setting of familial pancreatic cancer, since germline *BRCA2* mutations are found in 5–10% of familial cases, especially in individuals of Ashkenazi Jewish heritage [38, 39]. In addition, PDACs harboring Fanconi anemia mutations are exquisitely sensitive to DNA crosslinking agents, presenting an avenue for synthetic lethal therapy [36]. In patients with germline *BRCA2* mutations, loss of the second allele is observed in high-grade PanINs, suggesting that akin to p53 and Smad4, inactivation of BRCA2 function also constitutes a late genetic event [40].

Genomic Instability and Telomere Length Alterations in PanIN Lesions

Telomeres consist of hexameric TTAGGG repeats at the ends of chromosomal DNA strands, which confer chromosomal stability during cell division by preventing the ends from becoming sticky. Telomere attrition is among the earliest and most common alterations observed in PanIN lesions. Interestingly, significant telomere shortening is observed in over 90% of low-grade PanINs [41]. It has been speculated

that telomeres conduct a similar function to those of caretaker genes in pancreatic carcinogenesis, such that telomere dysfunction facilitates progressive accumulation of additional chromosomal abnormalities that culminates in the development of PDAC.

Reflecting their inherent genomic instability, structural and numerical chromosomal aberrations can be found in almost all cases of PDAC and often involve loss of significant proportions or the entirety of chromosomal arms. Chromosomal regions frequently involved in loss of one allele (designated loss of heterozygosity [LOH]) in PanINs include 1q, 6q, 7p, 9p, 10q, 14, 16q, 17p, and 18q [42]. Of note, the frequency of LOH observed at a given locus commonly increases from low- to high-grade PanINs. It has been proposed that LOH might in many cases be the first event in the "two-hit" cascade leading to inactivation of tumor suppressor genes. This concept is in line with the hypothesis of genomic instability beginning early in the PanIN progression model.

Epigenetic Alterations in PanIN Lesions

The most common form of epigenetic alterations found in PDAC, and also in PanIN lesions, consists of methylation of CpG islands within promoter regions, leading to transcriptional silencing of the regulated gene. Over recent years, epigenetic gene silencing – in addition to genetic alterations such as deletions and intragenic mutations – has increasingly been recognized as one of the most ubiquitous mechanisms exploited by cancer cells to alter their inherent transcriptomic programs in favor of more rapid cell growth, invasiveness, and resistance to apoptosis [43].

Current evidence supports the notion that aberrant DNA methylation occurs early during the progression of pancreatic cancer. Using a gene candidate approach, Rosty et al. demonstrated that PanIN lesions in patients with chronic pancreatitis show the loss of p16 expression, suggesting that this alteration may contribute to the predisposition of patients with chronic pancreatitis to develop PDAC [23]. In a large-scale methylation analysis with subsequent validation via methylation-specific PCR, Sato et al. analyzed DNA samples from 65 PanINs for methylation status of eight genes (*ST14, CDH3, CLDN5, LHX1, NPTX2, SARP2, SPARC*, and *Reprimo*) that were identified previously through a microarray approach as aberrantly hypermethylated in PDAC [44]. Among PanINs examined in this study, methylation of any of these eight genes was identified in 68% of cases with methylation prevalence increasing from low-grade to high-grade PanIN for *SARP2*, *Reprimo* and *LHX1*. Peng et al. had examined promoter methylation patterns of 12 cancer-related genes (*p14, p15, p16, p73, APC, hMLH1, MGMT, BRCA1, GSTP1, TIMP-3, CDH1*, and *DAPK-1*) in 40 microdissected PanIN lesions and 147 discrete areas sampled from PDACs [45]. The frequency of at least one methylated gene locus increased significantly from normal ductal epithelium lacking signs of inflammation to PanINs, and from PanINs to PDAC, respectively, further underscoring that epigenetic progression is also a feature of the traditional "PanIN-gram" model. Determination of aberrantly methylated gene promoters in pancreatic juice samples

has emerged as a potential diagnostic tool for PDAC and its precursor lesions, with a suggestion that it might be more specific than detection of mutated or differentially expressed genes [46]. In particular, certain promoter sequences like that of the *TSLC1* gene are methylated only in higher-grade PanIN lesions, and therefore, might identify those lesions that pose a greater relative risk of progression to invasive adenocarcinoma.

Transcriptomic Abnormalities in PanIN Lesions

With the advent and increasingly widespread deployment of global gene expression profiling techniques, including RNA sequencing, serial analysis of gene expression (SAGE), and various forms of oligonucleotide and cDNA/miRNA microarrays, there has been a dramatic increase in our knowledge of differential gene expression patterns in PDAC [47–51]. A few compelling examples of differentially expressed genes with translational potential will be discussed here. Although initially discovered in the context of invasive cancer, the differential expression of these genes has since been validated in varying grades of PanIN lesions as well.

Prostate stem cell antigen (PSCA) is overexpressed in 30–40% of low-grade IPMNs and 60% of high-grade IPMNs, in line with PSCA upregulation being an early event in the PanIN progression model [9]. Of note, the recent pilot studies showed that PSCA overexpression might be a suitable target for the development of novel diagnostic tools for PDAC [52]. Another example is mesothelin, a membrane-bound GPI-anchored protein known to play a role in cell adhesion. Unlike PSCA, mesothelin expression was detected only in 11% of PanIN lesions, but close to 100% of PDACs, suggesting that mesothelin overexpression is a late event [9, 53]. Recent studies have examined mesothelin as an antigen for cancer cell-specific drug delivery and for cancer immunotherapy [54]. A study by Sutherland et al. using oligonucleotide microarrays described the upregulation of several components of the retinoic acid signaling pathway, including RAR-alpha, HOXB6 and HOXB2 in PDAC, as compared to the normal pancreas [55]. In particular, HOXB2 expression was identified as prognostic marker in PDAC that correlated with survival, surgical resection, and tumor stage at the time of diagnosis. Nuclear immunostaining for HOXB2 was observed in 8% of normal pancreatic ducts, 14% of PanIN lesions, and 38% of PDACs. This suggests HOXB2 overexpression increases during pancreatic carcinogenesis.

Changes in microRNA (miRNA) expression are also important in the development of PDAC. miRNAs are small endogenous noncoding RNAs of 14–24 nucleotides that negatively regulate protein expression at the posttranscriptional level by inhibiting translation and/or by targeting mRNAs for degradation. Furthermore, because miRNAs are stable and detectable in human plasma, they are being investigated for their use as diagnostic serum markers. PDACs overexpress several miRNAs including miR-21, miR-34, miR-146a, miR-155, miR-196b, and miR-200a/b [56–58]. In a large comprehensive miRNA study by Yu et al., the authors identified 107 aberrantly expressed miRNAs based on the PanIN grades

and compared with normal pancreatic duct samples [59]. Further, 35 aberrantly expressed miRNAs in high-grade PanINs compared with normal pancreatic duct samples. These differentially expressed miRNAs included those that have been previously identified in PDACs as well as miRNAs not previously described as differentially expressed in these lesions (e.g., miR-125b, miR-296-5p, miR-183*, miR-603, miR-625/*, and miR-708). Interestingly, miR-196b was the most differentially expressed miRNA in high-grade PanINs.

Cell Cycle and Proliferation Abnormalities in PanIN Lesions

Much like PDAC, PanIN lesions also demonstrate aberrations in cell cycle checkpoint control and proliferation. While low-grade PanINs are minimally proliferative, this index significantly increases in high-grade PanINs, as assessed by nuclear expression of the proliferation antigen Ki-67/MIB-1. Klein et al. described mean nuclear Ki-67/MIB-1 labeling indices as 0.41% for normal ducts, 5.7% for low-grade PanIN, and 22.0% for high-grade PanIN [60]. The average labeling index for PDACs was 37.0%, reflecting the progressive increase in proliferative potential during the progression from normal ducts to PDAC [60]. Cyclin D1 is involved in regulating cell cycle progression by acting as a cofactor in phosphorylating and inactivating the retinoblastoma (Rb) protein, and its expression has been linked to poor prognosis and decreased survival in PDAC. Overexpression of cyclin D1 is observed in 14% of low-grade PanINs, 57% of high-grade PanINs, and up to 60–85% of PDACs [9]. $p21^{WAF/CIP1}$ acts as cyclin-dependent kinase inhibitor that inhibits cyclin E/CDK2 complexes and prevents phosphorylation of Rb. Overexpression of $p21^{WAF/CIP1}$ is an early event and is observed in 33% of low-grade PanINs, 80% of high-grade PanINs, and 85% of PDACs [61].

Aberrantly Activated Growth Factor Signaling Pathways in PanIN Lesions

Cyclooxygenase-2 (COX-2) is upregulated in PDAC, possibly secondary to activation of nuclear factor kappa B signaling, and is postulated to be involved in cell proliferation and tumor angiogenesis [62]. In PanINs, COX-2 is generally found to be overexpressed in high-grade PanINs as compared to low-grade PanINs and normal ducts [63]. COX-2 inhibitors have been suggested as potential chemopreventive agents against PDAC [64], but initial clinical efficacy data have been equivocal thus far. Members of the matrix metalloproteinase (MMP) family of zinc-dependent extracellular proteinases are involved in enabling cell invasion and metastasis [65]. Overexpression of MMP-7 is observed in the majority of PDACs, as well as in greater than half of low-grade PanINs [66]. Urinary plasminogen activator (uPA) converts plasminogen into plasmin, which in turn activates MMP precursors. In addition, uPA induces the upregulation of various downstream signaling molecules, including fibroblast growth factor 2 (FGF2) and angiostatin [67, 68]. In one study, uPA

immunolabeling was observed not only in the majority of PDACs but also in 19 of 27 (70%) low-grade PanINs and 12 of 27 (44%) high-grade PanINs [69].

Aberrantly Activated Embryonic Signaling Pathways in PanIN Lesions

Embryonic signaling pathways, including Hedgehog, Notch, and Wnt, which are usually inactive in differentiated tissues of the adult pancreas, have been found to be aberrantly reactivated in PDACs as well as in a variety of other epithelial human cancers [70–72]. This finding is of particular interest, since these signaling networks might contribute to maintain specific subpopulations of cancer cells with enhanced tumor-initiating properties, often referred to as "cancer stem cells." This concept has direct translational implications, since all of the three abovementioned embryonic signaling pathways represent candidate drug targets. The phenotype of the putative cancer stem cell compartment in PDAC has recently been elucidated by multiple groups. For example, Simeone et al. have demonstrated that a subpopulation of CD44+/CD24+/ESA+ cells, which represent less than 1% of cancer cells within a "bulk" isolate, harbor more than 100-fold increased tumorigenic potential in immunodeficient mice, as compared to nontumorigenic cells. Of note, in this population they also observed a ~10-fold overexpression of the Hedgehog ligand sonic hedgehog (Shh) as compared to bulk tumor tissues [73]. Similarly, Feldmann et al. found that inhibition of Hedgehog signaling by means of small molecule inhibitors diminished tumor initiation and metastasis in orthotopic xenograft models of PDAC, mirrored by significant reduction of a subpopulation of cancer cells with high aldehyde dehydrogenase (ALDH) activity in vivo and in vitro [74]. The concept that Hedgehog signaling is involved in maintaining a "cancer stem cell niche" would imply, that Hedgehog pathway reactivation occurs very early during the carcinogenic cascade, and indeed overexpression of Shh has been observed by immunohistochemistry in low-grade PanINs, but not in normal pancreatic ductal epithelium [75]. Further evidence came from another study by Leach et al. demonstrating that low-grade PanINs express a cluster of "foregut-specific" markers, including pepsinogen C, MUC6, KLF4, GATA6, Sox-2, Forkhead-6, and TFF1, which is very similar to differential gene expression patterns observed in immortalized pancreatic ductal epithelial cells upon transfection with the Hedgehog transcription factor Gli1 [76].

Analogous to the aberrant expression of Hedgehog pathway components, murine and human PanINs and PDACs also express multiple Notch components [72]. As observed for Hedgehog signaling, Notch pathway activation during pancreatic carcinogenesis is most likely to be due to endogenous ligand overexpression, rather than mutational events. For example, the activating Notch ligand, Jagged-1, is overexpressed in low-grade PanINs [76]. The activation of Wnt signaling in cancer tissues usually occurs due to intragenic mutations, i.e., either activating *CTNNB1/beta-catenin* mutations or loss-of-function mutations within the *APC* gene, resulting in nuclear translocation of beta-catenin and subsequent transcription

of Wnt target genes [77]. In PDAC, however, canonical pathway activation is more often ligand-dependent, than through mutational events [78]. Immunohistochemical detection of nuclear beta-catenin can be used as a surrogate marker of Wnt pathway activation. Al-Aynati et al. reported nuclear overexpression of beta-catenin in a small proportion of high-grade PanINs [79], but observations regarding PDACs have been conflicting [71].

Genetically Engineered Mouse Models and Murine PanINs (mPanINs)

A remarkable advance achieved in the last decade for pancreatic cancer research has been the development of genetically engineered mouse models, which resemble cognate properties of the human disease, such as a multistep progression involving noninvasive precursor lesions culminating in lethal disseminated malignancy [13, 14, 26]. In order to distinguish precursor lesions in mice from those arising in human pancreata, the former have been designated as murine PanIN (mPanIN) [80]. Interestingly, mPanIN lesions observed in these models also harbor many of the molecular alterations found in humans, including activation of the Notch and Hedgehog signaling pathways [13, 81]. These mouse models represent a unique platform for discovery of early pancreatic neoplasia-associated biomarkers in serum, as recently demonstrated by Hanash and colleagues [82]. In this study, the investigators identified a large panel of abnormally expressed protein the sera of mice from both early and late stage disease. Of note, when five of these proteins were examined in human sera obtained from PDAC patients, they were able to predict the diagnosis of malignancy as much as 7–13 months prior to onset of clinical symptoms, underscoring the commonalities between mouse and human disease models. Genetically engineered mouse models of mPanINs and PDAC have also begun to be utilized as in vivo platforms for assessment of novel chemoprevention and treatment modalities. For example, it has been demonstrated that the COX-2 inhibitor nimesulide can downregulate mPanIN formation in genetically predisposed mice [83], an expected finding, given that mPanINs (as well as their human counterparts) overexpress COX-2 [13].

Therapeutic Implications of Isolated PanIN Lesions

Currently, the detection of PanIN lesions is hampered by the lack of sensitive noninvasive diagnostic tools. Due to their microscopic size, PanIN lesions are usually not diagnosed by standard clinical imaging techniques. Recent data from the Johns Hopkins Hospital suggest that a combinatorial approach of collecting secretin-stimulated pancreatic juice, endoscopic ultrasound (EUS), and computer tomography might enable the detection of morphological and genetic changes associated with PanIN lesions in the adjacent pancreatic parenchyma [84]. In particular, Brune et al. showed that PanINs can be associated with a lobulocentric form of atrophy in the adjacent parenchyma, and a diffuse distribution of this atrophy

observed in patients with multifocal PanIN lesions confers a diagnostic pattern on EUS [85]. Even if further improvements in imaging techniques and other diagnostic tools will provide the means to reliably and noninvasively screen for the presence of PanIN lesions, the therapeutic implications that of such findings are largely unknown. While the pathophysiological concept of a multistep progression of PanINs culminating in PDAC has become acceptable, the appropriate clinical management of noninvasively diagnosed PanIN lesions in an individual patient still needs to be defined. In an effort to estimate the approximate probability of a single PanIN to progress to cancer, Terhune et al. applied a mathematical model, assuming that PanIN lesions can be found in 37.5% of cases in a normal population with an average of five foci per affected pancreas, and that 0.8% of pancreata develop PDAC [86]. The authors argued that based on these assumptions only about 1% on PanIN lesions progress to PDAC. These considerations underscore the caution mandated in drawing therapeutic conclusions based on the identification of PanIN lesions alone, in the absence of a discernible malignancy.

Interestingly, collection of secretin-stimulated pancreatic juice has emerged as a promising adjunct to the evaluation of precursor neoplasms. Digital next-generation sequencing ("digital NGS") to detect low-abundance mutations in secretin-stimulated pancreatic juice samples collected from the duodenum in subjects with a family history of PDAC has identified low abundance of *KRAS* mutations that are thought to arise from small PanIN lesions [87]. However, further studies are needed to assess whether the genetic alterations associated with high-grade PanINs can be reliably detected by digital NGS with a high sensitivity and high specificity.

Intraductal Papillary Pucinous Neoplasms (IPMN)

Clinical Features of IPMNs

Intraductal papillary mucinous neoplasms (IPMNs) are mucin-producing epithelial neoplasms that arise from the main pancreatic duct (main duct IPMN), branches (side branch IPMN), or both (mixed main and branch duct IPMN). A population-based study estimated the age and sex-adjusted cumulative incidence of an IPMN to be 2.04 per 100,000 individuals per year [88]. In comparison, the incidence of PDAC is 0.8 per 100,000 individuals per year. These neoplasms occur more frequently in men than women with a mean age at presentation of approximately 65 years. The majority of IPMNs are identified incidentally on abdominal computed tomography (CT) or magnetic resonance imaging (MRI), but a subset can be associated with epigastric/abdominal pain, pancreatitis, weight loss, and jaundice [89, 90]. IPMNs are usually greater than 1 cm in size, commonly arise in the head of the pancreas and can be multifocal. Similar to PanINs, the neoplastic cells may show varying degrees of dysplasia that can progress from low-grade dysplasia to high-grade dysplasia and PDAC [91]. In addition, the risk of high-grade dysplasia and PDAC is higher in patients with main duct IPMN and mixed main and branch duct IPMN than branch duct IPMN (60% vs. 25%, respectively) [89, 92]. Although the

rate of progression to advanced neoplasia in an IPMN has yet to be defined, patients with a PDAC arising in an IPMN are generally 3–5 years older than those with a non-invasive IPMN [93]. Thus, it is hypothesized that there is a substantial window of opportunity to detect and treat noninvasive IPMNs before they progress to PDAC.

Histopathological Features of IPMNs

As mentioned previously, IPMNs can be subdivided into three groups based on their location with respect to the pancreatic ductal system: main duct, branch duct, and mixed main and branch duct. Interestingly, main and branch duct IPMNs differ in their clinicopathologic features (Table 2). Based on the degree of architectural and cytologic atypia, IPMNs are graded as either low-grade or high-grade. Representative histologic images of these lesions are shown in Fig. 1c, d. Main duct IPMNs have an increased frequency of harboring high-grade dysplasia and more often associated with a PDAC than branch duct IPMNs [96, 97]. The neoplastic epithelium lining the papillae can demonstrate a variety of directions of differentiation, but the biologic and clinical significance of patterns of differentiation remain controversial. Most IPMNs adopt an intestinal differentiation and resemble intestinal adenomas with well-formed, long villous projections, lined by columnar mucinous epithelium with cigar-shaped nuclei. Most of the neoplastic cells contain abundant apical mucin and, in some cases, have scattered goblet cells. Gastric foveolar differentiation is characterized by eosinophilic cytoplasm, basally oriented nuclei, and abundant apical cytoplasm mucin. Gastric foveolar type IPMNs can be papillary or flat in appearance. The pancreatobiliary type IPMN is less common and the neoplastic cells form more complex papillae with bridging and cribriform structures. The nuclei are rounder than the intestinal type and the chromatin pattern is open, often with prominent nucleoli. This type contains less apical mucin and tends to harbor at least high-grade dysplasia. The intestinal and pancreatobiliary types of IPMN more commonly arise in the main duct, while the gastric type of IPMN is usually a branch duct lesion. The histological subtypes also demonstrate different patterns of apomucin labeling, with the intestinal-type IPMNs expressing MUC2, the pancreato-biliary type expressing MUC1, and the gastric type IPMN expressing MUC5AC, but usually lacking MUC1 and MUC2. In addition to intestinal, gastric

Table 2 Clinical and pathologic features associated with main duct and branch duct IPMNs [94, 95]

	Main duct IPMN	Branch duct IPMN
Age peak	55 years	65 years
Location in pancreas	57% in head	93% in head
Dysplasia/malignancy		
Low-grade dysplasia	43%	85%
High-grade dysplasia	20%	15%
Invasive adenocarcinoma	37%	0%

and pancreatobiliary type IPMNs, there is another histologic variant that is referred to as intraductal oncocytic papillary neoplasm (IOPN). The neoplastic cells found within IOPNs show abundant eosinophilic cytoplasm, due to the high number of mitochondria in these cells. However, whether IOPNs should be classified as a subtype of IPMNs or a distinct entity remains controversial.

IPMNs can be associated with two predominant subtypes of PDAC that include colloid (mucinous noncystic) carcinoma and conventional ductal adenocarcinoma [98]. Distinguishing the subtypes of PDAC is clinically important, since colloid carcinomas carry a significantly better prognosis [99]. Great care should be taken not to overlook an associated focal carcinoma, particularly because the neoplastic epithelium in an IPMN can extend intraductally for several centimeters beyond the grossly dilated duct. Of note, patients with IPMNs show an increased risk for extrapancreatic malignancies. In particular, higher rates of colorectal, gastric, esophageal, and lung malignancies have been reported [100].

Molecular Features of IPMNs

Studies have identified a variety of genetic alterations in IPMNs. The most frequent genetic alteration is an oncogenic *KRAS* mutation, which has a prevalence of >80%. *KRAS* encodes for a G-protein, or a guanosine-nucleotide-binding protein, that functions as a small GTPase and mediates downstream MAPK/ERK signaling from growth factor receptors [101, 102]. Missense mutations result in constitutive activation of *KRAS* and occur primarily in codon 12 and, to a lesser extent, codons 13 and 61 [101]. *KRAS* mutations are detected in all histologic subtypes of IPMNs, but are more likely present in the gastric and pancreatobiliary types. Further, Nikiforova et al. found *KRAS* mutations in IPMNs are associated with a branch duct location [101]. In addition to *KRAS*, 65% of IPMNs harbor somatic mutations in the oncogene *GNAS*, which encodes for the G-protein stimulating α subunit (Gsα) [102]. Mutations in *GNAS* at either codon 201 or 227 result in constitutive activation of Gsα and its effector adenylate cyclase, leading to autonomous synthesis of cAMP and uncontrolled growth signaling [102, 103]. *GNAS* mutations are more often present in IPMNs involving the main pancreatic duct than branch duct, and of an intestinal histologic subtype. Collectively, activating mutations in *KRAS* and/or *GNAS* are present in >96% IPMNs and considered early genetic events in the progression to PDAC.

In addition to *KRAS* and *GNAS*, inactivating mutations in the tumor suppressor gene *RNF43* occur in 14–38% of IPMNs with frequent loss of heterozygosity [104, 105]. *RNF43* encodes for an E3 ubiquitin ligase that regulates the Wnt signaling pathway. Similarly, activating mutations in *CTNNB1* also occur in small subset of IPMNs [106]. Other potential genes mutated in IPMNs include *TP53*, *PIK3CA*, *PTEN*, *CDKN2A*, and *SMAD4*. *TP53* mutations occur late in the neoplastic progression of IPMNs and are frequently seen in advanced neoplasia [107]. Similarly, Garcia-Carracedo et al. found *PIK3CA* mutations and deletions in *PTEN* are strongly associated with high-grade IPMNs and PDAC [108, 109]. Losses in *CDKN2A* are an

uncommon finding, but more prevalent in IPMNs with high-grade dysplasia than low-grade dysplasia [110, 111]. *SMAD4* is also rarely inactivated in low-grade IPMNs, but mutations with corresponding loss of heterozygosity are typically seen in the setting of advanced neoplasia. More recently, Hata et al. demonstrated an elevated telomerase activity, presumably due to *TERT* promoter mutations, in IPMNs is more often seen in IPMNs with high-grade dysplasia and/or invasive adenocarcinoma [112].

Epigenetic silencing by aberrant promoter methylation has been described for a number of candidate tumor suppressor genes in IPMNs, including *SOCS1, ppENK, CDKN1C*, and *CDKN2A* [113, 114]. In recent years, several studies have uncovered a plethora of differentially expressed genes in IPMNs. Transcripts found to be overexpressed in IPMNs that represent candidate biomarkers, and which might also potentially be involved in IPMN progression, include *lipocalin-2, galactin-3, cathepsin-E, claudin-4, TFF-1, TFF-2, TFF-3, CXCR-4, S100A4, matrix metalloproteinase 7 (MMP-7),* and *sonic hedgehog (SHH)* [115–117]. The recent availability of technologies that can enable mass spectrometric based approaches on microdissected tissues has enabled one of the first global proteomic analysis of a noninvasive IPMN [118]. This study, using microdissected material from an archival IPMN, identified tissue transgluaminase-2 (TTG-2) and deleted in malignant brain tumor 1 (DMBT1) as candidate biomarkers in these precursor lesions.

Genetically Engineered Mouse Model of IPMNs

In an elegant study, Schmidt and coworkers described that concomitant pancreas-specific expression of an oncogenic *Kras* allele and transforming growth factor-alpha (TGF-alpha) led to formation of acinar-ductal metaplasia, accelerated progression of *Kras*-induced mPanINs, as compared to *Kras* expression alone, and to the development of cystic lesions resembling key features observed in human IPMNs starting at 2–3 months after birth [119]. Histologically, these cystic lesions were characterized by papillary proliferations which had formed in branches of the main pancreatic duct. In line with findings in humans, the observed murine IPMNs were shown to express CK19, MUC1 and MUC5AC.

Studying the potential role of *GNAS* in pancreatic carcinogenesis, Taki et al. generated transgenic mice that included activated *GNAS* [120]. These mice showed elevated cAMP levels, small dilated tubular complex formation, loss of acinar cells, and fibrosis in the pancreas; but, no macroscopic tumorigenesis was apparent by 2 months of age. However, the combination of *KRAS* and *GNAS* resulted in mice developing cystic tumors consisting of markedly dilated ducts lined by papillary dysplasia epithelium in the pancreas that closely mimicked human IPMNs.

Interestingly, mutations in *Brg1* and other members of the SWI/SNF complex have been observed in over 30% of PDACs, and decreased Brg1 protein expression has been identified in a subset of IPMNs [121]. Inactivation of *Brg1* in combination with mutant *Kras* in mice promoted the development of cystic neoplastic lesions that resemble

IPMNs and over time progress to PDAC [122]. These findings suggest that chromatin remodeling may underlie the development of IPMNs and the formation of PDAC.

Therapeutic Considerations Regarding IPMNs

The major clinical challenge with IPMNs is differentiating IPMNs with high-grade dysplasia and PDAC from IPMNs with low-grade dysplasia. Moreover, another clinical conundrum is predicting whether an IPMN will follow an indolent or malignant disease course. As a consequence, a number of consensus- and evidence-based management and treatment guidelines have been developed for IPMNs and heavily rely on cross-sectional abdominal imaging, endoscopic ultrasound, and pancreatic cyst fluid ancillary studies, such as carcinoembryonic antigen (CEA) and cytopathology [89, 123, 124]. However, these diagnostic modalities have clear limitations in predicting malignancy with a high sensitivity and high specificity. Thus, there has been a growing interest in identifying molecular markers to guide management for IPMNs.

In a pilot study, Khalid et al. prospectively evaluated the presence of mutations in *KRAS* and allelic imbalance in seven tumor suppressor genes by Sanger sequencing in preoperative pancreatic cyst fluid [125]. The authors found the combination of *KRAS* mutations and allelic loss to be predictive of advanced neoplasia within an IPMN with a sensitivity and specificity of 91% and 93%, respectively. These results were later expanded into a multicenter prospective study (Pancreatic Cyst DNA Analysis Study or PANDA study) of 113 patients [126]. Pancreatic cyst fluid was collected preoperatively by EUS-fine needle aspiration (FNA) and assessed for *KRAS* mutations and the overall fraction of alleles lost compared to germline DNA (mean allelic loss amplitude or MALA).

In the PANDA study, the presence of mutant *KRAS* alone had a sensitivity and specificity of 45% and 96%, respectively, for a mucinous cyst, but was not predictive of advanced neoplasia. In contrast, a high MALA (>82%) had 90% sensitivity and 67% specificity for advanced neoplasia. But there were a number of weaknesses in the study design that diminished the overall significance of these results. Notably, it was unclear if DNA analysis would add value to established pancreatic cyst management guidelines. Furthermore, there was concern that MALA may be confounded by DNA degradation, gastrointestinal contamination during EUS-FNA, and other variables. Indeed, follow-up studies demonstrated broad variability in agreement between molecular and clinical diagnoses. Shen et al. reported an 89% concordance between molecular and clinical consensus diagnoses, while Panarelli et al. and Toll et al. reported a concordance rate of 39% and 56%, respectively [127–129].

Regardless of the issues with MALA, *KRAS* testing proved to be a cost-effective strategy to identify patients with IPMNs and MCNs. In a cohort of 618 patients, Nikiforova et al. found mutant *KRAS* had 54% sensitivity and 100% specificity for a mucinous cyst [101]. This assay was superior to CEA testing and utilized significantly less pancreatic cyst fluid for analysis. Moreover, the combination of *KRAS*

point mutations and elevated CEA improved the sensitivity to 83% and maintained a high specificity of 85%. The sensitivity of molecular analysis for mucinous cysts was further increased by the addition of *GNAS* testing. Singhi et al. showed the detection of mutant *KRAS* and/or *GNAS* had a sensitivity and specificity of 65% and 100%, respectively [103]. However, there was significant discordance in the rates of detection of *KRAS* and *GNAS* mutations between preoperative EUS-FNA and studies using postoperative pancreatic cyst fluid. The authors underscored the limitations of their assay may be due to the inherent sensitivity and specimen requirements of conventional Sanger sequencing.

The limit of detection of Sanger sequencing is approximately 15–20% of mutant alleles. In comparison, next-generation sequencing (NGS) has a limit of detection of approximately 3–5% of mutant alleles. Recent studies have shown the application of NGS to pancreatic cyst fluid ranges from 86% to 90% in sensitivity and 75% to 100% in specificity for mucinous differentiation [130, 131]. Other advantages of NGS are the small amounts of DNA required for analysis and the ability to assay multiple genes simultaneously. Using a broad panel of genes to include *KRAS*, *GNAS*, *VHL*, *TP53*, *CDKN2A*, and *SMAD4*, among others, Jones et al. identified a high concordance rate between molecular and clinical diagnoses [131]. Similarly, Singhi et al. found mutations in *TP53*, *PIK3CA*, and/or *PTEN* to have 83% sensitivity and 97% specificity in detecting advanced neoplasia within an IPMN [130]. However, as diagnostic DNA testing of pancreatic cyst fluid continues to evolve, questions remain as to how these alterations will influence patient management.

Mucinous Cystic Neoplasms (MCN)

Clinical Features of MCNs

Mucinous cystic neoplasms (MCNs) are also mucin-producing epithelial neoplasms that arise outside of the large ducts of the pancreas. The exact incidence and prevalence of MCNs is difficult to assess, but within a large surgical series represented, MCNs comprise a quarter of all resected cystic neoplasms of the pancreas. Over 90% of MCNs are diagnosed in females, and the mean age at diagnosis is between 40 and 50 years, with a wide range described in the literature (14–95 years) [132, 133]. Not surprisingly, patients presenting with noninvasive MCNs tend to be 5–10 years younger on average as compared to those carrying MCNs with associated invasive carcinoma, in line with the concept of MCN being a precursor lesion eventually progressing to PDAC. Clinical symptoms are often unspecific and include epigastric pain, a sense of abdominal fullness and abdominal mass. Carcinoembryonic antigen 19-9 (CA19-9) blood concentrations are usually normal in noninvasive MCN patients and elevated only in cases that are associated with a PDAC [134]. Of note, MCNs, like IPMNs, can be discovered as incidental cystic lesions of the pancreas. Computed tomography typically reveals a relatively large (up to 10 cm) intrapancreatic cystic mass. Intramural nodules are more common in MCNs with an associated invasive adenocarcinoma. The cysts

themselves are usually 1–3 cm in diameter and divided by fibrous septa, cyst contents vary from mucoid to hemorrhagic fluid. MCNs do not communicate with the pancreatic duct, and this feature is often exploited to differentiate MCNs from IPMNs in the clinical setting.

Histopathology of MCNs

The cysts of MCNs are lined by a columnar mucin-producing epithelium, associated with a spectrum of architectural and cytologic atypia, akin to what is observed in IPMNs. MCNs with low-grade dysplasia consist of uniform columnar cells with abundant supranuclear mucin. The nuclei are typically uniform, small, and basally located basally (Fig. 1e). In contrast, MCNs with high-grade dysplasia demonstrate significant degree of architectural and cytologic atypia, similar to what is seen in high-grade PanINs and high-grade IPMNs [4, 132] (Fig. 1f). In addition to neoplastic epithelium, MCNs comprise a distinct "ovarian-type" stroma [133, 135]. This ovarian-type stroma consists of densely packed spindle-shaped cells, which can in some cases even show luteinization, and that form a band directly underneath the neoplastic epithelium. Per the current consensus definition, the ovarian-type stroma is an essential prerequisite for the diagnosis of an MCN. Therefore, a proportion of lesions previously referred to as MCNs are now categorized as IPMNs, and the ratio of MCNs relative to IPMNs tends to decrease in newer reports. Diagnostically, ovarian-type stroma can be particularly useful for MCN samples where the neoplastic epithelium is focally denuded. Around one-third of resected MCNs are found to be associated with PDAC [132]. These carcinomas may arise focally in an MCN, and the extent of invasion has been shown to be one of the most important prognostic factors [133].

Molecular Genetics of MCNs

The genetic alterations found in MCNs are similar to those in IPMNs. Analogous to IPMNs, activating *KRAS* mutations are the most common finding, but their prevalence increases with the degree of dysplasia. Jimenez et al. detected KRAS mutations in 26% of low-grade MCNs, while in 89% of MCNs with advanced neoplasia [136]. *RNF43* alterations are also present in MCNs and range from 8% to 35% [104, 105]. In addition, mutations and/or deletions in *TP53*, *PIK3CA*, *PTEN*, *CDKN2A*, and *SMAD4* are detected in MCNs with advanced neoplasia. However, in contrast to IPMNs, *GNAS* mutations are distinctly absent in MCNs [102, 104]. Moreover, recent studies on global expression profiling of MCNs have uncovered tissue specific overexpression of a variety of proteins. Among others, c-met, S100P, prostate stem cell antigen (PSCA), jagged-1, c-myc, cathepsin E, and pepsinogen C were found to be overexpressed by neoplastic epithelial cells, and steroidogenic acute regulatory protein (STAR) and estrogen receptor-1 (ESR-1) by ovarian-type stroma cells, respectively [137, 138].

Genetically Engineered Mouse Models of MCN

Within the past decade, at least two genetically engineered mouse models have been described, closely resembling key features of human MCNs. Mao et al. reported that the activation of the Hedgehog signaling pathway through overexpression of a mutationally activated smoothened allele (R26-Smo-M2) in mice led to the rapid development of rhabdomyosarcomas, basal cell carcinomas, and medulloblastomas [139]. Of interest, they also observed the development of a novel form of pancreatic lesions resembling low-grade MCNs in approximately half of tamoxifen-induced mice. These lesions were characterized by cyst formation of varying size, lined by cuboidal epithelium with foci of columnar metaplasia and by a supporting proliferative ovarian-like stroma. Moreover, PAS and Alcian blue stains indicated mucin expression by the epithelial cells within these lesions. Izeradjene et al. described that pancreas-specific expression of oncogenic *Kras* in combination with *Smad4* haploinsufficiency led to the formation of macroscopically visible cystic lesions in the body and tail of murine pancreata [140]. Histopathological examination revealed formation of low-grade mPanINs as well as cystic lesions resembling histological features of human MCNs, including lining by a neoplastic epithelium consisting of columnar, mucin-filled, CK19 positive epithelial cells displaying focal areas of low to high-grade dysplasia, as well as a surrounding stroma that was frequently very cellular and contained spindle-shaped cells with distinctive "wavy" nuclei. Interestingly, the cysts did not seem to communicate with the duct system.

Therapeutic Implications of MCNs

The prognosis of MCNs depends largely on whether or not there is an associated adenocarcinoma and the extent of adenocarcinoma invasion. If a PDAC is not diagnosed after thorough histopathological evaluation of a surgically completely resected MCN, the patient has an excellent prognosis and can be considered as cured [133]. If, on the other hand, a surgically resected MCN is found to be associated with an invasive carcinoma, patients show a worse 5-year overall survival of only about 60%, which is, nevertheless, still considerably better than survival rates observed for PDAC that are not associated with an MCN [133]. However, the extent of invasion of the adenocarcinoma largely dictates prognosis. Both Crippa et al. and Lewis et al. found intracapsular PDAC as defined by invasion that did not go beyond the wall of the MCN to be associated with an excellent prognosis [141, 142]. Between both studies, only 4 of 30 (13%) adenocarcinomas with intracapsular invasion recurred. Similarly, Zamboni et al. reported three patients with intracapsular invasion and five cases with extracapsular invasion. All three patients with intracapsular invasion were alive and well after a mean follow-up of 22 months [133]. In contrast, two of three patients with extracapsular invasion died of disease.

At least two clinically relevant conclusions can be drawn from these observations: First, the striking difference in prognosis between MCN with and without accompanying PDAC underscores the importance and potential of early detection

and resection of these precursor lesions. Unlike noninvasive IPMNs, MCNs are typically unifocal and represent surgically curable lesions even if they are associated with high-grade dysplasia and minimally invasive adenocarcinoma at the time of diagnosis. The observed age difference of patients with and without associated adenocarcinoma further indicates that there is probably a sufficient time window of probably several years in a given patient, before an existing MCN develops an invasive adenocarcinoma, and during which early detection and resection with curative intent are possible. Secondly, pathologists need to carefully and entirely sample MCNs for histopathologic review to adequately assess for the presence of a PDAC and document the extent of invasion.

Conclusion

In summary, PanINs, IPMNs, and MCNs represent three well-defined precursor lesions of PDAC. In the last decade, significant progress has been made in understanding their molecular genetics, development of animal models, and improvements in early detection of these lesions in asymptomatic individuals. Further advances in early detection and possibly chemopreventive clinical trials are expected to occur within the next decade and are essential in the fight against pancreatic cancer.

Box 1 Key Research Points

Three types of precursor lesions are recognized that can progress to invasive adenocarcinoma of the pancreas – pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasm (IPMN), and mucinous cystic neoplasm (MCN). Over the past decade, consensus histopathological criteria have been established that facilitate the accurate diagnosis and classification of these precursors, and permit comparable data to be generated between different institutions. The multistep progression from early to later stages of these precursor lesions is mirrored by a series of accumulating genetic alterations.

Box 2 Future Scientific Directions

While potent therapeutic options for established PDAC are lacking accounting for its overall dismal prognosis, the precursor lesions of PDAC (e.g., PanINs, IPMNs, and MCNs) represent a unique therapeutic opportunity for curative intervention. Future research should be aimed at developing diagnostic and imaging tools which allow for reliable early detection of these precursor lesions in a clinical setting. This is particularly desirable for PanINs, which are by far the most frequently observed precursor lesions and are difficult or close to impossible to detect with current clinically available imaging

(continued)

Box 2 Future Scientific Directions (continued)
techniques. Moreover, prospective studies should address individual risk estimation of diagnosed precursor lesions to enable evidence-based guidelines for the appropriate clinical management in individual cases.

Box 3 Clinical Implications
Early detection of precursor lesions of PDAC has the potential to identify high-risk patients and treat a pancreatic lesion before it progresses into a frank malignancy. The clinical implications for some precursor lesions are more obvious than others. MCNs should always be resected and thoroughly evaluated histopathologically for the presence of an associated PDAC. The same holds true for main duct type IPMNs. However, there are currently opposing opinions as to the management and treatment of branch duct type IPMNs. PanINs are a common finding in the elderly population, but to date appropriate tools to reliably diagnose isolated PanINs in a clinical setting are lacking. Recently, endoscopic ultrasound has enabled the diagnosis of multifocal PanIN lesions in patients at risk for developing PDAC (e.g., individuals with a familial pancreatic cancer). Improvements in imaging strategy and the incorporation of molecular techniques in the diagnosis and workup of precursor lesions should facilitate improved therapeutic decision making.

Abstract

Defined as heritable changes in gene expression, which are not due to any alteration in the DNA sequence, epigenetic pathways have come to the forefront of research in disease, and in particular, cancer. In fact, these pathways are more prevalently altered in cancer than genetic alterations and most important, can be reversible, lending themselves as attractive therapeutic targets. This chapter will cover the basic aspects of transcriptional gene regulation, epigenetics, and chromatin dynamics and then focus on the intricacies of its application to pancreatic cancer biology and potential therapeutics. In addition, a model for better understanding pancreatic cancer is outlined to expand the highly provocative and productive "mutation centric" progression model, as defined by Hruban and colleagues, into a current model that formally includes chromatin-induced and noncoding RNA-induced epigenetic changes, as well as other alterations that result from changes in nuclear shape. This model offers a compass for further considerations aimed at illuminating the field of pancreatic cancer biology, diagnosis, therapeutics, and chemoprevention, in a similar, prolific manner as the original model.

Introduction

The phenomenon of epigenetics involves the regulation of gene expression via chromatin modifications and remodeling. Interestingly, an embryo is defined as human by the amount and sequence of DNA, which result from the fusion of the two parental gametes. However, as the embryo grows, cells will begin to differentiate from each other with this same amount and sequence of DNA. The ultimate results of the differentiation process seen in a young adult clearly show that despite all cells within the same organism carrying the same DNA sequence, a neuron, for instance, is totally different than a pancreatic acinar cell. Meditating on this phenomenon can leave one breathless. If one supposes that these two cells are independent unicellular organisms instead of both originating from a human, it would not be apparent that they have the same genome. Epigenetic mechanisms are responsible for defining cell phenotypes during the differentiation process by modulating the expression of the same genome in a different manner that is inheritable in each somatic cell division. Therefore, this chapter will (1) review the basic aspects of molecular mechanisms that are important for understanding gene regulation and epigenetics; (2) discuss the current model for better understanding pancreatic cancer,

which expands the extremely provocative and productive "mutation centric" model defined by Hruban et al. in 2000 [1] into one that formally includes chromatin-induced and noncoding RNA-induced epigenetic changes, as well as other modifications that result from alterations in nuclear shape; and (3) briefly consider drugs that may be important for the chemoprevention and/or treatment of pancreatic cancer.

Basic Concepts in Epigenetics

The study of epigenetics has been an example of how applicable the epistemological concepts behind the Thomas Kuhn's seminal work, "The Structure of Scientific Revolutions," are to this science [2]. In this work, Kuhn proposes that science moves ahead not by the incessant generation of data, but by work that changes preexistent paradigms. This is sometimes referred to as an epistemological fracture, meaning that the conceptual framework that was valid yesterday has evolved into a new theoretical framework that better explains reality. Therefore, the basis of epigenetics will be discussed through the progression of paradigms that have dominated this science at different stages of its development until today. These basic paradigms should be integrated into a picture of how chromatin and the transcriptional regulatory machinery work together in order to mediate epigenetic inheritance in somatic cells.

Evolving Paradigms in the Field of Transcription, Chromatin, and Epigenetics

The Universality of Promoters

This is the story of a remarkable journey since the work of Jacob and Monod [3] to the large amount of work that went into discovering the transcriptional mechanisms that regulate basal levels of expression before either activation or repression can occur (Basal Transcription). Prokaryote cells have only one RNA polymerase that binds to the promoter of genes and, aided by a transcription factor (factor σ), initiates the synthesis of an RNA molecule (Transcription) (reviewed in [4]). A remarkable finding is that promoters from bacteria to human contain similar sequences (e.g., TATA box). This concept has supported the prediction that the regulation of gene expression throughout evolution has been mechanistically very similar. This level of similarity was remarkable in its time, but was distant from the entire actuality. Hardcore evidence for the functional evolutionary-conservation thinkers has been further supported by the discovery that, at the atomic resolution, the tridimensional structure among RNA polymerases is strikingly high [5]. Thus, this theoretical framework paved the way for the search of eukaryote molecules that mediate transcription.

The RNA Pol II Components and the General Transcription Factors

The discovery of an RNA polymerase from eukaryotic cells highly stimulated studies aimed toward understanding transcriptional regulation [6]. However, the complexity of eukaryotes became apparent in comparison to bacteria, in particular, with the isolation of two additional RNA polymerases from higher organisms for a total of three RNA polymerase molecules, referred to as RNA polymerase I, RNA Polymerase II, and RNA polymerase III (reviewed in [7]). The intricacies of the eukaryotic system became further evident upon attempts to reconstitute transcription from isolated RNA polymerase II complexes bound to the core promoter of genes involved in basal transcription [8]. Transcription initiation at RNA polymerase II promoters in eukaryotes, which is the focus of the current chapter due to its association with protein-encoding gene expression, involves the assembly of a megadalton, multiprotein complex, comprised of the polymerase itself, as well as a variety of associated factors, known as the General Transcription Factors (GTFs). These general transcription factors function to properly position RNA pol II on the promoter DNA and to interact with transcriptional activators. The isolation and reconstitution of transcription in vitro to derive the resultant theoretical framework required several decades, until the details of the paradigm described in the following paragraph emerged.

The Step-Wise Assembly of the RNA Pol II Complex Versus the Holoenzyme Complex

To focus on the process of transcriptional initiation, it is most logical to begin with a description of RNA polymerase II complex, the transcriptional enzyme complex, responsible for making the protein-encoding RNA molecules, which includes the general transcription factors. Two paradigms exist for initiation of promoter occupancy by the RNA pol II complex: individual general transcription factors and the enzyme may be assembled in situ on the promoter in a step-wise fashion or the entire machinery and its associated factors bind the promoter collectively as the pre-assembled polymerase II holoenzyme (reviewed in [9]). Based on the step-wise assembly paradigm, the eukaryotic core promoter serves as a platform for the assembly of the transcription preinitiation complex (PIC). PIC assembly commences with TFIID binding to the TATA box, initiator, and/or downstream promoter element (DPE) present in most core promoters. The concept of the PIC was originated primarily from results of in vitro reconstitution assays, which subsequently led to the isolation of the GTFs that enter into the process of transcription in a step-wise manner to aid RNA polymerase II. These proteins include, in order of association to the promoter, TFIID, TFIIB, TFIIA, TFIIF, TFIIE, and TFIIH (reviewed in [10]). TFIID, the initial GTF to bind for PIC formation, is the only GTF with site-specific DNA binding ability and in itself a complex containing the TATA-binding protein (TBP) and numerous TBP-associated factors, termed TAF_{II}s. Subsequently, TFIIB recognizes the TFIID-promoter complex and, along with TFIIA, stabilizes the

nucleoprotein complex, which allows TFIIF to escort RNA pol II to the promoter. The interaction between TFIIB and RNA pol II is crucial for defining the proper start site of transcription [11]. Once RNA pol II is stably positioned, it is unable to initiate RNA transcription until the recruitment of two additional GTFs, TFIIE, and TFIIH. Transcriptional initiation requires two functions of the TFIIH, a helicase activity to open the double stranded DNA since the RNA polymerase will copy only a single strand of a gene, and a CDK kinase activity, which hyperphosphorylates the tail of the RNA pol II molecule to initiate transcription.

Two major discoveries have been the existence of the Mediator Complex [12], which is necessary for full function of the RNA pol II, as well as the possibility that the RNA pol II enzyme, GTFs, and Mediator could be preassembled to form the RNA polymerase II holoenzyme (enzyme with all the parts) prior to promoter recruitment. This process forms the basis of the holoenzyme paradigm [9]. The knowledge derived from both the step-wise assembly and the holoenzyme paradigm is currently operational.

The Promoter-Bashing Paradigm, Cis-Regulatory Sequences, and Sequence-Specific Transcription Factors

At the same time experiments were actively underway to understand the mechanisms regulating basal transcription, other investigators were searching for the basis of regulated transcription, namely, transcriptional activation (gene induction) and/or transcriptional repression (gene silencing). For this purpose, investigators adopted concepts and tools to dissect this process, including fusing promoter regions to reporter genes and performing deletions and site-directed mutagenesis for teasing out potential sites that could bind sequence-specific transcriptional regulators, which provided fruitful information as the promoter-bashing paradigm. In addition, promoter footprinting and Electrophoretic Mobility Shift Assays (EMSAs) were utilized to determine transcription factor binding to specific DNA sequences, called cis-regulatory sites [13]. These factors act either as monomers, such as the pancreatic tumor suppressor, and sequence-specific transcription factor, KLF11 [14], or as a complex, such as PTF1 [15], which recognizes the promoters of many acinar cell genes in a trimeric homeodomain complex including P48 and HEB. Some of this knowledge not only advanced the concept of transcription, but also generated useful tools for the Pancreatology field, since several tissue-enriched or developmental time-specific promoters (reviewed in [16]) are the key requirement for the creation of several animal models for pancreatitis and cancer.

The Coactivator-Corepressor Hypothesis

Studies designed to better decipher the way that sequence-specific transcription factors regulate gene expression led to the concept that these proteins behave as adaptors between the DNA and proteins that either induce or impede RNA pol II

transcription. This concept was based upon the recognition this type of transcription factor was modular in structure, composed of a DNA binding domain and a transcriptional regulatory domain to influence the rate of mRNA synthesis (reviewed in [17–19]). Conceptually, proteins responsible for promoting activation were called coactivators, while any corresponding repressor proteins were termed corepressors. Initially, some investigators searched for these factors among the hundreds of proteins that form the RNA Pol II holoenzyme. Indeed, interactions of transcription factors with certain members of the holoenzyme were necessary for regulated transcription. However, at the same time, a new era in studying the role of chromatin proteins was being born and starting to dominate, at the mechanistic level, the field of gene expression and apoptosis, proliferation, senescence, stem cell biology, cell migration, oncogenesis, tumor suppression, DNA replication, DNA repair, ploidy, as well as other processes integrally associated with the development and maintenance of the pancreatic cancer phenotype. For instance, it is now known that histone deacetylases (HDACs) play significant regulatory roles in gene expression during cancer [20], in particular in silencing tumor suppressor genes, and select inhibitors of these proteins are approved for clinical use in lymphoma and multiple myeloma and others are in various phases of clinical trials for the treatment of diverse malignancies [21]. HDACs are recruited into different protein corepressor complexes, which are brought to promoters via the transcriptional regulatory domain of a distinct transcription factor bound to DNA (reviewed in [22]). As a result, this transcription factor effectively deacetylates histones, which serves as a signal for gene silencing (Fig. 1). The reversal of this state is achieved through the function of histone acetylases enzymes (HATs), such as CREB binding protein (CBP)/P300 and P300/CBP-Associated Factor (PCAF) (reviewed in [23]). The deregulation of these types of enzymes leads to the aberrant activation of oncogenes (Fig. 2). Other nonhistone chromatin proteins function either as coactivators or corepressors via distinct mechanisms, as mediators of histone methylation, ubiquitination, sumoylation, and other modifications, which inform the cell toward dynamically changing gene expression patterns according to the corresponding function.

Chromatin Dynamics Forms the Basis of Epigenetics

Work on the role of histones in nuclear cell biology was very active in the 1970s with a detailed analysis of nucleosome composition and DNA packaging [24]. In terms of transcription, histones and nucleosomes were believed to be rich solely in heterochromatin, which is transcriptionally silent, and relatively poor in euchromatin, which is transcriptionally active. Unfortunately, however, how these states could be interchanged, meaning that chromatin was more dynamic than previously speculated, remained poorly understood until the 1980s and received a boost at the turn of the century (reviewed in [25]). Research on transcriptional regulation and its relevance to biological and pathobiological processes grew significantly with the discovery that indeed, chromatin is dynamic, often switching from euchromatin to heterochromatin and vice versa. Chromatin dynamics is regulated by (a) signaling

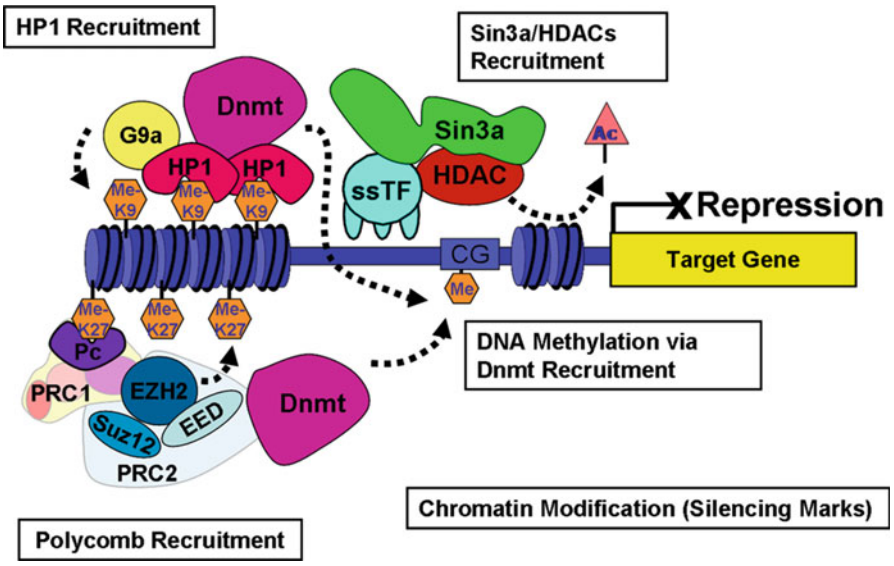

Fig. 1 Examples of Epigenetic-Mediated Tumor Suppressor Gene Silencing. This cartoon depicts a model for various roles of chromatin dynamics in tumor suppressor gene silencing, participating in the cancer phenotype. Several different mechanisms of epigenetic-mediated gene silencing can accomplish the same outcome of tumor suppressor gene silencing, including the HDAC system, polycomb proteins, and HP1 proteins. For example, a sequence-specific transcription factor (ssTF) may recruit the Sin3a-HDAC complex to a target gene promoter. The recruitment of Sin3a-HDAC to the promoter facilitates the remodeling of surrounding chromatin with silencing marks, namely the deacetylation of histones. Removal of acetylation signals short-term repression of a target gene and in addition, primes the histone for receiving additional long-term silencing marks, such as methylation of K9 or K27 on histone H3, binding marks for HP1 and polycomb, respectively. The recruitment of HP1 to a gene promoter facilitates the further recruitment of the G9a methylase, which creates more methyl-H3K9 silencing marks and thus, more HP1 binding sites. In addition, HP1 can recruit a DNA methyltransferase (Dnmt) to the promoter. In a similar manner for the polycomb group proteins, PRC1 recruitment results in the binding of the PRC2 complex, which contains the H3K27 methylase EZH2. The PRC2 complex also is capable of recruiting the DNA methyltransferases

events that form the basis of the histone code and subcodes, (b) mechanochemical enzymes that move nucleosomes from cis-regulatory sequences, an essential step in transcription, as well as (c) histone chaperones, which remove histones from nucleosomes to either activate or silence gene expression. Noteworthy, chromatin dynamics determines the epigenetic inheritance of a phenotypic trait either from the germ line (imprinting) or from one somatic cell to its daughter. DNA content is the same throughout the body, yet different types of cells with distinct characteristics and functions exist to create various organs and biological systems. Often not considered, the exact same DNA is in every cell, and thus, the distinction in the type of cell it becomes lies within epigenetics, and in particular, chromatin dynamics. Following, these three areas of chromatin dynamics are described in further detail.

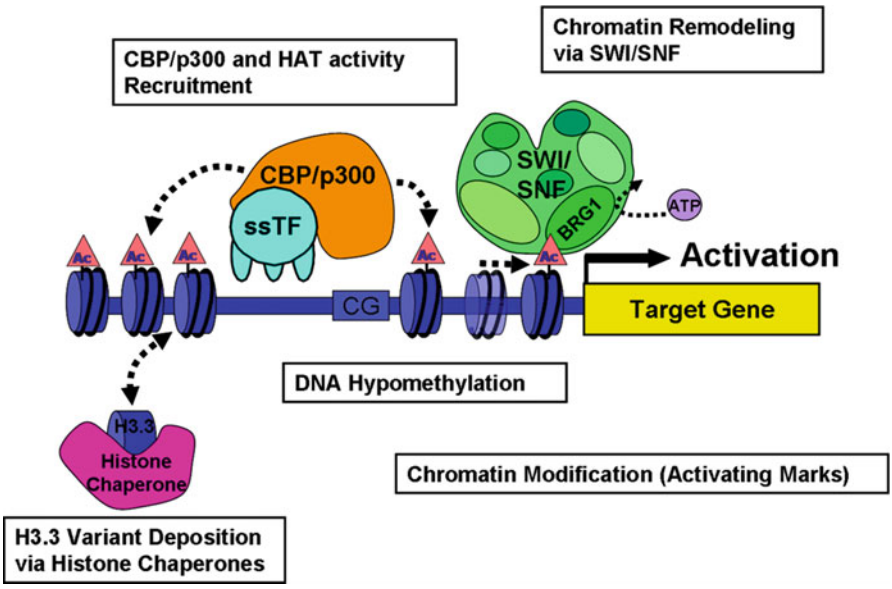

Fig. 2 Examples of Epigenetic-Mediated Oncogene Activation. This cartoon depicts a model for the role of chromatin dynamics in promoting the cancer phenotype through oncogene activation. In this model, a sequence-specific transcription factor (ssTF) triggers the recruitment of CBP/p300 (or PCAF) to a target gene promoter. The recruitment of CBP/p300 to the promoter also provides HAT activity, which facilitates the modification of surrounding histones to create "active" chromatin with acetylated histones. Addition of acetylated marks to histones signals activation of transcription through recruitment of other bromodomain-containing proteins, such as the SWI/SNF family of chromatin mechanochemical remodelers, which via the expenditure of ATP facilitate structural relaxation of chromatin and thus, access to transcriptional machinery. Additional players in the process of gene activation can include the histone chaperones, which through the exchange of histone variants, such as histone H3.3, provide activating signals. In addition, demethylation of DNA can trigger the activation of an oncogene promoter

The Histone Code and Subcode Hypotheses: Codifying Gene Activation and/or Silencing and Epigenetics

Elegant work from many laboratories around the world found its conceptual integration in the development of the histone code hypothesis [26]. Before describing this theoretical framework for understanding transcription and epigenetics, one should remember that histones are small, basic proteins that are extremely conserved throughout evolution [27]. To illustrate how conserved histones are and better explain how the histone code hypothesis operates, histone H3 (H3) is used here as an example, although the code considers all the histones and its genetic variants.

The first 24 amino acids of H3 are nearly identical in most organisms, known as the histone H3 tail. Collectively, the histone "tails" have been defined, from analysis of their crystal structure, as the regions of the histone sequences that extend from the nucleosomal disk [28]. The H3 tail contains several serine(S), threonine(T), and tyrosine(Y) residues, which have the ability to undergo phosphorylation, and other

residues, such as lysine(K) and arginine(R), which can be extensively modified by methylation, acetylation, ubiquitination, and sumoylation [26]. In fact, the lysines and arginines have the potential to possess different states of methylation, namely mono-, di-, and tri-methylated for lysines and mono-, symmetrically di-, and asymmetrically di-methylated for arginines [29]. These histone modifications have come to be known as "marks" because in many cases, they are utilized as clues for epigenetics. For instance, the Polycomb complex, which keeps stem cells in their undifferentiated state, binds to trimethylated K27 of H3 in order to mediate heterochromatin formation on target promoters and, as consequence of this event, to facilitate gene silencing [30]. This is one of the mechanisms for epigenetic inheritance in human somatic cells where the K27 trimethyl mark must be removed to initiate the hierarchical cascade of gene expression that leads to a cell fate decision. Interestingly, as described below, this epigenetic mechanism is often used for permanently silencing tumor suppressors without the need of gene mutation or deletion (Fig. 1). A similar function in gene silencing is performed by another protein, HP1, which binds to di- and tri-methylated K9 of H3. The histone code hypothesis predicts that the type, location, and combination of histone marks determine whether a gene is expressed or silent under a particular set of circumstances. Using HP1 as a model of a histone mark-binding protein, these nonhistone proteins were found to also be modified by the same enzymes that are responsible of creating the histone code, appearing to act in the fine-tuning of the instructions given by the histone marks [31], which has been subsequently supported by additional modifications in HP1 and other epigenetic regulators [32–34]. For instance, a required step for entering into cell senescence is the phosphorylation of HP1γ at residue S83 (S93 from alternative start site) [35], suggesting that this modification instructs HP1 to regulate the gene expression of key genes which will epigenetically influence the cell into senescence. In fact, the underlying mechanism driving these subcodes is believed to be "histone mimicry," which is the presence of histone-like modification cassettes within nonhistone proteins [36]. Thus, the histone code and its subcodes have fueled a new era of great productivity and optimism in the field of transcription, chromatin dynamics, and epigenetics, in particular as it relates to cancer.

Nucleosome Remodeling Machines

Nucleosome remodeling machines, containing ATP-dependent mechanochemical activity (molecular motors), were discovered using biochemical methods and in vitro assays. Using these approaches, numerous laboratories have isolated protein complexes that move nucleosomes along DNA thereby removing a repressive effect of histones on a specific cis-regulatory sequence. These nucleosome remodeling complexes include SWI/SNF, NuRD (nucleosome remodeling and deacetylation), and CHRAC (chromatin accessibility complex) (reviewed in [37]). Several of these molecular machines are conserved from organisms ranging from yeast to human. To demonstrate the basic mechanisms of these nucleosome remodelers, the SWI/SNF complex will be used as an example, which is the human homolog to the *Drosophila* trithorax complex [38]. The function of complexes like SWI/SNF is essential for the

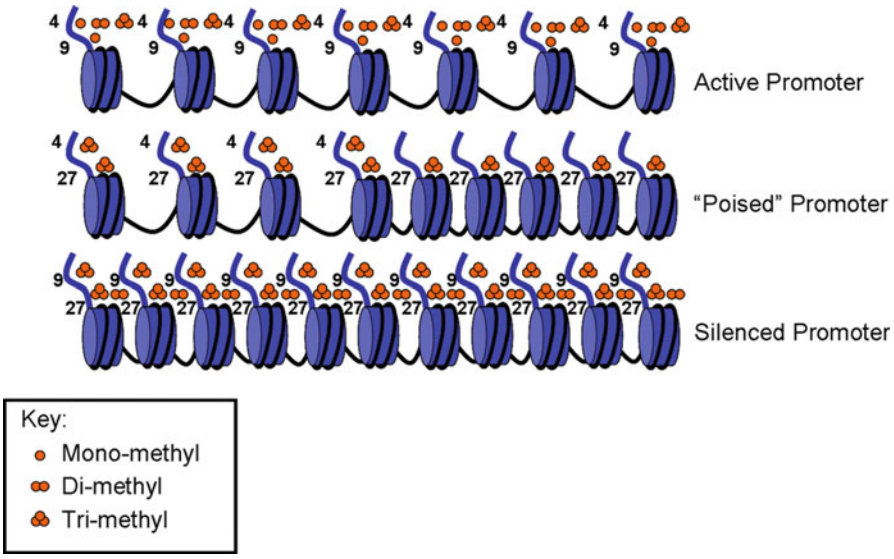

Fig. 3 Dynamics of Chromatin Marks on Promoters. The figure demonstrates three different promoter states of chromatin marks: active, "poised," and silenced (adapted from [44]). Nucleosomes encompassing the promoter region of a gene are shown. The numbers indicate the corresponding amino acid of the histone H3 tail. The orange circles represent the degree of methylation with multiple states possible for a given signal. For example, on active promoters, the chromatin marks are a signal of gene transcription, such as mono-, di-, or tri-methylation of K4 of H3 and mono-methylation of H3K9. Active promoters are also enriched in H3, H4, and H2A acetylation (not shown). On a "poised" promoter, a combination of active and repressive marks can leave genes ready for activation and forms a "bivalent domain." The promoter regions of this type are enriched in the repressive trimethyl-H3K27 mark, whereas the region around the transcription start is also enriched in the active trimethyl-H3K4 mark. Finally, a silenced promoter contains inactive chromatin marks. These nucleosomes are enriched in H3K9 tri-methylation (and sometimes di-methylation, not shown) and H3K27 di- and tri-methylation

expression of a myriad of genes via its recruitment to chromatin, hydrolysis of ATP, and utilization of this energy to remodel nucleosomes (Fig. 2). While *Drosophila* only possesses a single Swi2/Snf2 complex with ATPase activity, called Brahma (Brm) [39], mammals have two homologues, BRM and BRG1 [40]. The amino acid sequences of these two are 75% identical with broad expression. However, these subunits are mutually exclusive, since a single SWI/SNF complex contains either BRM or BRG1. Thus, there are several subtypes of SWI/SNF complexes that can be divided based on the ATPase molecule that generates the mechanochemical force for nucleosome movement. Interestingly, the genes encoding these subunits have been found to have mutations and/or loss of expression in some human tumor cell lines, as well as primary tumors, including pancreatic cancer [41, 42].

The trithorax complex recognizes methylated H3K4, actively participating in the epigenetics and chromatin dynamics of the cell. For instance, stem cells are characterized by having a subset of genes with dual marks, methylated at both H3K4 and

H3K27 (Fig. 3). These gene promoters are known to be in a "poised" state, since they are repressed by polycomb in the stem cells, but after removal of the dominant H3K27 mark, the remaining methylated H3K4 will signal for activation, leading to the initiation of cell differentiation [43]. Therefore, although heterochromatin is repressive, nucleosome remodeling machines, by binding to specific histone marks, sometimes already present on a promoter along with the silencing mark, will convert the region into active euchromatin. Tumorigenesis exhibits the culmination of alterations in several genetic pathways. Therefore, as is the case with many of the global epigenetic effects discussed in this chapter, it would only take a single mutation to inactivate a large subset of SWI/SNF complexes (such as a BRG1 mutation) to perturb the regulation of numerous downstream genetic pathways and as a result, trigger robust growth-promoting effects (Fig. 2).

Histone Chaperones

The discovery of histone chaperones constitutes later developments within the area of transcription [44]. The search for this type of proteins initiated from the understanding that there were many histones and histone variants that could occupy a nucleosome. For instance, histone H3 has four main isoforms in mammals [45]. Some of these variants act as activators, while others act as repressors in the context of a nucleosome [46]. Deposition of histone variant H3.3 has been associated with transcriptionally active genes in plants, flies, and humans. In addition to the possibility of different histone variants occupying a nucleosome, these variants are also substrates of enzymes that create histone marks. Therefore, the combinatorial effect between the existence of the histone variants and their participation in the histone code, which is known as the histone "barcode" [47], creates the possibilities of regulating activation or repression significantly complex. An important contribution to the field was the discovery that some histone variants are rapidly exchanged from nucleosomes, leading to the finding that this nucleosome-histone exchange codifies for either gene activation or silencing. Therefore, histone chaperones cooperate with the histone code in instructing cells to regulate a particular program of gene expression (Fig. 2). The role of histone chaperones involves binding highly basic histone proteins, which protects them from nonspecific interactions to facilitate either their deposition onto or eviction from DNA. Interestingly, despite their common functions, histone chaperone proteins structurally demonstrate highly divergent molecular structures and modest commonalities in their folds [47]. However, according to sequence-based predictions, these proteins have recently been shown to contain critical intrinsically disordered regions (IDRs) and acidic stretches, which are thought to play key roles in histone chaperone function, although this remains a currently active area of research.

Nuclear Shape and Nuclear Domains

The influence of nuclear shape in determining the tridimensional location of a particular gene within the nucleus in interphase is well known (chromosome

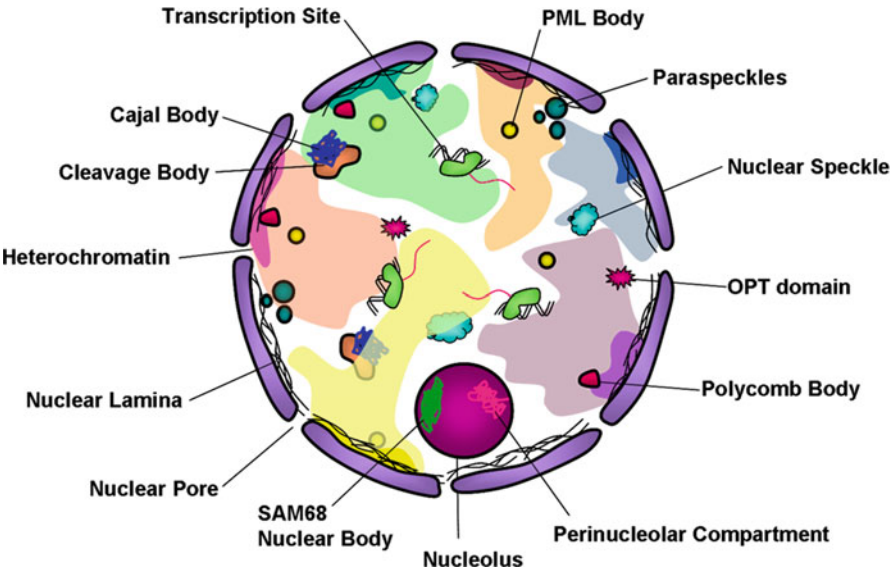

Fig. 4 Chromosomal Territories and Nuclear Domains. This cartoon of a mammalian nucleus illustrates the chromosomal territories and various nuclear bodies. Chromosomes occupy discrete territories in the nucleus. In addition, various functions within the nucleus occur in distinct locations, considered nuclear bodies or domains. Recent important and elegant work has demonstrated that alterations in nuclear shape will impact on these nuclear territories and domains, affecting gene expression in a manner resembles aging, polyploidy, and aneuploidy, all changes that are found in pancreatic cancer. Therefore, extending this area of research is of paramount importance for this field

territory) [48]. In addition, the nucleus consists of distinct nuclear domains with various components, which suggests that various nuclear functions occur at precise locations within the nucleus (Fig. 4). This knowledge supports the notion that changes in nuclear shape, by altering the nuclear position of the gene, can alter chromatin dynamics leading to aberrant gene expression. Clear support for this concept came from a naturally occurring mutation in the Lamin A gene [49]. Lamins are proteins that form intermediate filaments, which create a nuclear lamina covering the nucleus and extend toward the interior of this organelle to form a skeleton (reviewed in [50]). Thermodynamically speaking, the efficiency of an enzyme is better when in association with a surface rather than free floating in solution. Therefore, this lamin-based skeleton is necessary for all the processes that occur in the nucleus by helping to compartmentalize and concentrate specific molecular machineries into nuclear domains, which can be considered the nuclear equivalent of the cytoplasmic organelle, though not surrounded by a membrane. Mutations in lamin A significantly change nuclear shape, generating a new pattern of gene expression, which is responsible for the phenotype of premature aging and cancer in the Hutchinson–Gilford progeria syndrome [49]. With increasing focus on the functional relevance of morphological changes in the size and shape of the nucleus

during tumorigenesis, studies have found both increased and decreased lamin A/C levels to be correlated with poor prognosis in human cancers [51]. Notably, in considering the critical role of the tumor microenvironment in pancreatic cancer, aberrant levels of lamin A/C are also associated to collagen deposition and fibrosis, suggesting its effect reaches beyond the nuclear structure to influence the tissue architecture and microenvironment. This has inspired our laboratory to predict that some of the gross nuclear changes observed early during the progression of histopathological lesions in pancreatic cancer are not a consequence of cancer, but rather these changes help in the development and/or maintenance of this malignant phenotype. Therefore, nuclear shape must be included as a candidate modifier of pancreatic cancer progression, since the transition of PanIN 1B to PanIN 2 requires changes in nuclear shape [52]. The hypothesis is that these nuclear changes are responsible for extensively altering gene expression, independently of other epigenetic mechanisms, and thereby significantly contribute to the progression and maintenance of the pancreatic cancer phenotype. Thus, the "Triple Code Hypothesis," as illustrated in Fig.5a, is an integration of changes in DNA, such as mutation or deletion, which are an established part of cancer progression, alterations in chromatin, which are increasingly recognized as well, and the addition layer of changes in nuclear structure [53].

Epigenetics: Developing a Novel and Comprehensive Genomic-Epigenomic Model for Pancreatic Cancer that Includes Chromatin Dynamics and Nuclear Shape

The revolution of somatic genetics in the field of cancer brought about by the model developed by Fearon and Vogelstein in colon [54], which later led to an adaptation to the pancreas by Hruban et al. [1], opened a fruitful era for pancreatic cancer research, spanning approximately two decades. The basic premise of somatic genetics in cancer is that if a gene, which is suspected to play a role related to cancer, is overamplified, for instance, Myc in brain, it behaves as an oncogene, but if it is downregulated, like p16 in pancreatic cancer, it behaves as a tumor suppressor. Due to this premise, in the pancreatic cancer field, the changes in expression of both oncogenes and tumor suppressors, according to the Hruban model, were originally believed to occur via mutation or deletion and later with the work of Goggins, by promoter methylation [55–57]. The validity of this model has been elegantly demonstrated using Genetically Engineered Models (GEM), primarily supported by NIH via the "Mouse Model Consortium" funded by NCI [58].

In addition to the recognition of the outstanding contribution, this progression model of somatic genetics has had in advancing cancer research, the revised progression model for pancreatic cancer also must take into consideration the theoretical framework of epigenetics, and specifically, changes that occur at the protein level in the absence of DNA changes, such as deletion, mutation, or even promoter methylation. For instance, upon reading through the Hruban model of pancreatic cancer, in which the underlying conceptual framework is genetic in nature, one can infer that

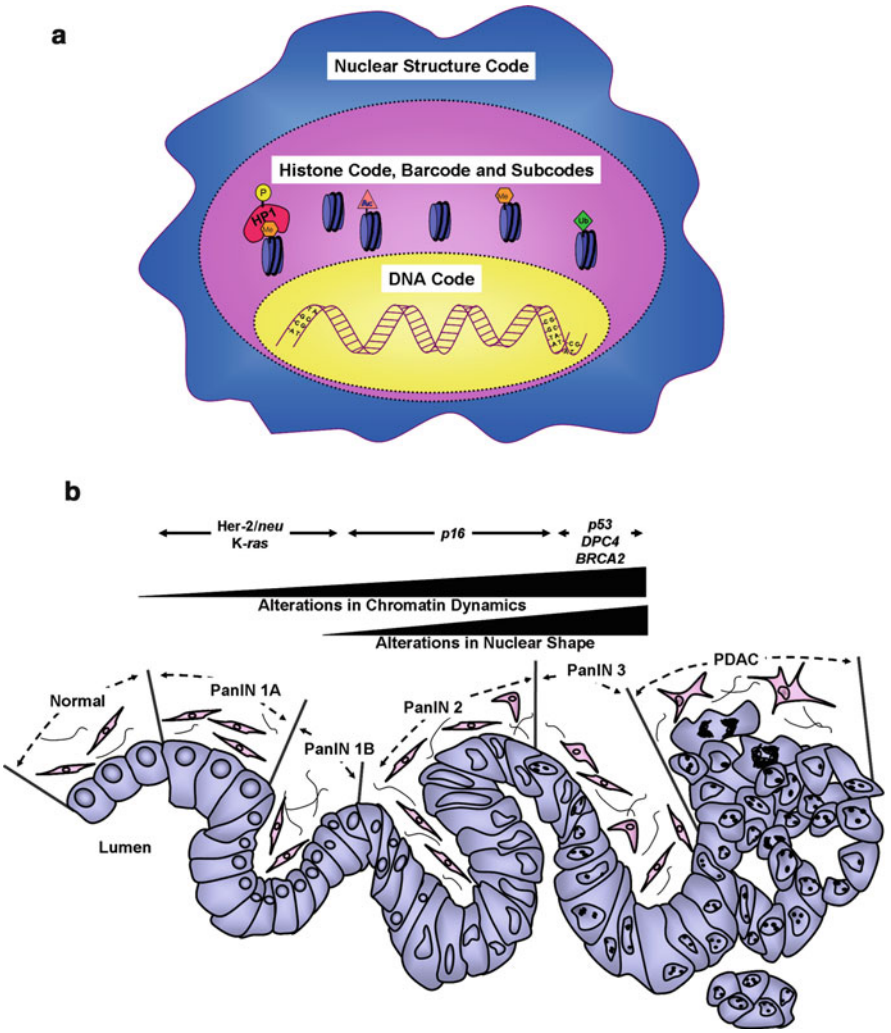

Fig. 5 (**a**) **The Triple Code Hypothesis**. This figure summarizes the integration of the well-known DNA-centric hypothesis for the establishment and maintenance of the cancer phenotype, which includes mutations and deletions, with changes in chromatin, signaled through the histone code, barcode, and its subcodes, and alterations in nuclear structure to form the "Triple Code Hypothesis." This "Triple Code Hypothesis" has formed the basis of the more comprehensive progression model for pancreatic cancer, proposed in **b**. (**b**) **Revised Comprehensive Progression Model for Pancreatic Cancer**. The model developed by Hruban and colleagues [1] was fundamental for expanding the work of many laboratories in the area of somatic genetics in pancreatic cancer to allow better understanding of the relationship between the morphological progression and mutations/deletion of important oncogenes and tumor suppressor pathways. However, the model excludes emerging knowledge on critical steps that occur between these mutations and even the potential cause of subsequent mutations and deletions. Most of these changes are epigenetic in nature with the underlying basic mechanisms of both chromatin dynamics and nuclear shape. Thus, a revised model for the progression of pancreatic cancer [53], which not only incorporates the

pancreatic cancer progresses through multistep mechanisms with different lesions evolving via mutations in different genes. However, this model does not explain what protein-mediated epigenetic changes, which can take place between the occurrences of landmark mutations, are responsible for cancer progression, nor this model has proven that a later mutation is caused by an earlier one. Therefore, in the following paragraphs, examples of epigenetic changes that occur in time between mutations and can lead to tumor suppressor silencing are provided, starting with DNA methylation and proceeding through some modifiers of chromatin. These examples highlight a paradigm for the progression of pancreatic cancer, which includes two additional types of phenomena (besides genetics), namely changes in chromatin dynamics and nuclear shape (Fig. 5b). The hope is for new investigators in this field to dive into pancreatic cancer with a more in depth mechanistic approach than using only the tools of molecular pathology and a combination of a multitude of arrays for different purposes.

While the field of epigenetics is vast and includes mechanisms of gene activation and repression, this chapter will focus on changes in epigenetics and chromatin dynamics that can silence tumor suppressor genes via mechanisms that are totally independent of either genetic deletions or mutations. In fact, in the case of *p16*, which is utilized here as a prime example for pancreatic cancer in the following paragraphs, epigenetic mechanisms lead to the final methylation of this gene, which should take the readers to consider that chromatin changes can occur before and lead to the inactivation of landmark mutations that were described in the original paradigm. Therefore, this journey will begin with a brief description of this final read-out in epigenetics, DNA methylation, since it is the most commonly known epigenetic alteration, and continue temporally backwards in epigenetics toward changes in chromatin and their modifiers. In addition, studies in the epigenetics of noncoding RNAs in pancreatic cancer will be described, which is the most recent area to develop in the field.

DNA Methylation

As mentioned, DNA methylation was the first type of epigenetic change to be studied as a mechanism for the inactivation of tumor suppressors [59]. DNA methylation occurs on dinucleotide CpGs, where cytosines precede guanines. The process of DNA methylation entails the addition of a methyl group to the number 5 carbon of

Fig. 5 (continued) elegant and extremely important data generated under the premise of the original model but, in addition, formally includes chromatin-induced and noncoding RNA-induced epigenetic changes, as well as other alterations caused by changes in nuclear shape, is illustrated. This model will hopefully serve as a compass to guide future experiments in these underexplored and yet crucial areas of knowledge. Experiments aimed at addressing the contribution of these phenomena to pancreatic cancer progression and their potential translation to clinical applications will be among the most promising areas of our field

the cytosine pyrimidine ring, which ultimately silences gene expression. Noteworthy, DNA methylation normally has significant physiological significance, as with genomic imprinting to ensure monoallelic expression and hypermethylation of repetitive genomic sequences to prevent chromosomal instability, translocations, and gene disruption caused by the reactivation of transposable DNA sequences. However, during tumorigenesis, aberrant DNA methylation can assist the cancer phenotype.

In pancreatic cancer, DNA methylation has been known for a long time as a mechanism to inactivate tumor suppressor genes, such as well-known inactivation of the p16 promoter via methylation [60]. In addition, loss of methylation of a normally silenced promoter in pancreatic cells, such as the gene encoding the hematopoietic-specific guanine nucleotide exchange factor, *VAV1*, can lead to its misexpression [61]. Initial methodologies only provided insights at the single gene level, but fortunately, recent developments in methodologies have advanced enough to perform genome-wide scale gene methylation analysis. With validity to both methodologies, methylation analysis of a single gene is practical as a specific candidate gene approach, while the genome-wide analysis possesses power in its unbiased approach. Several techniques utilized for methylation analysis include methylation-specific PCR, sequencing after bisulfite treatment, as well as mass spectrometry.

Although individual genes were discovered to be methylated in advanced pancreatic cancer, current evidence supports the idea that aberrant methylation occurs very early during the histopathological progression of this neoplasia. Using a specific gene candidate approach, Rosty and colleagues demonstrated that PanIN lesions in patients with chronic pancreatitis show loss of *p16* expression [62], suggesting that this alteration may contribute to the predisposition of patients with chronic pancreatitis to develop pancreatic ductal adenocarcinoma. Interestingly, in a study involving large-scale methylation analysis with subsequent confirmation via methylation-specific PCR, Sato and colleagues analyzed DNA samples from 65 PanIN lesions for methylation status of eight genes identified prior by a larger scale microarray approach as aberrantly hypermethylated in invasive pancreatic cancer [63]. Of the PanIN lesions examined in this study, methylation at any of these genes was identified in 68% of samples. Even more importantly, in the earliest lesions, which are the PanIN-1A, aberrant methylation was present in approximately 70%. Among the genes analyzed, methylation prevalence increased from PanIN-1 to PanIN-2 for *NPTX2* and from PanIN-2 to PanIN-3 for *SARP2*, *Reprimo*, and *LHX1*. The most striking result from both studies is that aberrant CpG island hypermethylation begins in early stages of PanINs and its prevalence progressively increases during neoplastic progression.

Additional studies on methylation patterns in pancreatic cancer compared to nontumor pancreatic tissues have followed to demonstrate a high level of differently methylated regions (DMRs) between the two groups, which offer a large list of candidate genes to serve as diagnostic biomarkers or therapeutic targets [64, 65]. A more recent study, using reduced-representation bisulfite DNA sequencing (RRBS) followed by targeted methylation-specific PCR to validate novel DNA methylation markers strongly associated with pancreatic cancer, could discriminate pancreatic

cases from controls in pancreatic juice, which offers clinical significance in terms of detection and would benefit further validation in patients with early PanIN lesions [66]. With the current interest in circulating cell-free DNA (cfDNA), Henriksen and colleagues identified differences in cfDNA promoter hypermethylation between malignant and benign pancreatic disease to suggest its utility as a noninvasive, blood-based screening tool for pancreatic cancer [67]. Thus, aberrant DNA methylation not only continues to reconfirm its clear role in the progression of pancreatic cancer, but holds promise as a diagnostic marker. Furthermore, since the current evidence indicates that methylation occurs at an early preneoplastic stage, pharmacological agents that target methylation, which are discussed in a subsequent chapter on "Epigenetic Pharmacology," may be effective not only for treatment, but perhaps also for chemoprevention.

Histone Acetylation and Deacetylation

An important mechanism underlying the epigenetic regulation of gene expression is the acetylation and deacetylation of lysine residues within histone tails [68]. For acetylation, this process occurs via HATs, such as CBP, P300, and PCAF, to result in gene expression activation, whereas deacetylation is mediated by two different families of HDACs, resulting in gene silencing. Together, these enzymes provide a fine-tuned mechanism, which upon alteration has the possibility to cause the activation of oncogenic pathways (Fig. 2) and the silencing of tumor suppressors (Fig. 1). However, apart from other epigenetic regulators, such as the polycomb complexes and HP1, which are discussed below, HATs and HDACs mediate short-term responses, a fact that should be taken into consideration when thinking about these molecules as potential therapeutic targets in cancer [68, 69].

As discussed, transcriptional regulation is mediated by the DNA binding properties of sequence-specific transcription factors and the recruitment of trans-activators or repressors to ultimately cause effects that alter chromatin structure and dynamics. Studies have demonstrated that HDAC activity is increased in various tumors compared with normal tissue, and this increase in HDAC activity has been associated with transcriptional repression of tumor suppressor genes that cause growth inhibition and apoptosis [70]. In a study performed by Blasco and colleagues, the differential gene expression in a pancreatic cancer cell line upon induction of apoptosis was analyzed using cDNA arrays [71]. Among the genes differentially expressed, one that was studied for further validation was histone deacetylase 1 (HDAC1). Inhibition of HDAC activity led to an increase in the level of apoptosis, in parental cells and doxorubicin-resistant cells. Thus, this study suggested that HDAC1 could be a possible target to develop modulators in cancer chemotherapy that would increase or restore apoptosis. In another study performed by Ouaïssi et al., approximately 80% of pancreatic adenocarcinoma samples examined showed a significant increase of HDAC7 RNA and protein levels [72]. Interestingly, in contrast to the pancreatic adenocarcinoma samples, HDAC7 RNA levels were reduced in samples from chronic pancreatitis, serous cystadenoma, and intraductal

papillary mucinous tumor of the pancreas (IMPN), suggesting that increased expression of HDAC7 can discriminate pancreatic adenocarcinoma from other pancreatic types of tumors. Immunohistochemical assessment of HDAC1, HDAC2, HDAC4, and HDAC6 protein levels in 70 PDAC patient tissue samples demonstrated enhanced HDAC1 levels in association with increased tumor proliferative capacity, while elevated HDAC4 expression was significantly correlated with the absence of organ metastases [73]. Significantly longer survival times were noted in patients with high HDAC1 and HDAC6 levels compared to those with low expression of these molecules, whereas HDAC2 had no significant association with any of the clinicopathological parameters considered. In addition, it has been shown that HDAC1 mediates transcriptional repression of the TGFβRII promoter in pancreatic ductal adenocarcinoma cells via recruitment to a specific Sp1 site [74]. This Sp1 site can be occupied by TGFβ-inducible members of the KLF family, including KLF14 [75] and the pancreatic tumor suppressor, KLF11 [76]. Interestingly, a genome-wide association study (GWAS) from 7683 patients with pancreatic cancer and 14,397 controls found that one of the four identified SNPs to reach genome-wide significance was located near KLF14 [77].

Using the *Pdx1*-Cre/*Kras*$^{LSL\text{-}G12D}$ mouse model of PDAC precursor lesions in combination with cigarette smoke exposure, Edderkaoui and colleagues determined that inhibition of HDAC3 reverses the accelerated PanIN formation observed from smoking and thus is a major player in mediating the pro-cancer effects resulting from this exposure [78]. This effect is facilitated, at least in part, through HDAC3-mediated regulation of IL-6 production in cancer cells to influence macrophage function, specifically the pro-tumor type-2 macrophage (M2) phenotype, in the tumor microenvironment. Several HDAC inhibitors have FDA approval, including Vorinostat, Romidepsin, and Belinostat [79], and thus, most ongoing studies in the field are focused on their use as targeted epigenetic therapeutics in PDAC, which is the topic of a subsequent chapter dedicated to "Epigenetic Pharmacology." In summary, it is clear that HDACs play an important role in the maintenance of the proper balance of chromatin marks on a given promoter, and if this balance is altered, such as HDAC expression in pancreatic cancer, the expected global effect on promoters is daunting.

Histone H3-Methyl-K27 and Polycomb

Polycomb proteins silence gene expression by specific methylation of histone H3 on K27 [68, 80]. At the simple core of this pathway, polycomb group (PcG) proteins act via the stepwise recruitment of PRC2, containing the H3K27 methylase activity, to chromatin. Subsequently, the trimethyl-H3K27 mark deposited by PRC2 recruits the PRC1 complex, thereby completing the gene silencing complex formation. The enzymatic activity of the PCR2 complex involves the H3K27 histone methylase, EZH2, but requires a complex with Suz12 and EED to function. The PCR1 complex contains the oncogene BMI1, as well as HPC1–3, HPH1–3, SCMH1, and the methyl-H3K27-binding proteins, Cbx 2, 4, 6, 7, and 8. However, which of the Cbx proteins is active at different loci under different circumstances is not known.

The role of polycomb proteins in pancreatic cancer has elicited significant attention over the recent years. For instance, new polycomb proteins have been discovered in pancreatic cancer cells [81]. More importantly, studies have demonstrated that loss of trimethylation at H3K27, which is achieved by EZH2, is a predictor of poor outcome in pancreatic cancers [82]. In fact, together with tumor size and lymph node status, the level of trimethyl-H3K27 was found to have a strong and independent prognostic influence in pancreatic cancer. Nuclear accumulation of EZH2 was identified as a hallmark of poorly differentiated pancreatic adenocarcinoma, and this nuclear overexpression of EZH2 contributes to pancreatic cancer cell proliferation, suggesting EZH2 as a potential therapeutic target for the treatment of pancreatic cancer [83]. In samples obtained by endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA), EZH2 expression was determined by immunohistochemistry to evaluate its use as a potential biomarker for treatment and disease prognosis [84]. However, EZH2 expression was heterogeneous and did not correlate inversely with E-cadherin expression as expected to serve as a hallmark of poorly differentiated pancreatic adenocarcinoma. Nevertheless, interest remains high for EZH2 as a therapeutic target in PDAC. Using the cerulein-induced model of pancreatic injury, EZH2 levels increase after injury, and this methyltransferase is required to promote the tissue repair process through inducing regenerative proliferation of progenitor cells [85]. With genetically engineered animal models, the same study revealed that EZH2 knockout impairs pancreatic regeneration and accelerates $KRas^{G12D}$-driven PanIN formation. Recent investigations found that activated CDK5 kinase is responsible for EZH2 phosphorylation, which is required for F-box and WD repeat domain-containing 7 (FBW7) to target EZH2 for ubiquitination and subsequent degradation [86]. As a result, this process suppresses EZH2 activity and thereby inhibits tumor migration and invasion of pancreatic cancer cells, not only highlighting the role of EZH2 overexpression present in PDAC samples, but providing additional therapeutic targets as well.

In terms of the PRC1 complex, a study on the ubiquitin E3 ligase Ring1B, a key component of PRC1 by catalyzing monoubiquitination of histone H2A at lysine 119 (H2AK119Ub1), and Snail, a transcriptional repressor and master regulator of epithelial-mesenchymal transition (EMT), demonstrated that elevated levels of these two molecules along with elevated monoubiquitination of H2AK119 are highly correlated with poor survival in PDAC [87]. On the other hand, reduction in CBX7 levels was associated with increasing malignancy grade in pancreatic adenocarcinoma and correlated with a loss of E-cadherin expression [88]. Conservation of CBX7 levels trended with longer patient survival rates, suggesting that loss of this polycomb protein contributes to a more aggressive pancreatic cancer phenotype. Moreover, CBX7 plays a role in suppression of cell proliferation, migration, and invasion, which is thought to occur in part through reducing PTEN/Akt signaling [89]. Pancreatic cancer stem cells, a small subset of distinct cancer cells with great proliferative potential and resistance to standard therapies, were identified to have upregulation of the PRC1 molecule Bmi-1, which enhances tumorigenicity and the function of the cancer stem cell population [90]. Interestingly, similar to CBX7, Bmi-1 influences the Akt signaling pathway, but by activating PI3K/AKT signaling

through the negative regulation of PTEN [91]. This mechanism was found to stimulate invasion and metastasis of the pancreatic cancer stem cells. Pancreas-specific inactivation of Bmi-1 in the *Pdx1*-Cre/*Kras*$^{LSL\text{-}G12D}$ murine model of pancreatic cancer initiation suggested that Bmi-1 is required for this process, in an Ink4a/Arf-independent manner [92]. Loss of Bmi-1 resulted in the upregulation of ROS, indicating that this PRC1 molecule regulates protection from excess ROS during neoplastic transformation, which is required for survival and progression. Thus, the association of this pathway with poor survival of patients affected by this disease renders this area of research one of paramount importance.

Mechanistically, one of the outcomes of aberrant polycomb regulation is the silencing of the *p16* gene, which could occur prior to DNA methylation, via altered direct recruitment of members of this family to the *p16* promoter sequence [93]. Upon studies in human cells, EZH2 and DNA methyltransferases (DNMTs) were found to physically and functionally interact, evidenced by the PRC2 subunits, EZH2 and EED, co-immunoprecipitating with all three human DNMTs and the co-dependency of certain target gene silencing requiring both EZH2 and DNMTs [94]. Therefore, the presence of polycomb proteins on the *p16* promoter can recruit DNA methylases which then further inactivate the expression of *p16* via DNA methylation (Fig. 1). However, whether histone H3K27 methylation and recruitment of DNMT to result in DNA methylation ultimately leads to permanent mutation/deletion of the gene or all mechanisms of *p16* inactivation are independent remains to be discovered.

Histone H3-Methyl-K9 and Heterochromatin Protein 1

As described in a prior section, HP1 binds methylated K9 of histone H3, causing transcriptional repression [68, 95]. This occurs through the N-terminal chromodomain of HP1, while the highly related C-terminal chromoshadow domain allows for dimerization of these HP1 molecules and serves as a docking site for various factors involved in a wide array of functions, from transcription to nuclear architecture. To mediate gene silencing via the formation of heterochromatin, HP1 isoforms must interact with different H3K9 histone methylases, G9a (EHMT-2), GLP (EHMT-1), and SUV39H1 [68, 95]. These methylases work in concert with HP1 in a circular manner to form silenced chromatin. When the methylases adds methyl groups to K9 of H3, this, in turn, forms an HP1 docking site on chromatin. Since HP1 also recruits the methylases, this cycle repeats, and the HP1–methylase pair can spread the formation of silenced chromatin to adjacent nucleosomes, causing long-term silencing of entire genes (Fig. 1).

Information regarding the function of HP1 proteins in both normal and tumor pancreatic cells is still emerging. However, HP1 proteins have altered expression in many different types of cancers, including breast, brain, ovarian, colon, and papillary thyroid cancers as well as leukemias [96]. Noteworthy, with the three human isoforms having over 80% similarity between them, the factors that influence these

differences remain unknown. Unfortunately, despite the identification of numerous HP1 binding partners, distinct signaling cascades that mediate the interaction with these proteins to ultimately "switch on" or "switch off" gene silencing remain largely unknown. Although the discovery of the previously mentioned HP1-mediated subcode [31] contributed to this understanding, it remains essential to carefully define these pathways to map useful networks of membrane-to-chromatin signaling cascades for better understanding of the regulation of activation, repression, as well as other cellular processes. The molecular mechanisms that operate as subcodes within the histone code trigger nuclear instructions imparted by H3K9 methylation, which are subsequently translated as silencing, and thus, potentially participating in the silencing of tumor suppressor genes.

One specific example of how the methyl-H3K9/HP1 type of chromatin dynamics can impact on the field of pancreatic cancer is the regulation of MUC1 expression. The sialylated form of MUC1 is overexpressed in invading and metastatic pancreatic cancer cells, but absent in normal pancreas, cases of chronic pancreatitis, and pancreatic ductal hyperplasia [97], lending this molecule to be an interesting target for immunotherapeutic strategies [98]. Strikingly, studies have recently demonstrated that a mechanism responsible for changes in the expression of MUC1, which can in turn make proposed vaccines less than optimal, is regulated by DNA methylation and H3K9 modification, which is bound by HP1, on the *MUC1* promoter [99]. Similar to polycomb, it is known that HP1 can recruit DNA methyltransferases [100], which can lead to the silencing of this important molecule for pancreatic cancer (Fig. 1). MUC1-negative cancer cell lines correlated with high DNA methylation and methyl-H3K9 levels, while MUC1-positive cell lines had low levels of these epigenetic marks. Increased expression of NFATc2 in advanced PanIN-2/PanIN-3 lesions and PDAC coincides with silencing of the $p15^{INK4b}$ tumor suppressor pathway, which mechanistically has been linked to recruitment of SUV39H1, to result in H3K9 trimethylation and subsequent binding of HP1γ [101]. Interestingly, the first genome-wide study on the epigenetic landscape, comparing matched primary and metastatic PDAC lesions collected by rapid autopsy, revealed widespread epigenetic reprogramming during the evolution of distant metastasis without the presence of metastasis-specific driver mutations [102]. This reprogramming presented as global changes specifically in histone H3K9 and DNA methylation within large heterochromatin domains, known as LOCKs, as well as regional changes in histone marks, such as acetyl-H3K27 at gene regulatory elements. Inhibition of the H3K9 pathway results in senescence of pancreatic cancer cells without inducing apoptosis, thereby reducing anchorage-dependent and anchorage-independent proliferation [103]. Furthermore, the combined inhibition of the Aurora kinase A oncogene with the H3K9 pathway impedes PDAC cell growth via a mechanism that, instead of senescence, involves perturbation of normal mitotic progression to end in mitotic catastrophe [104]. Therefore, chromatin dynamic-driven epigenetic changes have the potential to extend research beyond the minimal mutation paradigm to include other pathways that are also important for other key biological behaviors in pancreatic cancer.

Additional Nonhistone Chromatin Proteins as Epigenetic Targets

Other nonhistone chromatin proteins, such as the Sin3a scaffold, play a role in pancreatic cancer [105]. For instance, pancreatic cells express three different Sin3 proteins that are recruited by tumor suppressors, such as the Myc antagonist, Mad1, and KLF11, and these tumor suppressor proteins require binding to a Sin3a–HDAC complex to perform their function (Fig. 1). Thus, this system is both active and important for antagonizing pancreatic carcinogenesis. Furthermore, pathogenic mutations and structural variants have been discovered in several epigenetic regulator genes, resulting from whole genomic sequencing of 100 pancreatic cancer samples, including *KDM6A*, *ARID1A*, *ARID1B*, *PBRM1*, *SMARCA2*, *SMARCA4*, and *MLL2* [106]. Interestingly, *KDM6A*, which encodes for an H3K27me3 demethylase, was inactivated in as much as 18% of the pancreatic cancer patients. Another KDM6 family member, KDM6B, which also demethylates H3K27me3, has loss of heterozygosity in pancreatic cancer cells and its loss is associated with enhanced tumor sphere formation, as well as increased peritoneal dissemination and liver metastasis in vivo [107]. Thus, the future anticipates studies of these various complexes in the context of pancreatic cancer, which may reveal significant contributions to the initiation, maintenance, or spreading of this disease or to cancer-associated functions, such as stem cell maintenance, DNA repair, metastasis, and therapeutic response.

Noncoding RNAs and Pancreatic Cancer

Due to the discovery and increasing study of noncoding RNAs, including microRNAs (miRNAs), short interfering RNAs (siRNAs), piwi-interacting RNAs (piRNAs), and long noncoding RNAs (lncRNAs), a significant number of researchers are analyzing noncoding RNA signatures in pancreatic cancer. The best-characterized noncoding RNAs are miRNAs, which are endogenous noncoding RNA molecules approximately 21 nucleotides in length that have been found to play important roles in the regulation of genes in animals and plants via a process involving their pairing to the mRNAs of protein-coding genes to direct their post-transcriptional repression [108]. In fact, miRNAs are currently predicted to control the activity of approximately 30% of all protein-coding genes in mammals. Similar to coding transcripts, miRNAs are classified into oncogenic miRNAs and tumor suppressor miRNAs in relation to their function during tumorigenesis. In an early global profiling study, several miRNAs were identified as aberrantly expressed in pancreatic cancer or desmoplasia [109]. Interestingly, some of these have been previously reported as differentially expressed miRNAs in other human cancers, including miR-155, miR-21, miR-221, and miR-222, in addition to some novel ones not previously reported, such as miR-376a and miR-301. Typically, the most aberrantly expressed miRNAs were found to be downregulated in the tumor tissue. Several additional profiling studies have found miRNA deregulation in human PDAC. In another study, several miRNAs, including miR-205, −18a, −31, −93,

−221, and −224, were demonstrated to be overexpressed in primary neoplastic ductal cells and pancreatic cancer cell lines, representing promising biomarkers for pancreatic cancer [110]. Furthermore, 26 miRNAs were identified as the most significantly misregulated in pancreatic cancer and the analysis of only two miRNAs, miR-217 and -196a, allowed discrimination between normal and neoplastic tissues, further supporting the potential use of miRNAs for the diagnosis of pancreatic cancer. Bloomston and colleagues also performed a global analysis to compare miRNA profiles of normal pancreas, chronic pancreatitis, and pancreatic adenocarcinoma [111]. In 90% of the tested samples, 21 overexpressed and 4 downregulated miRNAs were capable of differentiating pancreatic cancer from benign pancreatic tissues via cross validation. Additionally, 15 miRNAs demonstrated increased expression and 8 showed decreased expression, which could distinguish pancreatic cancer from chronic pancreatitis with 93% accuracy. Noteworthy, a subgroup of 6 miRNAs was able to discriminate node-positive disease between long-term survivors and patients who would succumb to the disease within 24 months. Poor survival of pancreatic cancer, with a median survival of 14.3 months versus 26.5 months, could be predicted with 95% confidence through high expression of miR-196a-2.

Certainly, the studies of miRNAs in pancreatic cancer in general have grown significantly over the last decade. However, with increased interest and focus on identifying circulating biomarkers in PDAC as a noninvasive, cost-effective, and reliable means to detect and/or monitor the disease, it is important to discuss the use of miRNAs in this context, as well as the contribution of circulating miRNAs to the disease. miRNAs can be detected in human plasma, circulating as free RNAs, either bound to hAgo2 or included in exosomes, which are stable and protected from endogenous RNase activity [112]. The first relatively large study performed by multiple independent centers reported that 29 circulating miRNAs from pretreatment blood samples collected before clinical or surgical intervention had the potential to differentiate PC cases from healthy volunteers [113]. Of these, 13 miRNAs were selected for further validation. While their diagnostic value was not significantly different than CA19–9, this report represented a proof-of-principle that circulating miRNAs can serve as potential biomarkers for early pancreatic cancer. A meta-analysis performed on 29 published studies, including a total of 2225 patients and 1618 controls, to evaluate the diagnostic accuracy of circulating miRNAs for pancreatic cancer diagnosis found multiple miRNAs to have a relatively high diagnostic value compared to single miRNA diagnosis [114]. A retrospective screen of early stage pancreatic cancer patients and controls detected 15 differential candidate miRNAs in plasma samples from pancreatic cancer patients at diagnosis [115]. However, these circulating miRNAs, alone or in combination, were not significantly altered in prediagnostic plasma samples from an early detection case-control cohort, suggesting that these miRNAs emerge late in disease development and would not function for early detection. Studies of this nature are still in their relative infancy, and if reliable circulating miRNAs are identified for early detection and/or monitoring disease progression, this noninvasive and cost-effective window into an epigenetic signature has a promising future in clinical application.

In addition to miRNAs, another class of noncoding RNAs that have elicited attention as novel drivers of tumorigenesis are long noncoding RNAs (lncRNAs). lncRNAs are longer than 200 nucleotides in length with their genomic location mainly in intronic and intergenic regions [116]. These RNAs are transcribed by RNA polymerase II, even with similar mRNA structures, such as a 5′ cap and a 3′ poly (A) tail, and based on the proximity to protein-coding genes are classified as antisense, sense, bidirectional, intronic, and intergenic lncRNAs. lncRNAs are believed to function in a variety of ways, including as cis- or trans-regulators of gene activity, as scaffold elements, guides, or decoys for chromatin-modifying complexes, or as gene enhancers. In respect to pancreatic cancer, recent studies have revealed several lncRNAs with differential expression in pancreatic cancer, including well-known lncRNAs such as H19, HOTAIR, HOTTIP, and MALAT-1, among others [117]. Even though most non-protein-coding transcripts belong to this class of RNAs, representing more than 20% of the genome, their highly diverse structures and functions provide a source of much understanding that remains unknown regarding these molecules in both, health, and disease.

In summary, the revised paradigm for the better understanding and promoting further research in pancreatic cancer, besides taking into consideration only mutations and deletions, as well as promoter DNA methylation, now includes both chromatin dynamics, noncoding RNAs, and nuclear shape (Fig. 5a, b). It is noteworthy to underscore that although more work on chromatin dynamics is needed to understand pancreatic cancer development and phenotype, little has been done about the role of nuclear shape in this disease. Therefore, the purpose of this model is to further fuel a new era of experiments that expand the scope of the field from a DNA-centric paradigm to a holistic and more inclusive model, which takes into consideration protein-mediated epigenetics, noncoding RNA-mediated effects, and the biology of the nucleus as an altered organelle in the progression of pancreatic tumors (Fig. 5a, b).

Conclusion

Increasing studies on chromatin dynamics are unveiling the existence of robust machineries that can mediate epigenetic changes in pancreatic cells. The research community needs to focus not only on somatic genetics, since this mechanism certainly does not represent the full story of alterations in gene expression for pancreatic cancer. This important fact has led to the design of a more comprehensive model that widely includes the emerging data in the field of chromatin dynamics and nuclear shape. Guided by this model, the knowledge gathered on this disease can be more accurately mapped to a progression paradigm that will not doubt impact on many areas of pancreatic cancer research and practice. The era of epigenetics has emerged strongly with well-justified and energetic beginnings, which will continue into a frontier area for pancreatic cancer research. The reversibility of the epigenetic changes, in itself, makes the journey worthwhile; however,

further insights into the mechanisms behind pancreatic cancer make the journey indisputable.

Box 1 Key Research Points

- The field of epigenetics has evolved from the fusion of studies on RNA polymerase II transcription and chromatin. The current theoretical framework in this field has been distilled from different paradigms, which have evolved during almost half a century with some replacement of each other.
- Pancreatic cells are excellent models for developing knowledge of three types of transcriptional events, namely basal transcription, activated transcription (e.g., growth factor-inducible), and tissue-specific gene expression (e.g., secretory granule enzymes).
- Studies on chromatin dynamics, including noncoding RNAs as well as nuclear structure and shape in pancreatic cells continue growing. The emerging data from these studies are benefiting not only this field, but extending the knowledge of the biology of other cells in the body. In addition, current evidence links these phenomena to development, homeostasis control and diseases. Therefore, this area may constitute one of the most promising in basic and translational pancreatic cell research.

Box 2 Future Scientific Directions

- Epigenetic mechanisms that are involved in stem cell biology, organ morphogenesis, and pancreatic cancer development constitute a new and very promising frontier. In particular, the discovery of how signaling and chromatin together determine cell fate during development and regeneration as well as how epigenetics contributes to the cancer phenotype is of paramount importance, biologically and pathobiologically.
- Cell-specific mechanisms for regulating gene expression are well advanced only in acinar cells. Therefore, more studies are necessary to understand the biology of ductal cells. In addition, epigenetic mechanisms are known to take part in the processes of pattern formation, such as branching morphogenesis, which is better understood in *Drosophila melanogaster* where chromatin-mediated effects play a significant role in this process. Therefore, studies on chromatin may aid in better understanding the formation of the pancreatic duct and its branching, which is of significant biomedical interest.
- Animal models for studying the genetic mechanisms necessary for the progression of pancreatic cancer have been a major contribution to the field of pancreatic cancer. Models for studying epigenetic effects in pancreatic cells must follow to understand the role of epigenetics in the pancreas at the whole organism level.

Box 3 Clinical Implications

- The revised "holo-genetic model for pancreatic cancer" covered in this chapter may help to guide future research in pancreatic cancer in a similarly productive manner to the guidance provided by the original genetic model for pancreatic cancer.
- It would be important to map key epigenetic changes that occur in the sequence of PanIN lesions along with the known mutations, to develop a better understanding of their potential mechanistic interrelationship. Therefore, development of new markers with good predictive value for whether an earlier PanIN has the potential to transform into another more malignant lesion would be beneficial.
- The most relevant characteristic of epigenetics, which is extremely attractive for therapeutic purposes, is its reversibility. Due to the difficulties surrounding gene replacement, it is likely that gene therapy for pancreatic cancer will remain, at least for a while, a hard-to-reach ideal. Therefore, due to its reversibility, epigenetics may provide attainable useful tools for chemoprevention and chemotherapy.
- In general, nuclear proteins and noncoding RNAs, which are shed by tumors into the bloodstream and are specific to detect pancreatic cancer, may be another prolific area of investigation with a great impact on diagnostics.

Abstract

The molecular biology of pancreatic neuroendocrine tumors (pNETs) carcinogenesis is poorly understood and is generally different from that of exocrine pancreatic neoplasms. pNETs represent a rare group of neoplasms with heterogeneous clinicopathological features. They are generally sporadic but can also arise within very rare hereditary syndromes, such as multiple endocrine neoplasia type I (MEN-I), von Hippel-Lindau disease (VHL), neurofibromatosis type 1 (NF1), and tuberous sclerosis complex (TSC). In these syndromes although a specific genotype/phenotype association with pNETs has been described, exact mechanisms leading to tumors development are still debated. Some clinical and biological features of pNETs associated with hereditary syndromes are similar in sporadic cases.

The presence of germline mutations has been indeed recently proved also in a high proportion of sporadic pNETs (17%) by whole genoming sequencing. These mutations include (beyond the well-known MEN1 and VHL) also other genes (such as BRCA2, or other of the mTOR pathway). Overall, main genomic changes involve gain of 17q, 7q, 20q, 9p, 7p, 9q and loss of 11q, 6q, 11p, 3p, 1p, 10q, 1q that identify the region of putative candidate oncogenes or tumor suppressor genes (TSGs) respectively. For some of them a possible relevant prognostic role has been described. "Classical" oncogenes involved in exocrine neoplasms (k-Ras, c-Jun, c-Fos) are of limited relevance in pNETs; on the contrary, overexpression of Src-like kinases and cyclin DI oncogene (CCNDI) has been described. As for TSGs, p53, DPC4/Smad, and Rb are not implicated in pNETs tumorigenesis, while for $p16^{INK4a}$, TIMP-3, RASSF1A, and hMLH1 more data are available, with data suggesting a role for methylation as silencing mechanism. Different molecular pathways and the role of tyrosine kinase receptors have also been investigated in pNETs (EGF, c-KIT) with interesting findings especially for VEGF and m-TOR, which encourage clinical development. Microarray analysis of expression profiles has recently been employed to investigate pNETs, with a number of different strategies, even if these studies suffer from a number of limitations, mainly related with the poor repeatability and the poor concordance between different studies. However, apart from methodological limits, molecular biology studies are needed to better know this group of neoplasms, aiming at identifying novel markers and targets for therapy also highlighting relations with clinical outcome. Besides biomarkers recent studies are currently focusing on the role of the immune system in tumor pathogenesis of pNETs, paving the way to a new therapeutic approach also in these rare tumors: the immunotherapy.

Introduction

The molecular biology of pancreatic neuroendocrine tumors (pNETs) is poorly understood, and overall oncogenes and tumor suppressor genes (TSGs) more frequently involved in exocrine neoplasms, and particularly in pancreatic cancer, are not relevant. pNETs are generally sporadic, as their carcinogenesis is based on somatic mutations [1]. However, oncosuppressors responsible for pNETs can be involved by germline mutations, which are present also in a significant rate of sporadic pNETs [2]. This process may be spontaneous, without a previous family history, or more frequently inherited, as a part of well-described syndromes. The present paragraph will review in depth existing evidences for the molecular pathogenesis of pNETs, with a summary of data from studies of familial syndromes, genetic instability, as well as those examining the role of oncogenes, TSGs, and an insight into more recent microarray studies. A brief overview of the expression of growth factors and their receptors as possible therapeutic targets will also be presented.

Inherited Pancreatic Endocrine Tumors

The following hereditary syndromes have been associated with pNETs: multiple endocrine neoplasia type I (MEN-I), von Hippel-Lindau disease (VHL), von Recklinghausen's disease (neurofibromatosis 1 or NF1), and tuberous sclerosis complex (TSC) [3]. The latter three are phakomatoses, rare neurocutaneous syndromes characterized by uncontrolled growth of ectodermal tissues from which endocrine tumors arise.

The pNETs occurring in these hereditary forms are primarily nonfunctioning tumors or insulinomas, with different incidence, and do not differ from those detected as sporadic [3] (Table 1).

Multiple Endocrine Neoplasia Type I (MEN-I)

The most frequent inherited syndrome causing pNETs is MEN-I, a rare autosomal dominant disorder (incidence 1:20,000–40,000) clinically defined by the presence of two or more of the following neoplasms: gastroenteropancreatic neuroendocrine tumors, parathyroid gland adenomas, pituitary adenomas, with other neoplastic lesions (i.e., thyroid adenomas, multiple lipomas, bronchial or thymic carcinoids) occurring occasionally [4]. About 10% of pNETs occur as a part of MEN-I.

The MEN-I syndrome is the result of an inactivating mutation of the Menin gene, an oncosuppressor gene located on chromosome 11q13 [4].

This gene, consisting in 10 exons, encodes for a 68 KDa nuclear protein of 610 amino acids, named Menin. Menin functions include binding and inactivation

Table 1 Described syndromes associated with inherited pancreatic endocrine tumors, including clinical features and molecular defects

Syndrome	Gene	Gene function main molecular consequences	Major clinical features	Patients with pNETs (%)	pNETs subtype	Metastatic pNETs (%)
Multiple endocrine neoplasia type I	Menin (11q13)	Oncosuppressor deregulation of JunD, SMAD3 $p27^{KIPI}$ $p18^{Ink4c}$	2 or more between:	20–60%	80% NF	<10%
					15% insulinomas	
					3% glucagonomas	
			(a) GEP-NET		1% gastrinomas and vipomas	
			(b) Parathyroid adenomas			
			(c) Pituitary adenoma			
von Hippel-Lindau disease	VHL (3p25-26)	Oncosuppressor overexpression of HIF and VEGF	1 or 2 between:	5–17%	80–100% NF	<10%
			(a) Retinal or cerebellar hemangioblastomas			
			(b) Renal cell carcinoma			
			(c) Pheochromocytoma			
Von Recklinghausen's disease	NF1 (17q11.2)	Oncosuppressor deregulation of Ras pathway mTOR	(a) Café-au-lait skin spots	Rare	Insulinomas and somatostinomas	–
			(b) Neurofibromas of any type and localization			
Tuberous sclerosis complex	TSC 1 (9q34) TSC2 (16p13.3)	Oncosuppressor deregulation of mTOR pathway	(a) Skin alterations	Very rare	Mainly NF	–
			(b) Renal angiomyolipomas			
			(c) Multiple and diffuse hamartomas			
			(d) Neurological alteration			

of many nuclear transcription factors (especially JunD but also SMAD3, mSin3a, and trithorax family histone methyltransferase complex), upregulation of cell cycle inhibitors expression ($p27^{KIPI}$ and $p18^{Ink4c}$), and influence on DNA repair process, all of which result in inhibition of cellular proliferation [5–8].

The spectrum of possible mutations is greatly various. In the last decade, more than 1,300 germline variants (the half of which with pathological effect) have been identified, and 10–12% of them occur without a positive family history. Some 23% are nonsense mutations, 9% splicing-site mutations, 41% frameshift deletions or insertions, 6% in-frame deletions or insertions, 20% missense mutations, and 1% whole or partial gene deletions [4].

Even though any genotype/phenotype association with pNETs have been described, the exact mechanism leading to the neoplasia is still debated and the role of Menin on cell cycle negative control and DNA stability is somehow controversial.

Gene mapping in MEN-I patients have shown loss of heterozygosis (LOH) in half of the cases, confirming the oncosuppressor function of Menin and the tumorigenesis Knudson's two-hit hypothesis. LOH of the Menin gene and other somatic mutations on wild-type allele behave as a second hit after a first hit germline, inherited mutation. LOH on Menin allele, as described in sporadic pNETs, can also involve other terminal region of 11q, suggesting implications of additional genes in neoplastic development and progression. A heterogeneity among tumors even in the same patient, suggesting that different tumor-specific tumorigenic mechanisms may contribute to the pathogenesis of MEN1 tumors. The present study supports the clinical applicability of the WES strategy to research on multiple tumor samples and blood [9, 10].

pNETs patients with pathological Menin gene mutation do not differ from sporadic forms in terms of clinical features (age of onset, hormone and/or neoplasia-related symptoms), but only 10% develop metastases, especially in the case of tumors larger than 3–5 cm (irrespectively to its histotype) [1, 3].

In up to 80–90% of cases, endocrine pancreatic involvement consists in endocrine islet cell hyperplasia, without somatic LOH on Menin, and microadenomatosis (multiple indolent tumors <5 mm). These latter kind of lesions are characterized by trabecular structure and distinctive stroma, and, in spite of being asymptomatic and without metastases, in about 50% of the cases LOH of Menin gene is detectable [11–13].

In a variable percentage of MEN-I patients (20–60%), microadenomatosis is associated to one or multiple pancreatic "macro-tumors," which are larger than 5 mm but less than 3–5 cm. These neoplasms are NF pNETs in about 80% of cases, 15–20% insulinomas, 3% glucagonomas, and rarely VIPomas or gastrinomas [1–3].

These tumors are often clinically silent and just 10% of cases lead to metastases, but they are often associated with other symptomatic more aggressive gastrointestinal neuroendocrine tumors, especially duodenal gastrinomas and somatostatinomas [3, 14, 15].

In fact, although 20–60% of MEN-I patients have Zollinger-Ellison syndrome (20–40% associated with gastric carcinoid type II), gastrinomas arise far more

frequently in the duodenum as single or multiple small tumors (not unfrequently undetectable) rather than as pNETs [3, 16, 17].

Von Hippel-Lindau Disease (VHL)

pNETs also occur in a significant percentage of individuals affected by Von Hippel-Lindau disease (VHL). It is a very rare (1:30,000–1:50,000) autosomal dominant phakomatosis with a variable phenotype characterized by the presence of at least one of these major manifestations: single retinal or cerebellar hemangioblastoma (HB), renal cell carcinoma (RCC) or pheochromocytoma and other more rare multiorgan lesions such as pancreatic cysts or pNETs, renal cysts, endolymphatic sac tumors, epididymal papillary cystoadenomas, paragangliomas, polycythemia, and other rare tumors [18].

The gene responsible for this disease is VHL gene, an oncosuppressor of three exons located on 3p25-26 that by alternative splicing can encode for two proteins (pVHL), respectively of 213 and 160 amino acids [18].

The two VHL products accomplish to similar activities in the cytoplasm; in particular, they make an ubiquitin complex with cullin-2, Rbx1, and elongins B named VBC, which in case of normoxia binds and inactivates hypoxia-inducible factor (HIF) [14].

Inactivating mutation of VHL gene causes an overexpression of HIF, especially of vascular endothelial growth factor which lines to tumorigenesis [15].

Until now, more than 300 germline mutations have been found, 60% of which are truncating or missense mutations while 40% are deletions. These mutations are associated with different phenotypical expressions: only patients with missense mutations develop pheochromocytoma (VHL type 2) associated (2b) or not (2a) to RCC, whereas patients affected by other mutations will develop the remaining related disease manifestations (VHL type 1) [15, 18].

Disease penetrance grows by age (90% at 65 years), as germline mutations have to be followed by another somatic event in the wild-type allele.

As far as pNETs, LOH in the VHL allele or, less frequently, methylation or neomutation are frequent findings [15, 19]. Indeed, pancreatic involvement by multiple indolent cysts is typical of VHL (50–75%), but pNETs are also frequent (5–17%) [20].

Strict associations between specific mutations and phenotypic expression of pNETs have been reported, but tumor cells show a typical LOH in chromosome 3p which is not limited to the VHL gene, but also involves other adjacent genes (such as not papillary renal carcinoma-1) possibly implicated with tumorigenesis and progression [20].

Biological and clinical features of VHL-associated pNETs are similar to sporadic forms: they are typically nonfunctioning and asymptomatic, generally expressing somatostatin receptors and in 30–50% of cases are multifocal in the pancreas [3, 20, 21].

However, pNETs arising in VHL disease are usually small (<2–3 cm) and without liver metastases in about 80–90%, with a consequent better prognosis

compared to sporadic ones. This difference is most likely due to earlier detection (at a mean of 35 vs. 58 years) thanks to investigations due to other malignancies' symptoms [2, 3, 21].

Von Recklinghausen's Disease or Neurofibromatosis Type 1 (NF-1)

Occurrence of gastroenteropancreatic NETs in NF-1 is less frequent than in MEN-I and VHL disease, and in particular the rate of pNET is very low [22].

NF-1 is an autosomal dominant phakomatoses (1:3,000–1:4,000) with high penetrance, defined by multiple café-au-lait skin spots, neurofibromas of any type and localization (10% malignant), and characterized by predisposition to various other malignancies development (3–30%) such as gliomas, myeloid leukemia, and pheochromocytoma [23].

NF-1 arises from mutation of the NF-1 gene, a large oncosuppressor of 50 exons located on the 17q11.2 chromosome. Its product, called neurofibromin, is a GTPase acting as a negative regulator of mitonegic Ras pathway, especially of the mTOR signaling [24].

Many NF-1 gene mutations have been identified, of which up to 50% arising "de novo"; however, all the significant genotype/phenotype association have been demonstrated [23].

Rate of associated pNETs is undeterminable [3, 25–27]. They arise from germline NF1 mutation and deletion; insulinomas and somatostatinomas are similar to sporadic forms as in the tumor cells there is low expression of NF-1. The risk of pNETs development is often increased in this disease, probably because of mTOR pathway upregulation; however, more cases are needed to study the genotype/phenotype relation.

Tuberous Sclerosis Complex (TSC)

The rarest inherited disease associated with gastroenteropancreatic NETs is TSC. This phakomatosis (1:10,000) is a hereditary multiorgan disease transmitted by autosomal dominant inheritance. TSC has a 100% penetrance and a highly variable expression; clinical manifestations are typical skin alterations, renal angiomyolipomas, multiple and diffuse hamartomas, mental retardation, and neurological alterations. pNETs are occasionally associated [28].

Two genes are responsible for this disease: TSC1 (9q34) and TSC2 (16p13.3) that respectively encode for hamartin and tuberin. These two proteins make a dimer that multi-modulates cell growth, interacting with phosphoinositide 3-kinase pathway-mTOR activity and insulin receptor signaling.

Several genotype/phenotype associations have been described and related to many different mutations (50% occurring de novo); somatic tumor cells show a secondary mutation or a large deletion, up to a complete LOH on the two alleles often involving large chromosomal region.

The described cases of pNETs associated with this disease are mainly nonfunctional, and few cases of insulinoma and somatostinoma, with a behavior similar to sporadic forms [5]. In particular, one case of pNETs described in literature, a nonfunctional tumor identified in a child, exhibited a TSC2 gene LOH; this confirms its oncosuppressor role, such as in other TSC-related neoplasm [29, 30].

Genetic Instability in Sporadic Pancreatic Endocrine Tumors

Genetic instability represents the necessary condition for tumor development, through the clonal expansion of cancerous cells that have acquired a selective advantage. Among the different events (point mutations, chromosomal rearrangements, gene amplifications, microsatellite sequences alterations, and epigenetic changes) occurring during the multistep process of somatic cells transformation, alterations in DNA copy number are the commonest events.

Allelic imbalances, that result from incorrect mitotic division and consequent abnormal chromosomal separation, may be revealed by a variety of methods including karyotyping, comparative genomic hybridization (CGH), microsatellite analysis, or, more recently, single nucleotide polymorphisms (SNPs) allelotyping.

Conventional CGH is a molecular cytogenetic genome-wide technique for the analysis of copy number changes in DNA of tumor cells. Through this method, differentially labeled test DNA and normal reference DNA are hybridized simultaneously to normal chromosome spreads and the hybridization is detected with two different fluorochromes. Regions of gain or loss of DNA sequences, such as deletions, duplications, or amplifications, are seen as changes in the ratio of the intensities of the two fluorochromes along the target chromosomes. In brief, the regions frequently identified with decreased copy number are likely to harbor tumor suppressor genes (TSGs), whereas regions with increased copy number may contain dominant oncogenes.

Furthermore, allelotyping, that is the systematic analysis of the allelic losses in single chromosomes thus exploring loss of heterozygosity (LOH), is another strategy to determine the most probable locus of a TSG: it can be based on polymorphic microsatellite DNA or on SNPs, assaying the frequency and extent of lost regions on all chromosomal arms. SNPs allelotyping is more sensitive than microsatellite analysis and is also useful to detect DNA copy number.

Genome-Wide Studies in Sporadic pNETs

During the last decade, several studies with different approaches have addressed to look for specific genomic defects in sporadic pNETs [31–42]. As shown in Table 2, CGH has been largely used to explore genetic aberrations. Most of the available data refer to small, heterogeneous tumor series and essentially regard well-differentiated pNETs. In addition, several different tumor classifications have been used by investigators in their studies during time making difficult a possible analysis of

Table 2 Main genome-wide studies of pNETs series

pNETs subtypes. In this paragraph, data are presented separating nonfunctioning (NF-) from functioning pNETs (F-pNETs), and among these, further taking account of benign insulinomas, malignant insulinoma, and gastrinomas to possibly identify specific genomic patterns.

In the ten published studies [31, 32, 35–38, 40–43] of CGH/genomic wide-allelotyping, 101 NF pNETs have been studied (Tables 3 and 4). The most frequent findings were losses of 11q (38.6%), 6q (37.6%), 11p (33.7%), 3p (26.7%), 1p (27.7%), and 10q (25.7%), while the most frequent gains involved 17q (41%), 7q (35.9%), 12q (34.6%), 14q (34.6%), 4p (32%), and 20q (30.7%).

As for the 31 gastrinomas investigated in seven studies, loss of 3p (19%) and gain of 9p (29%) represented the most common chromosomal aberrations [31, 32, 34–37, 40].

In benign insulinomas (116 overall tumor samples in seven studies), most frequent losses were found on 11q (19%), Xq (18%), and 1p (17%), while most frequent gains regarded 9q (41%), 7p (20%), and 7q e 5q (both 19%). Malignant insulinomas (30 tumor samples), defined by the presence of loco-regional advanced or metastatic disease, harbored more genomic alterations than benign counterpart [32, 33, 35–37, 39, 40]. In particular, most frequent losses were found on 6q (70%), Y (43%), 2q (33%), 3q (30%), 6p (30%), 10q, 11p, 11q, and Xq (all 23%), while main gains involved 17q (57%), 17p (53%), 12q (53%), 14q (50%), 7q (47%), 20q, and 9q (43%).

The identification of gains and losses on chromosomal regions helps to highlight loci potentially containing putative oncogenes and TSGs. Tables 5 and 6 summarize main losses and gains, together with candidate TSGs and oncogenes, the associated disorders for which a pathogenetic link has been already described and, finally, the prognostic significance of the particular genetic change.

TSGs tumor suppressor genes, *NF* nonfunctioning, *B or M Ins* benign or malignant insulinoma, *Gas* gastrinoma

On the whole, NF-pNETs seem to present more genomic aberrations, then malignant insulinomas, with benign insulinomas and gastrinomas presenting the lowest amount of changes. This tendency is consistent with the finding by Speel and colleagues that pNETs larger than 2 cm exhibited significantly more aberrations than lesions smaller than 2 cm given that NF-pNETs are often larger than 2 cm at diagnosis [32].

All these observations strongly suggest that pNETs subtypes may evolve along different molecular pathways: deciphering their specific signatures would help to implement pNETs classification system, with obvious implications for a better understanding of this complex nosological entity.

Prognostic Relevance

Accumulated evidences showing that pNETs from patients with advanced disease harbored significantly higher numbers of genetic aberrations than tumors from patients with localized disease suggest that malignant progression of pNETs

Table 6 Main gains in sporadic neuroendocrine tumor of the pancreas

Location	% Gain				Putative oncogenes	Associated disorder	Prognostic relevance

NF nonfunctioning, *B or M Ins* benign or malignant insulinoma, *Gas* gastrinoma

progression is driven by the progressive accumulation of multiple genetic changes [32, 36, 39, 50], as is also known to occur in other types of human carcinomas [46].

Another interesting issue is the possible relationship between molecular genetic defects (number and type of genomic changes) and tumor progression or malignancy in pNETs.

Several LOH studies [45, 47–49], using microsatellite markers, demonstrated that LOH at *chromosome 1*, and in particular of its long arm, is a common event among pNETs subtypes (12/27 gastrinomas, 35/40 insulinomas, 10/29 different pNETs subtypes) and was significantly associated with the presence of hepatic metastases regardless of tumor type. Moreover, Chen and colleagues (2003) found in their series of gastrinomas that allelic loss at 1q31-32 as well as 1q21-23 significantly correlated with tumor aggressive growth and postoperative development of liver metastases [48]. Likewise, Yang and colleagues (2005) reported high frequency of LOH at 1q 21.3-23.2 and 1q31.3, significantly associated with malignancy of insulinomas suggesting in these two regions the presence of putative tumor suppressor genes important for aggressive growth of these tumors [49]. Although these two studies narrowed region of potential candidate genes, to date actual genes involved remain undefined (Table 5).

As for *chromosome 3*, LOH was demonstrated to be a common event (frequency ranged from 33% to 83%) in pNETs regardless of tumor subtypes and its frequency was significantly higher in malignant than in benign neoplasms, on the whole finding a correlation with clinically metastatic disease in several studies [44, 51–53]. As common deleted regions were different (3p14.2-21; 3p25.3-p23; 3q27-qter, all outside of the VHL locus) in the same studies, different putative tumor suppressor genes other than VHL on chromosome 3 may play a role in the latest steps of tumorigenesis of sporadic pNETs.

Only one LOH study reported by Barghorn and colleagues (2001) described allelic loss at *chromosome 6* in 62.2% of cases in a heterogeneous cohort of pNETs, the majority of which were insulinomas and NF-pNETs (with common deleted regions mapped at 6q22.1 and 6q23-q24), and it was significantly more common in tumors larger than 2 cm in diameter than below this threshold as well as in malignant than in benign tumors [43]. Previously, Speel and colleagues (1999) had reported an overall loss at 6q in 39% of pNETs (with a common deleted region at 6q21-22) and in all of six insulinomas, again indicating a locus harboring a potential TSG involved in tumor development [32]. To further support this hypothesis, combined data from abovementioned genome-wide studies show that 6q loss occurs in 70% of malignant insulinomas and in 37.6% of NF-pNETs, as shown in Table 2 .

Chromosome 17. In a study of 20 mixed functioning and nonfunctioning pancreatic endocrine tumors, Beghelli and colleagues (1998) found allelic losses on 17p13 in ~24% of the chromosomal loci analyzed with a higher frequency of allelic losses significantly associated with a high proliferation index and malignancy of the tumors [54]. Moreover, the absence of p53 gene mutations in nearly all these tumors

suggests the existence of another tumor suppressor gene in the same chromosomal area. However, according to genomic-wide studies, loss of 17p is a rare event (<10%) and probably does not play a central role in the majority of endocrine tumors development. On the opposite, gain of 17q is a frequent event, especially in malignant insulinomas (>50%). The oncogene Her-2/Neu, frequently overexpressed in breast and esophageal cancer which is identified as more aggressive phenotype, is located on chromosome 17q21. Her-2/Neu gene amplifications were identified in 40% of 11 gastrinomas [55], the majority of which were locally advanced or metastatic, while in another study by [56] the same gene was amplificated in 14% of 43 gastrinomas and this time higher mRNA levels in tumor cells were correlated with liver metastases [56].

LOH on *chromosome 22q* was detected in 14 of 15 insulinomas (93%) by Wild and colleagues (2001). The shortest region of overlap implicated a deletion at 22q12.1-q12.2 where hSNF5/INI1 gene is located but no alteration was identified by single strand conformational polymorphism analysis, direct DNA sequencing, or RNA expression analysis [57]. The same group [58] described LOH on chromosome 22q in 22 of 23 pNETs (including nonfunctioning tumors, gastrinomas, and vipomas) showing a LOH rate of 85% at locus 22q12.1, with LOH strongly correlated with the presence or the development of distant metastases [58]. Moreover, LOH on 22q12.3 was significantly associated with distant metastases, an area where two putative candidate gene are located, that is, synapsin3 (SYN3) and tissue inhibitor of metalloproteinase-3 (TIMP-3). Also in this instance, genome-wide studies tend to underestimate genetic changes: in particular, loss of 22q was found in ~20% of NF-pNETs and in less than 10% of other pNETs subtypes.

Sex Chromosomes. According to combined data from genome-wide studies reported, Xq loss mainly occurs in insulinomas (~20% of cases) and one CGH-study also noted an association between Xq loss metastatic disease, raising the hypothesis that X chromosome changes plays a role in defining the more aggressive nature of endocrine lesions [32, 43].

Aberration of X chromosome has been described mainly in gastric carcinoids and pNETs, and in malignant compared with benign endocrine tumors. Pizzi et al. [59] comparing pNETs and endocrine tumors of the ileum and appendix noted that LOH on chromosome X was evident in 60% of malignant gastric and pancreatic tumors but in only 4.5% of benign tumors. Similarly, none of the benign midgut tumors exhibited X chromosome LOH, whereas 15% of malignant tumors contained this aberration [59]. On the whole, an association between X chromosome LOH and malignancy clearly has been found. In LOH analysis, allelic losses on X chromosome were revealed in 50% of type III gastric carcinoids, but not in type I tumors. Again, tumors that exhibited LOH were associated with metastasis [60]. Also in a series of 16 female patients with gastrinomas reported by Chen et al. 56% presented X chromosome LOH, was significantly associated with aggressive postoperative tumor growth and with increased primary tumor size [61]. Missiaglia and colleagues (2002), in their microsatellite and FISH analysis extended to chromosome Y, described that pNETs from females had loss of chromosome X in 40% of cases whereas pNETs from males showed loss of chromosome Y in 36% of case but never had loss of the X chromosome [62]. A significant association of sex chromosome

loss with metastases, local invasion Ki-67 > 5% was also described. Sex chromosome loss was found to be an independent variable associated with a shorter survival period and an increased risk of death of approximately fourfold.

Recently, in a comparative LOH analysis on X chromosome by Azzoni et al. [63] higher rate of allelic loss was found in poorly differentiated endocrine carcinomas than in well-differentiated endocrine carcinomas with two chromosomal regions, Xq25 and Xq26 showing LOH with a relatively high frequency [63]. Candidate tumor suppressor genes mapping at Xq25 are ODZ1, encoding Tenascin, a glycoprotein of the extracellular matrix involved in morphogenetic movements, tissue repair and tumor spreading and SH2D1A, whose mutation was described in X-linked lymphoproliferative disease and in non-Hodgkin Lymphomas [64]; while potential tumor suppressor genes for Xq26 are MEF, a transcription factor capable to suppress the transcription of the genes encoding for the matrix metalloproteinases, MMP-2 and MMP-9, and interleukin-8 as demonstrated in cell lines of human nonsmall cell lung carcinoma [65]; and GPC-3, a heparan sulfate proteoglycan linked to the cell membrane, involved in the progression of several types of malignant tumors, including mesotheliomas, ovarian, and lung carcinomas [66].

Loss of DAXX or ATRX protein and alternative lengthening of telomeres have also been proved to show a prognostic meaning in pNET cases. They were indeed associated to tumor stage, relapse-free survival, and decreased time of tumor-associated survival in 243 patients affected by pNETs [43].

Final Considerations

The limited resolution of the conventional CGH method, its low reliability (emerged from the observation that some regions – 1p32- pter, 16p, 19, and 22 – showed gains in negative control experiments), and its feature to be a laborious method remain the principal limits. On the other hand, LOH analysis, depending on number and type of microsatellite markers used, often offers contradictory results. For this reason, caution is needed in interpreting their results, awaiting further studies to confirm available data.

Array-CGH technology can improve the resolution of conventional CGH on metaphase chromosomes from 5 to 10 Mb to $\leq$1 Mb on arrayed DNA. In a series of 27 insulinomas, Jonkers and colleagues (2006) performed a genome-wide array-based CGH analysis detecting in >50% of cases loss of chromosomes 11q and 22q and gains of chromosome 9q with the first two alterations only partially identified before by conventional CGH (11q loss and 22q loss were found in ~20% and ~10% of benign and malignant insulinomas, respectively) [67].

The chromosomal regions of interest included 11q24.1 (56%), 22q13.1 (67%), 22q13.31 (56%), and 9q32 (63%). Comparing their alteration frequencies in tumors with benign, uncertain, and malignant behavior according the most recent WHO classification, the authors suggest that gain of 9q32 and loss of 22q13.1 are early genetic events in insulinomas, occurring independently of the other alterations. Finally, in this study further evidence was found for the accumulation of chromosomal alterations which run parallel with increasing malignant potential.

Genetic Alterations of Oncogenes and Tumor Suppressor Genes, and Expression of Growth Factors and Their Receptors

Oncogenes

The role of *k-Ras* has been investigated by a number of authors, with findings suggesting limited relevance if any, thus differentiating pancreatic endocrine neoplasms from the exocrine counterpart. *K-ras* mutations were found in a risible proportion of cases [50, 54, 55, 68–72], without any significant clinical association. Not surprisingly, the BRAF gene, one of the human isoforms of RAF, which is activated by ras, does not seem to have a role in tumorigenesis of pNETs [73]. However, a possible role for the ras signaling pathway in pNETs may depend on inactivation of the TSG RASSF1 (see below).

Similarly, there is limited evidence for a role of either *c-Jun* or *c-Fos* [71, 74]. On the other hand, *c-Myc* is overexpressed in most studies either at the RNA or protein level [50, 68, 75, 76]. The proto-oncogene *Bcl-2*, which acts as an antiapoptotic factor, has been detected in up to 45% of examined pNETs samples [75]; however, there are no data examining the overall balance of the pro/antiapoptotic machinery in pNETs.

Src is a family of proto-oncogenic nonreceptor tyrosine kinase including nine members. *Src-like kinases* act downstream of growth factor receptors and integrins transmitting messages that are crucial for several aspects of cell growth and metabolism, as for example cell cycle regulation, cell adhesion, and motility. Overexpression of *Lck*, a member of *Src* family, has been recently demonstrated in metastatic progressive pNETs in a microarray study [74]. The expression and activity of *Src* have been also described in pNETs cell lines and tissues, and inhibition of *Src* activity has been shown to interfere with adhesion, spreading, and migration of cells [77].

As far as cell cycle, although animals with constitutive activation of CDK4 develop pNETs [78], mutations have not been found in insulinomas [79]. A more relevant role for the cyclin DI oncogene (CCNDI) is suggested by findings of its overexpression and relation with disease stage [80, 81].

The Wnt signaling pathway is relevant for a number of neoplasms, and β-catenin activation is frequently detected in such cancers. However, no mutations of the β-catenin gene have been detected in a study including 108 pNETs, and nuclear accumulation of the β-catenin protein seems a rare and late event [82].

In a further study, 52% of pNETs showed abnormal β-catenin staining, which was related with loss of normal E-cadherin staining and more aggressive behavior [83].

Tumor Suppressor Genes

The role of MEN-I and VHL mutations, either in genetic or sporadic forms, has been summarized in the previous paragraphs.

The role of the *p53* TSG has been investigated in a wide number of studies. A rationale for such investigations comes from studies of mice with *p53* mutations and

pNETs development. However, most studies found no mutations of *p53* and/or no overexpression of the mutated protein in human pNETs [50, 54, 55, 68, 69, 72, 73, 84–87]. These data suggest that findings of LOH at 17q13 may be related with other unknown TSGs.

Similarly, although LOH at 18q is fairly frequent in pNETs, the DPC4/Smad gene has not been found to be mutated in the majority of published papers [50, 68, 88], and the retinoblastoma TSG (Rb) is also not implicated [89].

On the other hand, the p1*6 INK4a* TSG, which encodes for an inhibitor of CDK4, seems relevant for at least a portion of pNETs. Particularly, inactivation of *p16*, either by mutations or by methylation is common in gastrinomas, but less frequent in NF-pNETs and insulinomas [55, 68, 90, 91].

The expression of the putative tumor suppressor gene tissue inhibitor of metalloproteinase-3 (TIMP-3) has been found to be altered by either promoter hypermethylation or homozygous deletion. The predominant TIMP-3 was described in 44% of examined pNETs, with as significant relation with the metastatic process [92].

The Ras-association domain family 1A (RASSF1A) is a TSG, interacting with ras. It is inactivated in a variety of solid tumors, usually by epigenetic silencing of the promoter or by loss at 3p21.3. RASSF1A induces cell cycle arrest through inhibition of cyclin D1 accumulation. RASSF1A hypermethylation was detected in 10 out of 12 (83%) endocrine tumors [93], and in a further publication RASSF1A silencing by methylation and 3p21.3 deletion was associated with tumors from foregut only, and with malignant behavior [94].

Loss of expression of the p27 protein has instead been paradoxically related with well-differentiated pNETs, with most indolent features, while its expression was associated with metastatic disease [95].

The aberrant promoter methylation of the mismatch repair gene, hMLH1, is associated with microsatellite instability (MSI). Hypermethylation of the hMLH1 promoter has been found in 23% of pNETs. Some 50% of hMLH1-methylated pNETs were found to be microsatellite unstable, and MSI was restricted to pNETs with hMLH1 hypermethylation. Tumors with MSI-positive had a better survival compared with MSI-negative [96].

Growth Factors and Their Receptors (Receptor Tyrosine Kinases)

The expression of growth factors, and their receptors, generally tyrosine kinases, is an interesting issue and offers the opportunity for targeted therapy. Angiogenesis has been studied in depth in transgenic mouse model (Rip1-Tag2) in which mice develop pNETs [97]. Although pNETs are highly vascular, some studies have suggested that they express VEGF, which correlates with a more aggressive tumor [98], while others detailed how pNETs present a wide range of microvascular density (MVD) according to the malignant potential, with malignant tumors showing lower MVD and VEGF expression than benign ones [99].

The surface of pNETs cells presents several other growth factor receptors, including receptor tyrosine kinases such as the epidermal growth factor receptor

(EGFR), the stem cell factor (SCF) receptor c-KIT, and the platelet derived growth factor receptors (PDGFR) [100–103].

The EGFR (ErbB-1) is a member of a receptor tyrosine kinase family also including HER2/Neu (ErbB-2), HER-3 (ErbB-3), and HER-4 (ErbB-4), whose activation after interaction with their ligands leads to a number of downstream cascade molecular events involving cell proliferation and transformation. Although the expression of the EGFR and its phosphorylation seems more relevant in carcinoids than pNETs, phosphorylated-EGFR expression was found to be an unfavorable prognostic marker only in pNETs [104]. As far as other members of the Erb family, the expression and amplification of HER-2/Neu were explored in patients with gastrinoma, with relevant data presented above [55, 56].

c-KIT (CD117) is a type III tyrosine kinase receptor which, once activated by its ligand, stem cell factor (SCF), induces dimerization and autophosphorylation of the receptor at specific tyrosine regions, which acts as docking sites for other intracitosolic proteins important for intracellular signal transduction. Abnormal expression of c-KIT and/or SCF has been described in a variety of solid tumors, and activating mutations of c-KIT are a typical feature of gastrointestinal stromal tumors (GIST). Several studies have investigated the expression of c-KIT, together with other receptor tyrosine kinases in gastroenteropancreatic endocrine tumors, by immunohistochemistry [102, 105]. The results are inconsistent and, as hypothesized for other cancer types, inter-studies disagreement may be explained by different antibodies employed or different immunohistochemistry protocols.

A recent study including 98 pNET samples [2] has proved that sporadic pNETs contain germline mutations in about 17% of patients. These mostly interest genes involved in four main pathways: chromatin remodeling, DNA damage repair, activation of mTOR signaling (including previously undescribed EWSR1 gene fusions), and telomere maintenance, hypoxia, and HIF signaling. Also further mutations involving MUTYH, APOBEC, und BRCA have been described, paving the way to further molecular targets for therapeutic approach.

The (PI_3K)/Protein Kinase B/AKT/mTOR Pathway

The mammalian target of rapamycin (mTOR) is a serine-threonine kinase involved in the mechanisms of regulation of cell growth and death through apoptosis. It plays a critical role in transducing a number of different proliferative signals mediated through the phosphatidylinositol 3 kinase (PI_3K)/protein kinase B (AKT) pathway, principally by activating downstream protein kinases that are required for both ribosomal biosynthesis and translation of key mRNAs of proteins required for cell cycle progression.

The signaling pathways upstream of mTOR include several tumor suppressors, such as PTEN, NF1, the kinase LKB1, and oncogenes such as Ras and Raf. mTOR also mediates signaling downstream of a number of growth factors such as IGF-1 and VEGF (Fig. 1). These signaling pathways converge on the tuberous sclerosis

complex (TSC1/TSC2), which inhibits the mTOR activator Rheb, a small GTPase. In turn, activation of the mTOR pathway enhances the activity of HIF1α and of VEGF itself [106, 107].

Tumors exhibiting constitutively activated PI_3K/AKT/mTOR signaling due to mutations or loss of the abovementioned tumor suppressor genes (PTEN or TSC), or overexpression of upstream genes, are potentially susceptible to mTOR inhibitors, therefore making the investigation of this pathway particularly interesting for pNETs.

Microarray Studies

Global expression profiling has been often employed in the past decade to better understand molecular changes occurring in a number of tumors. This approach has been proved useful to identify novel markers and targets for therapy or to highlight relations with clinical outcome.

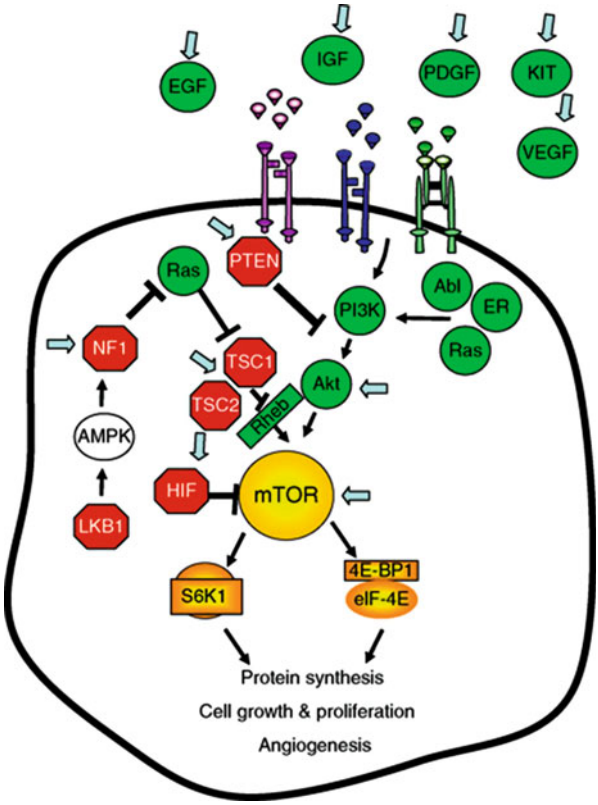

Fig. 1 Schematic representation of the PI_3K/AKT/mTOR pathway. Green color indicates overexpression or activation, and red color indicates reduced expression or deactivating mutations. Overall, the balance of such events suggests an important role for this signaling pathway in pNETs. Notably, mutations of TSC1/TSC2 and PTEN may reduce the negative effect of hypoxia on the mTOR pathway

However, microarray studies suffer a number of limitations, mainly related with the poor repeatability, and the poor concordance between different studies [108].

Microarray analysis of expression profiles has recently been employed to investigate pNETs, with a number of different strategies. These studies are summarized in Table 7 [74, 109–114].

Overall, the studies differ significantly in terms of different samples and design, different platforms and statistical/bioinformatics methods. Two of the studies [74, 113] employed a wider platform. Two main different design subgroups can be identified: (1) comparison of pNETs samples versus purified pancreatic islets [74, 109, 110] and (2) comparison of metastatic versus non-metastatic pNETs [112–114]. One other study compared expression profiles of pooled biopsy material of pNETs with that obtained from other pancreatic pathologies and normal pancreata [111], making its comparison with the other studies of poor sense. However, some of these studies did not provide clinical or histopathologic data sufficient to determine the clinical behavior of the investigated patients, and only one of the studies also compared primary lesions versus liver metastases [74], with findings suggesting a striking similarity between matched primaries and metastases.

Overall, none of the studies could identify novel dysregulated genes associated with a certain clinical behavior or with prognosis or response to treatment. The overlap between the different gene lists is very poor, as previously reported for pancreatic adenocarcinoma [115]. However, some interesting candidates for further evaluation as prognostic factors or therapeutic factors may have been identified.

A single paper examined the expression of microRNAs in pNETs [116]. MicroRNAs are small noncoding RNAs able to regulate gene expression by targeting specific mRNAs for degradation or translation inhibition. A role for microRNAs in tumor development and progression has been ascertained for many human cancers including pancreatic adenocarcinoma. Using a specific custom microarray, Roldo et al. explored the global microRNA expression of 40 pNETs (12 insulinomas, 28 non functioning tumors) compared to normal pancreas, and showed that a common pattern of microRNA distinguishes pNETs from normal pancreas. Specific microRNAs were identified, such as miR-204, primarily expressed in insulinomas and miR-21 which was strongly associated with both high Ki67 and liver metastases.

Conclusion

Research has made significant progresses in the knowledge of pNETs' molecular biology but still the carcinogenesis involves mechanisms that need to be clarified. This multistep process may involve mutations of oncosuppressors genes, as well as germline mutations, which have been identified also in sporadic tumors. Further studies have to focus on immunotherapy and on the development of new target therapies to offer new treatment options to these patients.

Table 7 Summary of gene expression profile studies of pancreatic endocrine tumors

Author [reference]	Samples	Comparison(s)	Platform	Upregulated genes	Downregulated genes	Relevant genes	Confirmation
Capurso [74]	13 NF pNETs (8 primary, 5 metastasis), 3 cell lines (BON CM QGP), 4 purified islets	1. pNETs versus islets	Affymetrix U133A + B	668	323	LCK, BIN1, BST2, SERPINA10	IHC qRT-PCR
		2. Primary versus Metastases		_	_		
Maitra [109]	8 NF pNETs, 3 purified islets	pNETs versus islets	Affymetrix U133A	66	119	IGFBP3, fibronectin, MIC2, p21	IHC
Dilley [110]	8 pNETs samples from 6 MEN-I patients (2 insulinomas, 2 NF, 1 vipoma, 1 gastrinoma), 4 purified islets	pNETs versus islets	Affymetrix U95AV2	45	148	IER3, IAPP, SST, PHLDA2	qRT-PCR
Bloomston [111]	Pooled biopsies from 9 pNETs, normal pancreas, PDAC, CP	pNETs versus normal pancreas	Affymetrix U133A	Ns	Ns	ANG2, NPDC1, ELOVL4, CALCR	IHC RT-PCR
Duerr [112]	24 pNETs (9 insulinomas, 4 NF, 3 gastrinoma, 1 glucagonoma, 1 ACTHoma, 1 PTHRPoma), 6 GI carcinoids	1. 12 WDETs versus 7 WDECs	Affymetrix U133A	71	41	FEV, NR4A2, ADCY2, GADD45β	qRT-PCR
		2. pNETs versus carcinoids		228	157		
Hansel [113]	12 primary pNETs	7 metastatic versus 5 nonmetastatic	Affymetrix U133A + B	65	57	IGFB3, MET	IHC
Couvelard [114]	24 well-differentiated pNETs (20 NF)	12 WDETs versus 12 WDECs	Sanger center custom 10 k	72	51	CD-34, MDR1, E-selectin, MKK4	IHC

TSGs tumor suppressor genes, *WDET* well-differentiated endocrine tumor, *WDEC* well-differentiated endocrine carcinoma, *NF* nonfunctioning

Key Research Points

- The molecular pathology of pancreatic endocrine tumors has been further investigated in the last 5 years, mostly thanks to whole genomic sequencing.
- CGH studies suggest a plausible role for a number of TSGs, which is partially confirmed by specific studies. The role of epigenetics changes, especially of methylation deserves more attention.
- A number of alterations of tyrosine kinase receptors (VEGFR), and molecular pathways (mTOR) expression and activity have been described.
- Data of microarray studies suffer of the poor heterogeneity of the samples and have not described a specific relation between expression profiles and prognosis or response to therapy.

Future Scientific Directions

- Future studies should always classify pNETs samples according to clinical and pathological standards, including WHO and TNM classification. Moreover, the tumor behavior (stable or progressive) is an issue in such an "indolent" tumor type.
- CGH array studies may help identifying putative oncogenes or TSGs.
- Microarray studies conducted in wide series of well-investigated pNETs with a relation with clinical behavior and follow-up are needed.
- More in vitro models (animal models and cell lines) are sorely needed to better understand the process of tumor growth and progression, and possibly the role of novel therapies with targeted agents.
- The relation between pNETs cells and the surrounding stroma has not been investigated and may be important, similarly to pancreatic adenocarcinoma.
- The main future focus will be the role of the immune system in pNET tumorigenesis and proliferation control, starting from PD1/PDL-1 evaluation, paving the way to immunotherapy application also in these tumors (first trials ongoing).

Clinical Implications

- Clinicians dealing with pNETs should keep in mind the possibility of inherited disorders, as the diagnostic and therapeutic strategy is different from that of sporadic cases.
- Molecular alterations may somehow predict the clinical course and possibly suggest the use of certain novel targeted therapies, such as VEGF and mTOR inhibitors.
- In this view, referral of patients to centers with more experience in clinical and molecular aspects of neuroendocrine tumors should be recommended.
- Further knowledge about molecular pathways and mutations could pave the way for new tailored target therapies.

Abstract

Pancreatic endocrine neoplasias (pNENs) are uncommon but fascinating tumors with an annual incidence of 1 per 100,000 people. pNENs present as either functional tumors, causing specific hormonal syndromes like Zollinger-Ellison syndrome (ZES) or organic hyperinsulinism, or as pancreatic endocrine non-functional tumors (NF-pNENs). The natural history of pNENs is highly variable. Ninety percent of all insulinomas or small NF-pNENs are readily curable by surgical resection. Most other functional and late detected NF-pNENs have a less favorable chance for cure. Patients with completely resected tumors generally have a good prognosis, and an aggressive surgical approach combined with conservative treatment options in patients with advanced disease often results in long-term survival.

Keywords

Neuroendocrine tumors of the pancreas · Insulinoma · Gastrinoma · Pancreatic endocrine nonfunctional tumors · Surgical therapy

Introduction

Pancreatic endocrine neoplasias (pNENs) represent an important subset of pancreatic neoplasms (Table 1). They account for 2–4% of all clinically detected pancreatic tumors. They consist of single or multiple neoplasias and are associated in 10–20% with multiple endocrine neoplasia type 1 (MEN1). pNENs present as either functional tumors, causing specific hormonal syndromes, like Zollinger-Ellison

Table 1 Neuroendocrine neoplasias of the pancreas

Tumor (syndrome)	Incidence (%)	Presentation
Insulinoma	60–70	Weakness, sweating, tremulousness, tachycardia, anxiety, fatigue, headache, dizziness, disorientation, seizures, and unconsciousness
Gastrinoma	20–25	Intractable or recurrent peptic ulcer disease (hemorrhage, perforation), complications of peptic ulcer, diarrhea
VIPoma	4	Profuse watery diarrhea, hypotension, abdominal pain
Glucagonoma	4	Migratory, necrolytic skin rash, glossitis, stomatitis, angular cheilitis, diabetes, severe weight loss, diarrhea
Somatostatinoma	<5	Weight loss, cholelithiasis, diarrhea, neurofibromatosis
Carcinoid	<1	Flushing, sweating, diarrhea, edema, wheezing
ACTHoma	<1	Cushing's syndrome
GRFoma	<1	Acromegaly
PTH-like-oma	<1	Hypercalcemia, bone pain
Neurotensinoma	<1	Hypotension, tachycardia, malabsorption
Nonfunctional tumors	40–50	Obstructive jaundice, pancreatitis, epigastric pain, duodenal obstruction, weight loss, fatigue

syndrome or organic hyperinsulinism, or as nonfunctional pNENs with symptoms similar to pancreatic adenocarcinoma [1]. This chapter focuses on the management and surveillance of sporadic pNENs.

Epidemiology

pNENs are rare tumors but are detected more and more often [2]. They occur in approximately 1 in 100,000 people per year [3]. pNENs show no significant gender predilection and occur at all ages. Overall, the sporadic form occurs 10–20 years later than inherited pNENs in multiple endocrine neoplasia type1 (see following chapter).

Classification of pNENs

The WHO classification 2000 of neuroendocrine tumors introduced the terms "neuroendocrine tumor" and "neuroendocrine carcinoma." It aimed to separate benign from malignant tumors, introducing the concepts of benign NET, NET of unknown behavior, and malignant neuroendocrine carcinoma. The important change implied by the classification of gastrointestinal NEN 2010 was based on the introduction of the concept of grading (based on Ki-67) and staging, in analogy to other malignant neoplasias [1]. The 2010 classification also separated between so-called

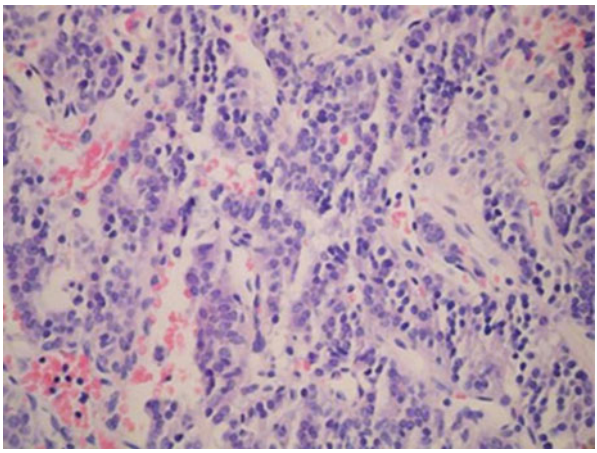

Fig. 1 H&E staining with the typical trabecular pattern of a well-differentiated pNEN

well-differentiated NET (G1 and G2) (Fig. 1) and poorly differentiated neuroendocrine carcinomas (NEC-G3) [1].

While the well-differentiated pNEN carry organ-specific somatic genetic alterations such as *MEN1*, *DAXX*, *ATRX*, *TSC*, and *NF1* mutations in, poorly differentiated NEC seem to share mutations of the non-endocrine carcinomas of the respective organs together with *p53* or *RB* mutations [4].

Imaging and Staging of pNENs

Morphological Imaging

Conventional radiological imaging modalities, such as ultrasound, CT, and MRI, are used in general for abdominal imaging and are also important in patients with pNENs. Specific protocols should be used for CT and MRI, because they are mandatory to achieve high tumor detection rates in patients with pNENs [5].

Computed Tomography

Multiphase, contrast-enhanced CT protocols are obligatory for pNEN imaging. To achieve adequate separation of the contrast phases, short scan times facilitated by multislice scanners and high-contrast agent flow rates should be used [6]. Scans before contrast which facilitate to detect calcifications, in the arterial phase with the typical pNEN enhancement and the portal venous phase to detect liver lesions, should be carried out. Because pNENs have a strictly arterial blood supply, the exact timing of the arterial phase is critical for successful pNEN imaging and should start to enhance as soon as the contrast material arrives through the arterial system. Consequently, optimal lesion to pancreas contrast can be obtained between arrival in the aorta and the pancreatic parenchymal phase [6].

Magnetic Resonance Imaging

Abdominal protocols for pNEN imaging can be derived from standard abdominal imaging protocols, including morphological T1- and T2-weighted images in different orientations. Thin slice imaging of the pancreas should be used for pNENs [2].

Molecular Imaging

The role of molecular imaging in staging, follow-up imaging, and localization of pNENs and their metastases became more important recently owing to the identification of new targets with concomitant development of respective tracers.

Somatostatin Receptor Scintigraphy and SPECT/CT

Because pNENs express somatostatin receptor (SSTR) in 80–100% of cases, somatostatin receptor scintigraphy (SRS) with ^{111}In-diethylenetriaminepentaacetic acid-D-Phe^{1}-octreotide (^{111}In-DTPA-octreotide) turns out to be an essential part of the management of patients with this type of tumor [7]. False-positive results in SRS are possible in nonneoplastic SSTR-positive tissue-like inflammatory lesions [8]. Furthermore, the sensitivity of SRS in the detection of benign insulinomas remains low with 50–60% [2].

Somatostatin Receptor PET/CT

PET imaging with ^{68}Ga-labelled somatostatin agonists provides better results than SRS and provides numerous advantages. The European Neuroendocrine Tumor Society (ENETS) guidelines recommend imaging of pNENs with SRS; nevertheless, SSTR PET/CT should be the first choice wherever available because the higher sensitivity of PET-based molecular imaging changes the management strategy in more than 70% of patients [2, 7]. One should keep in mind that a physiological tracer uptake in the uncinate process of the pancreas, adrenal glands, thyroid gland, and accessory spleen is possible and can lead to false-positive diagnosis [9].

^{18}F-Fluorodeoxyglucose (^{18}F-FDG) PET/CT

As pNENs usually do not have a high glucose turnover rate, the sensitivity of ^{18}F-FDG PET/CT is low, especially in well-differentiated NET (G1 and G2). Therefore, ^{18}F-FDG should not be used for this purpose. In contrast, high glucose metabolism is found in poorly differentiated NETs, resulting in a high tumor detection rate of ^{18}F-FDG PET/CT in G3 NECs. In consequence, negative ^{18}F-FDG PET/CT scans imply a low aggressiveness and a higher survival rate [10].

Glucagon-Like Peptide-1 Receptor (GLP-1R) Imaging

GLP-1R is overexpressed at a high incidence in almost all insulinomas. They are, therefore, an ideal target for molecular imaging [11].

Insulinomas

Insulinomas are the most frequent of all functioning pNENs. The incidence was reported to be two to four patients per million population and year. Insulinomas have been diagnosed in all age groups with a highest incidence found at age 40–60 years. Females seem to be slightly more frequently affected [12]. The etiology and pathogenesis of insulinomas are unknown. No risk factors have been associated with these tumors. Virtually all insulinomas are located in the pancreas or are directly attached to it. Tumors are equally distributed within the gland. Approximately 90% of insulinomas are solitary; the remaining 10% are multiple and are associated with MEN1 syndrome [13]. Most insulinomas are small. Forty percent are less than 1 cm in diameter, 66% are less than 1.5 cm, and 90% are less than 2 cm. Only 10% of the tumors are malignant at time of diagnosis.

Clinical Symptoms

Insulinomas are characterized by fasting hypoglycemia and neuroglycopenic symptoms, and occasionally sympathoadrenal autonomic symptoms [12, 13]. The episodic nature of the hypoglycemic attacks is due to the intermittent insulin secretion by the tumor. Most important symptoms of central nervous system dysfunction include diplopia, blurred vision, confusion, abnormal behavior, and amnesia. Some patients might develop loss of consciousness and coma or even permanent brain damage. The release of catecholamines produces symptoms such as sweating, weakness, hunger, tremor, nausea, anxiety, and palpitation. Whipple developed a symptom triad bearing his name to identify patients with insulinoma more accurately. These symptoms include signs and symptoms of hypoglycemia after fasting or exercise, blood glucose of less than 45 mg/dL when symptomatic, and symptoms relieved by intravenous or oral glucose. These symptoms usually occur when serum glucose is less than 40 mg/dL [14].

Special Diagnostic Procedures

Biochemical Testing

A fasting test that may last up to 72 h is regarded as the most sensitive test. Usually insulin, proinsulin, C-peptide, and blood glucose are measured in 1–2 h intervals to demonstrate an inappropriately high secretion of insulin in relation to blood glucose.

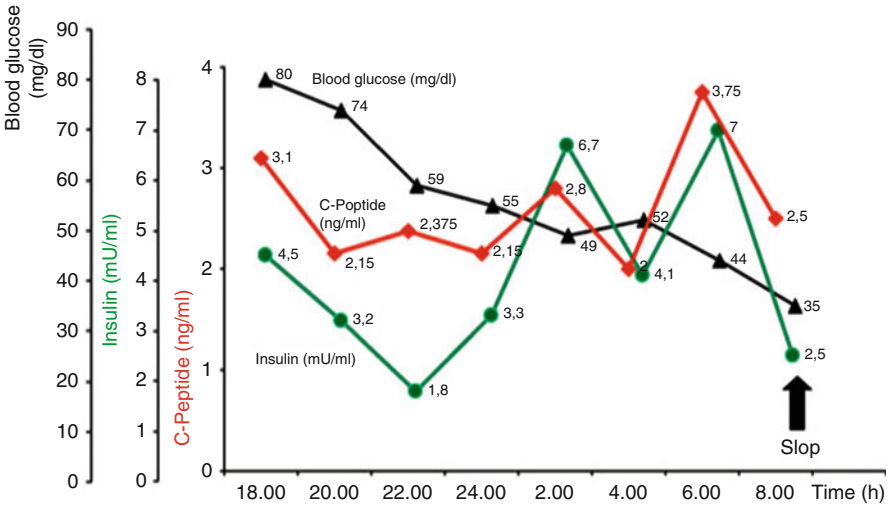

Fig. 2 Example of a typical fasting test of a patient with an insulinoma

About 80% of insulinomas are diagnosed by this test, most of them in the first 24 h [12]. In most reports, one-third of patients develop symptoms within 12 h, at least 80% within 24 h, 90% in 48 h, and 100% in 72 h [12]. Continuous C-peptide level demonstrate the endogenous secretion of insulin and exclude factitious hypoglycemia by insulin injection. An example of a fasting test is given in Fig. 2.

Treatment

Surgical cure rates in patients with the biochemical diagnosis of insulinoma range from 77% to 100% [13]. At surgical exploration, the abdomen is initially explored for evidence of metastatic disease. Then a meticulous surgical exploration should follow, i.e., an extended Kocher maneuver to be able to palpate the head, and mobilization of the distal pancreas and the spleen should follow to explore the body and tail of the gland to examine the distal pancreas carefully and completely. IOUS should then be used to confirm the presence of the insulinoma (Fig. 3) or to detect nonpalpable lesions and also to realize the relation of the tumor to the pancreatic duct. Identification of the pancreatic duct and determination of its proximity to the insulinoma can guide safe enucleation of the tumor. This approach can minimize the likelihood of a postoperative pancreatic fistula. Tumor enucleation, when feasible, is the technique of choice. If the tumor is located in the pancreatic tail, a distal spleen-preserving pancreatic resection might be the procedure of choice. To be considered malignant, these tumors must show evidence of either local invasion into surrounding soft tissue or verification of lymph node or liver metastasis. Malignant insulinomas account for only about 5–10% of all insulinomas. Aggressive attempts for resection are indicated, since there is no effective medical treatment

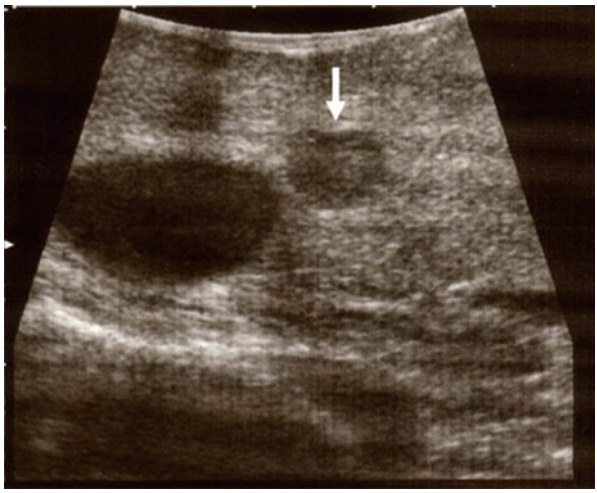

Fig. 3 Endosonography shows a typical hypoechoic insulinoma (*arrow*) in the head of the pancreas

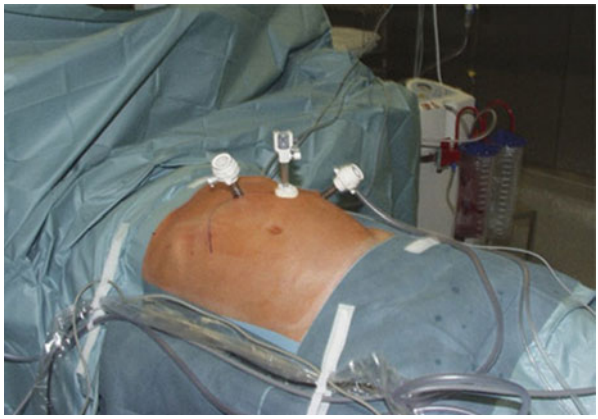

Fig. 4 Laparoscopic operation for pNENs. The patient is placed in a half-lateral decubitus position with the *left side* uppermost for tumors in the body/tail of the pancreas. The surgeon and assistant stand on the *left* of the patient, the cameraman and scrub nurse on the opposite side. Two monitors are used. Typical port sites for resection of lesions in the body/tail of the pancreas are shown

option to control hypoglycemia. Malignant insulinomas located in the body or tail of the pancreas are effectively treated by distal pancreatectomy with splenectomy and lymphadenectomy. For tumors located in the head of the gland, resection requires pancreaticoduodenectomy [15].

Recent advances in laparoscopic technique and instrumentation have enabled surgeons to approach complex procedures laparoscopically. This is also true for insulinomas [16–18], which should be favored as the procedure of choice [1]. The patient is placed in half lateral position with the left side up for tumors located in the body or tail of the pancreas, or with the right side up for tumors in the head of the gland, and in the reverse Trendelenburg position. Four 10–12 mm trocars are inserted in the abdominal wall: 3–4 cm above the umbilicus, in the xiphoid area, subcostal on the mid-axillary line, and in the subcostal midclavicular line (see Fig. 4). The pancreas is exposed after opening the lesser sac after mobilizing its head. Laparoscopic ultrasound can be used to identify nonvisible tumors and

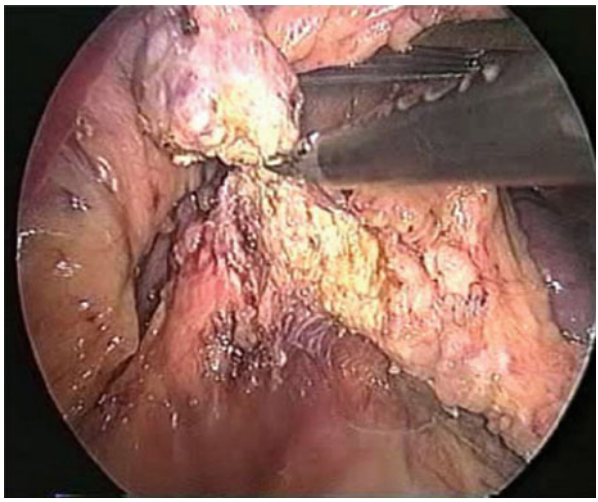

Fig. 5 Laparoscopic enucleation of an insulinoma in the pancreatic tail

determine the relationship of the lesion to surrounding veins and the pancreatic duct. Laparoscopic ultrasound can be particularly helpful in identifying lesions in the tail that are often missed by endoscopic ultrasound. For superficial ventral tumors, laparoscopic enucleation is undertaken with electrocautery or laparoscopic coagulating shears (see Fig. 5). Small pancreatic vessels can be clipped and cut. Tumors located deep in the body or tail of the pancreas and those in close proximity to the pancreatic duct require distal pancreatectomy. In cases where visualization and ultrasound fail, a hand port can be used to allow palpation of the gland. Tumors situated very distally near the splenic hilum are especially difficult to identify. It is worthwhile preserving the spleen during this procedure if it can be accomplished safely. The pancreatic tail and/or body should be meticulously dissected from the splenic vessels (Kitamura technique), or these vessels may be resected together with the pancreas, leaving the spleen vascularized by the short gastric vessels [19].

Postoperatively, blood sugar levels begin to rise in most patients within the first hours after removal of an insulinoma (reactive hyperglycemia). To preserve pancreatic function and reduce the risk of iatrogenic diabetes mellitus, patients in whom tumor localization is not successful at operation should not undergo blind resection.

Nonfunctioning Tumors

Clinically pancreatic endocrine nonfunctional tumors (NF-pNENs) produce none, or insufficient quantities of peptides, or hormones, such as pancreatic polypeptide, that do not cause any hormonal symptoms [20]. Because of modern imaging modalities, they have been diagnosed more frequently and now represent at least 50% of pNENs. At operation these tumors are generally larger than their functional counterparts and are located equally throughout the pancreas.

Clinical Symptoms

Nowadays a significant number of NF-pNENs are detected incidentally during abdominal imaging for unspecific symptoms or for reasons not attributed to the pancreas. Other patients with large tumors usually present late owing to the lack of a clinical/ hormonal marker of the tumor's activity. Therefore, in contrast to functioning pNENs, patients with NF-pNENs present either with various nonspecific symptoms, as abdominal pain, weight loss, or pancreatitis. In some cases, liver metastases are the first symptom or finding [20].

Differential Diagnosis

Because an aggressive surgical approach is justified even in locally advanced or metastatic NF-pNENs, differentiation from the more aggressive pancreatic adenocarcinomas is extremely important (Table 2).

Diagnostic Procedures

Biochemical Testing

Measurement of detectable serum or plasma levels of various hormones can establish the diagnosis of a NF-pNENs. Chromogranin A (CgA) is considered the best tumor marker currently available for the evaluation and follow-up of patients with NF-pNENs, as these tumors do not reliably produce any other suitable marker. Plasma CgA is elevated in 60% to 100% of patients with NF-pNENs. Furthermore, up to 75% of NF-pNENs are associated with increased serum levels of pancreatic polypeptide [21]. The combination of chromogranin A with measurement of pancreatic polypeptide increased the sensitivity from 84 to 96% in NF-pNENs.

Table 2 Differences between pancreatic cancer and pancreatic endocrine nonfunctional tumors (NF-pNENs)

	Pancreatic cancer	NF-pNENs
Tumor size	<5 cm	>5 cm
CT scan	Hypodensity	Hyperdensity
	No calcifications	Calcifications possible
Chromogranin A in blood	Negative	Positive
Somatostatin-receptor-scintigraphy	Negative	Positive

Treatment

According to the WHO classification, the size of the endocrine tumor correlates with malignant growth. Therefore, in localized tumors larger than 2 cm, aggressive surgery and, if required, resection of adjacent organs (stomach, colon, kidney, adrenal gland) and/or major venous resection are indicated [22]. At the present time, most would advocate an aggressive surgical approach for the management of malignant NF-pNENs even in the presence of localized metastases [15, 22]. The major goal is a potentially curative R0 resection by either partial pancreatoduodenectomy or distal splenopancreatectomy depending on the localization of the tumor. As lymph node metastases are frequently encountered, regional lymphadenectomy with en-bloc resection of the primary tumor is the goal [15, 22]. In case that the diagnosis is already made preoperatively and it is a highly proliferative (Ki67 $>$ 20%) G3 tumor, several experts would deny the indication for resection, since the prognosis is extremely poor [22]. In contrast, no data exist with respect to a positive effect of surgery on overall survival in small ($<$2 cm), possibly benign or intermediate-risk pancreatic endocrine tumors. Thus, the possibility of surgical cure has to be weighed against the operative morbidity, mortality, and long-term complications associated with pancreatic surgery [22].

Laparoscopic and Robotic Surgery for pNENs

As already mentioned, most patients with insulinomas are ideal candidates for a minimally invasive approach, because these tumors are small, solitary, and benign. The first successful laparoscopic resection was first reported by Gagner et al. in 1996 [23]. As mentioned earlier, the most sensitive method of localization is intraoperative palpation and IOUS. In laparoscopic surgery, palpation is not possible. It has been reported that preoperative localization, mainly by endoscopic ultrasonography, is crucial for the decision to operate laparoscopically [24, 25] and that minimally invasive surgery for pNENs should be undertaken only if laparoscopic ultrasound is available. Laparoscopic ultrasound helps the surgeon to decide whether to use enucleation or resection, a decision that will depend on the proximity to the main pancreatic duct or large blood vessels.

Laparoscopic enucleation is reserved for tumors less than 2 cm diameter located on, or near, the surface of the pancreas, and not in contact with splenic vessels, the portal vein or the main pancreatic duct. If these criteria are not met, laparoscopic spleen-preserving distal pancreatectomy should be the preferred choice.

MEN1 patients who have an insulinoma or small NF-pNENs can also benefit from a laparoscopic approach [26]. Gastrinomas are yet not considered candidates for a laparoscopic approach for two reasons. First, most gastrinomas are usually located in the duodenum and bidigital palpation after duodenotomy is essential to identify the small tumor. Second, most pancreatic gastrinomas are over 2 cm in diameter at diagnosis and reveal metastases in up to 70% of patients requiring a

meticulous lymphadenectomy, which is not ideal for a laparoscopic approach. The same holds true for rare functioning pNENs [15]. Given the current data, laparoscopic enucleation or resection of insulinoma and most NF-pNENs is feasible and safe, so that it might be become the future procedure of choice for insulinomas [16–18]. Nevertheless, it seems clear that such treatment should be offered only by surgeons who are experienced in both endocrine pancreatic operations and advanced laparoscopic surgery. The same is true for robotic surgery, which emerged in the last years as a new technical possibility [27, 28]. As technology advances and experience with robot-assisted surgery will increase, it is likely to become an alternative method of pancreatic resection for pNENs.

Gastrinomas (Zollinger-Ellison Syndrome)

Gastrinomas are functionally active endocrine tumors of the pancreas accounting for about 20% of pNENs, second in frequency to insulinomas. Gastrinomas were first described in 1955, when Zollinger and Ellison, of the Ohio State University Medical School, described two patients with islet cell tumors associated with atypical peptic ulceration of the jejunum [29]. Approximately 0.1% of patients with duodenal ulcers have evidence of Zollinger-Ellison syndrome. The reported incidence is between 0.5 and 4 per million of the population per year. Zollinger-Ellison syndrome is more common in males than in females, with a ratio of 3:2. The mean age at the onset of symptoms is 38 years, range 7–83 years in some series. The etiology and pathogenesis of sporadic gastrinomas are unknown. The anatomical area harboring the vast majority of these tumors encomprise the head of the pancreas, the superior and descending portion of the duodenum, and the relevant lymph nodes and has been termed the "gastrinoma triangle" (see Figs. 6 and 7) [30]. More than 90% of the duodenal gastrinomas are located in the first and second part of the duodenum and are limited to the submucosa in 54% of patients.

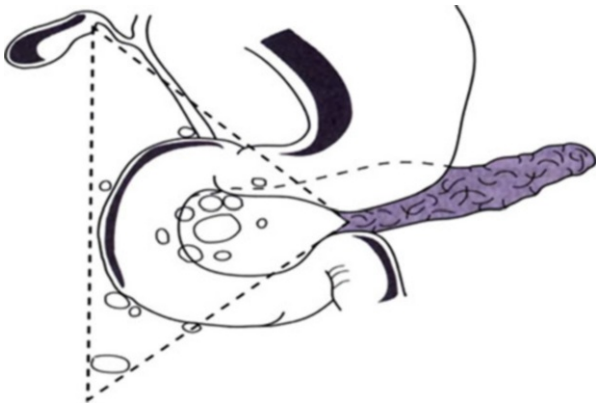

Fig. 6 Gastrinoma triangle

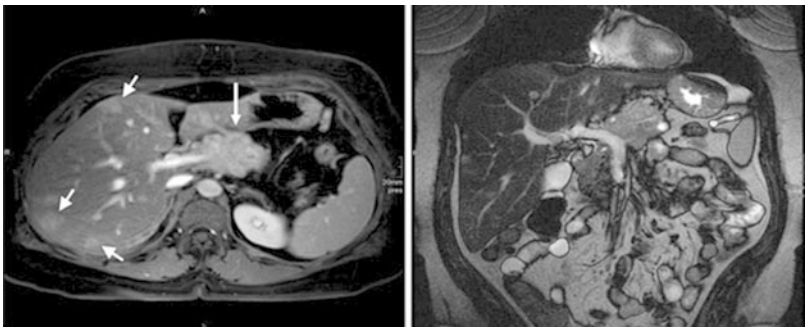

Fig. 7 Enhanced computed tomographic scan demonstrates a large pancreatic gastrinoma (*large arrow*) with diffuse liver metastases (*arrowheads*)

Clinical Symptoms

In patients with ZES, abdominal pain is the most frequent complaint either alone or with diarrhea, followed by heartburn, nausea, or bleeding. The abdominal pain is primarily due to peptic ulcer disease or gastroesophageal reflux disease (GERD) and is indistinguishable in character from that seen in ordinary ulcer patients. All of the symptoms early in the course of ZES are due to the gastric acid hypersecretion secondary to the ectopic secretion of gastrin by the tumor [31].

Differential Diagnosis

In the study of Roy et al., 164 of 168 (98%) patients with ZES were misdiagnosed before the diagnosis of ZES could be established [32]. The most common misdiagnoses were idiopathic peptic ulcer disease, chronic idiopathic diarrhea, GERD, Crohn's disease, and irritable bowel syndrome.

Hypergastrinemia can be caused by conditions other than ZES. Hypergastrinemia can be associated with increased gastric acid (e.g., retained gastric antrum, short bowel syndrome, gastric outlet obstruction) or with little or no gastric acid (e.g., pernicious anemia, chronic atrophic gastritis or vagotomy).

Diagnostic Procedures

Biochemical Testing

If the patient presents gastric pH below 4.0 and serum gastrin concentration above 1000 pg/ml (normal $<$100 pg/ml), then the diagnosis of Zollinger-Ellison is confirmed. Unfortunately, the majority (40–50%) of patients present serum

gastrin concentrations between 100 and 500 pg/ml, and in these patients a secretin test should be performed. The secretin stimulation test can differentiate between patients with ZES and those with other causes of hypergastrinemia. Patients with pernicious anemia or chronic atrophic gastritis have a lost antral gastrin release, due to their achlorhydria. In contrast to ZES, these patients can be identified by gastric pH greater than 4. The patients receive 2 μg/kg of secretin intravenously. A rise in serum gastrin by more than 200 pg/ml is typically considered positive. This test has a sensitivity and specificity of >90% for detecting gastrinomas [33].

Treatment

As with all pNENs, the only chance for cure of gastrinoma is complete surgical resection, which is achieved in 26 to 100% of patients. A study compared 160 patients with ZES undergoing resection with 35 patients who had a similar stage of disease but did not undergo surgical exploration [34]. After a follow-up of 12 years, 41% of patients were cured with surgery, and significantly more patients developed liver metastases with conservative treatment (29 vs. 5%; $P < 0.001$). Fifteen-year disease-related survival was 98% after surgery and 74% after medical treatment ($P < 0.001$). These results demonstrate that routine surgical exploration increases survival in patients with ZES by increasing disease-related survival and reducing the rate of advanced disease. Therefore, routine surgical exploration should be performed in all patients with sporadic gastrinomas without evidence of diffuse hepatic metastases and who are fit for surgery.

Duodenal Gastrinomas

Duodenotomy (DUODX) should be routinely performed for all patients with ZES. Recently, Norton and colleagues underlined the importance of DUODX in patients with ZES [35]. They performed DUODX in 79 patients, and no DUODX was performed in 64 patients. Gastrinoma was found in 98% with DUODX compared with 76% with no DUODX. They could show that the use of routine DUODX increases the short-term and long-term cure rate. Duodenal exploration is undertaken via longitudinal duodenotomy in the descending part of the duodenum. Small tumors can be identified by palpation. Duodenal tumors smaller than 5 mm can be enucleated with the overlying mucosa (see Fig. 8); larger tumors are excised with full-thickness excision of the duodenal wall. After completion of this exploration, the duodenotomy is cautiously sutured longitudinally.

Because of the high incidence of lymph node metastases associated with duodenal gastrinomas, prophylactic lymph node dissection should be done [36]. In a recent study, the distribution of lymph node metastases found at the time of operation in 38 patients with sporadic duodenal gastrinomas were analyzed by mapping their location in relation to the duodenal primary [37]. Patients who had primary duodenal tumors located above the ampulla of Vater, in general, harbored positive lymph

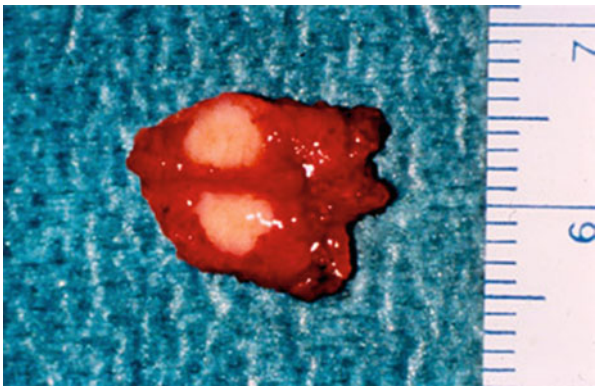

Fig. 8 Duodenal gastrinoma after duodenotomy

nodes in the superior periduodenal area, celiac axis, or periportal area. Those with primary tumors in the third and fourth portions of the duodenum had positive lymph nodes located most commonly in the superior mesenteric artery or inferior periduodenal areas. Lymph nodes were found close to the primary tumor in most cases.

Pancreatic Gastrinomas

The role of operative exploration in patients with sporadic gastrinomas is relatively well defined. Most of these non-MEN1 gastrinomas are solitary, identifiable at laparotomy, and resectable with simple enucleation. Formal pancreatic resections are typically reserved for patients with local tumor invasion. In practice, this leads to distal pancreatic resection, splenectomy, and peripancreatic lymph node dissection for gastrinomas in the pancreatic body or tail. Most of the pancreatic gastrinomas are located in the head of the gland or uncinate process. An enucleation with peripancreatic lymph node dissection is the procedure of choice in gastrinomas of the pancreatic head. For large pancreatic head gastrinomas, a pylorus-preserving pancreaticoduodenectomy is justified [15].

After removal of a gastrinoma, serum gastrin should be measured before discharge of the patient and then at 3-month intervals for the first year. Hypergastrinemia indicated residual gastrinoma tissue. A normal gastrin level may indicate a surgical cure, but a positive secretin provocative test unmasks some patients who still harbor tumor tissue.

Rare Functioning pNENs

VIPomas

Vasointestinal peptide-secreting tumors, also called VIPomas, Verner-Morrison syndrome, or watery diarrhea, hypokalemia, and acidosis (WDHA), account for fewer than 5% of islet cell tumors [1]. The two patients described by Verner and Morrison in 1958

died from dehydration and renal failure in spite of attempted intravenous hydration. The VIP directly inhibits gastric acid secretion causing achlorhydria. Sporadic VIPomas are solitary tumors, arising from the VIP-secreting cells that are usually located in the region of the pancreatic tail and body [1]. More than 60% of these tumors are malignant and metastasize to lymph nodes, liver, and bone. The secretory diarrhea ranges between 0.5 and 15 L/24 h and is usually the most prominent symptom at presentation. It results in severe loss of potassium and bicarbonate, which in turn lead to metabolic acidosis and dehydration [20]. Additional features include hypercalcemia with normal parathyroid hormone levels, hyperglycemia, and occasionally flushing of the face and the chest. The diagnosis of a VIPoma is confirmed by measurement of plasma VIP, and levels above 60 pmol/L are diagnostic.

Nearly all patients with rare functional pNENs should have abdominal exploration with the intent of complete resection of tumor. The goals of operative exploration are not only complete resection but also preparation for nonoperative management, if a complete resection is not possible. Total surgical removal of the primary tumor may be curative in approximately 60% of patients [1, 15]. In patients with metastatic VIPomas, cytoreductive debulking surgery may result in considerable palliation. The patients often require an intensive intravenous supplementation of fluid losses (often exceeding 10 l/day) and a careful correction of electrolyte and acid-base abnormalities. Somatostatin analogues reduce tumoral VIP secretion by more than 50% and inhibit intestinal water and electrolyte secretion. Via this mechanism, these drugs control the secretory diarrhea in more than 50% of patients, and significant clinical improvement is attained in another 25%. The 5-year survival rate is 60% for patients with metastases and over 90% for patients without distant metastases [1].

Glucagonomas

Glucagonomas arise from the glucagon-producing a-cells of the pancreas. Around 60% of patients already have liver metastases at the time of diagnosis [1]. Tumors that produce excessive glucagon cause a specific syndrome of diabetes mellitus, a skin rash (necrolytic migratory erythema), hypoaminoacidemia, and a tendency for deep venous thrombosis. Patients also often have stomatitis, glossitis, and cheilosis associated with the skin rash (see Fig. 9). The syndrome is diagnosed by elevated

Fig. 9 Necrolytic migratory erythema in a patient with a malignant glucagonoma

plasma level of glucagon. Levels greater than 1000 pg/ml are diagnostic of the syndrome, while levels between 150 and 1000 pg/ml are suggestive. Once the syndrome is diagnosed, surgical resection of the tumor is indicated whenever possible. Preoperatively a management with somatostatin analogues and nutritional supplementation is indicated [38] to correct the nutritional deficiency and resolve the rash.

Treatment of Rare Functioning pNENs

Curative surgery is always recommended whenever feasible after careful symptomatic control of the clinical syndrome; the latter may be achieved by medical or locoregional treatments [1, 15]. Curative surgery should include an oncological pancreatic resection with lymphadenectomy. Laparoscopic resection is generally not recommended because of the need for lymphadenectomy and careful inspection for invasion/metastases.

Management of Metastases

Surgery for Liver Metastases

Liver metastases (LM) develop in 30–80% of patients with pNENs [39]. In metastatic pNENs, 5-year survival rates are around 40–60% [22]. Patients with gastrinoma and no metastatic disease have a 20-year survival rate of 95% while a 10-year survival of only 15% is reported when diffuse metastatic liver disease is present [40]. The decision for liver surgery is based on multiple factors, like tumor grading, the presence of extrahepatic distant metastases, and the presence of hormone-related symptoms [40]. Around 20–30% of patients with LM are suitable for curative intent at presentation. Cytoreductive debulking surgery in incompletely resectable metastatic disease is discussed controversially, but particularly in symptomatic patients, it may improve the quality of life [40]. For surgery with curative intent, ENETS have proposed the following criteria: (i) resectable G1/G2 liver disease with acceptable morbidity and less than 5% mortality, (ii) absence of right heart insufficiency, (iii) absence of unresectable lymph node and extra-abdominal metastases, and (iv) absence of diffuse peritoneal carcinomatosis [39]. The overall survival after hepatic resection is 46–86% at 5 years and 35–79% at 10 years in selected patients [22]. In referral centers, the 5-year survival for hepatic resections of patients with NET LM commonly exceeds 60%. Resection shows low mortality rate (0–5%) and acceptable morbidity (30%). Preselection biases due to better performance status or less advanced disease are influencing such differences in favor of the outcomes of pNEN patients undergoing surgery. Evaluation of histopathology specimens showed that often the metastatic burden in the liver is underestimated, with almost 50% of LM from NENs undetectable on preoperative imaging [22].

Ablative Therapy

Ablation of liver metastases either alone or in combination with surgical resection can be considered for appropriately selected patients [39, 41]. Image-guided ablation is an option, either alone for limited disease (tumors ideally <3 cm) or in combination with surgical resection. The lack of randomized data makes the comparison of these techniques with a surgical approach in terms of survival benefit and symptomatic relief difficult.

Liver Transplantation for Metastatic NENs

In selected cases, liver transplantation (LT) has been used to treat liver metastases from NENs. However, considerable controversy exists due to the absence of adequate available data comparing transplantation for unresectable liver metastases to other treatment modalities [42]. LT has been advocated in patients with bilateral unresectable liver metastases that are refractory to other treatments. Only a few multicenter studies and several single-center retrospective studies with small number of patients are available evaluating the survival benefits of LT for the treatment of NEN metastases [42].

Peptide-Receptor Radionuclide Therapy

In the last years, the number of pNENs that are detected is increasing. A relative new and promising therapy for patients with metastatic or non-resectable disease is peptide receptor radionuclide therapy (PRRT). The results of PRRT with ^{111}In-DTPA-octreotide were promising, whereas the number of patients with a complete or partial response was low. In the following years, radiolabelled somatostatin analogue therapy became more advanced, with the introduction of PRRT with analogues labelled with the β-emitting radionuclides lutetium-177 or yttrium-90 [43].

The efficacy of lutetium-177 in SSR-positive NENs is supported by the phase III NETTER-1 trial [44]. This trial compared ^{177}Lu delivered concurrently with standard dose (30 mg) octreotide to high dose (60 mg) octreotide LAR for patients with disease progression on standard dose octreotide. At the time of analysis, both median PFS (not yet reached vs 8.4 months, HR = 0.209; 95% CI: 0.129–0.388; $p < 0.0001$) and OS (22 vs. 13 months; $p < 0.0186$) were significantly improved for patients on the ^{177}Lu arm.

For pNENs, the possibility of a neoadjuvant PRRT was evaluated in the very last years. There is not much experience with this specific indication for PRRT. However, the few case reports available show promising results, even in patients with limited metastatic disease. Data from Van Vliet et al. showed successful surgery in 9 of 29 patients treated with neoadjuvant PRRT [45].

Biotherapy

Somatostatin Analogues (SSAs) and Interferon

Very recently, the phase III placebo-controlled CLARINET trial expanded the role of SSAs for tumor control in NEN [46]. In this study, over 200 patients with well- or moderately differentiated, nonfunctioning, SSTR-positive NENs with a Ki-67 of <10% were randomized to receive either lanreotide 120 mg every 4 weeks or placebo. Lanreotide was associated with a significant prolongation of PFS, with a median not reached versus a median of 18 months in the placebo arm (hazard ratio (HR) 0.47; $p < 0.001$). The estimated rates of PFS at 24 months were 65.1% in the lanreotide group and 33% in the placebo group. The benefit in the patients with midgut NET (HR 0.35; $p = 0.009$) was greater than in the pancreatic subset (HR 0.58; $p = 0.06$).

SSAs in Insulinomas

Most insulinomas are benign and can be cured by surgery. In the rare metastasizing insulinomas, SSA treatment often is of limited value for glycemic control. One probable reason is the low expression of SSTR2 [47]. Further studies are needed to evaluate the potential role of pasireotide in patients with malignant insulinoma. Pasireotide does not inhibit counter-regulatory glucagon secretion and often induces hyperglycemia. Therefore, it could be helpful for treating hypoglycemia in insulinoma patients.

SSAs in Zollinger-Ellison Syndrome

SSA lowers gastrin levels and can ameliorate symptoms of Zollinger-Ellison syndrome. However, proton pump inhibitors are the treatment of choice for symptom control as they are highly effective and oral available [47].

SSAs in Verner Morrison Syndrome

Treatment with SSAs results in a rapid reduction of the excessive secretory diarrhea caused by vasoactive intestinal polypeptide (VIP) secreting pNENs and is indicated in this disease.

SSAs in Glucagonoma Syndrome

The necrolytic migratory erythema – a characteristic skin rash caused by glucagon secreting pancreatic NETs – can resolve rapidly after initiation of SSA treatment. The European Neuroendocrine Tumour Society (ENETS) therefore recommends treatment with SSA in patients with glucagonoma syndrome [47].

Interferon

According to the ENETS guidelines, IFN-α can be considered for symptomatic treatment of functional pNENs [47] in case of intolerance of SSAs and insufficient

antisecretory effects of SSA. However, due to the unfavorable toxicity profile, IFN-α is not first therapeutic choice in pNENs.

Novel Targeted Drugs

Novel targeted drugs (everolimus and sunitinib) are approved for pNENs based on the results of two placebo-controlled trials on progressive pNENs [48, 49]. The median PFS is around 11 months with either of the drugs, while tumor remission occurs in 5% and <10% of the patients with everolimus and sunitinib, respectively [39]. The use of either everolimus or sunitinib is recommended in progressive G1/G2 pancreatic NET, irrespective of Ki-67 and tumor burden. While comparative data of both drugs are lacking, the selection of the targeted drug is based on the medical history of the patient, the side effect profile of the drug and accessibility to the treatment.

Chemotherapy

Chemotherapy is one of different treatment options in pNENs and can be used in G1 or G2 neoplasias. Cytotoxic therapy combinations include: streptozotocin/5-FU or doxorubicin with streptozotocin as an alternative option. Usually, patients with pNENs with Ki-67 of 5–20% can be treated with chemotherapy. Other factors that favor chemotherapy compared to targeted drugs include bulky disease, a symptomatic patient, rapid tumor progression in ≤6–12 months, and patients with a possible chance of achieving a response to allow for surgery [39].

In NEC G3 patients, a cisplatin-based chemotherapy (e.g., cisplatin/etoposide) is considered as standard therapy and recommended as a first-line therapy (Pavel 2016). Although objective remission rates are high (40–67%), the median PFS is limited with 4–6 months [50]. Second-line systemic therapy options include FOLFOX and FOLFIRI [39].

Conclusion

PNENs are rare but fascinating tumors. Biochemical diagnosis justifies laparotomy in patients with insulinomas and gastrinomas, even if a tumor is not detected preoperatively. Whereas patients with insulinomas are usually cured, also in patients with gastrinoma, a significant surgical cure rate can be achieved. The prognosis of pNENs is much better than that of pancreatic adenocarcinoma, even though patients are frequently diagnosed with metastatic disease. Therefore, an aggressive surgical approach leads to long-term survival even in patients with malignant PETs. Although long-term cure can only be realized in a proportion of patients, significant long-term palliation can be achieved.

Molecular Pathology of Carcinomas of the Ampullary/Periampullary Region

Lena Haeberle, Jasmin Riemer, and Irene Esposito

Contents

Abstract

The ampullary/periampullary region is a complex anatomical environment giving rise to a number of heterogeneous malignancies. Ampullary carcinomas should be distinguished from periampullary duodenal, biliary, and pancreatic adenocarcinomas. A meticulous classification of periampullary/ampullary carcinomas is of great importance, as the biological behavior of the various types of carcinomas differs significantly, affecting their prognosis and therefore their clinical

management. Subtypes of ampullary carcinomas, namely, intra-ampullary, ampullary ductal, periampullary duodenal, and ampullary NOS (not otherwise specified) carcinomas, have been recently proposed based on a detailed assessment of their gross appearance in correlation with microscopic findings. Moreover, ampullary carcinomas can be further classified as intestinal type, pancreatobiliary type, or mixed type based on the tumor's histomorphology and immunohistochemical profile.

In recent times, crucial advances have been made in characterizing carcinomas of the ampullary/periampullary region on a molecular level. Several molecular patterns seem to correlate with prognosis. Moreover, some molecular pathways, e.g., the *WNT* pathway, represent potential therapeutic targets to be used in the context of personalized medicine in the future. Gene panel analysis is a promising approach that could be used to translate these findings into clinical applications.

Introduction

The ampulla of Vater is a small but complex anatomical landmark. It is formed by the common bile duct and the pancreatic duct, which converge to create a short common channel that drains through the papilla of Vater located in the wall of the second part of the duodenum. However, the pancreatobiliary duct system can be subject to a number of anatomical variants (Fig. 1A). For example, the common channel created by the common bile duct and pancreatic duct often does not represent a "true ampulla," which has been defined as a dilated reservoir [1]. Moreover, the length of the common channel can vary greatly. In many patients, a common channel is completely missing and the common bile duct and the pancreatic duct drain independently into the duodenum.

Anatomical regions that harbor different types of epithelia are often relevant in carcinogenesis. In the ampullary/periampullary region, the pancreatobiliary epithelium of the common bile duct, pancreatic duct, and common channel merge into the intestinal epithelium of the duodenum. This is thought to be the reason why the ampullary/periampullary region represents a hot spot for cancers of the small intestine, together with the fact that this region is also exposed to biliary juice, pancreatic juice, and duodenal juice [2].

The term "periampullary cancer" refers to neoplasms originating from four different anatomic locations within 2 cm of the major papilla of Vater (Fig. 1B) [3, 4]: (1) adenocarcinoma of the head of the pancreas, (2) ampullary cancer, (3) duodenal cancer, and (4) distal bile duct cancer (Table 1). Obstructive jaundice is a common symptom of cancers located in the vicinity of the ampulla of Vater [5].

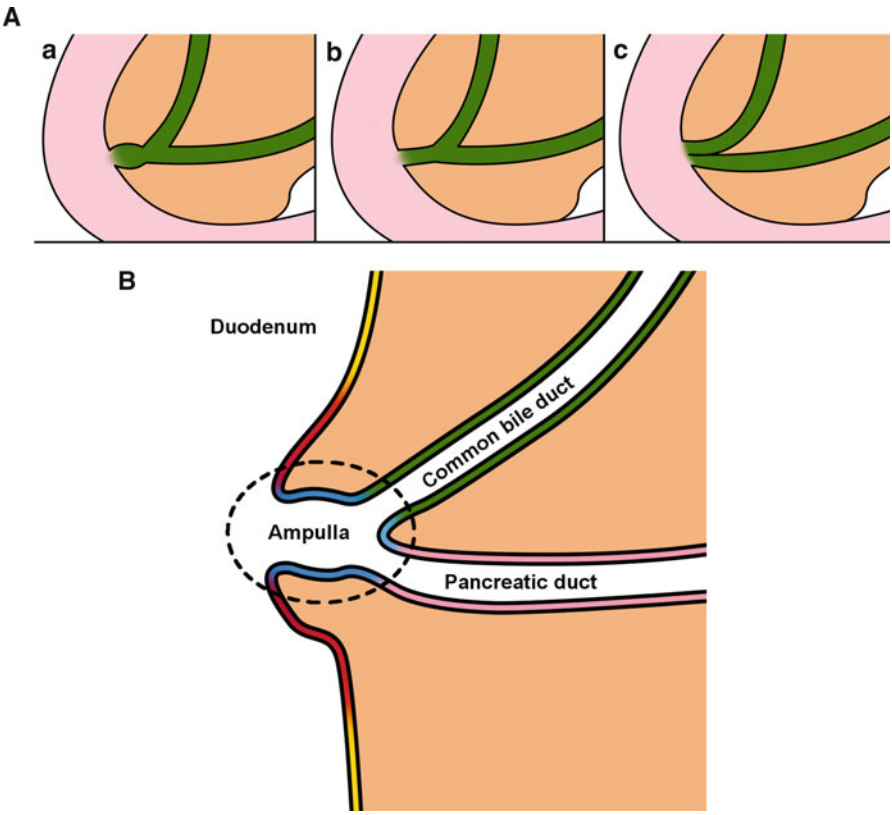

Fig. 1 (**A**) Anatomical variants of the Vaterian system: (*a*) common bile duct and pancreatic duct converge to form a dilated reservoir ("true ampulla"), (*b*) common bile duct and pancreatic duct converge to form a common channel that does not represent a true ampulla and can vary in length, and (*c*) common bile duct and pancreatic duct do not converge and drain into the duodenum independently. (**B**) Overview of the different locations of cancers of the ampullary/periampullary region: extra-ampullary duodenal carcinoma (*yellow*), periampullary duodenal carcinoma (*red*), ampullary carcinoma (*blue*), distal bile duct carcinoma (*green*), and pancreatic ductal adenocarcinoma (*pink*) (Modified from Refs. [4, 6])

Table 1 Proportion of the different tumor types among resected cancers of the ampullary/periampullary region [7–9]

Cancer type	Proportion of resected cancers (%)
Ampullary carcinoma	15–25
Duodenal carcinoma	4–9
Distal bile duct carcinoma	9–15
Pancreatic carcinoma	56–66

Other very rare tumor entities, which may also be found in the periampullary region, include duodenal neuroendocrine neoplasms, lymphomas, gastrointestinal stromal tumors (GIST), and hamartomas in patients with Peutz-Jeghers syndrome.

Distinguishing between pancreatic, ampullary, duodenal, and bile duct origin of ampullary/periampullary carcinomas can be difficult due to overlapping histopathological characteristics [4]. However, determining the exact origin is of great prognostic relevance. Survival rates are, in general, greatest for duodenal and ampullary cancers, intermediate for distal biliary cancers, and lowest for pancreatic cancer [3, 4, 7]. Although a Whipple procedure or its variants are the therapy of choice for all four cancer entities, discrepancies in survival among cancers of this region remain even after radical resection [3, 4, 8].

Several explanations exist for these differences in survival [5]: Early diagnosis due to early symptoms in small tumors arising directly from the ampulla or the periampullary duodenum compared to the usually late diagnosis of pancreatic cancers, in which biliary obstruction is often a sign of advanced disease, is one point to be considered [4]. However, there are also differences in both macroscopic and microscopic growth patterns between the tumor types, reflecting a different biological behavior: for example, ampullary and duodenal cancer generally show less vascular and perineural invasion compared to pancreatic cancer and distal bile duct cancer, which are both characterized by a highly invasive growth pattern [4, 5]. However, recent data suggest that, once adjusted for survival-determining factors like tumor size or lymph node invasion, the overall survival of patients depends on the histological type of the tumor (i.e., intestinal vs. pancreatobiliary) and not on its anatomical origin [10].

Another important aspect, which has become evident from recent studies, is that a different molecular pathogenesis affects the different biological behavior of cancers arising in the ampullary/periampullary region.

The aim of this article is to give an overview of the available data on the molecular pathology of non-pancreatic cancers of the ampullary/periampullary region. The increasing knowledge of the molecular alterations responsible for the different biological behavior of these tumors can lead to improvements in diagnosis and tumor-type-specific therapy in the future.

Sporadic Cancers of the Ampullary/Periampullary Region

A careful gross assessment of pancreatoduodenectomy specimens of patients with neoplasms of the ampullary/periampullary region represents a fundamental step and a prerequisite for the further histopathological and molecular characterization. Standard protocols that take into account the complex anatomy of such resection specimens, as well as the growth characteristics of pancreatic ductal adenocarcinoma, have been developed [11, 12] and can be applied to other neoplasms arising in the ampullary/periampullary region, which are resected according to the same surgical procedure as ductal adenocarcinoma of the pancreatic head [13].

Ampullary Cancer

Ampullary cancer is defined as a neoplasm involving the ampulla of Vater (if anatomically present), the major duodenal papilla and/or the distal ends of the common bile duct, and the main pancreatic duct, as well as their opening on the duodenal surface (Fig. 1B) [14].

Gross Appearance and Histopathological Classification

Carcinomas of the ampulla of Vater are often diagnosed when they are still relatively small, because they can lead to biliary obstruction and consecutive jaundice at an early stage (Fig. 2). Traditionally, ampullary carcinomas were classified as polypoid or ulcerating, with ulcerating carcinomas harboring a poorer prognosis [2]. In a more meticulous approach, ampullary carcinomas can be classified into four subtypes based on the site from which the tumor is thought to arise in correlation with microscopic findings regarding preinvasive and invasive components [14]: (1) *intra-ampullary* carcinomas, which show significant preinvasive exophytic components within the common channel, but no involvement of the duodenal surface; (2) *ampullary ductal* carcinomas, which are characterized by invasive components on

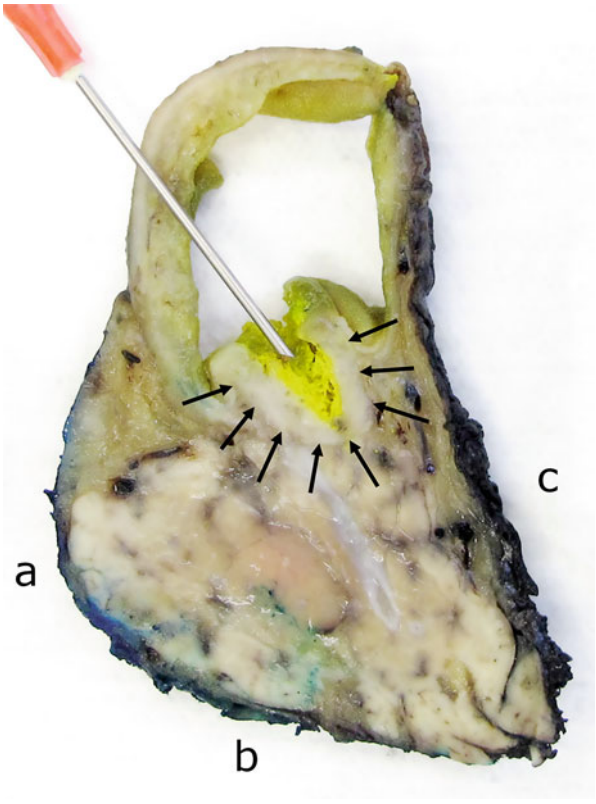

Fig. 2 Macroscopic section of an ampullary adenocarcinoma (*arrows*). The papilla of Vater was inked *yellow*, the anterior free surface of the pancreatic head was inked *blue* (*a*), the medial (superior mesenteric artery/uncinatus) margin was inked *green* (*b*), and the posterior margin was inked *black* (*c*)

the distal walls of the common bile duct and/or pancreatic duct without any significant preinvasive growth; (3) *periampullary duodenal* carcinomas, which grow into the duodenal lumen and involve the duodenal surfaces, but rarely the lumen of the ampullary common channel; and, lastly, (4) *ampullary NOS* (not otherwise specified) carcinomas, which are located at the papilla of Vater, but do not specifically fit into one of the three previous categories.

This classification is of prognostic significance. Intra-ampullary carcinomas showed the best prognosis (3-year survival 73%), while the prognosis of periampullary duodenal carcinomas was not quite as good (3-year survival 69%) and ampullary ductal carcinomas displayed the poorest prognosis (3-year survival 41%) [14]. However, this classification is not of widespread use yet; in particular, periampullary duodenal carcinoma could be still considered a separated entity and will be discussed in the section "Duodenal Cancer."

A reproducible classification of ampullary carcinomas into histological subtypes remains challenging [4]. In 1994, Kimura et al. distinguished for the first time between two histological types of ampullary carcinomas, an intestinal type and a pancreatobiliary type (Fig. 3) [15]. These were later defined as the two main types of ampullary cancer, while other rare types, like mixed-type, signet ring cell, or clear cell carcinoma, were also described [16].

Ampullary carcinomas with intestinal differentiation resemble colorectal carcinomas. They are characterized by the presence of goblets cells and frequently display adenomatous components within the tumor [4, 5]. Ampullary carcinomas of the pancreatobiliary type more closely resemble carcinomas of the pancreas or extrahepatic bile ducts [2, 4].

Determining the histological type of ampullary carcinomas is of great significance, because it acts as an independent predictor of survival: Ampullary carcinomas of the intestinal type show a significantly better prognosis than carcinomas of the pancreatobiliary type [15, 17].

The immunohistochemical analysis of selected mucins (MUC) has successfully been used to achieve a more reliable differentiation between intestinal-type and pancreatobiliary-type ampullary carcinomas [18]. Ampullary carcinomas can be classified as intestinal type either by positivity for CK20, CDX2, or MUC2 and negative staining for MUC1 or by positivity for CK20, CDX2, and MUC2, irrespective of the MUC1 staining result, while pancreatobiliary-type ampullary carcinoma can be defined as an ampullary carcinoma staining positive for MUC1 and negative for CDX2 and MUC2, irrespective of the CK20 staining result (Fig. 3) [18]. CK7 has been used to differentiate between intestinal-type and pancreatobiliary-type ampullary carcinomas in the past and was thought to be negative in the intestinal type and positive in the pancreatobiliary type, but it has not been proven as a reliable marker [18].

Precursor Lesions

In analogy to pancreatic and biliary intraductal papillary and tubular neoplasms, the term "intra-ampullary papillary-tubular neoplasms" (IAPN) has been proposed for tumor-forming preinvasive precursor lesions of the periampullary/ampullary region

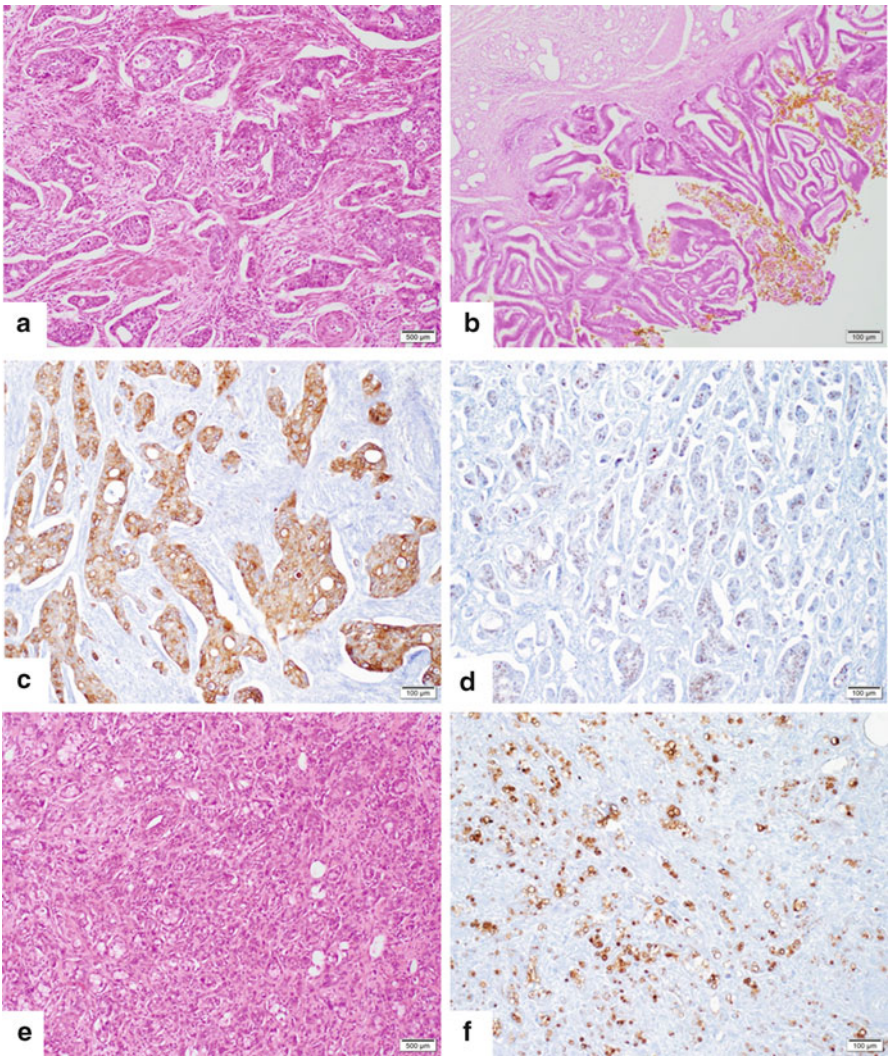

Fig. 3 Ampullary carcinoma, intestinal type (**a**–**d**) and pancreatobiliary type (**e**, **f**). (**a**) HE staining of ampullary carcinoma, intestinal type. (**b**) Intra-ampullary papillary-tubular neoplasm (*IAPN*) as a precursor lesion of ampullary carcinomas. (**c**) Positive immunostaining for CK20 in ampullary carcinoma of intestinal type. (**d**) Positive nuclear immunostaining for CDX2 in ampullary carcinoma of intestinal type. (**e**) HE staining of ampullary carcinoma, pancreatobiliary type. (**f**) Positive immunostaining for MUC-1 in ampullary carcinoma of pancreatobiliary type

(Fig. 3) [14, 19]. IAPN can show papillary and/or tubular growth patterns, low- or high-grade dysplasia, and different cell lineage morphologies (intestinal vs. gastric/pancreatobiliary) [14, 19]. Additional, non-papillary precursors seem to exist, but they have not been well characterized as a separate entity so far.

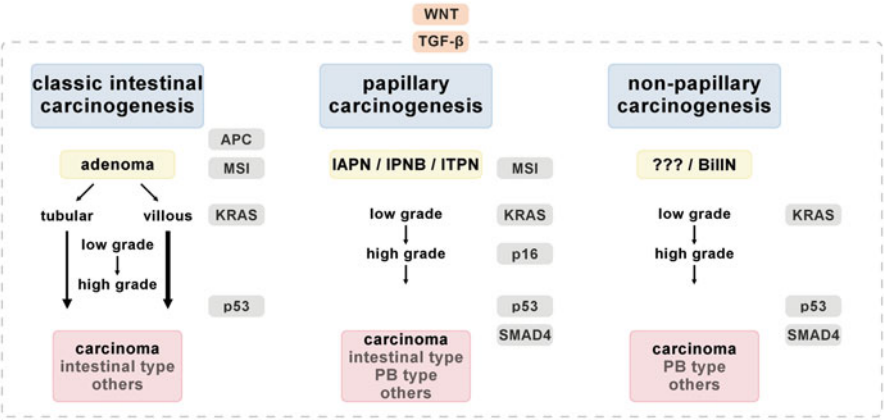

Fig. 4 Molecular pathological concept of carcinogenesis in the ampullary/periampullary region: While extra- and periampullary duodenal carcinomas most often develop from adenomas in a classical adenoma-carcinoma sequence (*left*), many carcinomas of the Vaterian system rise from papillary, tumor-forming precursor lesions like IAPN (intra-ampullary papillary-tubular neoplasms) or IPNB/ITPN (intraductal papillary neoplasms of the bile duct/intraductal tubulo-papillary neoplasms of the bile duct) (*middle*). The non-tumor-forming precursor lesions of the biliary tract are called BilIN (biliary intraepithelial neoplasia), whereas similar "flat" precursor lesions of the ampulla have not been well characterized yet (*right*). An important role of the *WNT* and TGF-β pathways has recently been described in different subtypes of cancers of the ampullary/periampullary region

Molecular Pathology

Recent advances have been made in the molecular characterization of ampullary carcinomas (Fig. 4).

Some mutations, which are shared with pancreatic ductal adenocarcinoma (PDAC) and colorectal cancer (CRC), were described in ampullary cancer over a decade ago: For example, *KRAS* mutations are detected in all three types of cancer, although the frequency varies significantly (>90% in PDAC, 31% in CRC, 37% in ampullary carcinomas) [20–22]. Mutations in tumor suppressor genes like *TP53* and *SMAD4* have been found to occur in PDAC and ampullary carcinoma in a similar frequency [5, 23]. A loss of mismatch repair proteins and a microsatellite instability, as known in the context of CRC, have also been described in ampullary carcinomas (Fig. 5) [24].

In a recent study by Gingras et al., the molecular profiles of duodenal carcinomas, bile duct carcinomas, and ampullary carcinomas were compared [25]. Some common mutations, like *KRAS*, *SMAD4*, and *TP53* mutations, as well as a high rate of microsatellite instability, could be confirmed. In addition, alterations in the *WNT* signaling pathway were found in all three cancer types and, overall, in almost half of the patients, independently from the tumor subtype. *WNT* signaling pathway disruption was found in 49% of ampullary carcinomas, and while it was more frequent in the intestinal subtype (67%), it was found in 30% of the ampullary carcinomas of the

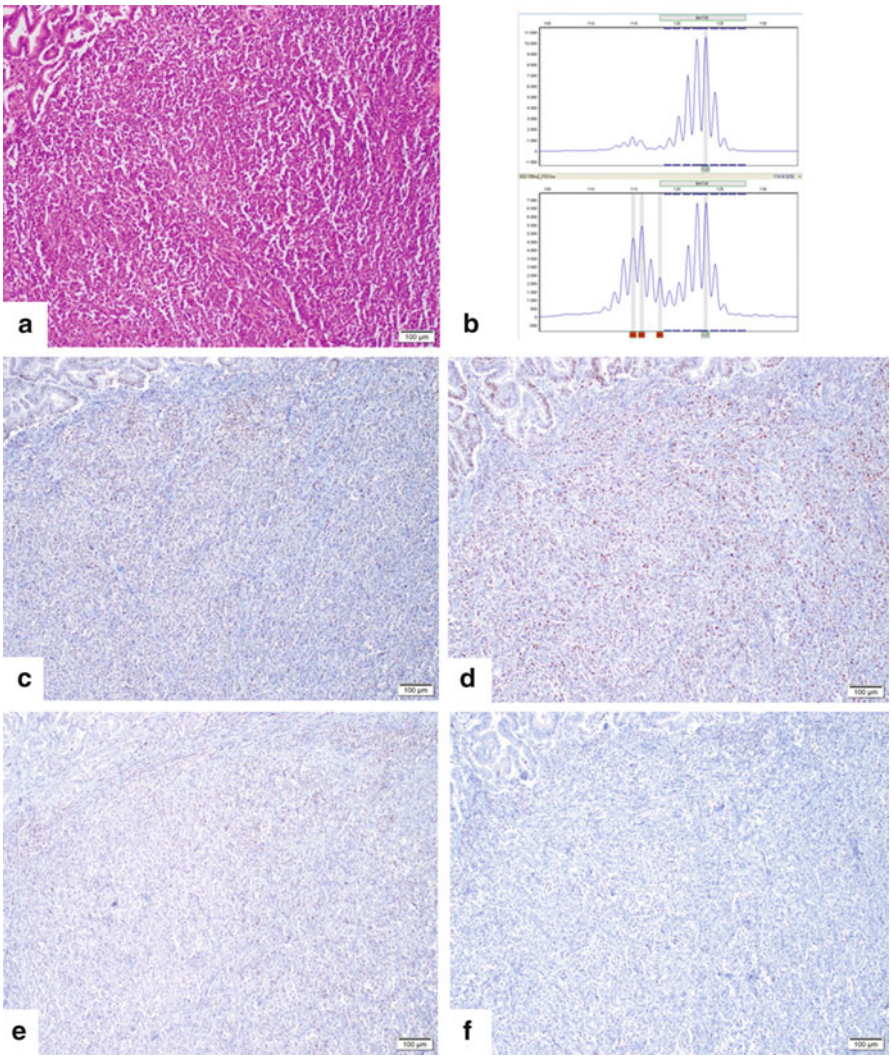

Fig. 5 Loss of mismatch repair proteins and microsatellite instability in ampullary carcinoma. (**a**) Well-differentiated glandular (*upper left*) and poorly differentiated solid pattern with many infiltrating lymphocytes in ampullary carcinoma (HE). (**b**) *BAT25* microsatellite fragment analysis. (**c**–**f**) Immunostaining for mismatch repair proteins: positive nuclear staining in 80% for *MSH2* (**c**) and *MSH6* (**d**) and negative nuclear staining for *PMS2* (**e**) and *MLH1* (**f**)

pancreatobiliary subtype as well. Interestingly, inactivating mutations of *ELF3*, a transcriptional regulator in the TGF-β pathway, were found in 11% of all carcinomas investigated in the study.

Some of the molecular alterations found in ampullary carcinomas act as prognostic factors. Microsatellite instability appears to be associated with a survival

advantage similar to what has been observed in colorectal carcinomas [25]. Mutations in the TGF-β pathway (e.g., alterations of *TGFBR2*, *ACVR1B*, *ELF3*, *SMAD4*) also seem to be associated with a better survival [25].

Mutations found in ampullary carcinomas also represent potential therapeutic targets. For example, several molecules targeting the *WNT* signaling pathway are currently being developed. The molecular status of an individual patient's ampullary carcinoma will therefore be of great interest in the future in order to perform successful personalized medicine. Thus, using next-generation sequencing (NGS) to assess ampullary carcinomas for mutations in a large panel of cancer-associated genes seems like a promising approach, especially because this can be achieved using material from EUS-guided fine needle aspiration and is therefore an option even if surgical specimens cannot be obtained [26].

Duodenal Cancer

The duodenum is the most common site of origin of adenocarcinomas of the small bowel, which altogether represent a quite rare tumor entity, accounting for less than 2% of all gastrointestinal cancers [27]. The second portion of the duodenum, including the periampullary region, represents the most common localization of small bowel adenocarcinomas with a rate of about 80% [28]. It is therefore important to distinguish between periampullary duodenal carcinomas, one of the four subgroups of cancers of the ampullary/periampullary region, and carcinomas elsewhere in the duodenum (extra-ampullary duodenal carcinomas) (Fig. 1b).

Gross Appearance and Histopathology

Macroscopically, most duodenal adenocarcinomas are relatively circumscribed with a polypoid configuration and central ulceration. Periampullary duodenal carcinomas usually do not involve much of the ampullary common channel itself, but rather grow on the duodenal surface of the papilla.

In analogy to the other cancers of this region, periampullary duodenal carcinomas are histopathologically classified as intestinal type, pancreatobiliary type, or mixed type based on their histomorphological appearance and their immunophenotype. Most often (75%) periampullary duodenal adenocarcinomas are of the intestinal type [14]. Extra-ampullary adenocarcinomas of the duodenum can histologically be distinguished in a gastric, intestinal, pancreatobiliary, and indeterminate subtype [28]. The gastric and intestinal subtypes are the most common (50% and 37%, respectively), while the pancreatobiliary type is very rare in this entity [29].

Precursor Lesions

The precursor lesions of extra-ampullary duodenal carcinomas are often referred to as adenomas in analogy to the precursors in the colorectum and are classified in tubular, tubulo-villous, and villous adenomas (Fig. 5). An adenoma-carcinoma sequence is widely accepted for small bowel adenocarcinomas as well [2].

Molecular Pathology

According to the classical intestinal adenoma-carcinoma sequence, microsatellite instability and mutations of *APC*, *KRAS*, *TP53*, and β-catenin have been described in duodenal cancers [30, 31]. While alterations in *KRAS* and *TP53* seem to occur in a similar frequency as in CRC (43% and 42%, respectively) [30], *APC* mutations are quite infrequent (0–18%) [31], suggesting some differences between the colorectal and the small bowel adenoma-carcinoma sequence.

In the previously mentioned study by Gingras et al., duodenal carcinomas were tested for the same molecular alterations as ampullary carcinomas. Interestingly, *ELF3* mutations and *WNT* signaling disruption were also found in duodenal carcinomas and were more frequent than in other cancers of the ampullary/periampullary region (72% vs. 49%) [25].

Similar to what has been observed for CRC, microsatellite instability is a positive prognostic factor in small bowel adenocarcinomas [30]. Both microsatellite instability and mutations in the TGF-β pathway (see section about ampullary cancer) seem to be associated with a better survival [25].

Distal Bile Duct Cancer

Bile duct cancer (cholangiocarcinoma) is a rare, heterogeneous entity that represents only 3% of all gastrointestinal malignancies [32]. It can be classified according to its anatomical site as peripheral intrahepatic, (peri)hilar, or extrahepatic [33].

Gross Appearance and Histopathology

Distal extrahepatic bile duct cancer can involve the ampullary/periampullary region and therefore be misdiagnosed as ampullary cancer (Fig. 1b).

Histopathologically, distal bile duct cancers are adenocarcinomas with a tubular or tubulo-papillary growth pattern and mostly a pancreatobiliary differentiation with expression of CK7 and CK19, MUC1, BER-EP4, and CEA at immunohistochemistry [33]. Gastric, intestinal, mucinous (colloid) variants, as well as undifferentiated subtypes, have been described as well.

Precursor Lesions

There are three distinct types of precursor lesions of distal bile duct adenocarcinoma: biliary intraepithelial neoplasia (BilIN), intraductal papillary neoplasms (IPN or IPNB), and intraductal tubulo-papillary neoplasms (ITPN) (Fig. 5) [34–36].

BilIN are non-tumor-forming, flat precursor lesions in analogy to PanIN of the pancreas. Molecular alterations of BilIN include *KRAS* mutations, which increase in frequency during progression from low-grade to high-grade BilIN, as well as *p53* overexpression, loss of *SMAD4*, p16 inactivation, and an altered expression of p21 and cyclin D1 [34].

IPNB/ITPN are tumor-forming papillary precursor lesions of distal bile duct carcinomas. In analogy to intraductal papillary mucinous neoplasms (IPMN) of the

pancreas, IPNB can be classified as intestinal, pancreatobiliary, gastric, or oncocytic subtype [35]. A stepwise progression from IPNB to invasive adenocarcinoma is assumed [35]. Important molecular alterations that occur during the progression from IPNB to invasive carcinoma include *KRAS*, *TP53*, and p16 mutations as early events and loss of *SMAD4* as a late event [35]. In contrast, molecular alterations frequently observed in ITPN include p16 and *TP53*, while mutations of *KRAS* and *PIK3CA* and loss of *SMAD4* seem to be rare events [36].

Molecular Pathology

NGS has been used in recent studies in order to shed light on the molecular alterations underlying the carcinogenesis of the biliary tree. These studies unraveled a number of novel molecular alterations in biliary carcinomas in general, as well as significant differences in the molecular pathology of intrahepatic and extrahepatic bile duct carcinomas. While, for example, *IDH1*/*IDH2* mutations seemed to be restricted to intrahepatic biliary carcinomas, genetic alterations of *ERBB2* were more frequently found in extrahepatic biliary carcinomas [37, 38]. *TP53* and *KRAS* are the most frequently observed mutated genes in extrahepatic bile duct cancer (45% and 40%, respectively) [37]. Other molecular alterations frequently found in extrahepatic bile duct carcinoma include mutations of *SMAD4*, *FBXW7*, *CDKN2A*, and *CDKN2B* or aberrations in the MAPK, mTOR, and DNA repair pathway [37]. Alterations of molecules of the MAPK and mTOR pathways can be used as druggable targets in new approaches of personalized molecular therapy [38].

As mentioned above, a recent study by Gingras and colleagues found *ELF3* and *WNT* pathway alterations also in distal bile duct cancers. However, alterations of the *WNT* pathway were found significantly less frequently in distal bile duct cancers than in ampullary cancers and duodenal cancers (30% vs. 49% vs. 72%) [25].

TP53 and *KRAS* mutations were both found to be negative prognostic factor in bile duct carcinomas, with *TP53* being an independent prognostic factor at multivariate analysis [38].

Alterations in the chromatin-modulating genes *BAP1* and *PBRM1* were also associated with a poor prognosis in extrahepatic bile duct carcinomas [37].

Cancers of the Ampullary/Periampullary Region in Hereditary Cancer Syndromes

Familial Adenomatous Polyposis (FAP)

Familial adenomatous polyposis (FAP) is a rare autosomal dominant disease caused by an inactivating germline mutation in the adenomatous polyposis coli (*APC*) gene on the long arm of chromosome 5 [4]. *APC* is a tumor suppressor protein in the *WNT* signaling pathway and is part of a complex that prevents the nuclear translocation of the transcription factor β-catenin. Extensive colorectal polyposis is pathognomonic for FAP. Patients with FAP have a lifetime risk of up to 100% for CRC if they are not treated by prophylactic proctocolectomy. The majority of all FAP patients will

develop duodenal polyps, normally with a slow progression and an overall risk of duodenal cancer of 5% (100- to 330-fold higher compared to the general population) [39–41]. Duodenal adenocarcinoma, preferentially located in the periampullary region, and ampullary carcinoma are two of the most common causes of death in FAP patients (approximately 3%) [42].

In analogy to sporadic tumors, an adenoma-carcinoma sequence is well established for duodenal/ampullary carcinomas in FAP patients. FAP patients may additionally develop dysplastic lesions in the biliary tree and bile duct cancer.

Ampullary and Duodenal Cancers in Hereditary Nonpolyposis Colorectal Cancer (HNPCC)

Lynch syndrome is an autosomal dominant genetic condition with incomplete penetrance and represents the most common inherited colon cancer syndrome [4]. The underlying molecular alterations in patients with Lynch syndrome are germline mutations of mismatch repair genes: *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Mutations in *MLH1* and *MSH2* are the most frequent (about 90%) [4]. Compared to the general population, the lifetime risk of colon cancer in Lynch syndrome patients is 100-fold higher (1–4%) and the patients are on average 10 years younger [43, 44]. In addition, this genetic disorder also predisposes for other malignancies such as endometrial, ovary, genitourinary tract, stomach, hepatobiliary, pancreas, and small bowel cancers. Small bowel cancer can be the only cancer manifestation in Lynch syndrome patients [31]. Interestingly, the incidence of small bowel cancer in *MLH1* and *MSH2* carriers appears higher compared to *MSH6* [43]. Adenocarcinomas of the ampulla of Vater additionally belong to the spectrum of HNPCC [45].

Conclusion

Cancers of the ampullary/periampullary region represent a heterogeneous group of malignancies originating in a complex anatomical environment. A careful gross and histopathological assessment according to standardized protocols represents a first important step to differentiate these entities and their respective precursor lesions for appropriate classification and staging. This is mandatory considering the different biological behaviors, which further affect clinical management. In addition, exact morphological characterization represents the basis for further molecular analysis. Gene panel analysis might help in addition to conventional morphology and immunohistochemistry in the preoperative diagnosis of cancers of the ampullary/periampullary region, especially in case of cytological specimens or if the material is scarce. Moreover, recent data coming from ultra-deep sequencing studies have revealed on one side important correlations between mutational patterns and prognosis. On the other side, it seems that common genetic alterations, especially those involving the *WNT* pathway, can be found in subgroups of cancers of the

periampullary/ampullary region independently from the histotype and could be used for individual therapeutic approaches in the near future.

Key Research Points

- Neoplasms of the ampullary/periampullary region include ductal carcinomas of the pancreatic head, carcinoma of the ampulla of Vater, duodenal cancers, and distal bile duct cancers.
- Subtypes of cancers of the ampullary/periampullary region seem to originate from different precursors along different molecular pathways.
- A careful gross assessment of pancreatoduodenectomy specimens according to standardized protocols allows in most cases a differentiation between different cancer subtypes originating in the periampullary/ampullary region and is mandatory for determining prognostic relevant parameters, such as staging and resection margin status.
- Histopathological analysis accompanied by immunohistochemistry and molecular analysis is important for identification of special subtypes (e.g., intestinal vs. pancreatobiliary ampullary cancers, MSI vs. MSH neoplasms) with different prognosis and, possibly, different therapy response.

Future Scientific Directions

- Efforts are ongoing to elucidate further the molecular pathology underlying the observed histopathological and prognostic differences among cancers of the ampullary/periampullary regions.
- A better morphological and molecular characterization of the precursor lesions of different cancer types will also be helpful to better understand the biological behavior of cancers arising in the ampullary/periampullary region and their respective subtypes.
- Gene panel analysis should be exploited and possibly included in routine assessment in order to increase diagnostic sensitivity in the preoperative setting.
- NGS-based analyses have recently identified common molecular pathways in duodenal, ampullary, and distal bile duct cancers, which offer the possibility to apply individually targeted therapies.

Clinical Implications

- Despite similar approach for the treatment of resectable disease, the prognosis of cancers of the ampullary/periampullary region varies considerably depending on the tumor subtype, with survival rates being highest for ampullary and duodenal cancers, intermediate for distal bile duct cancer, and lowest for pancreatic cancer.

- Due to the differences in biological behavior and survival, accurate classification of carcinomas of the ampullary/periampullary region is crucial for an adequate prognostic estimate and an individualized therapeutic decision. Moreover, a subset of cancers of this region arises in a hereditary context (FAP or HNPCC), and these patients should therefore undergo a close surveillance program using upper gastrointestinal endoscopy.
- A better definition and characterization of precursor lesions, also on the molecular level, may improve early recognition, thereby significantly affecting treatment and prognosis.
- Molecular profiling should be exploited to increase diagnostic accuracy and to provide the basis for individual targeted therapies.

Abstract

Nonendocrine, nonpancreatic periampullary tumors are generally classified as arising from the ampulla of Vater, distal common bile duct, or duodenum. The most common clinical finding on presentation is obstructive jaundice. These lesions may occur spontaneously or as part of a hereditary syndrome (familial adenomatous polyposis, Gardner's syndrome, and inflammatory bowel disease). The most effective diagnostic strategies for determining extent of disease and resectability of periampullary tumors include dual-phase computed tomography and endoscopic ultrasound. Small, benign periampullary lesions may be amenable to endoscopic resection. For benign lesions <3 cm that are unable to be completely removed endoscopically, transduodenal local resection should be considered. Appropriate surgical candidates with larger lesions >3 cm or suspicion of invasive carcinoma should undergo a pancreaticoduodenectomy. Five-year survival for duodenal, ampullary, and distal common bile duct carcinomas are 51–59, 37–39, and 23–27%, respectively. For each of these tumors, both lymph node status and negative margins are significant predictors of outcome. At this point, neoadjuvant and adjuvant therapies have not clearly demonstrated a survival benefit for nonpancreatic periampullary cancers. The future success in treating these cancers likely rests in the development of novel biological and targeted therapies in the setting of well-designed multi-institutional clinical trials. This chapter will focus on benign and malignant nonpancreatic and nonneuroendocrine periampullary tumors and will include the pathology, clinical presentation, diagnostic workup, and management strategies to approach these neoplasms.

Keywords

Cholangiocarcinoma · Bile duct cancer · Ampullary adenoma · Ampullary cancer · Duodenal neoplams

Epidemiology

The majority of periampullary tumors are malignant, with pancreatic adenocarcinoma being the most common followed by cancers of the ampulla of Vater, distal common bile duct, and duodenum, respectively. Periampullary adenocarcinoma has a yearly incidence in the United States of approximately 35,000 cases which has remained stable over the last few decades [1]. Pancreatic adenocarcinoma likely accounts for up to 90% of these cases, although without surgical resection and pathologic analysis, the specific organ of origin can be difficult to determine. The relative frequency of malignant periampullary neoplasms in resected specimens is

Table 1 Relative frequency periampullary neoplasms in resected specimens

Location	Percentage (%)
Head of pancreas	56
Ampulla of Vater	21
Distal common bile duct	17
Duodenum	3

shown in Table 1 [2]. The percentage of nonpancreatic malignancies is likely higher in this surgical resection series given such tumors have a higher rate of resection compared to primary pancreatic cancers.

Pathology

Ampullary Neoplasms

Tumors of the ampulla can be either benign or malignant, both of which are rare. Autopsy studies demonstrate that the overall prevalence of ampullary adenomas is approximately 0.04–0.12% [3]. Among all malignancies of the gastrointestinal tract, ampullary neoplasms account for only 0.5% [4].

Benign Ampullary Tumors

Benign adenomas are generally defined as adenomatous lesions arising on or within 2 cm of the ampulla of Vater. They are classified by their microscopic findings as either intestinal type or biliary type. Ampullary adenomas are seen both sporadically and in association with familial syndromes such as familial adenomatous polyposis (FAP). The incidence of sporadic adenomas appears to be increasing, which is likely the direct result of increased detection due to the increased utilization of upper endoscopy. Sporadic ampullary adenomas usually occur during the sixth decade of life and are an average diameter of 2 cm [5, 6] (Fig. 1).

Ampullary adenomas are frequently identified in patients with FAP, who have a cumulative lifetime risk near 100% [3]. The median age at presentation for familial adenomas is earlier than the sporadic cases, presenting at 30–40 years of age. The diagnosis of periampullary adenomas associated with FAP usually occurs well after the diagnosis of colonic polyps typically at a mean follow-up of 17 years after colectomy [7]. At presentation, these lesions can often be multiple and involve both the ampulla and duodenal mucosal surface simultaneously.

Similar to the well-defined transformation of colonic adenomas into adenocarcinoma, ampullary adenomas have the potential for malignant degeneration. Patients with FAP have a 100–200-fold higher risk of periampullary cancer compared to the general population and a prevalence of ampullary cancer of 3–12% [4]. Thus, close screening and follow-up is extremely important in this population.

Fig. 1 Endoscopic appearance of benign villous adenoma

Fig. 2 Surgical specimen demonstrating an ulcerated ampullary carcinoma. The papilla is replaced by an exophytic papillary and ulcerated tumor (Reprinted from Mino and Lauwers [8])

Malignant Ampullary Tumors

Ampullary carcinoma is classified as four types based on macroscopic features: intra-ampullary (24%), periampullary duodenal (6%), mixed exophytic (31%), and mixed ulcerated (39%) (Fig. 2). Overall, intra-ampullary cancers have a better prognosis than other subtypes as these tumors usually present smaller lesions with less angiolymphatic invasion, fewer lymph node metastases, and less direct invasion of the pancreas.

Adenocarcinomas of the ampulla are further divided into intestinal-type (50%) and pancreaticobiliary type (20%) based on histologic features The most prevalent type of ampullary adenocarcinomas are intestinal-type which resemble primary adenocarcinomas of the colon pathologically with simple or cribriform glands lined by atypical cells with features of intraluminal necrosis and inflammation (Fig. 3). Pancreaticobiliary-type resembles primary pancreatic and biliary

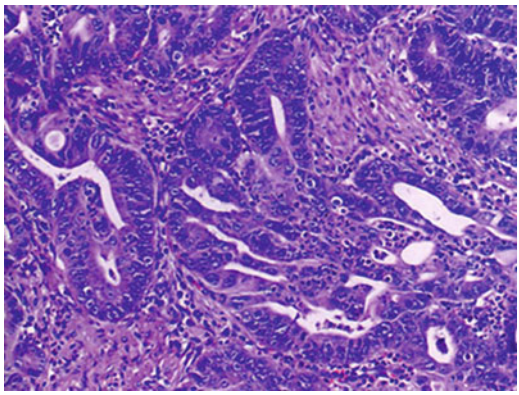

Fig. 3 Adenocarcinoma, intestinal type. The tumor is composed of complexed glands lined by atypical cells. Note the typical luminal inflammation (Reprinted from Mino and Lauwers [8])

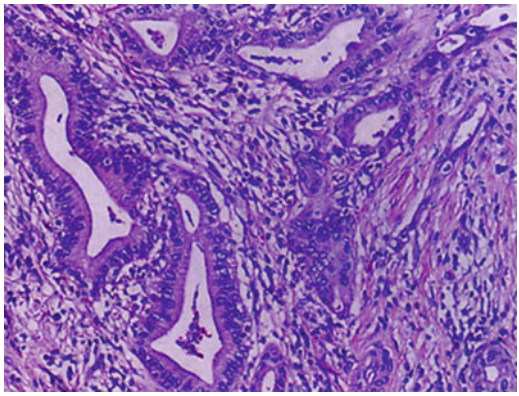

Fig. 4 Adenocarcinoma, pancreatobiliary type. The tumor is composed of simple malignant glands lined by low columnar cells. Note the markedly atypical nuclei and the surrounding desmoplasia (Reprinted from Mino and Lauwers [8])

adenocarcinomas. These tumors are composed of simple glands lined with low columnar cells with features of atypical nuclei and surrounding desmoplastic stroma (Fig. 4). Compared to the intestinal type, the pancreaticobiliary type more often demonstrates perineural invasion, but angiolymphatic invasion is less common. In instances where both microscopic features of intestinal and pancreaticobiliary are present, these tumors are classified as intestinal, unless there is a predominant pancreaticobiliary phenotype. A 2008 series from the University of California San Francisco of 118 patients with ampullary adenocarcinomas noted patients with pancreaticobiliary type presented with jaundice more frequently and had significantly worse survival compared to those with intestinal type [9].

There are several unusual subtypes of ampullary cancers including papillary, mucinous, and signet-ring carcinomas. Papillary carcinomas are uncommon and are reported in 6% of ampullary carcinomas. They are classified as either invasive or noninvasive. Invasive papillary carcinomas appear as complex branching papillary structures with fibrovascular cores and/or micropapillary structures without fibrovascular cores. These are lined by either intestinal or pancreatobiliary-type cells. In contrast, noninvasive papillary carcinomas are exophytic tumors arising in

the intra-ampullary mucosa and lined by pancreatobiliary-type epithelium. The neoplasms are similar to noninvasive papillary carcinomas of the extrahepatic bile ducts and noninvasive intraductal papillary mucinous neoplasms of the pancreas.

Mucinous or colloid carcinomas represent only 4–7% of ampullary carcinomas. These neoplasms demonstrate two particular morphologies both with greater than 50% containing extracellular mucin. These carcinomas are composed of columnar epithelium with nuclear atypia or contain clusters of neoplastic cells.

Signet-ring cell carcinomas of the ampulla are extremely rare. These neoplasms contain cells with nuclei forced to the periphery by intracytoplasmic mucin. In order to diagnose these tumors, greater than 50% of the tumors must contain signet-ring cells with a diffuse growth pattern, and a primary from another site must be excluded.

Distal Common Bile Duct Neoplasms

The common bile duct (CBD) is divided into four parts: (1) supraduodenal, (2) retroduodenal, (3) intrapancreatic, and (4) intraduodenal. The periampullary distal CBD is considered to include the intrapancreatic and intraduodenal segments. Tumors of epithelial, nonepithelial, and mesenchymal origin can arise from the distal CBD.

Benign Distal Bile Duct Tumors

Adenomas are extremely rare lesions of the distal common bile duct and are less common than carcinomas. These lesions are usually small, often single, and may appear as pedunculated or sessile polyps. They are histologically classified similarly to adenomas of the colon: tubular, tubulovillous, and villous. Reports of distal common bile duct adenomas have been reported in familial adenomatous polyposis and Gardner's syndrome [10].

Cystadenomas are mucinous cystic tumors that can arise from various structures in the upper gastrointestinal tract, most commonly seen in the liver, pancreas, and extrahepatic bile ducts. These tumors occur in the biliary tree of middle-aged females and may grow as large as 20 cm. Malignant transformation is rare, although dysplasia is seen in 13% of these tumors [11]. Complete local excision for symptomatic lesions is necessary due to a high rate of recurrence if incompletely resected. Cystadenomas can be differentiated from intraductal papillary mucinous neoplasms (IPMN) of the biliary tract by the presence of mesenchymal stroma in the former. Biliary IPMN, also seen originating from the pancreas, has emerged as a unique entity and may account for $>7\%$ of biliary neoplasms. These lesions are considered precursors to cholangiocarcinoma with risk of malignant transformation [12].

Biliary papillomatosis is a rare phenomenon of multicentric complex papillary neoplasms which involve the extra- and intrahepatic biliary systems and gallbladder, and may extend into the pancreatic ducts. It affects both males and females equally

during the sixth decade of life. Surgical resection is difficult and recurrence is common. The treatment of choice is total hepatectomy and liver transplantation.

Granular cell tumors are neoplasms of the extrahepatic biliary system usually involving the common bile duct. These tumors typically occur in young women (median age 34 years). Patients typically present with jaundice and abdominal pain. Granular cell tumors are occasionally multicentric with lesions in the gallbladder, skin, omentum, esophagus, and stomach. Within the common bile duct, these lesions appear as small (<2 cm), firm, submucosal nodules that invade the lumen. These tumors are not malignant, however may invade into periductal tissue and adjacent pancreas. Diagnosis usually occurs by ultrasound with subsequent MRCP/ERCP. These lesions are clinically similar to malignant distal common bile duct tumors and often require operative resection to make the diagnosis.

Malignant Distal Bile Duct Tumors

The incidence of extrahepatic cholangiocarcinoma in the United States is low, with approximately 6,000 new cases diagnosed annually [13]. Using the classification system proposed by Nakeeb and colleagues, cholangiocarcinoma lesions are divided into intrahepatic, perihilar, and distal subgroups [14]. Up to 45% of these malignancies are classified as extrahepatic [13]. Although the etiology is unknown, there are several well-documented risk factors. The incidence of all types of cholangiocarcinoma increases with age and is higher in males. Patients with ulcerative colitis and sclerosing cholangitis have a significantly increased risk of developing both intra- and extrahepatic cholangiocarcinoma at 65%, which is 4x higher than that of the general population. Although patients with Crohn's disease are at an increased risk for developing cholangiocarcinoma, the risk is approximately half of that for ulcerative colitis patients [15]. Biliary pathology such as cholangitis, choledocholithiasis, cholecystitis, and choledochal cysts are also independent risk factors for development of cholangiocarcinoma. Hepatolithiasis and biliary parasitic infestation (*Clonorchis sinensis* or *Opisthorchis viverrini*), both prevalent in parts of Asia, also increase the risk of cholangiocarcinoma.

Adenocarcinoma is the primary histologic subtype in the distal common bile duct malignancies. The three macroscopic classifications of cholangiocarcinoma are sclerosing, nodular, and papillary. Sclerosing lesions are the most common and appear as thickening of the bile duct with diffuse infiltration of adjacent tissues. Nodular tumors are irregular nodules that invade into the lumen of the bile duct. Nodular-sclerosing lesions, as implied, have characteristics of both. The papillary subtype represents only 10% of cholangiocarcinomas and is more common in the distal bile duct than the hepatic bifurcation [16]. These tumors are soft polypoid lesions with little or no invasive component and generally have a more favorable prognosis compared with the sclerosing subtype [17, 18]. These tumors spread longitudinally along the duct wall beneath the epithelial lining. As a result, preoperative imaging and intraoperative examination may not appreciate the extent of submucosal spread, highlighting the importance of intraoperative frozen section to determine adequate margins for resection (Table 2).

Table 2 Tumor classification table

Miscellaneous nonpancreatic nonneuroendocrine tumors	
Periampullary tumor classification	
1. Ampullary neoplasms	3. Duodenal neoplasms
A. Benign adenomas	A. Benign adenomas (tubular, villous, Brunner gland)
B. Adenocarcinomas (intestinal type, pancreaticobiliary type)	B. Lipomas
C. Papillary carcinoma (invasive, noninvasive)	C. Hamartomas
D. Mucinous or colloid carcinomas	D. Hemangiomas
E. Signet-ring carcinomas	E. Primary duodenal adenocarcinomas
2. Distal common bile duct neoplasms	4. Mesenchymal neoplasms
A. Benign adenomas	A. Leiomyomas, lipomas
B. Cystadenomas	B. Neurogenic tumors (neurofibromas, ganglioneuromas)
C. Biliary papillomatosis	C. Vascular tumors (hemangiomas, lymphangiomas)
D. Granular cell tumors	D. Granular cell tumors
E. Cholangiocarcinoma (sclerosing, nodular, papillary)	E. Schwann cell tumors
	F. Gastrointestinal stromal tumors (GIST)
	5. Lymphomas (B cell lymphomas)
	6. Metastatic tumors (renal cell carcinoma, melanoma, breast cancer, squamous cell carcinoma, endometrioid adenocarcinoma, osteosarcoma)
	7. Pseudotumors (myoepithelial hamartoma, Brunner gland hyperplasia)

Duodenal Neoplasms

Benign Duodenal Tumors

Small bowel tumors are rare and represent only 1–1.5% of all gastrointestinal neoplasms. Depending on the series, the proportion of benign small bowel tumors ranges from 14% to 52% [19]. Familial syndromes such as Gardner's syndrome and familial adenomatous polyposis are often associated with duodenal adenomas. Adenomas are comprised of three types: (1) tubular, (2) villous, and (3) Brunner gland. Tubular adenomas are usually pedunculated and generally have low risk for invasive carcinoma. Villous adenomas have a higher malignant potential, especially when greater than 2 cm. Brunner gland adenomas originate from hyperplastic exocrine glands in the proximal duodenum and carry no malignant risk.

Lipomas are rare tumors of the duodenum and are usually identified as incidental findings on CT as circumscribed tumors of fat density in the bowel wall. If symptomatic, they present as bleeding or obstruction. If small (<2 cm) and asymptomatic, they do not require resection. However, symptomatic, large or increasing size on serial CT requires endoscopic or segmental resection to rule out the possibility of liposarcoma.

Hamartomas are lesions seen almost exclusively in Peutz-Jeghers syndrome, an autosomal dominant condition characterized by multiple GI hamartomas throughout the bowel with mucocutaneous pigmentation. Rarely, these tumors cause obstruction or bleeding. Malignant transformation is rare but requires that these patients have close surveillance. Surgical intervention should be considered for symptomatic lesions or concern for the development of malignancy.

Hemangiomas are rare congenital lesions that present as acute or chronic bleeding during midlife. They are usually single and have no malignant potential. If these tumors are symptomatic, treatment consists of endoscopic or segmental resection. Additional treatment modalities including endoscopic sclerotherapy or angiographic embolization have also been described.

Malignant Duodenal Tumors

The incidence of small bowel cancer in the United States is approximately 10,000 cases per year with approximately 1300 deaths per year as a result [20]. The majority of small bowel adenocarcinomas arise in the duodenum and up to half of primary duodenal adenocarcinomas occur in the periampullary region [21, 22]. The incidence is higher in older patients and males more than females. Most cancers of the duodenum are sporadic. Familial adenomatous polyposis is the most prominent genetic predisposing factor with a relative risk of over 300 times that of the normal population. Hereditary nonpolyposis colorectal cancer, celiac sprue, and Crohn's disease are also associated with duodenal cancer.

Most of these tumors are solitary, sessile lesions, which often appear in association with adenomas. They are usually moderately well-differentiated. These lesions are similar to the malignant transformation of adenocarcinomas found in the colon with similar pathologic features.

Rare Periampullary Tumors

Mesenchymal Neoplasms

Benign and malignant periampullary mesenchymal tumors are extremely uncommon. The most common benign neoplasms are leiomyomas or lipomas. Other rare benign lesions consist of neurogenic tumors (neurofibromas, ganglioneuroma), vascular tumors (hemangiomas, lymphangioma), or granular cell tumors of Schwann cell origin. Neurogenic tumors involving the ampulla may arise in patients with neurofibromatosis.

Malignant mesenchymal tumors mostly consist of gastrointestinal stromal tumors (GISTs). Duodenal and periampullary stromal tumors compose about 3–5% of all GI stromal tumors [23]. The sub-proliferation in the majority of gastrointestinal stromal tumors is thought to be driven by gain-of-function mutations of the *KIT* gene, which encodes a type of tyrosine kinase receptor. Activating mutations of *KIT* can be found in most periampullary stromal tumors. These tumors can occur at any age and usually present with gastrointestinal bleeding associated with a growth of a large size with central necrosis. Complete surgical excision is the treatment of choice.

Because lymph node metastasis is rare, local resection can be employed selectively. Larger tumors, however, may require pancreaticoduodenectomy.

Lymphomas, Metastatic Tumors, and Pseudotumors

Other rare periampullary tumors include lymphomas and metastatic tumors. Most reports of lymphoma involving the ampulla of Vater involve high-grade B cell lymphoma and marginal zone B cell lymphoma. Metastatic disease involving the periampullary region is often from direct extension from an adjacent locally advanced tumor. Hematogenous spread from a primary neoplasm is extremely rare but most commonly reported with renal cell carcinoma. Other malignant tumors reported to metastasize to the periampullary region include melanoma, breast cancer, squamous cell carcinoma of the larynx, endometrioid adenocarcinoma, and osteosarcoma. Pseudotumors are recognized as 23% of tumors identified in the ampullary region [24]. They include myoepithelial hamartoma and Brunner gland hyperplasia, which collectively are more common than adenomas. It can be challenging to discern pseudotumors from neoplastic lesions, and often result to unnecessary surgery.

Clinical Presentation

Benign periampullary and duodenal adenomas are often asymptomatic and discovered incidentally or during surveillance for familial syndromes. Presenting symptoms depend on location and size of the tumors but can include jaundice, bleeding, and obstruction such as are seen with malignant periampullary tumors.

Generally, periampullary and pancreatic carcinomas are difficult to diagnose in their early stages. Symptoms tend to be nonspecific and often the diagnosis is not made until patients develop jaundice. Compared to pancreatic primaries however, tumors of the ampulla of Vater, distal common bile duct, and periampullary duodenum tend to present at an earlier stage due to higher propensity for biliary obstruction leading to jaundice. The mean diameter in one series of 149 patients diagnosed with ampullary cancer (2.7 cm) was significantly smaller, compared to pancreatic head cancer (3.5 cm) [25]. This generally translates to higher resectability rates than pancreatic cancers. Usually jaundice is progressive and relentless and may be associated with significant pruritus. Occasionally however, ampullary carcinomas may present with intermittent jaundice due to the "ball valve" effect of a polypoid tumor or necrosis during the growth phase leading to extrahepatic biliary obstruction. The development of jaundice is more commonly associated with a periampullary carcinoma (70%) than a benign tumor (20–30%) [26–30].

Periampullary neoplasms may also present with abdominal pain, anorexia, nausea, weight loss, and gastrointestinal bleeding. Partial biliary or pancreatic duct obstruction may result in complaints of abdominal pain prior to the development of jaundice. This pain is usually dull, moderate intensity, located in either the epigastrium or right upper quadrant, possibly radiating to the back, and aggravated by eating. Vomiting secondary to duodenal obstruction is usually a late manifestation of periampullary cancers in general, but may occur earlier in bulky duodenal cancers.

Ampullary or duodenal cancers may present with chronic or intermittent gastrointestinal bleeding. An episode of acute pancreatitis of unclear etiology should raise suspicion for an underlying periampullary neoplasm and initiate a thorough evaluation once the acute episode has resolved. In a report by Rattner et al., acute pancreatitis was the presenting symptom in 25% of patients diagnosed with ampullary neoplasms [31].

Duodenal adenocarcinomas not immediately adjacent to the ampulla of Vater may present with vague complaints of abdominal pain, weight loss, symptoms of bowel obstruction, or bleeding. These lesions tend to represent more advanced disease than periampullary adenocarcinomas.

Past medical and family history may be significant in evaluating a patient for a possible periampullary neoplasm. Patients with Gardner's syndrome and familial polyposis may carry a 200-fold increased risk for ampullary and duodenal carcinomas [32]. These patients will often have multiple polyps involving a significant portion of the duodenal mucosa.

Aside from jaundice, physical examination findings are commonly absent in patients with periampullary tumors. Hepatomegaly may be present and usually reflects hepatic congestion from biliary obstruction, not necessarily the presence of metastatic disease. Ascites, however, may represent advanced disease. A palpable gallbladder may be present in approximately 25% of patients. Occult fecal blood may be seen in those with bleeding periampullary cancers as well.

Diagnostic Evaluation

Laboratory Data

Nearly all patients with periampullary cancers present with abnormal liver function tests which includes increased plasma bilirubin and alkaline phosphatase, characteristic of extrahepatic obstruction. Transaminase levels may also be increased but usually not as significantly as alkaline phosphatase levels. In cases of longstanding extrahepatic obstruction, the prothrombin time may be prolonged. Anemia may be present with any periampullary cancers arising from the ampulla or duodenum secondary to gastrointestinal bleeding. Tumor markers, such as CEA and CA19-9, are generally not of diagnostic value as they are not specific for malignancy and may be elevated in benign causes of extrahepatic obstruction.

Imaging Studies

Early diagnosis of periampullary cancers is dependent on prompt evaluation of the jaundiced patient. Current imaging modalities provide detailed information regarding the level and etiology of biliary obstruction. Once these lesions are identified, a focused surgical approach gives these patients the best chance for long-term survival.

Ultrasonography

Transabdominal ultrasound (US) is often used in the initial evaluation of patients presenting with abdominal pain or obstructive jaundice, as it documents the presence of biliary obstruction with a dilated biliary tree and can define the level of biliary obstruction thereby narrowing the differential diagnosis. Other important findings that can be visualized with US include gallstones, ascites, and liver metastases. A major limitation of US is the frequent inability to identify a periampullary tumor and the high rates technically inadequate studies, which can result from patient body habitus, the presence of intervening bowel gas, or technical limitations of the operator. Conversely, the lack of radiation exposure and its relatively low cost are some of the advantages offered by US.

Computed Tomography

Despite the advantages of US, the high accuracy and reproducibility of computed tomography (CT) and its widespread availability, make it the most useful, and often the most cost-effective test in the initial evaluation of a patient with a suspected periampullary malignancy [33]. CT can detect the presence of a periampullary mass of at least 2 cm in size and also provides important information about the level of biliary obstruction with respect to the pancreatic parenchyma, if no mass is seen (Fig. 5). Pancreatic duct dilatation may also be seen. The optimal technique for evaluation of the periampullary region involves administration of both intravenous and oral contrast and obtaining 1- to 3-mm slices within a single breathhold during both the arterial and portal venous phase of intravenous contrast enhancement [34, 35]. Scans obtained during the rapid intravenous injection of an iodinated contrast agent result in an increase in the pancreatic parenchymal attenuation, as well as excellent contrast enhancement of the major peripancreatic blood vessels. This technique not only results in clear delineation of the tumor but may also demonstrate involvement of adjacent major visceral vessels, such as the portal/superior

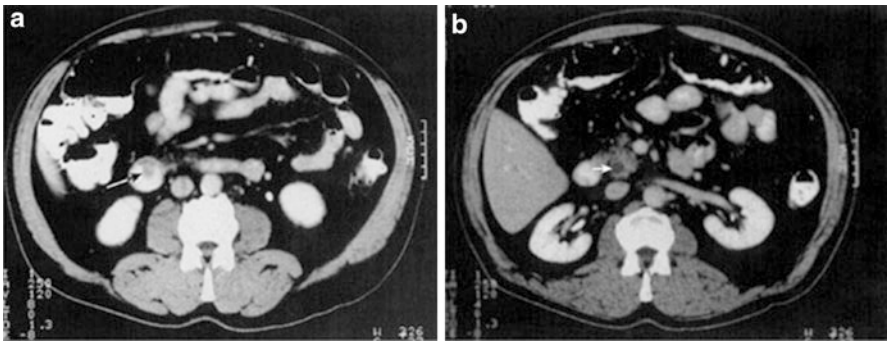

Fig. 5 Computed tomography scan of a patient with obstructive jaundice due to ampullary carcinoma: (**a**) Scan demonstrated a 3-cm ampullary mass (*black arrow*) and (**b**) scan at higher level demonstrating bile duct dilation within pancreatic parenchyma indicating distal duct obstruction (*white arrow*)

mesenteric vein complex or superior mesenteric or hepatic arteries, suggesting unresectability. The value of CT lies in the virtual absence of technically unsatisfactory examinations and in its high accuracy in both the detection and staging of periampullary carcinoma. The positive predictive value associated with CT-determination of unresectability is greater than 90% [34]. Magnetic resonance imaging (MRI) is equivalent to, but not superior to, CT for detection and staging of periampullary tumors and has a higher cost [36]. However, it does offer the advantages of avoiding exposure to radiation or ionic contrast and so is a more suitable test for patients with contrast allergies or renal insufficiency.

Magnetic Resonance Cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) has emerged as a noninvasive method to determine the most likely etiology of a pancreaticobiliary abnormality. It is most helpful in evaluating abnormalities of the proximal bile ducts and liver. In periampullary lesions, the thick slab MR images will delineate the biliary and pancreatic ductal anatomy with detail that is similar to the more invasive techniques of endoscopic retrograde cholangiopancreatography (ERCP). The other MR sequences will define the presence or absence of a mass, the level of the obstruction and the location of any given abnormality relative to the regional vessels.

The pattern on cholangiopancreatography can be characteristic for ampullary, bile duct, and pancreatic carcinomas. Cancers of the ampulla or duodenum will obstruct both the pancreatic and bile duct at the ampulla whereas pancreatic cancer will show the classic “double duct” sign. Distal bile duct cancers show a characteristic “apple core” appearance, with a normal appearing pancreatic duct.

Endoscopy/Endoscopic Ultrasound

Simple upper endoscopy can define the extent, size, and gross appearance of a periampullary lesion suspected of being malignant and allows for simultaneous performance of an endoscopic biopsy and cytologic brushings. The endoscopic appearance of an ampullary lesion, however, is often similar for benign and malignant tumors. Furthermore, endoscopic biopsies can reveal false negative results due to sampling error, with accuracy rates ranging from 62% to 79% in various series [37–40]. The demonstration of malignancy on biopsy specimens is definitive and will in most cases indicate the need for pancreaticoduodenectomy. However, a diagnosis of a benign adenoma does not rule out the presence of an adenocarcinoma elsewhere in the adenoma. Finally, an important consideration is that ampullary adenomas are a premalignant condition since they tend to progress to carcinoma. Therefore, regardless of whether the biopsy shows a malignant or benign histology, complete resection (either operative or endoscopic) is warranted.

Endoscopic ultrasonography (EUS) is a very useful modality in diagnosis of periampullary disease, which combines and modifies the techniques of gastrointestinal endoscopy and US. This combination decreases the distance between the ultrasonic source and the organ of interest, thereby markedly improving the resolution and imaging of the surrounding structures. Real-time EUS enables one to evaluate and integrate, on the same examination, mucosal, vascular, ductal, and

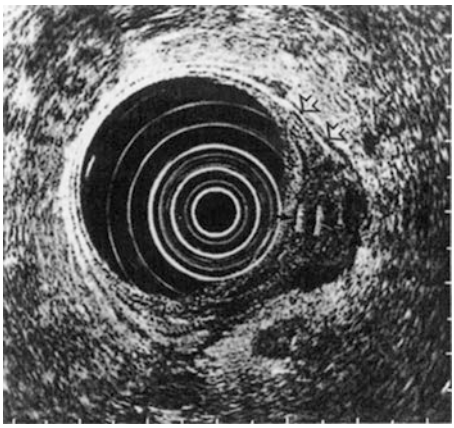

Fig. 6 Endoscopic ultrasonography scan of ampullary tumor, represented by the hypoechoic area on the *right*. An endoprosthesis (*small black arrows*) can be seen running through the center of the tumor. The tumor infiltrates beyond the muscularis propria (*open arrows*) into the pancreas.

parenchymal abnormalities. It allows detection of periampullary tumors, evaluation of their size and depth of invasion, as well as assessment of regional lymph nodes. EUS appears to be superior to CT and MRI for the detection of small pancreatic tumors (<2 cm) [41]. However, the sensitivity of EUS decreases in the setting of chronic pancreatitis [34]. EUS is able to demonstrate depth of invasion (T stage) of mucosal-based ampullary and duodenal tumors with an accuracy rate of 73–84%, increasing accuracy with higher T stages [42–44] (Fig. 6). This feature is of importance in detecting noninvasive benign periampullary neoplasms from malignant tumors with invasion through the bowel wall. Although results are not conclusive, several reports have also indicated that EUS has greater sensitivity and accuracy in detecting vascular invasion than CT [41, 43, 45].

The value of defining a benign versus a malignant periampullary mucosal-based tumor is the opportunity to locally excise a benign lesion as opposed to offer pancreaticoduodenectomy for malignant tumors. However, since frozen section analysis of resected specimens can fail to detect malignancy in 14% of patients [46], the surgeon always risks the possibility of a final diagnosis of cancer following local excision. Furthermore, with a sensitivity of approximately 75% in predicting T1 lesions, this modality is not necessarily optimal for predicting endoscopic resectability. Underestimating the depth of the tumor penetration seldom occurs, while overestimation is more common and is often due to edema of the submucosa from associated pancreatitis or from peritumoral inflammation in ampullary carcinoma. Similarly, indwelling transpapillary stents can cause inaccuracies and overstaging [47].

Finally, EUS can determine the presence or absence of enlarged regional lymph nodes. Reported accuracies of EUS-assessment of lymph node status have ranged from 63% to 84%, which is at least equivalent to CT [34, 41, 43, 48]. Furthermore, EUS offers the ability to perform fine-needle aspiration (FNA) of both the lesion and suspicious regional lymph nodes.

Limitations of EUS include its complexity and in operator variability in both performing and interpreting, its invasive nature, and its limited view (2–4 cm depth),

which does not allow evaluation for distant sites of metastases. The combination of CT and EUS is better than either alone in detecting resectability in patients with periampullary cancers. The strategy of obtaining a CT for all patients with suspected periampullary malignancies, followed by EUS in those patients in whom CT does not clearly demonstrate unresectability has been shown to be the most cost-effective strategy for preoperative staging of and determination of resectability in these tumors [45, 48].

Endoscopic Retrograde Cholangiopancreatography

With advances in cross-sectional imaging and the introduction of endoscopic ultrasound and MRCP, the role of endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of periampullary lesions has become limited (Fig. 7). The

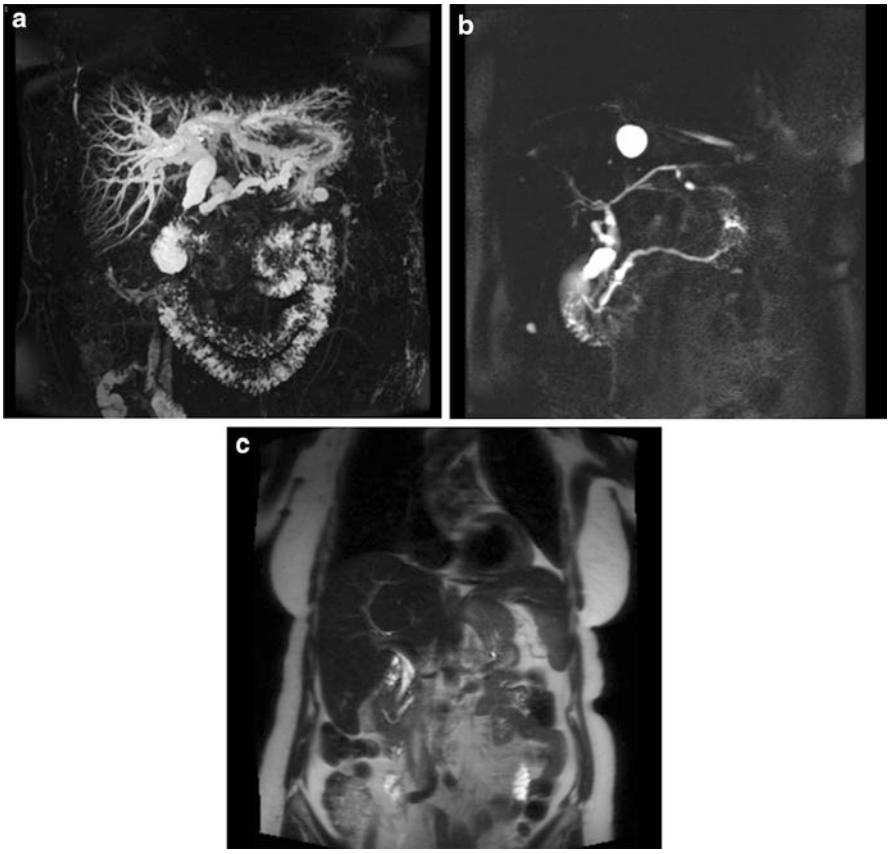

Fig. 7 (**a**) Magnetic resonance cholangiopancreaticogram (*MRCP*) showing an ampullary carcinoma obstructing the distal common bile duct, (**b**) MRCP with distal common bile duct carcinoma. Note the normal appearance of the main pancreatic duct, indicating a bile duct origin for the tumor, and (**c**) MRCP of a pancreatic carcinoma, with partial obstruction of both the main pancreatic duct and the common bile duct ("double-duct" sign)

Fig. 8 Endoscopic photo of biliary stent placed through an obstructing ampullary carcinoma

most common current indication for ERCP in patients with periampullary tumors is for placement of a temporary stent in the common bile duct to relieve biliary obstruction preoperatively or as palliation (Fig. 8). Although stent placement will lead to colonization of the biliary tree and a higher perioperative infection rate in resected patients, it is appropriate in a number of clinical circumstances: (1) patients who present with symptoms of cholangitis requiring immediate intervention to treat the biliary infection, (2) patients presenting with intractable pruritus that can be relieved during the period of preoperative evaluation, and (3) patients with hyperbilirubinemia associated with renal insufficiency, which will correct with relief of the biliary obstruction. Under these circumstances, at least 2–3 weeks should be allowed prior to definitive resection to allow the metabolic derangements to normalize and to ensure the absence of active infection after instrumentation. Endoscopic stenting can provide relief of jaundice in patients in whom delay in surgery may be necessary to allow referral to a high-volume institution or for planned neoadjuvant therapy.

A final role for ERCP is to provide a tissue diagnosis of malignancy by either histology or cytology through direct brushings. A tissue diagnosis is valuable primarily for isolated bile duct strictures in clinical settings in which a benign etiology of the stricture would alter management (resection vs. stenting or bypass). In selected cases, Spyglass technology, essentially a smaller scope inserted the working channel of a standard ERCP scope, can allow directed visualization of the stricture for biopsy [49].

Percutaneous Transhepatic Cholangiography

As with ERCP, percutaneous transhepatic cholangiography (PTC) for diagnosis of a periampullary malignancy is seldom indicated due to the availability of noninvasive techniques. It does remain a therapeutic option in some patients, particularly when the endoscopic route is unsuccessful due to complete obstruction of the ampulla by tumor or the ampulla is not accessible due to a prior surgical procedure such as gastric bypass. PTC is often technically easier with a dilated biliary tree and is useful in defining the proximal biliary system, which is critical in the decision-making process concerning biliary reconstruction. Percutaneously placed catheters can be helpful during operative management for either resection or palliation, especially in reoperative cases or in the early postoperative period to allow biliary decompression in order to protect the biliary anastomosis. In most patients, however, PTC offers little advantage over ERCP, has a greater morbidity, and should be considered only if ERCP is technically not possible.

Preoperative Staging

The goal of preoperative staging is to determine which tumors are potentially resectable and have not already metastasized to distant sites or directly invaded the major peripancreatic vessels. This is more important in patients with pancreatic periampullary neoplasms because of the lower rate of resectability in this group. In the past, laparotomy was required in all patients to establish the diagnosis and, thereafter, resection or operative palliation was performed. Today, modalities including dual-phase CT, EUS, and diagnostic laparoscopy allow us to clinically stage patients preoperatively. The dynamic spiral CT scan is currently the most valuable of these studies, playing a role in both diagnosis and staging of periampullary neoplasms. Its primary advantages are the lower cost and noninvasive nature of the technique. Computed tomography can detect liver metastases (>1.0 cm) or larger peritoneal implants [34]. EUS has high accuracy for evaluating T stage and defining malignancy by demonstrating invasion. The technique can also be used to perform an FNA for histologic evaluation of suspicious lymph nodes. However, EUS cannot be used as the sole modality for staging. Given its inability to adequately rule out peritoneal or hepatic metastases, it should be combined with CT or laparoscopy for complete staging.

One of the limitations of CT is its poor sensitivity for detecting lesions in the liver, omentum, or peritoneal surface that are less than 1 cm in size. In an attempt to identify such metastases in a minimally invasive manner, laparoscopy has been suggested as a method for further staging. A recently published Cochrane review of 16 studies and a total of 1,146 patients with pancreatic or periampullary cancer suggests that the addition of diagnostic laparoscopy decreases the rate of unnecessary laparotomy in those patients deemed resectable on CT scan by 20% [50]. However, this review includes studies with dates ranging from 1986 to 2014, and CT has become more effective at picking up suspicious small volume metastases with

dual-phase imaging. Furthermore, the yield of diagnostic laparoscopy is likely lower for patients with ampullary and duodenal tumors than those with pancreatic cancer, leading many surgeon to avoid this step in patients with these tumors [51, 52].

The decision to stage patients with periampullary neoplasms via laparoscopy is largely dependent on the treatment algorithms of the surgeon. Those surgeons favoring surgical palliation as opposed to nonoperative palliation of unresectable tumors consider laparoscopy unnecessary. Whereas those surgeons who feel endoscopic palliation is adequate for most patients suggest that laparoscopy can save a substantial number of patients from the morbidity of a noncurative laparotomy. Those centers currently investigating neoadjuvant chemotherapeutic and radiation protocols also feel that laparoscopy is important in order to document the absence of liver or peritoneal metastases. Improvements in preoperative imaging and the addition of EUS to our clinical armamentarium has allowed for better selection of patients for operation with fewer patients being found to be unresectable at the time of operation, thereby minimizing unnecessary morbidity. Nonoperative techniques for the management of obstructive jaundice secondary to a periampullary tumor have also improved and can provide adequate palliation for most patients with unresectable neoplasms. However, as mentioned, patients with nonpancreatic periampullary neoplasms typically present earlier in the progression of their disease and have a much higher rate of resectability, thus in many cases preoperative staging with the currently available imaging modalities is sufficient.

Surgical Management

Endoscopic Resection

Benign periampullary tumors and small, ampullary tubular adenomas with very low malignant potential may be endoscopically resected. Small, pedunculated adenomas of the distal common bile duct can also be successfully treated and excised endoscopically. For tubular duodenal and Brunner gland adenomas, endoscopic excision is the most suitable option. With villous duodenal adenomas, transduodenal local excision should be considered depending on the size of the lesion. Endoscopic resection of a villous adenoma may be performed only if the entire lesion can be safely removed (Fig. 9). Close follow-up with repeat endoscopy is indicated in such cases, as recurrence rates can be seen in 10–25% of cases [53]. Finally, it is reasonable to consider endoscopic resection as a palliative option with patients that cannot tolerate general anesthesia to perform even a local excision for periampullary cancers.

Complications following endoscopic resection of ampullary tumors includes pancreatitis (5–15%), bleeding (4–15%), perforation (<2%), and cholangitis (<2%). Mortality, however, remains very uncommon.

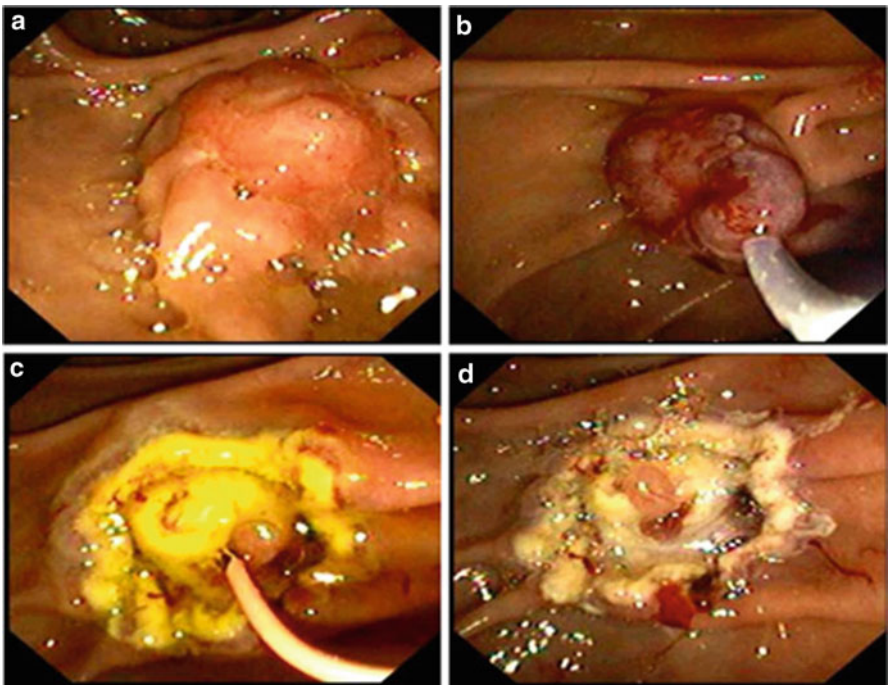

Fig. 9 (**a**) Endoscopic appearance of a benign periampullary adenoma, (**b** and **c**) endoscopic cautery excision of lesion, and (**d**) final appearance after complete endoscopic excision

Local Excision

Local resection of an ampullary tumor with reimplantation of the pancreatic and common bile ducts was first described by Halsted in 1899. Initially, this procedure was associated with high operative mortality and low long-term survival; however, with improvements in technique and preoperative staging, transduodenal ampullary resection has regained popularity. Local resection of the ampulla of Vater has been suggested for benign ampullary tumors or low grade ampullary carcinomas. Histologic confirmation of malignancy, large size, or extension into the common bile duct or pancreatic duct precludes local excision. Furthermore, the false negative rate of endoscopic biopsy (up to 25%) or even intraoperative frozen section (up to 14%) requires that complete histologic diagnosis of the entire resected specimen be completed [37, 46]. If invasive cancer is found in permanent sections, subsequent resection with pancreaticoduodenectomy is necessary.

The operation begins with an exploration of the abdomen through a right subcostal or upper midline incision to rule out metastatic disease. An extended Kocher maneuver is performed to mobilize the duodenum. A longitudinal duodenotomy is made over the junction of the second and third portions of the duodenum. Stay sutures are placed to expose the ampullary lesion, and the common bile duct is

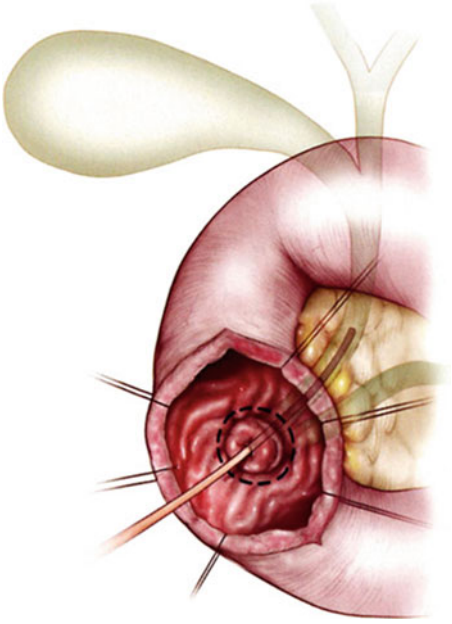

Fig. 10 The ampulla is exposed via a longitudinal duodenotomy, and the common bile duct is cannulated (Reprinted from Clary et al. [54])

cannulated through the center of the mass. If the common bile duct cannot be directly entered, passage of a biliary Fogarty catheter from above via cannulation through the cystic duct following cholecystectomy is advisable. Next, a resection margin of 0.5–1.0 cm of normal tissue is created by scoring the mucosal surface with electrocautery (Fig. 10). The lesion is excised by dissecting lateral to medial in the submucosal plane. In this approach, the common bile duct located at 11 o' clock, is transected prior to the pancreatic duct and located at 5 o' clock. The specimen is sent to pathology for frozen-section analysis. If a negative margin is not accomplished or an invasive component is identified, then a pancreaticoduodenectomy should be performed. In a series of 39 patients undergoing ampullectomy at Duke University Medical Center, the negative predictive values of frozen-section analysis was 94% [29]. If the lesion is benign and negative margins are achieved, then the common channel between the common bile duct and pancreatic duct is reconstructed by dividing the intervening septum with scissors. Next, the circumferential anastomosis between the duodenal mucosa to the common channel is performed with 5-0 Vicryl interrupted sutures. Lastly, the duodenum is closed transversely in two layers.

Recurrence rates after local excision in patients with sporadic adenomas are 0–26% [28–30, 54, 55]. Significantly, increased rates of recurrences are seen in patients with polyposis syndromes and approximately 25% of all recurrences are invasive carcinomas [30]. This highlights the importance of surveillance endoscopy following ampullectomy. Most series demonstrated complication rates of 20–25% which included delayed gastric emptying, duodenal leak, pancreatitis, cholangitis, and common bile duct stricture.

Pancreaticoduodenectomy

Since its introduction by Whipple et al. in 1935, pancreaticoduodenectomy has been the most effective treatment for periampullary carcinomas [56]. Either classic or pylorus-preserving pancreaticodenectomy is appropriate for most periampullary cancers, with the exception of patients with extensive duodenal polyposis associated with FAP. In such cases all duodenal mucosa should be removed, and therefore the total duodenectomy approach of the classic resection is appropriate. A prospective randomized study by Yeo and colleagues, showed no advantage to an extended retroperitoneal lymphadenectomy when performing a pancreaticoduodenectomy for periampullary adenocarcinomas including ampullary and distal common bile duct primaries [57].

Perioperative morbidity and mortality rates have continued to improve over the past decade with mortality rates of 2% or less and morbidity rates of 30–40% expected in patients treated at high volume centers [58–60]. One of the complications of pancreaticoduodenectomy that may be slightly increased in nonpancreatic tumors is the rate of pancreatic anastomotic leak due to the normal, soft texture of the pancreas. On the other hand, since local vascular invasion by periampullary nonpancreatic tumors is uncommon, the procedures are often technically easier.

To date, no study has directly compared local ampullary resection with pancreaticoduodenectomy for small ampullary cancers. There are several series including subsets of patients with T1 lesions for whom local resection was performed, usually in high-risk patients that were poor candidates for the more radical resection [28, 31, 61, 62]. Although these subsets are not prospectively randomized, patients that underwent pancreaticoduodenectomy for T1 tumors generally experienced both higher disease-free and overall survival rates [27, 28, 63, 64]. As a result, local excision is only acceptable for patients with small ampullary cancers that are unable to tolerate a pancreaticoduodenectomy. Refer to the clinical algorithm in Figure 11 for the evaluation and management of periampullary tumors (Fig. 11).

Segmental Resection

Surgery options for duodenal adenocarcinomas include segmental resection and pancreaticoduodenectomy. For lesions involving the proximal first and second portions of the duodenum, the treatment of choice is a Whipple procedure. Patients with more distal tumors involving the third and fourth portions of the duodenum, an en bloc segmental resection of the distal duodenum and proximal jejunum with lymphadenectomy is appropriate. Past studies have demonstrated that pancreaticoduodenectomy has an improved disease free interval and overall survival compared to segmental resections. This difference was most likely due to the earlier detection of periampullary duodenal adenocarcinomas than more distal tumors. More recent research suggests that although radical resection with pancreatiocduodenectomy is associated with a greater number of lymph nodes sampled, the overall survival is the same as with segmental resection [65, 66].

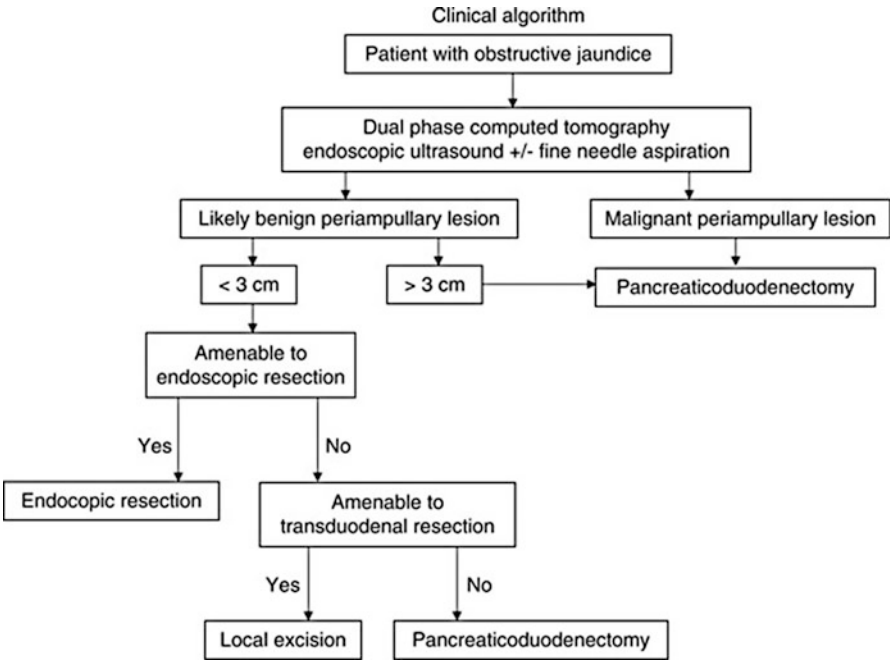

Fig. 11 Clinical algorithm for the evaluation and management of a periampullary lesion. Note: If invasive carcinoma discovered on endoscopic or local resection, proceed with pancreaticoduodenectomy

Palliative Procedures

In patients with unresectable or metastatic disease found at exploration, palliative operative gastric or biliary bypass should be strongly considered and performed especially if patient is symptomatic. For those with recurrent disease or known metastatic disease prior to exploration, palliative biliary stents and duodenal wall stents placed endoscopically may be the most appropriate local therapy to relieve symptoms and avoid delaying any additional systemic therapies being considered. In patients with bulky bleeding tumors, gastrojejunostomy (potentially performed laparoscopically), and radiation therapy can usually control symptoms.

Adjuvant and Neoadjuvant Therapy

The use of adjuvant and neoadjuvant therapies for nonpancreatic periampullary cancers has been reported. Due to the rarity of these lesions, most series remain low-powered and nonrandomized. Nevertheless, the use of neoadjuvant strategies for treatment of periampullary malignancies is becoming more popular. These approaches are mostly observed with pancreatic adenocarcinoma as very little

published data exists at this point regarding nonpancreatic periampullary primaries. The theoretical advantages include the delivery of a systemic therapy to well-oxygenated tissues, and the potential for down-staging unresectable and borderline resectable lesions. In multiple series, neoadjuvant chemoradiation did not increase the mortality or morbidity of pancreaticoduodenectomy for periampullary cancers, and interestingly yielded fewer pancreatic leaks and leak-associated morbidity and mortality compared to those not receiving neoadjuvant therapy [67, 68]. Critics of neoadjuvant protocols for potentially resectable periampullary cancers point to selection biases based on favorable biology in those that proceed on to resection following chemoradiation treatment.

The role of adjuvant therapy in ampullary cancer has been assessed in numerous small studies. In a series from Stanford, 12 patients with resected ampullary cancers having lymph node metastases, positive margins, tumor size >2 cm, poorly differentiated, or neurovascular invasion were given adjuvant chemoradiation resulting in an 89% actuarial 1-year survival [69]. In another series from Johns Hopkins, 17 of 106 patients with a resected ampullary cancer received adjuvant therapies without any survival benefit [26]. In the European Organization for Research and Treatment of Cancer (EORTC) Trial 40,891, there was no benefit of adjuvant chemoradiation over observation for nonpancreatic periampullary malignancies [70]. Finally, a recent meta-analysis of ten retrospective studies, including 3,361 patients, has demonstrated adjuvant chemoradiation therapy improved overall survival [71]. Due to these mixed results, chemotherapy with regimens similar to those used for colon cancer rather than the more aggressive chemoradiation protocols.

Adjuvant therapies for cholangiocarcinoma are also not well defined. A Japanese randomized, multi-institutional trial of 139 patients with bile duct cancer showed no difference in 5-year survival for patients receiving adjuvant chemotherapy [72]. In contrast, there is some data to support its use from a recent retrospective study. A Johns Hopkins study from 1994 to 2003, treated 34 patients with distal bile duct adenocarcinomas with pancreaticoduodenectomy followed by adjuvant chemoradiation and compared with historical controls from the same institution. For both lymph node positive and negative patients, overall survival was improved in patients that received surgery plus adjuvant chemoradiation [73]. There are a few prospective, randomized trials ongoing to determine the role of adjuvant chemoradiation for biliary tract cancer [74].

Due to the relatively rare incidence of primary duodenal adenocarcinomas, current data regarding its utility has not been able to identify a role for adjuvant therapy. The group at Johns Hopkins published a small retrospective series of 14 patients with stage III/IV periampullary adenocarcinoma of the duodenum that were treated with pancreaticoduodenectomy and adjuvant chemoradiotherapy. Comparing their results with historic controls, there was no difference in overall 5-year survival between surgery plus adjuvant chemoradiation versus surgery alone [75]. Despite the lack of data to justify adjuvant therapies for primary duodenal adenocarcinoma at this time, most medical oncologists would recommend its use for advanced stage disease.

Finally, the European Study Group for Pancreatic Cancer (ESPAC) – 3 trial was reported in 2012 [76]. This open-label phase 3 randomized controlled trial involving 100 centers included 428 patients with resected nonpancreatic periampullary cancers and compared adjuvant therapy via multiple regimens with observation. The results were mixed with adjuvant chemotherapy not showing significant survival benefit over observation (43.1 months vs. 35.2 months). However, multivariable analysis adjusted for prognostic variables did show significant survival benefit with adjuvant chemotherapy.

Survival

Overall, the survival following surgical resection for nonpancreatic periampullary cancers are substantially better than periampullary pancreatic cancer (Fig. 12). In the series from Johns Hopkins, duodenal and ampullary cancers demonstrate the 5-year survival rates of 51–59 and 37–39%, respectively [2, 77]. In the same series, distal cholangiocarcinomas and pancreatic cancers have the lowest 5-year survival rates, at 23–27 and 15–17%, respectively. In the Memorial Sloan Kettering experience, ampullary carcinomas had the highest overall survival rates (median 43.6 months) and resectability (82.1%) for periampullary tumors [64]. Beger et al. reviewed 171 cases of consecutive ampullary cancer treated by local or radical resection. The 5-year survival rates by stage in that series were 84% (stage I), 70% (stage II), and 27% (stage III) and 0% (stage IV) [28]. Poor prognostic indicators for recurrence

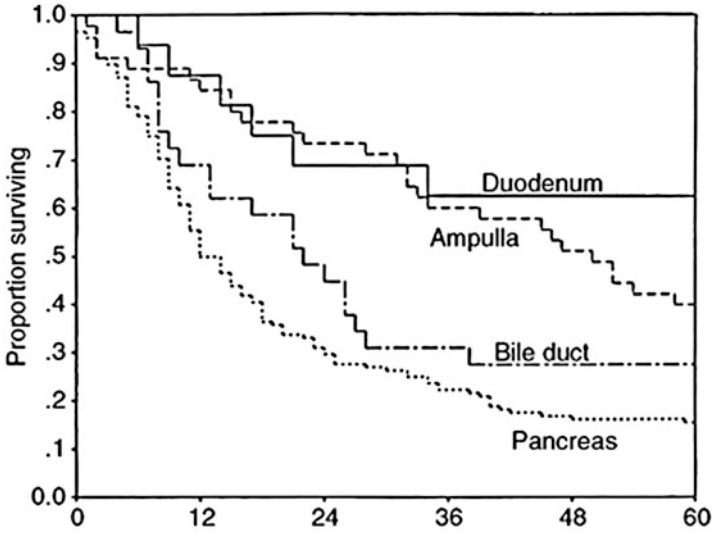

Fig. 12 The tumor-specific actual 5-year survival curves for the cohort of 242 patients treated by pancreaticoduodenectomy for periampullary adenocarcinoma (Reprinted from [77])

after resection of ampullary adenocarcinoma are advanced T stage, lymph node involvement, positive margins, neural invasion, and poor differentiation [26, 27, 63, 64]. The two most important factors commonly found among different series are T stage and nodal status, where the rate of lymph node involvement is a reflection of the T stage progression. For T1–T2 and T3–T4 tumors the percent of lymph node positivity is approximately 20 and 50%, respectively [28]. However, as previously stated, there is no advantage to an extended retroperitoneal lymphadenectomy when performing a pancreaticoduodenectomy for any periampullary adenocarcinoma [57].

With complete resection of distal cholangiocarcinoma, 5-year survivals range from 21% to 54% [78–80]. Resection rates are generally between 40% and 85%. In the series from DeOliveira et al., reviewing 564 patients with bile duct cancer undergoing surgery, the 239 patients with distal cholangiocarcinoma had an overall 5-year survival for all patients and those after R0 resection were 23 and 27%, respectively. The significant predictors of survival for patients with distal cholangiocarcinoma included negative margins, lymph node involvement, size >2 cm, and degree of differentiation [81]. The Japanese have compiled their extensive experience of distal cholangiocarcinomas into a national registry demonstrating a similar 5-year survival of 26% [82].

The most significant predictors of long-term survival for primary duodenal carcinoma include margin negative resection and lymph node involvement. For node-negative patients, overall 5-year survival following resection varies from 38% to 83%. For node-positive patients, the 5-year survival drops to 15–56%. In a 2000 series from the Mayo Clinic of 101 consecutive patients undergoing surgery for adenocarcinoma of the duodenum, lymph node involvement, stage III or greater, positive margin, and weight loss each carried a significantly negative impact on survival [83]. In the same series, the tumor grade, size, and location within the duodenum had no impact on survival (5-year survival, 54%). In the Memorial series, the survival benefit between node-positive (5-year survival, 56%) and node-negative (5-year survival, 83%) tumors demonstrated in patients with ≥ 15 nodes sampled did not carry a similar positive prognostic impact on survival when <15 lymph nodes were sampled [84]. The Hopkins group published their retrospective experience of 55 patients surgically treated primary adenocarcinoma of the duodenum [85]. Similar to other series, the 5-year survival was 53%. In this series, negative margins, pancreaticoduodenectomy, and tumors involving the first and second portions of the duodenum were favorable predictors of long-term survival. Nodal status, tumor diameter and grade did not influence survival in this study.

Conclusion

Nonendocrine, nonpancreatic periampullary tumors are rare lesions that encompass a large array of pathology, originating most commonly from the ampulla of Vater, distal common bile duct, and duodenum. These tumors are often asymptomatic and have a tendency to be malignant. Treatment options depend on size and malignant potential, ranging from endoscopic resection to pancreaticoduodenectomy. Further

research is required both to better understand the molecular biology of periampullary tumors and the role of perioperative chemotherapy.

Key Practice Points

- Nonpancreatic periampullary malignancies originate from the distal common bile duct, ampulla of Vater, and duodenum.
- Clinical findings of biliary obstruction require cross-sectional imaging and evaluation of the biliary system to exclude periampullary malignancies.
- Patients with familial syndromes (FAP, Gardner's syndrome, inflammatory bowel disease) must undergo close surveillance for periampullary cancers.
- Preoperative staging with CT and endoscopic ultrasound are the most cost-effective diagnostic strategies for determining resectability.
- In general, due to the higher rate of resectability of nonpancreatic periampullary neoplasms, preoperative staging and laparoscopic exploration are less important than pancreatic primary tumors.
- Small, benign periampullary lesions may undergo endoscopic resection.
- Transduodenal resection should be considered for small (<3 cm) ampullary tumors or low grade ampullary malignancies in patients unable to tolerate a pancreaticoduodenectomy.
- For large periampullary lesions (>3 cm) and invasive periampullary malignancies, pancreaticoduodenectomy remains the standard treatment.
- Adjuvant and neoadjuvant treatments for nonpancreatic periampullary tumors have been investigated; however, no clear survival benefit has been identified.
- Actual 5-year survival rates following surgical resection for nonpancreatic periampullary cancers as 51% for duodenal cancer, 37% for ampullary cancer, and 23% for distal common bile duct cancer.
- Poor prognostic indicators for ampullary adenocarcinoma include advanced T stage, lymph node involvement, positive margins, neural invasion, and poor differentiation.
- Significant predictors of survival for distal cholangiocarcinoma include negative margins, lymph node involvement, size >2 cm, and degree of differentiation.
- Significant predictors of survival for duodenal carcinoma include margin negative resection and lymph node involvement.

Future Research Directions

- Translational investigations to better understand the molecular biology of periampullary tumors to improve early detection and targeted therapies.
- Technologic advances to improve local endoscopic diagnosis, staging, and management.
- Multi-institutional clinical trials to investigate adjuvant and neoadjuvant therapies for resectable periampullary cancers.

Abstract

Inflammatory diseases are the most common conditions of the exocrine pancreas. Chronic pancreatitis is often the result of recurrent bouts of acute pancreatitis and is a risk factor for pancreatic cancer. There has been a long interest in modeling the pathophysiological relationship between chronic pancreatitis and cancer and the recent development of genetic mouse models of pancreatic diseases has accelerated the discovery of mechanistic insights. The current paradigm proposes that the inability of normal pancreatic cells to recover from injury establishes a biological landscape that promotes cancer development. Multiple types of mechanisms concur in this process, in which both epithelial and nonepithelial cells participate, leading to persistent inability of epithelial cells to restore their differentiation programs. Developmental pathways involved in pancreatic differentiation are subverted to maintain cellular phenotypes that promote signaling from mutant KRAS, preneoplasia, and neoplasia. Downstream from KRAS, and in parallel with it, tyrosine kinase receptors, the MAPK, PI3K, NF-KB, and STAT pathways, and the mechanisms that control senescence and autophagy, contribute to the emergence of transformed clones. These signaling pathways, whose activity is modulated through complex cross-talks between epithelial, mesenchymal, and inflammatory cells, play crucial roles in the pancreatitis-to-cancer progression and provide opportunities for intervention in high-risk patients.

Keywords

Pancreatitis · Pancreatic cancer · Caerulein · Acino-ductal metaplasia

List of Abbreviations

ADM	Acinar-to-ductal metaplasia
AP	Acute pancreatitis
CCK	Cholecystokinin
CCKR	CCK receptor
CDE	Choline-deficient, ethionine-supplemented diet
CFTR	Cystic fibrosis transmembrane conductance regulator
CP	Chronic pancreatitis
ECM	Extracellular matrix
EGF	Epidermal growth factor
ER	Endoplasmic reticulum
EUS-FNA	Endoscopic ultrasound-guided fine needle aspiration
GEMM	Genetically engineered mouse models
IPMN	Intraductal papillary mucinous neoplasm
JAK	Janus-activated kinase
LPS	Lipopolysaccharide
PanIN	Pancreatic intraepithelial neoplasia
PDAC	Pancreatic ductal adenocarcinoma
PDL	Pancreatic duct ligation
PSC	Pancreatic stellate cells

TGF-β	Transforming growth factor beta
TNF-α	Tumor necrosis factor alpha
WT	Wild type

Introduction

Acute and chronic pancreatitis are the main inflammatory disease of the pancreas. Current thoughts support the existence of a continuum whereby a relatively low proportion of patients who develop a first episode of acute pancreatitis go on to develop recurrent bouts of the disease that eventually lead to persistent unrepaired damage. Chronic pancreatitis (CP) has been recently defined as "a progressive inflammatory disease, which leads to loss of pancreatic function and other disease-associated morbidities" [1]. Chronic pancreatitis is a well-established risk factor for the development of pancreatic ductal adenocarcinoma (PDAC) [2], providing a strong argument supporting the role of damage/regeneration cycle and inflammation in tumor development. Recent evidence also supports that it is a risk factor for intraductal papillary mucinous neoplasms (IPMNs) [3]. The increase in risk is much higher for patients with hereditary chronic pancreatitis, caused by mutations in genes involved in the regulation of trypsin activation (up to 70-fold) [4]. However, such cases are very rare. The fold-increase risk of developing PDAC in patients with "sporadic" CP is almost one order of magnitude lower [2]. This explains that only a fraction of patients with PDAC have a history of pancreatitis.

Modeling the role of pancreatitis in PDAC progression should be a bidirectional endeavor, whereby the knowledge acquired through studies with patients is tested in mice and the experimental studies should lead to novel hypotheses whose significance can be again tested in the context of the human disease.

Some of the main questions regarding the relationship between pancreatitis and PDAC are: (1) Does chronic inflammation cause mutations that contribute to PDAC? (2) Does pancreatitis act as a tumor-promoting event (i.e., through inflammation, oxidative stress, or genomic instability)? and (3) In which cells do the mutations that cause human PDAC arise? A fact that complicates some of these analyses is that PDAC itself can lead to a chronic pancreatitis-like lesion through duct obstruction, a situation that should be clearly distinguished from primary CP.

Animal Modeling of Pancreatitis

The anatomical location of the pancreas and the difficulties in obtaining tissue samples from patients, especially during the early stages of the disease, has underscored the need to develop animal models of pancreatitis. Currently, much of our understanding of the pathogenesis of acute and chronic pancreatitis comes from animal models. It is, however, important to remark that most of the experimental approaches used do not fully recapitulate the human disease, and the limitations of each of them need to be carefully considered. The very first experiments were

performed in 1856 by the physiologist Claude Bernard. Since then, many species have been used to model pancreatitis, including mice, rats, rabbits, cats, dogs, pigs, and opossum; however, rodents are most commonly used and standardized protocols have been established.

A first important consideration is that the human pancreas shows significant anatomical differences with respect to the pancreas of other species. The human pancreatic and bile ducts are separate and normally form a very short common channel in the duodenal wall, at the hepatopancreatic ampulla (ampulla of Vater), while in rodents, the two ducts fuse before they enter the duodenum, forming a long common duct that transports both bile and pancreatic juice. In the opossum, the bile and pancreatic ducts merge early and a long common duct drains into the duodenum.

Similar methods are used to induce experimental acute and chronic pancreatitis but, for the sake of clarity, they will be described separately.

Models of Acute Pancreatitis

In humans, approximately 80% of acute pancreatitis (AP) cases are related to either duct obstruction or ethanol abuse. However, only less than 10% of patients with gallstones or alcohol drinkers will develop pancreatitis [5]. Whether this reflects the contribution of additional factors or the severity of the primary cause is not well known. The complex etiology of acute pancreatitis has represented a challenge for the development of reliable animal models.

Animal models of AP can be classified based on the underlying strategy to mimic human disease etiology and pathophysiology: some of them aim at reproducing the putative triggering event (gallstone-dependent obstruction of the pancreatic duct, or excessive alcohol consumption), while others mimic the downstream biological processes (premature activation of pancreatic enzymes). Table 1 summarizes the characteristics of the main models used.

Obstructive Models

Mechanical approaches to mimic gallstone pancreatitis are largely based on the "common channel" theory proposed by Opie in 1901, whereby the presence of a stone in the ampulla of Vater would create a communication between the main pancreatic duct and the common bile duct, thus causing the retrograde reflux of bile in the former. Although many observations suggest that this theory is inaccurate, multiple models have been developed and are still used, which re-create the pancreatic duct obstruction, alone or in combination with bile reflux. These models include the closed duodenal loop, pancreatic duct ligation, and retrograde ductal infusion. All three techniques require surgery, involving anesthesia, and therefore necessitate skilled operators.

The **closed duodenal loop** protocol was first described in dogs [57] and consists of placing two ligatures upstream and downstream of the site of entry of the common bile duct and causing duodenal obstruction. This results in the reflux of the duodenal content into the biliopancreatic duct, which leads to AP. Because the procedure is

Table 1 List of the most common animal models used to study acute and chronic pancreatitis

Models of acute pancreatitis			
Type	Model	Species (most used)	References
Obstructive	Closed duodenal loop	Rat, dog	[6, 7]
	Duct ligation (pancreatic or biliary duct)	Rat, mouse, dog, rabbit, opossum	[8–11]
	Retrograde infusion	Rat, mouse, rabbit, dog	[12–15]
Nonobstructive	Caerulein administration	Mouse, rat	[16–23]
	Basic amino acids	Rat, mouse, rabbit	[24–27]
	Choline-deficient (CDE) diet	Mouse, hamster, cat, dog, monkey	[28]
	Alcohol administration	Rat, mouse, dog, cat	[29–32]
Models of chronic pancreatitis			
Type	Model	Species (most used)	References
Mechanical	Pancreatic duct ligation	Rat, mouse, dog	[33–35]
Chemical	Repeated caerulein administration	Mouse, rat	[36–44]
	Repeated L-arginin administration	Rat	[45]
	Prolonged CDE diet	Mouse	[46]
	Prolonged alcohol administration (combined with other triggers)	Rat, mouse	[47–51]
Genetic	*Cftr* inactivation	Mouse, pig	[52, 53]
	PRSS1 R122H mutant overexpression	Mouse	[54, 55]
	Spink3 inactivation	Mouse	[56]

difficult to standardize, there is wide variability in disease severity. This protocol has been adapted for rats [6], with the concomitant injection of either infected bile or combinations of bile salts and digestive enzymes, to increase damage. Infections are a major complication of this protocol, which is currently rarely used.

Duct ligation has been used in various species, including mice, rats, dogs, rabbits, and opossums. Ligation of the pancreatic duct alone is not sufficient to induce severe AP, with the interesting exception of the opossum, where the pancreatic and the biliary ducts merge early into a common duct, thus recreating the situation hypothesized by Opie in the common channel theory mentioned above [7]. Unfortunately, the opossum is not a particularly convenient species for experimentation, as animals need to be collected from the wilderness and there is a very high interindividual variation. Ligation of the common biliopancreatic duct leads to pancreatitis in rats [8], with multiple organ effects resembling the human disease. In mice and rats, bile duct ligation has been combined with bile infusion, or with stimulation of pancreatic secretion, in order to induce severe necrotizing pancreatitis [9, 10]. In addition to requiring surgical skills and to the variability associated with each individual procedure, other complications (e.g., peritoneal sepsis, duodenal wall necrosis) hamper the use of these models.

Retrograde infusion of bile acids, enterokinase, trypsin, or other digestive enzymes, into the pancreatic duct via the ampulla of Vater has also been used in

multiple species. The severity of the disease depends on the pharmacological agent administered, its concentration, volume, as well as on the pressure used for the infusion. Major limitations of this approach are the interindividual variability and the significant severity and mortality. The most common protocol consists of administering sodium taurocholate, a bile salt, into the pancreas of rats [11], and it has been adapted for rabbits, dogs, and, more recently, for mice [12]. In this procedure, a cannula is inserted in the pancreatic duct while the bile duct is clamped, to avoid that taurocholate reaches the liver. Taurocholate is infused through the cannula, which is then removed to allow the normal flow of bile and pancreatic juice. Immediately after infusion, hemorrhagic necrosis can be observed in the surrounding pancreatic parenchyma, which led to the hypothesis that taurocholate induces pancreatitis merely through its detergent activity. Nowadays it is known that multiple receptors are activated in response to taurocholate infusion, indicating broader mechanisms of action. In mice, administration of sodium taurocholate (50 μl of 2%) leads to hyperamylasemia at 24 h, as well as tissue edema and infiltration by neutrophils [12]. Higher concentrations of taurocholate cause more severe pancreatitis, with a 60% mortality rate at the highest dose used (5%), which is accompanied by systemic inflammation [13]. Notably, the ductal retrograde infusion method generally induces a severe hemorrhagic AP, which can even be lethal.

Nonobstructive Models

Caerulein is by far the most commonly used pharmacological agent to induce experimental AP. Caerulein is a peptide analog of the gastrointestinal hormone cholecystokinin (CKK), which was originally extracted from the skin of the Australian green tree frog (*Litoria caerulea*). There are two types of CCK receptors, CCK1R (alimentary, also known as CCK-A) and CCK2R (brain, also known as CCK-B), with species-specific cell and tissue distribution [14]. CCKR belong to the family of G protein-coupled membrane receptors and therefore signal through the activation of multiple downstream pathways including phospholipase C, phosphoinostide 3 kinase, and MAP kinase. The CCK1R receptor binds preferentially the sulfated form of CCK, while CCK2R can bind either sulfated or non-sulfated CCK, as well as gastrin, with similar affinity [15]. CCK1R is the major receptor responsible for CCK-induced secretion of pancreatic enzymes [16]. The expression, localization, and function of CCK1R and CCK2R in the human pancreas are still under investigation. There is no conclusive evidence that human acinar cells display a functional response to CCK or gastrin or that they express CCKR [58]. There are substantial differences in receptor expression among species, as well as controversy on their function.

In rodents, physiological plasma levels of CCK (or caerulein) bind to the high-affinity receptors and evoke production and secretion of pancreatic enzymes. Supramaximal concentrations of either CCK or caerulein engage the low-affinity receptors, which block exocytosis [14]. This causes the accumulation and abnormal subcellular distribution of the digestive proenzymes, mainly trypsinogen, with premature fusion of zymogen granules with lysosomes, leading to their activation within the acinar cells. Cathepsin B has been proposed to play a key role in this

process [59]. The consequence is tissue damage, due to an autodigestive process, followed by edema and inflammatory cell infiltration, thus recapitulating a mild, transient, and self-limiting acute pancreatitis.

Caerulein-induced AP has been extensively used in mice and rats, with multiple protocol variants. In rats, caerulein is typically administered intravenously (i.v.) either as a bolus or by continuous i.v. infusion. In mice, intraperitoneal (i.p.) administration has been preferred, usually through multiple (4–12) hourly injections. A very common protocol to induce a mild edematous AP with caerulein in mice includes 7-hourly administration of the drug at 50 μg/kg [60]. However, in recent years, a wider variety of protocols has been applied, mainly in combination with genetically engineered mouse models (GEMMs) of pancreatic disease. A common variant implies the administration of two rounds of 6–7 hourly doses, either on two consecutive days or on days 1 and 3 [17]. As described below, it is important to distinguish between the 1-day and 2-day protocols because they generate significantly different extents of tissue damage, followed by tissue remodeling and regeneration, and they might even engage distinct cellular/molecular processes [18]. Molecular signaling events activated by caerulein are induced as early as 30–60 min after the first injection. These include the activation of the MAPK cascade, activation of the PI3K pathway, and the consequent induction of NF-κB, as well as the Stat3 pathway. Thereafter, the single-day protocol causes extensive edema, infiltration by inflammatory cells, and acinar cell vacuolization and collapse, with a peak around 24 h from the first injection and full recovery by day 7. The 2-day protocol, particularly on consecutive days, results in extensive loss of the acinar cell compartment, caused by massive cell dedifferentiation and tissue remodeling through a transient acinar-to-ductal metaplasia (ADM), whereby acinar cells rapidly lose the expression of acinar markers and ectopically express markers of the ductal lineage (see also Sect. 5.1 below) [18, 19, 60]. The 2 consecutive-day protocol has a low lethality rate and animals that survive treatment display complete recovery within 7–14 days, similar to the 1-day protocol.

In most of the experiments described above, pancreatitis was induced in young mice (around 1.5–2 months). Interestingly, Okamura et al. have shown that the multidose 1-day caerulein acute pancreatitis is significantly more severe in older (23–25 months) mice, as evidenced by increased plasma amylase and Il-6 levels at 12–24 h, higher neutrophil infiltration, and more severe extrapancreatic tissue damage, including evidence for disseminated intravascular clotting and extensive fibrin deposition in the lung and kidney of old mice [20].

Caerulein-induced AP models have several advantages, as they are simple, reproducible, inexpensive, and noninvasive. They can also be paralleled with ex-vivo studies using primary acinar cell cultures, which are extremely useful to acquire mechanistic insights. However, their relevance to the human disease has been questioned. Although Mouret reported already in 1895 that excessive cholinergic stimulation produced vacuolization and necrosis of pancreatic acinar cells in dogs, and proposed that activation of trypsin could be involved in the process, the supramaximal stimulation of the human pancreas has been reported only very rarely. Pancreatitis was reported in patients after intoxication with anticholinesterase-

containing insecticides and after exposure to the acetylcholine-inducing scorpion venom. In all these cases, excessive amounts of acetylcholine are released by pancreatic nerves, resulting in hyperstimulation of enzyme secretion, often leading to uncontrolled and premature activation of the digestive enzymes within the tissue. Furthermore, most of the genetic alterations that have been associated with increased risk of CP involve genes coding for proteins involved in the activation of the digestive enzymes, or their inhibitors [21], supporting the use of caerulein to study the mechanistic events underlying pancreatitis, regardless its relevance as potential cause of AP.

On the other hand, caerulein induces in rodents a regenerative/inflammatory pancreatitis that possibly recapitulates the milder forms of disease in humans, rather than the severe necrotizing disease that is more clinically worrisome and life-threatening. Finally, there are major differences between humans and rodents regarding the mechanisms of stimulation of secretion.

Basic amino acids, such as L-arginine, L-ornithine, and L-lysine, administered i.p. at high doses cause selective damage to acinar cells in rats, rabbits, and mice, resulting in an acute necrotizing pancreatitis associated with a strong inflammatory reaction [22, 23]. A variable fraction of the animals succumb within the first 48 h due to poorly characterized, pancreatitis-unrelated, reasons. Animals that survive display complete recovery by day 14. The marked histological selectivity for acinar cells is reminiscent of human necrotizing pancreatitis, where nerves, major ducts, and islets are not affected but, unlike in patients, systemic complications are rare. The mechanism of induction of pancreatitis is not known. It has been proposed that inhibition of protein synthesis, excessive nitric oxide production, or increased lipid peroxidation play a role [61, 62].

Choline-deficient, ethionine-supplemented (CDE) diet is the least invasive method to induce AP, since it only requires a change in the diet. Administration of a CDE diet for a short time (2–5 days) has been shown to induce pancreatitis in multiple species including mice, hamsters, cats, dogs, and monkeys. In female mice, CDE diet induces an acute hemorrhagic pancreatitis with fat necrosis and prominent liver injury already after 3 days, resulting in high mortality. Male mice are resistant, unless estrogen is administered, suggesting the involvement of sex hormones in the response [24]. The exact mechanisms through which CDE diet induces pancreatitis are not known. Importantly, the CDE diet-induced pancreatitis shares a number of features with the human disease, including the histological appearance of the pancreatic and peripancreatic inflammation, the clinical and biochemical course, necrosis, and systemic hypoxia. Adjusting the duration of the diet can modify the severity and mortality of this model. However, implementation of the CDE diet might be troublesome, because animals tend to dislike it and a careful monitoring of the dietary intake is necessary.

Alcohol administration has also been extensively used to induce AP, based on the established epidemiological association between AP and alcohol consumption in patients. However, acute or chronic administration of alcohol alone fails to induce pancreatitis in all of the species used. Multiple studies where ethanol was administered either acutely or chronically through different routes (intravenous, oral, or

intragastric) showed that alcohol can enhance the acute and chronic pancreatitis induced by other experimental manipulations, including secretagogue or lipopolysaccharide (LPS) administration, high-fat diet, or surgical intervention [25, 26]. It is possible that the failure to reproducibly induce pancreatitis with ethanol alone in experimental models reflects the fact that alcoholic pancreatitis is a multifactorial disease, whereby other lifestyle and environmental factors (i.e., smoking, obesity), as well as genetic predisposition, play a role [27].

Models of Chronic Pancreatitis

Chronic pancreatitis is currently thought to result from recurrent AP. It involves continuous or recurrent damage/inflammation of the pancreatic parenchyma, which undergoes progressive and morphological and histological changes including loss of exocrine and endocrine mass, fat replacement, inflammatory cell infiltration, necrosis, stellate cell activation, fibrosis, calcification, and nerve enlargement. The notion that the pathological features of CP are irreversible is currently being challenged and the hypothesis that irreversibility might be the consequence of late diagnosis is under examination [1]. Animal models of CP have been developed which, however, do not fully reproduce the clinical presentation and clinical course of the human disease. This may be related to the fact that in humans, the diagnosis of CP is commonly made late during disease progression, but it may also reflect important species-specific pathogenic responses.

Two theories have been proposed on how CP develops in patients: as a result of multiple bouts of AP (either subclinical or clinically evident) or through a single severe initiating event whose effects are prolonged and sustained until they become irreversible. Experimental models suggest that both mechanisms can indeed lead to CP. Three major types of experimental CP have been used: ***mechanical*** (e.g., duct ligation) – mimicking the obstructive lesions that are associated with CP in patients; ***chemical*** (e.g., caerulein, L-arginine, or ethanol administration), reproducing the downstream mechanisms of injury or relating to the human CP etiology; and ***genetic,*** based on the germline mutations identified in humans. Importantly, a general feature of all mouse models of CP is the lack of the massive fibrosis that is observed in patients, possibly indicating species- or strain-specific biological differences.

Pancreatic duct ligation (PDL) (partial, selective, or complete) has been used for the induction of CP in dogs, rats, and mice, with markedly species-dependent outcomes. This approach aims to mimic the obstruction caused by protein plugs in the small pancreatic ducts of CP patients, which cause increased retrograde pressure. In mice, ductal ligation induces a massive loss of acinar cells that are replaced by adipocytes, consistent with clinical-pathological observations in humans. PDL is often combined with the administration of ethanol or caerulein [63]. A modification of this method is the pancreatic duct hypertension procedure [28], developed for rats, where hydrostatic pressure is exerted in the pancreatic duct, mimicking the pressure resulting from duct obstruction. This method is technically challenging and has not been adapted for mice.

Caerulein, administered repeatedly over several weeks, is probably the most commonly used pharmacological agent used to induce CP, especially in studies assessing the relation between inflammation and cancer [29]. This approach is based on the clinical observation that chronic ethanol consumption and repeated events of AP can lead to CP. Although single AP events are fully self-limiting and reversible, as mentioned above, repetitive insults eventually result in chronic inflammation, acinar cell atrophy, ADM, fibrosis, and – in extreme cases – diabetes. In rats, these effects are partially reversible upon discontinuation of caerulein administration [30]. It remains to be determined whether the same is true in mice.

The amount, frequency, and total duration of caerulein administered differ substantially among studies and the optimal schedule is far from being standardized. Protocols used include full AP induction, i.e., 6–7 hourly injections of caerulein during 1 day, two or three times per week, over 6–10 weeks [31, 32, 64], or are limited to single daily injections, 5 days per week, over 10–12 months [65]. Severity and kinetics of disease progression can therefore vary widely and a systematic comparison of these protocols has not been reported. Caerulein is often used in combination with other pharmacological agents, such as LPS, a bacterial endotoxin that can activate stellate cells and stimulate inflammation, thus increasing the extent of fibrosis induced by caerulein and accelerating the disease in mice [33]. Cyclosporine was also used to exacerbate the chronic inflammation induced by caerulein in rats [34]. Finally, caerulein administration has been combined with PDL in rats, where it induces CP with necrosis followed by fibrosis, and in mice.

Repeated administration of **L-arginine** and chronic administration of the **CDE diet** has also been used to induce CP. Serial injections of L-arginine to rats induce severe acute pancreatitis, which progressively results in chronic damage, characterized by persistent acinar cell atrophy and fat replacement, occasionally accompanied by necrosis and fibrosis [35]. On the other hand, mice intermittently fed with the CDE diet for a prolonged period of time (up to 54 weeks), develop acinar atrophy, ADM, and a mild fibrosis [36].

Alcohol abuse is among the major causes of CP in patients but, as mentioned above for AP, the many models of alcohol-induced pancreatitis that have been explored have not successfully recapitulated the human disease, so far. This is consistent with the fact that less than 10% of alcoholics develop CP, despite regular excessive alcohol consumption. Ethanol supplementation to the diet for up to 6 months causes a partial exocrine impairment in rats, but no morphological changes characteristic of CP are observed [37]. Administration of higher doses of ethanol with the Lieber–DeCarli liquid diet [38] fails to induce severe damage to the pancreas, but it sensitizes cells to other triggers, such as caerulein [39] or LPS [40], although the resulting disease resembles more acute than chronic pancreatitis. CP can be successfully and consistently induced in rats when alcohol is administered through intragastric infusion in gradually increasing doses, in combination with a diet rich in unsaturated fat [41]. This protocol produces hyperamylasemia and hyperlipasemia, as well as acinar cell atrophy, inflammatory cell infiltration, and focal necrosis. Longer treatment also induces some extent of fibrosis. Disease development is paralleled by increased levels of free radicals within the pancreas,

supporting the hypothesis that oxidative stress is at the basis of alcohol-induced pancreatitis. This model suggests that the total amount of alcohol consumed and the type of dietary fat that is ingested are crucial determinants of CP [41].

Genetically engineered animal models (mostly mice, with few exceptions) have been developed, aiming at recapitulating the genetic alterations that have been associated with higher risk of CP in patients. These models have high clinical relevance but the extent of their similarity to the human disease varies considerably. For example, inactivating mutations of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene cause cystic fibrosis, a hereditary disease of chloride ion channel, which is associated with lung, intestinal, and pancreatic disease including a chronic pancreatitis-like lesion and increased risk of cancers of the digestive tract [42]. *Cftr* inactivation in mice produces only mild pancreatitis [43], while its inactivation in pigs causes rapid progressive pancreatic disease similar to what is observed in patients with cystic fibrosis [44].

One of the putative triggers for pancreatitis is the premature, intracellular activation of trypsinogen [45]. The design of GEMMs aimed at recapitulating these alterations is complicated by the existence of multiple genes coding for trypsinogens in human and mice and lack of knowledge about which are the most appropriate orthologues. Germline mutations in *PRSS1*, most notably the R122H mutation, are strongly associated with autosomal dominant hereditary CP [46]. When a mutant mouse cDNA harboring an equivalent mutation was expressed in the pancreas of transgenic mice, fibrosis and acinar cell dedifferentiation consistent with CP were observed [47], while the ectopic expression of the human mutant cDNA did not induce any histological change [48]. In both cases, expression of mutant Prss1 rendered animals more susceptible to caerulein-induced pancreatitis [47, 48]. Mutations in other genes whose products are involved in enzyme secretion and activity, such the serine protease inhibitor Kazal type 1 (*SPINK1*), chymotrypsinogen C (*CTRC*), and the calcium-sensing receptor (*CASR*) have also been associated with increased risk of pancreatitis [49]. Deletion of *Spink3*, the mouse homologue of *SPINK1*, causes elevated trypsin levels followed by massive autophagy in acinar cells, which is lethal within 2 weeks from birth [50]. Currently, no genetically engineered mouse model is available, expressing mutations in *Ctrc* or *Casr*.

Genetic Models of Pancreatic Inflammation

Several GEMMs have been reported, displaying spontaneous pancreatic damage mimicking acute or chronic pancreatitis. For example, the overexpression of the proinflammatory cytokine Il-1β in acinar cells is sufficient to induce CP in mice, with the first signs of inflammation starting already at 1 week and progressing with age [51]. Similarly, overexpression of Cox2, a molecule that is activated by inflammatory cytokines, under the control of the *Krt5* promoter, also induces CP and even some ductal neoplastic lesions [66]. NF-κB is activated in acinar cells during the early stages of experimental pancreatitis [67], therefore multiple models have been developed which induce the activation of the NF-κB pathway. These models,

however, reveal a more complex role of this pathway, since its activation can lead to both aggravation [52] and amelioration of pancreatitis [53], due to the known dual role of NF-κB, which can be both pro- and anti-inflammatory. Furthermore, members of the NF-κB pathway seem to also have a NF-κB-independent function in protecting acinar cells from endoplasmic reticulum (ER) stress and autophagy [68]. Finally, mice lacking the essential autophagy-related proteins Atg5 [69] and Atg7 in pancreatic cells also develop a pancreatitis-like phenotype, due to ER stress [70], suggesting a more complex mechanism than induction of autophagy (see below).

Somatic Genetic Alterations in Chronic Pancreatitis

Chronic pancreatitis is characterized by ADM, acinar atrophy (focal or diffuse), ductal stasis, and all types of pancreatic intraepithelial neoplasia (PanIN), as well as mesenchymal cell proliferation and activation, extracellular matrix (ECM) deposition with collagen accumulation, and inflammatory cell infiltration.

Experimental and molecular pathology evidences suggest that ADM and PanINs can be the precursors of PDAC and at least two-thirds of patients with CP undergoing surgery have PanINs, their prevalence decreasing with increasing dysplasia [54].

Accordingly, it is conceivable that some of the genetic alterations characteristic of PDAC would be present in epithelial lesions associated with CP. Because >95% of PDAC harbor *KRAS* mutations and because of the proposed tumor-initiating role, these mutations are top candidates for being present in CP tissue samples. However, the cause of *KRAS* mutations in PDAC is not known and there is not clear evidence that mutations are linked to the most common risk factors for PDAC. Overexpression of Ikk2 or Cox2 in p53-null acinar cells causes tumors that are *KRas*-wild type, suggesting that chronic inflammation does not efficiently cause *KRas* mutations in mice [55]. It is likely that the almost universal occurrence of mutant *KRAS* in PDAC reflects the exquisite sensitivity of pancreatic cells to this oncogene rather than the action of a single specific mutagenic event that could be used to model their appearance in experimental animals. Several studies have assessed the prevalence of *KRAS* mutations in samples from patients with CP (pancreatic/duodenal juice, endoscopic ultrasound-guided fine needle aspiration (EUS-FNA), pancreatic tissue, or plasma). In all cases, the prevalence of *KRAS* mutations was lower than in patients with PDAC, ranging from 11–37% in juice, being lower in EUS-FNA or in tissue, and essentially undetectable in plasma [56, 71–73].

The tumor suppressor genes *CDKN2A* (coding for $p16^{INK4A}$), *TP53*, and *SMAD4* are inactivated in approximately 90%, 50–75%, and 60% of PDAC cases, respectively, through mutation, genomic loss, or promoter hypermethylation [74]. There is less information regarding alterations in these tumor suppressors in CP tissue, in part due to the limitations derived from tissue sampling, histopathological heterogeneity, and sensitivity of the techniques used. Heterozygous mutations in $p16^{INK4A}$ and

TP53 have been detected in a low fraction of PanIN and ADM lesions from patients with CP without cancer; mutations were homozygous in PanIN-3 but not in low-grade PanINs, suggesting clonal evolution associated with lesional progression [71]. The prevalence of *KRAS* and *TP53* mutations, and of $p16^{INK4A}$ methylation, in pancreatic juice was intermediate in CP compared to PDAC and control samples [73]. Aberrant gene methylation was found to be higher in pancreatic juice or tissue from patients with CP than in controls, although it was lower than in patients with PDAC (it was similar to high-risk individuals), suggesting that epigenetic mechanisms contribute to the progression of CP to PDAC [56, 72]. Using immunohistochemistry, $p16^{INK4A}$ – but not SMAD4 – has been found to be lost only in PanIN-2/3 [56, 75].

So far, there have been no reports on the genetic landscape of somatic mutations in CP samples using massive parallel sequencing, or the more recent techniques with a high sensitivity to detect gene mutations (i.e., digital PCR, Beaming), to shed light on the genetic events that precede PDAC development in patients with CP. It will be important to determine whether distinct genetic/genomic alterations characterize the CP-associated tumors.

In summary, there is strong evidence that the pancreas of patients with CP harbors genetic alterations that are characteristic of invasive PDAC, albeit at lower frequency but much work remains to be done in this domain.

Modeling of the Contribution of Pancreatitis to Cancer in Mice

Most of the experimental information gathered in the last 15 years on the contribution of CP to PDAC has been acquired using GEMMs. This has been possible thanks to the fact that PDAC is one of the human tumors that has been best recapitulated using GEMMs in which the main PDAC-associated mutations have been introduced.

Current evidence indicates that mutations in *KRAS* oncogene are the main, if not exclusive, oncogenic event leading to PDAC [76]. Therefore, the best models to assess the contribution of pancreatitis to cancer are those in which mutant KRas is conditionally expressed in the pancreas through the activation of Cre recombinase in specific cell populations. The second main oncogene involved in PDAC is *GNAS*. Hotspot codon 201 mutations have been described in a variety of human tumors; in the pancreas, *GNAS* mutations occur mainly in IPMNs and most of the PDAC harboring these mutations result from the progression of IPMN precursor lesions [77, 78]. *GNAS* functions downstream of G-coupled membrane receptors and inhibits the activation of adenylyl cyclase which, in turn, raises cAMP levels. Mice expressing both mutant KRas and mutant Gnas in the pancreatic lineage develop tumors reminiscent of IPMN [79]. Recently, induction of chronic inflammation by overexpression of the p65 subunit of the inhibitor of NF-kB kinase (Ikk2) or Cox2 in acinar cells, together with the deletion of *Trp53*, has been shown to lead to the formation of *KRas*-wild type (WT) tumors displaying a wide variety of histologies (acinar, ductal, sarcomatoid, neuroendocrine) [55].

The Conditional Mutant *KRas* Mouse Models: Twenty-First Century Tools

Studies in the second half of the twentieth century aimed at developing animal models of pancreatitis and pancreatic cancer, used predominantly chemical carcinogenesis, mainly in mice, rats, and hamsters [80]. Many of the models used yielded acinar rather than ductal tumors, and these studies rarely addressed the pathophysiological and molecular relationship between both tumor histologies and the causes for the species-specific differences.

Since 2003, two main conditional GEMMs have been used to activate expression of mutant *KRas* in the pancreas, based on either the G12D [81] or the G12V [65] codon 12 mutation. In most studies, expression was activated during embryonic development in multipotent pancreatic progenitors. Using the G12D mutant and a $Pdx1^{Cre}$ driver strain (KC mice), PanIN-1 and PanIN-2 lesions are detected by weeks 10 and 20–24, respectively. PanIN-3 are exceptional in young mice and only appear later. In older mice, PDAC develops and causes the death of 50% of mice by 12 months age. The simultaneous introduction of a *Trp53* mutation in this strain (KPC mice) leads to faster tumor initiation and progression, with frequent development of metastases; median survival is 6 months and no mice are alive by 12 months age [82]. Similarly, simultaneous activation of mutant *KRas* and inactivation of both alleles of $p16^{Ink4a}$/$p19^{Arf}$ leads to very aggressive tumors with anaplastic/sarcomatoid features and to the death of all mice by 16 weeks [83]. When *KRas* mutations and *Smad4* inactivation are introduced simultaneously, all mice have tumors by 6 months and the histology is often reminiscent of IPMNs [84]. In summary, the cooperation of *KRas* mutations with other genetic alterations common in PDAC has been clearly demonstrated.

Using the G12V conditional allele, Guerra et al. have confirmed the ability of mutant *KRas* to induce PanINs and PDAC when activated in acinar cells during embryonic development using a doxycycline inducible strategy to express Cre recombinase (e16.5). In this model, PanIN-1 lesions are focally detectable in the majority of 3-month-old mice and by 6 months, most mice have acquired multiple PanIN-1 lesions diffusely, some PanIN-3, and occasional PDAC. By 1 year, the majority of the mice have PanIN-1 lesions, 35% have high-grade PanINs, 50% of mice have PDAC, and 12% of them have died [65]. PanINs and PDAC are commonly embedded in a desmoplastic microenvironment containing abundant collagen fibers and fibroblasts, as is characteristic of the lesions found in the pancreas of patients with PDAC. Notably, several important observations have been made using this strain (Fig. 1). First, it was shown for the first time – using lineage tracing – that PDAC can arise from acinar cells in which the expression of the mutant *KRas* oncogene is selectively activated, raising the question of the cell of origin of human PDAC. Second, when mutant *KRas* expression was activated in young adult mice (2 months), no PanINs or tumors developed by 1 year, indicating that – in homeostatic conditions – adult acinar cells are largely refractory to the oncogenic effects of mutant KRas. Importantly, daily administration of a single dose of caerulein to mice in which the mutant *KRas* allele is activated at the age of 2 months leads to the rapid development of low-grade PanINs (within 1 month), increased acinar cell

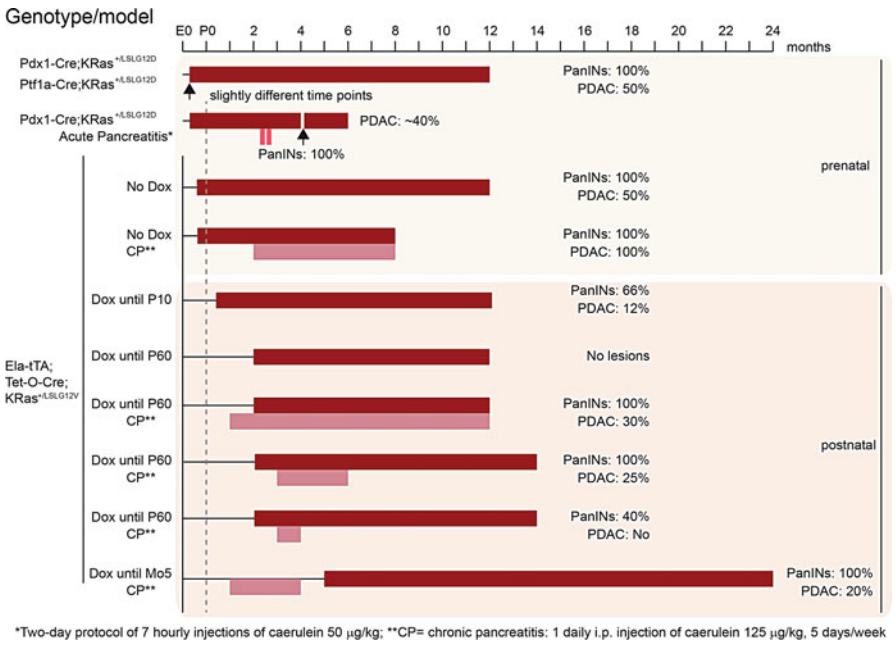

Fig. 1 Main *KRas*-mutant GEMM and protocols of acute and chronic pancreatitis used to study the pancreatitis-to-PDAC progression process

proliferation, and inflammatory cell infiltration. By 8 months, an increasing number of low-grade and high-grade PanINs is observed and one-third of the mice have developed invasive PDAC. A similar enhancement of the tumorigenic effect of mutant *KRas* by chronic caerulein administration is observed when the oncogene is activated during embryo development [29]. The persistence and the extent of the caerulein-induced damage are important variables and longer caerulein treatment is associated with a higher prevalence of PanINs and PDAC or a shorter latency of lesion development (Fig. 1). Caerulein administration is associated with increased inflammatory infiltrates in which neutrophils and eosinophils predominate in a first phase, subsequently containing a more complex constellation of cell types (macrophages, B and T cells, and plasma cells) (see below).

An additional important finding made using this strain was the fact that adult acinar cells were resistant to mutant KRas-mediated transformation, in the absence of pancreatitis, even when *Trp53* or $p16^{Ink4a}$ were simultaneously inactivated in the same cells of the adult pancreas. By contrast, deletion of these tumor suppressors effectively cooperates with mutant *KRas* when activated during embryo development. Inactivation of the tumor suppressors *Trp53* or $p16^{Ink4a}$ in adult mice never leads to PanIN or PDAC in the absence of mutant *KRas*, even when caerulein is administered, strongly supporting the initiating nature of this mutation [29]. Administration of caerulein over 3 months to young mice, and subsequent activation of the *KRas* oncogene, also leads to the appearance of PanINs and PDAC [29]. These results are

in agreement with the notion that chronic inflammation does not efficiently cause *KRas* mutations and point to the relevance of the sequence of events, suggesting that preexisting damage sensitizes acinar cells to the effects of mutant KRas.

Altogether, there is compelling evidence supporting the usefulness of GEMMs to model and recapitulate the interaction of genetic (somatic mutation) and nongenetic (epithelial cell remodeling and inflammation) factors driving PDAC development, as occurs in patients.

Acute Pancreatitis-Associated Damage Promotes PDAC

A question raised by the studies described above was whether more limited damage could also enhance the oncogenic effects of mutant *KRas*. Carriere et al. were first to show, using 2-month-old mice in which mutant *KRas* had been activated in pancreatic progenitors, that a 2-day caerulein acute pancreatitis is sufficient to enhance PanIN development and accelerate mutant KRas-driven PDAC progression [17]. This effect was confirmed in several additional studies [85, 86]. Similar results were obtained when mutant *KRas* was activated only in nestin-expressing cells [87]. In these experiments, pancreatitis was resolved within 1 week, when inflammatory infiltrates had almost completely disappeared but increased acinar Ki67 expression was noted. This was followed by extensive replacement of the acinar parenchyma by ADM, low-grade and high-grade PanIN lesions, with later development of PDAC. Subsequent to this work, it has been shown that the mildest form of acute pancreatitis – resulting from 7-hourly injections of caerulein – also accelerates PanIN formation and PDAC development in a context in which mutant *KRas* is concomitantly expressed in the pancreas [88]. As will be discussed below, these studies strongly suggest that perturbation of acinar cell homeostasis for a brief period of time also sensitizes pancreatic cells to mutant KRas (Fig. 1).

Regarding humans, there is little epidemiological evidence that past medical history of a single episode of AP is associated with an increased risk of developing PDAC. Recently, the occurrence of AP in the months preceding the diagnosis of PDAC has been reported but it is not known whether such event simply heralds the development of the tumor or it could, in fact, act to promote its progression [89] and further work in this area is warranted.

Developmental and Cellular Mechanisms Involved in CP-to-PDAC Progression

The cellular mechanisms underlying the tumor-promoting effect of both acute and chronic pancreatitis are still under investigation. The GEMMs have pointed to the contribution of both cell autonomous and non-cell–autonomous events. Epithelial cell-autonomous processes include tissue regeneration, acinar cell proliferation, and escape from senescence. Additionally, an important role of nonepithelial cells such as pancreatic stellate cells (PSC) and inflammatory infiltrates has been demonstrated.

Epithelial Cell-Autonomous Mechanisms

Dedifferentiation of Acinar Cells and ADM

The experimental models of acute and chronic pancreatitis described above have unveiled the remarkable plasticity of the pancreatic parenchyma, particularly of acinar cells. As mentioned above, one single episode of caerulein-induced AP is sufficient to induce a drastic loss of the exocrine function within the first 24 h; however, the pancreas is histologically back to normal already after 5–7 days. Transcription of acinar-specific genes, such as amylase, is rapidly downregulated to be restored almost to baseline levels after 7 days [18]. Jensen and colleagues showed, in a comprehensive analysis of tissue regeneration after AP, that acinar cells rapidly silence the expression of the acinar differentiation marker amylase. This is followed by the induction of Pdx1, a major driver of pancreatic development, which in the adult is expressed at high levels only in endocrine cells, while expression in exocrine cells is very low. Rapid activation of the Notch pathway is also observed in this model, suggesting a broad reactivation of transcriptional programs that are normally restricted to embryonic development [18]. Extensive data currently support the notion that during AP, acinar cells lose their identity, reexpress markers of multipotent progenitors, including Pdx1, Sox9 [85], and Nestin [19], and reactivate developmental programs, such as Notch, Hedgehog, and Wnt pathways, which are thought to be essential for the efficient regeneration of the tissue. More in detail, expression of genes involved in the Notch pathway (i.e., Notch1, Dll1, Rbp-jk, and Hes1) is induced after caerulein-induced pancreatitis in mice [18], and pharmacologic or genetic ablation of Notch signaling results in strongly impaired regeneration after AP [90]. Also the Hedgehog pathway is extensively induced after caerulein-induced AP, where the expression of Hedgehog ligands Shh and Ihh, as well as the receptor Smo and the Hedgehog-regulated genes Ptch1 and Gli1, are strongly upregulated during the regenerative phase. Also in this case, pharmacologic blockade or genetic ablation of signaling components impairs tissue regeneration [19]. Strong induction of β-catenin, the prime transcriptional activator of the canonical Wnt pathway, takes place in regenerating acini after caerulein-induced pancreatitis, with a predominant accumulation at the cell periphery and in the cytoplasm, corresponding with a general activation of canonical Wnt signaling [18, 85]. Genetic ablation of β-catenin impairs the regeneration of pancreatic tissue after pancreatitis [85].

In this line, a recent study by Kong and colleagues has compared the dynamics of AP in WT mice and in mice expressing mutant KRas and shown that the response of the WT pancreas to caerulein-induced AP (2-day protocol) includes three phases: (i) acute inflammation, characterized by edema, immune infiltration, and ADM; (ii) regeneration, during which immune cell infiltration and ADM gradually disappear; and (iii) refinement, during which the tissue recovers completely. In the presence of mutant KRas, this sequence is perturbed, and the initial phase of inflammation does not resolve [91]. An important event during the acute inflammatory phase in both WT and mutant KRas-bearing mice is the rapid inhibition of a transcriptional program linked to acinar cell homeostasis, which is only reactivated

during the regeneration phase in the WT pancreas. This transcriptional program is strongly downregulated in PDAC cells suggesting that its inhibition favors tumor development.

Likewise, dedifferentiation of acinar cells has been reported in two distinct models of CP in mice, namely PDL and caerulein administration, in association with the upregulation of the progenitor markers Pdx1, Sox9, Hfn1b, and Hes1 [92]. Some differences in gene and protein expression exist between the two protocols, suggesting that the extent of tissue damage might influence the amplitude of the response [92].

It was mentioned above that adult acinar cells are refractory to transformation induced by mutant KRas, while pancreatic multipotent progenitors as well as unipotent acinar progenitors are susceptible. The observation that acute and chronic pancreatitis produce a transient dedifferentiation of acinar cells towards a progenitor-like phenotype might support the hypothesis that pancreatitis favors PDAC development through the transient expansion of the pool of cells sensitive to mutant KRas, thereby increasing the probability that at least one of the cells targeted by mutant KRas progresses towards PanIN and PDAC. This notion would be consistent with the observation that loss of major drivers of acinar cell differentiation and maintenance, such as Ptf1a, Gata6, Nr5a2, and Mist1 – alone or in combination with pancreatitis – significantly accelerates the development of tumors in the presence of mutant KRas [88, 93–95].

The transiently dedifferentiated acinar cells observed after pancreatitis are not identical to the pancreatic progenitors present during development, as they additionally express some markers of ductal cells, such as Krt19, revealing a process of ADM [85]. ADM was suggested to be a precursor of PanINs and PDAC and is therefore considered one of the first events induced by mutant KRas during tumorigenesis. Indeed, expression of mutant KRas on its own is sufficient to induce an ADM that closely resembles the phenotype shift induced by pancreatitis [96]. Importantly, although some differences have been observed in the ADM-inducing mechanisms between mouse and human acinar cells, ADM takes place in human primary acinar cells upon treatment with TGF-β in vitro [97] and it can even occur spontaneously [98] indicating that it is a biologically relevant process and that the acinar program is sustained actively. Therefore, it is conceivable that the pancreatitis-induced ADM generates a tumor-competent environment, which facilitates cell transformation driven by oncogenic KRas.

Pancreatitis and mutant KRas activate similar transcriptional programs to induce dedifferentiation and ADM, involving transcription factors such as Sox9, Myc, Klf4, and Pdx1. However, ADM becomes irreversible and progresses towards PanINs and PDAC only in the presence of mutant KRas. This might not reflect the simple additive effect of similar ADM-inducing signals originating from pancreatitis and oncogenic KRas, as shown by the observation that the initial histological and transcriptional patterns are similar in mice harboring the mutant oncogene and in WT mice [85, 91], but more complex mechanisms might be involved. The major consequence of *KRas* mutation is that acinar cells are locked in a dedifferentiated state, and tissue regeneration is inhibited due to a failure to transiently induce β-catenin and activate the Wnt pathway [85]. The stronger and persistent activation

of the MAPK pathway (and possibly other signaling pathways) in the presence of mutant KRas may be the major underlying cause [85]. Kong et al. have identified a complex network of molecular interactions that is responsible for tissue regeneration in WT mice, involving both intrinsic and extrinsic cues. Interestingly, this network is very much simplified in the presence of mutant KRas, thus impairing the proper resolution of tissue damage and favoring tumor initiation [91].

Acinar Cell Proliferation

Tissue regeneration after AP is associated with a peak of proliferation of acinar cells, which are normally quiescent. In a model of AP where mice receive 8-hourly injections of caerulein over two consecutive days, the proportion of acinar cells expressing phosphorylated histone H3, a marker of mitotic cells, increases 40-fold 3 days after caerulein injection and then gradually decreases to baseline after 7 days [18]. Similar findings have been made using BrdU uptake in a mouse model of AP that used the 1-day caerulein protocol, where the peak in acinar cell proliferation occurs 4 days after injection [60]. Interestingly, increased proliferation of interstitial cells, mainly myeloid cells, takes place as early as 7 h after the first injection of caerulein, again pointing to an orchestrated response involving both epithelial and stromal cells.

Hyperproliferation of acinar cells might contribute to the protumorigenic effect of pancreatitis through an increase in DNA replication, which provides an opportunity for errors and disease-causing mutations. Interestingly, however, two distinct cell populations displaying opposite phenotypes have been identified in two models of CP; while some acinar cells express proliferation markers, another subpopulation expresses markers of senescence, suggesting that a protective mechanism against the potential danger of uncontrolled proliferation is activated during tissue regeneration following damage [92]. Whether a subpopulation of progenitor-like adult acinar cells that become active after tissue injury participates in regeneration needs to be definitely ruled out. Lineage tracing experiments strongly support the notion that all acinar cells have similar potential to reenter the cell cycle and divide during tissue regeneration [99] but recent work points to the existence of a previously undescribed heterogeneity of adult acinar cells both in murine and human pancreas [100].

Inhibition of Oncogene-Induced Senescence

Another cellular mechanism involved in the protumorigenic effects of pancreatitis is the inhibition of oncogene-induced senescence in the early stages of PanIN progression [29]. Hyperactivation of oncogenes in normal cells can cause senescence, mediated by the $p16^{Ink4a}/p19^{Arf}$ or *TP53* tumor suppressors, as a mechanism of defense against malignant transformation [101]. Markers of senescence have been detected in ADM and early PanINs in two distinct mouse models of PDAC induced by mutant KRas but not in high-grade PanINs and PDAC [102, 103]. Based on this observation, Guerra and colleagues hypothesized that adult acinar cells are refractory to transformation induced by oncogenic KRas due to the activation of cellular senescence. Genetic ablation of either $p16^{Ink4a}/p19^{Arf}$ or *Trp53* in mice is not

sufficient to overcome this barrier, suggesting that oncogene-induced senescence in this context depends on more complex regulatory networks [29]. However, when caerulein-induced CP is combined with the loss of $p16^{Ink4a}/p19^{Arf}$, the mice show similar numbers of low-grade PanINs, indicating similar sensitivity to tumor-initiating insults, but the number of high-grade lesions is significantly increased and the overall survival of the mice is shorter. This observation was interpreted as loss of the barrier to progression from low-grade to high-grade PanINs. Consistently, the expression of senescence markers is lost in low-grade PanINs in the mice treated with caerulein [29]. Most importantly, senescence markers are detected in low-grade PanINs in patients with untreated CP but not in those from patients with CP treated with anti-inflammatory drugs, nor in PDAC [29, 103].

Recently, extensive massive parallel sequencing and bioinformatics efforts have provided convincing evidence that the progression from low-grade to high-grade PanINs and then to PDAC might not necessarily be as linear as it was originally hypothesized, and that PanINs might not be the precursors of PDAC [104]. This new concept of PDAC progression, however, does not exclude that the actual precursor cells might undergo a senescence-like process, such as PanINs, which is also inhibited by pancreatitis.

Contribution of the Nonepithelial Compartment: A Cellular Orchestra

Although epithelial cells constitute the vast majority of the normal pancreatic parenchyma, other cell types are present and play a major role in tissue homeostasis and during response to injury, including pancreatitis (Fig. 2). Fibrosis and stromal activation are characteristics of both CP and PDAC, and the histological composition of the stroma is similar in both pathologies, with the presence of activated α-smooth muscle actin (α-SMA)-positive PSC, macrophages, and many other inflammatory cells. The well-orchestrated continuous exchange of signals between epithelial and stromal cells, as well as among distinct populations of stromal cells, is essential for tissue regeneration after pancreatitis, and is hacked by oncogenes such as *KRas* to generate the protumorigenic and immunosuppressive environment that is almost universally observed in PDAC.

The role of microenvironment in PDAC initiation and progression will be extensively explained in another chapter of this book, therefore the available data supporting the importance of PSC and inflammatory cells during pancreatitis will only be mentioned.

Pancreatic Stellate Cells

PSC are present in the normal pancreas, mainly with a periacinar distribution, and they are in a quiescent state, characterized by the presence of vitamin A-containing lipid droplets. Their function in the normal pancreas is still not fully established. In response to pancreatic injury and inflammation, PSC are rapidly activated, express α-SMA characteristic of myofibroblasts – which are proliferative and migratory –

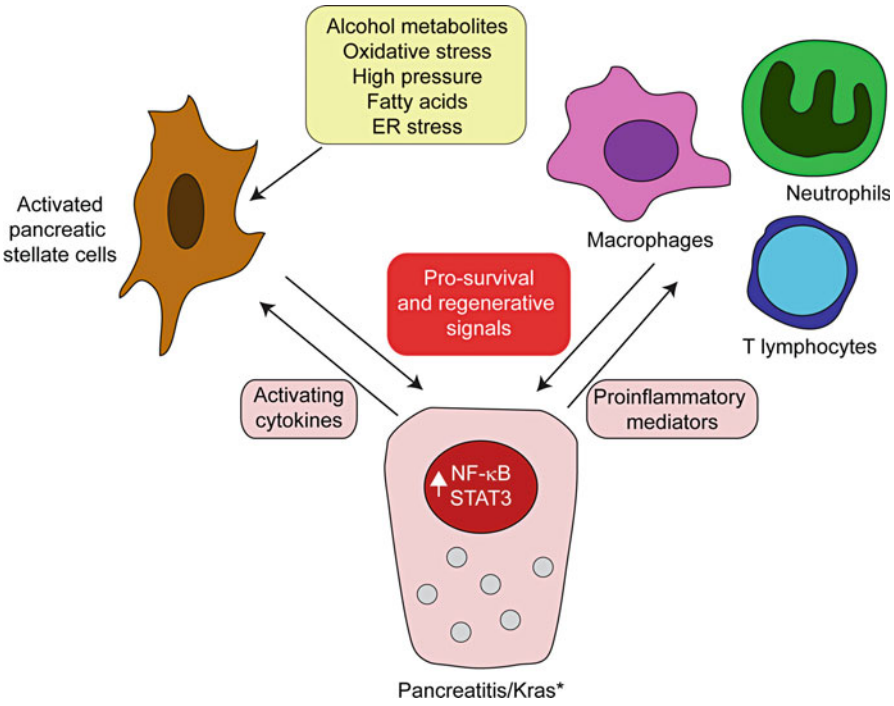

Fig. 2 Cellular mechanisms involved. In the normal pancreas, >95% of cells are epithelial. However, in pancreatitis and PDAC there is a dramatic increase in the number of stromal and haematopoietic cells that cross-talk with exocrine epithelial cells activating multiple signaling pathways that contribute to modulate their functional status. Depicted are the major players contributing to this cross-talk

and produce abundant ECM proteins, as well as matrix metalloproteases and their inhibitors, indicating a pivotal role in ECM homeostasis [105].

Activation of PSC during AP is important for the successful regeneration of the tissue, mainly because of the mentioned role in ECM production and degradation. In particular, the equilibrium between ECM production and its degradation is essential for the full recovery and the fact that no fibrosis is observed in AP strongly indicates that this equilibrium is not perturbed by mild injury. On the contrary, upon prolonged injury, such as in CP or PDAC, the equilibrium is disrupted towards the excessive ECM deposition that finally produces the characteristic fibrotic microenvironment observed in both cases [106].

In vitro experiments have shown that PSC can be activated by multiple factors that are involved in pancreatitis, including alcohol and its metabolites, oxidative stress, pressure, growth factors such as platelet-derived growth factor and TGF-β, and cytokines produced by the damaged acinar cells or by resident and recruited inflammatory cells, such as Il-1, Il-6, and tumor necrosis factor α (TNF-α) [106]. In turn, PSC also produce cytokines and growth factors that contribute to maintain their

own activation, in a paracrine loop, as well as chemokines such as Il-8 and monocyte chemoattractant protein 1, which contribute to the recruitment of inflammatory cells [107]. PSC also produce toll-like receptors (TLRs), which activate the recruited immune cells [108]. Importantly, modulation of the ECM can also restore PSC to quiescence, providing opportunities for pharmacological intervention [109, 110]. In conclusion, the current understanding of the role of PSC in fibrosis and cancer is that they initially function to sustain the immune-mediated resolution of the damage and the regeneration of the tissue; however, when the damage is prolonged, such as in CP or in the presence of mutant KRas, the equilibrium of their multiple activities is perturbed in favor of the generation of a fibrotic and immuno-suppressive environment, which favors PDAC development and progression.

Inflammatory Cells

Animal models of AP have demonstrated that, in response to the initial insult, acinar cells produce and release multiple inflammatory mediators, including Il-1β, Il-6, and Tnf-α, that first recruit neutrophils and then macrophages, monocytes, and lymphocytes. Activation of the transcription factor NF-κB is known to be crucial in the induction of the cytokine production by acinar cells, and its role will be discussed in more detail below [111]. Once inflammatory cells are recruited to the pancreas, the inflammasome is activated in macrophages and contributes to the severity of pancreatitis. The inflammasome is induced also by damage-associated molecular pattern molecules, which are released by damaged or dying cells [112]. In animal models of AP, as in most patients with AP, the inflammatory phase resolves and tissue homeostasis is recovered.

Compared to AP, much less is known about how inflammation is first induced in CP. Patients with CP show pancreatic infiltration of macrophages, T- and B- lymphocytes, and in particular immunosuppressive Tregs [113]. Similarly, both macrophages and T-lymphocytes have been observed in animal models of CP, which are normally based on repetitive induction of AP, as explained above [114]. It is possible that the persistent inflammation observed in CP is also initiated by signals released by damaged acinar cells, which induce the recruitment of inflammatory cells and the activation of the inflammasome, as in AP, although the exact mechanisms that impede the resolution of inflammation are not fully clear.

It is known that up to 50% of the whole tumor cell mass in PDAC can be composed of stroma including ECM, mesenchymal cells, and immune cells, including macrophages, myeloid-derived suppressor cells, neutrophils, dendritic cells, and B- and T-lymphocytes [115]. This cell composition is rather similar to what observed in CP, suggesting that pancreatitis might provide a favorable landscape for the proliferation of precancerous cells and their progression to carcinoma. Importantly, persistent autocrine and paracrine loops mediated by interleukins – such as Il-6, TNF-α, and Il-1α – are present between myeloid cells and epithelial cells in the preneoplastic and neoplastic inflammatory environment, which maintain and amplify the activation of pro-proliferative and proinflammatory signals such as the Stat3 and NF-κB pathways [116, 117].

Signaling Pathways Relevant to the Pancreatitis-to-Cancer Sequence

The signaling mechanisms that are involved in triggering the changes in epithelial differentiation described above emanate from both the causal events of pancreatitis and the cross-talk of epithelial cells with mesenchymal and haematopoietic cells (Fig. 2). The focus here will be on the signaling pathways that have been shown to contribute to the pancreatitis-to-cancer sequence (Fig. 3). They are particularly relevant because these biochemical mechanisms may be more amenable to pharmacological targeting than the transcription factors involved in developmental/cellular reprogramming described above.

MAP Kinase

While it is textbook knowledge that mutant KRas activates the MAP kinase pathway constitutively, there is scarce evidence of downstream signaling – and even less of cellular changes – when the oncogene is activated in pancreatic precursors or in adult

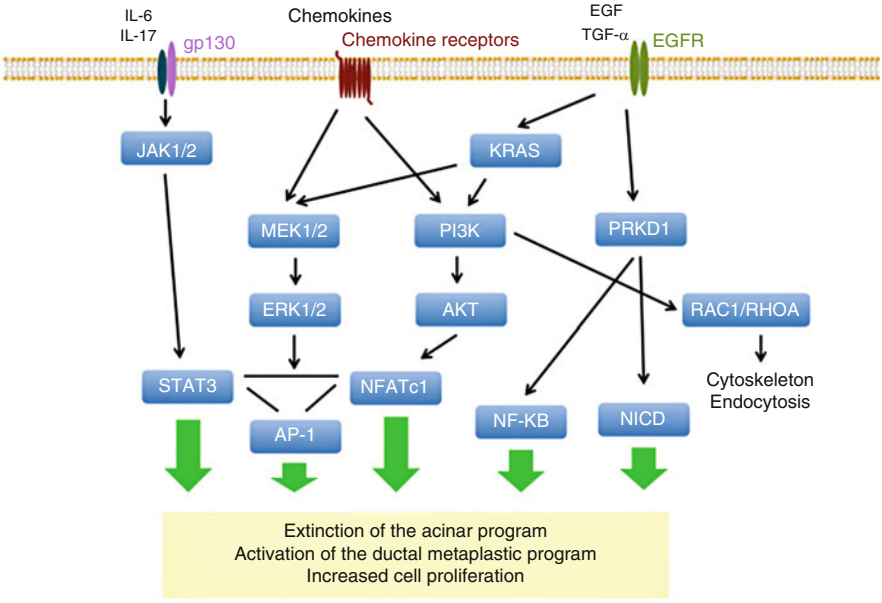

Fig. 3 Signaling pathways involved in the regulation of cellular phenotypes that favor the pancreatitis-to-pancreatic cancer progression. KRAS activation status is modulated through both genetic (mutation) and nongenetic (biochemical regulation from receptor tyrosine kinases, among others) mechanisms and plays a crucial role in pancreatic cancer development. Cytokine receptors, through the JAK/STAT pathway, and chemokine receptors, through the MAPK and PI3K pathways, contribute to the deregulation of cell fate. Signals contributing to this process emanate from both epithelial and nonepithelial cell types, as outlined in Fig. 3

acinar cells [64, 118]. In vitro studies have shown that basal levels of active KRas in acinar cells from KC pancreata are low but they can be markedly increased by adding epidermal growth factor (EGF), suggesting that there is ample opportunity to modulate RAS activity even in cells with mutant *KRas* [119]. Using a doxycycline-inducible mutant *KRas* (iKRas*) model, Pasca di Magliano and colleagues have shown that sustained expression of mutant KRas is required for PanIN formation, both spontaneously and as a result of pancreatitis induction [120]. Acute pancreatitis leads to sustained MEK/MAPK activation in the presence of mutant KRas, but not in WT mice, and the administration of the MEK1/2 inhibitor PD325901 not only leads to reduced development of ADM and PanINs but also to a lower number of established PanINs. This effect is mediated by an increase in cell death and the redifferentiation of cells to acquire an acinar phenotype, through the upregulation of key pancreatic transcription factors such as Mist1 and the participation of epithelial and stromal/haematopoietic cross-talk [120, 121].

The contribution of MEK to the tumor-promoting effect of caerulein pancreatitis could be mediated, at least in part, by the regulation of ADM. Pharmacological inhibition of MEK1/2 with Trametinib, and genetic deletion of *Mek* in epithelial cells, reduces ADM in vitro and in vivo but it does not affect AP. In established caerulein CP, systemic and epithelial MEK inhibition reduces acinar loss and fibrosis but systemic MEK inhibition impairs epithelial cell proliferation and pancreas regeneration, indicating that MEK activity in both epithelial and nonepithelial cells contributes to chronic pancreatic damage [122] that may favor tumor progression.

Different arms of the MAP kinase pathway can contribute differently to the pancreatitis-to-PDAC progression. Accordingly, MKK4 and MKK7 are required for acinar redifferentiation upon damage, possibly through sustained expression of Sox9 and other transcriptional regulators, and have been shown to act as tumor suppressors in the KC model [123].

The RAS-MAPK, EGF receptor (EGFR), and NF-kB pathways, as well as endocytic traffic and Golgi integrity, are also regulated by the Prkd1 kinase, which is required for EGFR ligand- and mutant KRas-driven ADM in vitro and in vivo and is sufficient to induce metaplasia in vitro [124].

Epidermal Growth Factor Receptor

EGFR signaling is required for regeneration upon induction of pancreatitis, in part through Agr2, which contributes to the membrane expression of EGFR and downstream signaling [125]. A role of EGFR and its ligands in ADM was first shown by transgenic overexpression of TGF-α in the pancreas [126] and subsequently in vitro through the activation of Notch [127]. More recently, it has been shown that EGFR is activated during mutant KRas-driven ADM and PanIN formation, and pharmacological and genetic inhibition of EGFR suppresses PDAC initiation through the regulation of MAPK activation. These studies suggest that EGFR contributes to reach the threshold of active mutant KRas required for ADM during tumor initiation. The effects of EGFR are mediated by ADAM17, a mechanism that also participates

in pancreatitis-stimulated PDAC development [29, 128]. The requirement of EGFR for PDAC initiation is independent of senescence induced by mutant KRas, as shown by the concomitant inactivation of $p16^{Ink4a}/p19^{Arf}$, but it is completely overridden by the inactivation of *Trp53* in pancreatic epithelial cells [29]. In the mutant KRas model, EGFR can also activate Nfatc1 which – in cooperation with AP1 – upregulates Sox9 expression [129] that is critically required for ADM and PDAC initiation [130].

PI3K Pathway

The PI3K pathway is activated downstream of mutant KRAS. In KC mice, genetic inactivation of p110α in epithelial cells using a kinase-dead mutant, as well as pharmacological inhibition, reduces AKT activation and caerulein-mediated damage, and PanIN and PDAC formation [131, 132]. By contrast, inhibition of p110β has no effects. p110α has been shown to induce cytoskeletal reorganization through the regulation of small GTPases and there is strong evidence that activation of Rac1 in the KC model is required for ADM, PanIN formation and PDAC progression, downstream of p110 activation [131–133], in part through the regulation of endocytosis [134].

Stat3

The STAT transcription factors are regulated by phosphorylation by the Janus-activated kinases (JAK) that, in turn, are downstream of the gp130 coreceptor involved primarily in cytokine signaling. This pathway crucially links inflammation and carcinogenesis in multiple tissues, including the pancreas. Pap1 (Pancreatitis-associated protein) was shown to suppress the inflammatory response during pancreatitis and – in vitro – it inhibits the NF-κB pathway in a Stat3-dependent manner [135]. In vivo, genetic deletion of *Stat3* in pancreatic cells suppresses ADM resulting from transgenic overexpression of Pdx1 [136] and pharmacological inhibition of JAK with AG490 ameliorates caerulein AP in rats [137]. In the KC model, Fukuda et al. showed that mutant KRas activates Stat3 and that deletion of *Stat3* in pancreatic cells suppresses spontaneous and caerulein-induced inflammatory cell infiltration and cytokine mRNA production, ADM, and PanIN formation [86]. The activation of Stat3 in epithelial cells was subsequently shown to be primarily caused by Il-6 trans-signaling, a mechanism that involves myeloid Il-6 secretion and binding to the soluble Il-6 receptor which then engages gp130 and JAK/STAT signaling in acinar cells leading to the secretion of Cxcl1 [116]. While this mechanism was initially shown to play a role in systemic effects of AP, namely lung injury, subsequent work from the same group revealed that Il-6 trans-signaling and Stat3 activation upregulates survival (Mcl-1, Bcl-x, and survivin) and cell cycle pathways (cyclin D1 and c-myc) and is required for the progression of PanIN to PDAC in the KC mouse model. The crucial role of Stat3 was additionally revealed by genetic deletion

of the suppressor of cytokine signaling *Socs3* in epithelial cells, which accelerates PanIN to PDAC progression [116]. Reg3β, a pancreatitis-response factor, is regulated in response to Il-17 and – in turn – it activates the JAK/Stat3 pathway; its systemic deletion in KC mice results in reduced PanIN formation and PDAC initiation [138]. A link between Stat3 activation and the transcriptional control of pancreatic homeostasis has been also established using mice heterozygous for *Nr5a2*, a crucial regulator of acinar differentiation [88], which display increased inflammation and ADM in response to induction of pancreatitis, in association with Stat3 induction in acinar cells.

Stat3 also cooperates with – and binds to – Nfatc1, which is activated by inflammation and itself promotes inflammation-driven carcinogenesis in KC mutant mice. Chromatin immunoprecipitation, followed by massive parallel sequencing, has shown that Stat3 is required for the binding of Nfatc1 at enhancers to regulate the expression of cancer genes such as EGFR and cyclin D3, and that genetic and pharmacological inhibition of Nfatc1 attenuates the protumoral activity of Stat3 [139]. In *Ela-CreERT2* mice in which PDAC is induced by oncogene activation in adult acinar cells followed by pancreatitis, YAP1 and TAZ – two major transcriptional regulators of the Hippo pathway which are upregulated upon caerulein-induced pancreatitis – were shown by genetic means to be required for the upregulation of multiple components of the JAK/Stat3 pathway [140].

NF-KB Pathway, Autophagy, and COX2

Several studies have consistently shown that suppressed activity of the NF-κB pathway is critical for pancreatic homeostasis. In adult acinar cells, inducible overexpression of the p65 subunit does not have a major phenotype, likely due to compensation by an increased expression of the Ikkα inhibitor. By contrast, prolonged induced transgenic overexpression of Ikk2 leads to increased NF-κB activity and pancreatitis, associated with loss of acinar cells, PSC activation, and fibrosis [52]. Accordingly, *Ikk2* deletion prevents the development of preneoplastic lesions [141]. In agreement with these findings, deletion of *Ikkα* in the pancreas causes acinar loss and a spontaneous pancreatitis phenotype. In *Trp53* WT mice, persistent NF-κB activation leads to CP, but no tumors, likely through regulation of DNA repair and/or apoptosis. However, upon *Trp53* inactivation, Ikk2-overexpressing mice show hyperactivation of the MAPK and Hippo pathways and increased Myc activity and develop a wide variety of *KRas*-wild type tumors [55].

The pancreatic changes observed in Ikk2-overexpressing mice are associated with an accumulation and aggregation of the autophagy regulator p62 and with increased ER and oxidative stress. The deletion of *p62* attenuates all of these processes, indicating that the role of NF-κB in pancreatic homeostasis is due – at least in part – to its cross-talk with autophagy pathways [68]. This notion is further supported by the fact that inactivation of *Atg5* [69] or *Atg7* [70] in pancreatic epithelial cells leads to severe acinar degeneration and a chronic pancreatitis-like phenotype with increased epithelial cell proliferation, inflammation, and fibrosis. ER stress is

evidenced by increased Perk and eIF2a phosphorylation and Chop levels and by partial loss of the rough ER with a reduction in protein synthesis. *p62* deletion attenuates these changes but ER stress, reduced protein synthesis, oxidative and DNA damage persist. The antioxidant butylated hydroxyanisole also partially restores the acinar phenotype with increased amylase expression and reduced fibrosis but no attenuation of inflammation, ER stress, p62 accumulation, or mTORC inhibition [70].

COX2 is another mediator of the effects of NF-κB activation. In mice expressing mutant KRas in the pancreas, inflammatory stimuli trigger NF-κB activation and Cox2 expression, leading to persistent KRas activation, downstream signaling, and PanIN formation. Deletion of *Cox2* has similar effects as deletion of *Ikk2*, suppressing the development of preneoplastic lesions [141]. Cox2 is induced in epithelial and nonepithelial cells during pancreatitis and its sole transgenic overexpression in adult acinar cells is sufficient to cause acinar atrophy, stellate cell activation, matrix deposition, inflammatory infiltrates, epithelial cell proliferation and DNA damage; after 20 weeks, a fraction of mice develops PanIN-1 (30%) and PanIN-2 (5%) lesions without PDAC. However, sustained Cox2 overexpression in a p53-null context leads to increased MAPK activity and development of KRas-wild type tumors [55].

A role in progression from CP to PDAC has been shown in the model of Guerra and Barbacid, where Sulindac – a COX1/2 inhibitor – reduces the number of low-grade, high-grade PanINs, and PDAC [29]. In the KC model, Cox2 is required for the high fat diet-induced inflammation, fibrosis, and KRas activation that results in enhanced PanIN and PDAC development [142].

Conclusions and Implications for Preventive/Therapeutic Opportunities

Epidemiological, clinical, and experimental evidences support the notion that pancreatic inflammation plays an important role in malignant transformation in the pancreas. The animal models and in vitro studies have provided insightful evidences regarding the mechanisms involved in the pancreatitis-to-cancer progression.

The work described above, largely based on the use of genetic mouse models of pancreatitis-to-PDAC progression, provides the basis for a variety of preventive/therapeutic opportunities. Three important aspects for the translation of this knowledge will be:

1. The selection of patients for clinical trials. Except for patients with hereditary chronic pancreatitis – who have a huge increase in PDAC risk but are rare – all other patients with CP have a lower risk.
2. The identification of intermediate biomarkers of response. Because the natural history of progression from CP to PDAC is long, studies would benefit from the use of surrogate markers of disease progression including inflammatory biomarkers or – possibly – detection of somatic genetic alterations in liquid biopsies.

3. The selection of drug interventions. Approved drugs such as COX2 inhibitors or vitamin D may be easier to test through investigator-initiated trials. By contrast, it may prove more challenging to justify trials testing the effects of chronic treatment with the inhibitors of EGFR, MEK1/2, JAK/STAT and other related signaling pathways, particularly in low/intermediate risk populations.

Abstract

Cancer stem cells (CSCs) are a distinct subpopulation of cells within a tumor that are capable of self-renewal and producing differentiated progeny. These cells appear to be more resilient to treatment than bulk tumor cells. Pancreatic CSCs have distinct markers; the most common identifiers are CD44, CD24, ESA, and CD133; however, other surface markers, characteristics, and intracellular signaling have been found to be unique to this population of tumor cells. New studies also indicate that CSCs may also have a distinct metabolic profile that distinguishes them from non-CSC tumor cells. There are many promising new targets on the horizon to strategize how to inhibit the growth of pancreatic CSCs by capitalizing on these features. However, many questions must be answered in order to translate this knowledge into therapeutic treatments for patients.

Keywords

Cancer stem cells · Pancreatic cancer · CD44 · CD24 · ESA

Introduction

One of the great barriers to treating pancreatic cancer is the relative resistance to standard treatments, including radiation and chemotherapy. Surgical resection remains the only potential curative treatment; however, only 15–20% of patients have disease amendable to surgical resection at the time of diagnosis. Despite surgery, nearly 85% of patients will die of their disease due to undetected micrometastasis at the time of treatment [1, 2]. Emerging studies show that underlying this resistance is a distinct population of cancer cells termed cancer stem cells (CSCs). Cancer stem cells are thought to comprise a very small portion of pancreatic tumors, in many cases as few as 0.2–5% of the cancer cell population. Intriguingly, this small population of cells has been implicated in carcinogenesis, early metastasis, and drug resistance in multiple solid tumor types, including pancreatic cancer [3–6]. In patients where the bulk tumor appears to be eradicated by therapy and relapse occurs, there is increasing experimental evidence that small populations of CSCs have not been destroyed and are responsible for disease recurrence [7–11] (Fig. 1). Rapidly expanding evidence in the field of CSCs makes them an attractive target for future therapeutic strategies.

The general definition of a CSC parallels that of nonmalignant stem cell: a cell that is capable of both self-renewal and propagation of differentiated progeny [12]. Currently, there is no precise consensus on the definition of a CSC as multiple cell surface markers and transcriptomic and genomic "signatures" of cancer cell populations possessing stem cell-like features have been identified. This has prompted the use of the term tumor-initiating cells (TIC) or stem-like cells interchangeably with the term CSCs [13–15]. Regardless of terminology, there is a large amount of evidence that these populations play a paramount role in tumorigenesis and therapeutic evasion that warrants ongoing investigation.

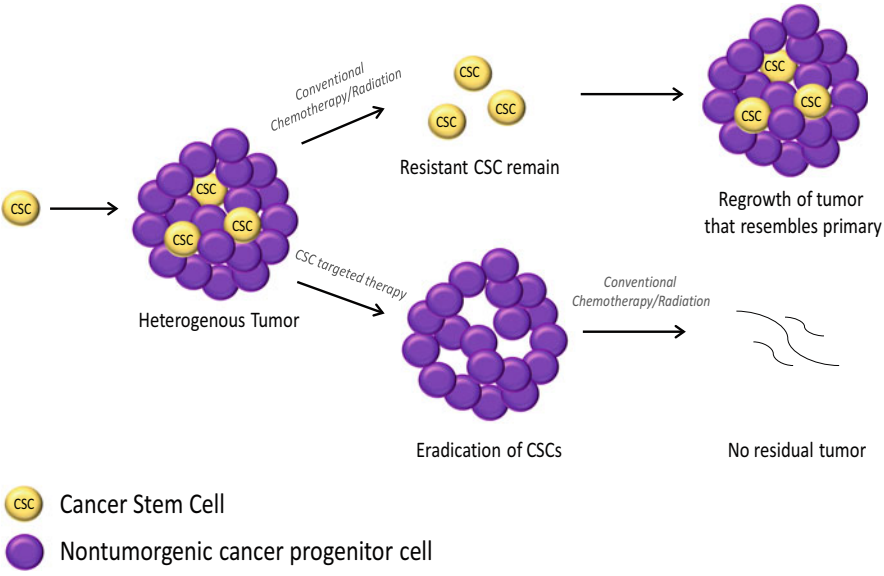

Fig. 1 The cancer stem cell theory. Conventional therapies such as chemotherapy and radiation only eradicate bulk tumor cells and leave CSC behind to regenerate the primary tumor. Future therapeutic targets that can eradicate CSCs can be used in combination with conventional therapies to eliminate all components of a tumor

The cancer stem cell hypothesis was put forth over 150 years ago [16]; however, proof of the existence of CSCs came many years later in 1997 when John Dick and colleagues first identified cancer stem cells in acute myeloid leukemia [17]. This discovery was enhanced by advances in techniques such as fluorescence-activated cell sorting (FACS) analysis which allowed more efficient separation of subpopulations of cells based on rare cell surface markers in combination with in vivo limiting dilution assays in immunodeficient mice. This pioneering work in leukemia demonstrated that these rare subpopulations ($CD34^+/CD38^-$) could regenerate a tumor identical to the parent neoplasm with very few cells. In contrast, tens of thousands of leukemic cancer cells lacking this phenotype were not tumorigenic. In 2003 Al-Hajj et al. opened up the field of cancer biology by identifying CSC in solid tumors, where they noted a subpopulation of CSCs in human breast cancer specimens [18]. They found that as few as 100 $CD44^+/CD24^-$ cells could initiate tumor formation and that these cells could undergo self-renewal and also produce more differentiated cell populations in secondary recipient mice. Subsequently, CSCs have been identified in multiple solid tumors including pancreatic cancer by Li et al. [3] and Hermann et al. in 2007 [4]. Li et al. studied human primary pancreatic tumors and low-passage primary tumors expanded as xenografts to identify a population of putative pancreatic cancer stem cells with the surface markers $CD44^+$ $CD24^+$ ESA^+. The pancreatic cancer stem cells demonstrated a 100-fold greater tumor-initiating potential than tumor cells that were negative for these markers. Data generated from ten tumors showed that cells expressing the three surface markers, $CD44^+$ $CD24^+$ ESA^+, comprised only 0.2–0.8% of all human pancreatic

cancer cells. This rare population had the highest tumorigenic potential when injected into NOD-SCID mice, with only 100 cells with stem cells markers $CD44^+$ $CD24^+$ ESA^+ being required to form tumors in 6 out of 12 mice. Subpopulations of tumor cells that were negative for cancer stem cells markers $CD44^-$ $CD24^-$ ESA^- were much less tumorigenic, with 10,000 cells required to generate tumors in 1 of 12 mice.

Hermann et al. identified a population of CSCs in human pancreatic tumor specimens using the hematopoietic stem cell marker CD133+ [4]. Flow cytometry analysis demonstrated that bulk tumors contained 1–3.2% CD133+ cells. Orthotopic implantation of as few as 500 CD133+ cells was able to generate tumors in athymic mice that reproduced the primary tumor at the histological level, whereas 10^6 CD133− cells were not found to be tumorigenic. This population of CSC did not express the epithelial differentiation marker cytokeratin, suggesting that they are a progenitor population distinct from the bulk tumor cells. Co-expression of CD44 and CD24 was observed in ∼0.1% of $CD133^+$ CSCs, suggesting the possibility that multiple, distinct populations may exist. Furthermore, this population of pancreatic CSCs was enriched in xenograft tumors following gemcitabine treatment, implicating this population in therapeutic resistance.

Characterization of Pancreatic CSCs

It is agreed that CSCs possess the ability to self-renew and create differentiated progeny. In vivo criteria to define CSCs come from limiting dilution assays in immunodeficient mice which demonstrate the ability of CSCs to regenerate malignant populations that histologically resemble the parental cancer. Hallmarks of CSCs in vitro include slow proliferation and the ability to form spheres in nonadherent cultures due to their anchorage-independent growth properties [19]. There is currently no consensus on the phenotypic or genotypic characterization of pancreatic CSCs. Multiple studies have identified rare populations of cells in pancreatic cancer primary cultures or cell lines that meet the above criteria; however, no single marker is common to each study. Furthermore, the biological function of the respective surface markers and their contribution to "stemness" of the expressing cell remains unclear in most cases [6]. This indicates that there may be an array of phenotypes of pancreatic CSCs that may be influenced by the specific microenvironment, that CSCs with varying surface markers may represent various stages of differentiation, or that there is a common, currently unidentified, marker uniting these populations (Table 1).

CD44, CD24, and ESA

Li et al. demonstrated that CD44+ CD24+ ESA+ cells isolated from xenograft tumors originating from patients with pancreatic cancer showed a 100-fold enrichment for tumor formation compared to CD44− CD24− ESA− cells [3]. These markers were chosen based on previous work demonstrating breast CSCs had

Table 1 Pancreatic cancer stem cell markers

Marker	First author, year
CD44+/CD24+/ESA+	Li, 2007 [3]
CD44+/c-Met^{high}	Li, 2011 [31]
CD133+	Hermann, 2007 [4]
CD133+/CXCR4+	Hermann, 2007 [4]
ALDH1	Kim, 2011 [13]
Autofluorescence	Miranda-Lorenzo, 2014 [42]
Side populations (ability to efflux the Hoechst 33342 dye)	Neiss, 2015 [6]

similar properties [18]. In vitro work in Panc-1 cells demonstrated that CD44+ CD24 + cells comprise 2.1–3.5% of the culture population and that these cells have a 20-fold increase in tumorigenicity compared to cells negative for these markers [20]. It is unclear if these unique cell surface markers functionally contribute to the pancreatic CSC phenotype or if their expression is a by-product of upstream signaling events in pancreatic CSCs. CD24 is a heavily glycosylated cell surface protein that plays an important role in cell selection and maturation during hematopoiesis. CD24 is also known to be an alternative ligand for P-selectin and may facilitate cell-cell interactions and has been proposed to play a role in metastasis. Interestingly, growth of multiple pancreatic cancer cell lines has been shown to be dependent on CD24 signaling [19, 21]. ESA (also known as EpCAM) is expressed on the basolateral cell surface of most human simple epithelia and is also expressed in the vast majority of carcinomas lending to its common use as a tumor marker [22]. CD44 is a cell surface glycoprotein that is broadly expressed by cells of epithelial, mesenchymal, and hematopoietic origin. It is involved in cell-matrix adhesion, survival, and growth and has been implicated to have a role in tumorigenesis and metastasis [23]. CD44 is thought to have a functional role in CSC biology in regulating stemness, as a splice variant of CD44 has been shown to activate the ectodomain of c-Met. CD44-positive cells have been identified as a population of cells that leave the pancreas early to disseminate systemically in a Cre-lox-based mouse model of PDA that was used to study the fate of pancreatic epithelial cells during various stages of tumor progression. In this model, Rhim et al. used a YFP lineage label to identify PDA cells that had completed an EMT and then examined the proportion of YFP+ cells in the circulation expressing CD44+/CD24+. Using fluorescence-activated cell sorting (FACS) analysis, it was shown that 23.1% ± 12.9% and 46.4% ± 14.7% of sorted YFP^{+} circulating pancreatic cells from PanIN and PDA samples were found to be CD24^{+}CD44^{+}, representing a greater than 100-fold enrichment when compared to the source pancreas [24]. Furthermore, work by Wang et al. identified in a novel PDA mouse model expressing ATDC (ataxia-telangiectasia group D complementing gene) that, in the presence of oncogenic KRAS, the formation and the development of invasive and metastatic cancers were markedly accelerated. It was shown that ATDC upregulates CD44 in mouse and human PanIN lesions via activation of β-catenin signaling, leading to the induction of a CSC/EMT phenotype [25]. Knockdown of CD44 in primary colon

cancer cell lines reduces clonogenicity in vitro and tumorigenicity in vivo [8]. Interestingly, CD44 is also a receptor for the glycosaminoglycan (HA). HA is found in high levels in the extracellular matrix in PDA. HA signaling via CD44 and other receptors has been found to regulate receptor tyrosine kinase and small GTPase activity and is implicated in the processes of angiogenesis, epithelial-mesenchymal transition, and chemoresistance [26]. This evidence suggests that the stroma may contribute to the ongoing survival of PCSCs and that current clinical trials using recombinant human hyaluronidase in the treatment of PDA may be effective, at least in part, by affecting pancreatic CSC function [27].

CD133

CD133 is a transmembrane glycoprotein expressed on normal stem cells and progenitor cells. CD133 has also been shown to identify CSC populations in multiple solid tumors, including pancreatic cancer [4, 7, 8, 28]. Hermann et al. demonstrated that CD133+ cells had increased tumorigenicity compared with CD133− cells and that the CD133+ population was enriched in xenograft tumors in mice treated with gemcitabine. Interestingly, they reported partial overlap of CD133+ cell populations with CD44+ CD24+ ESA+ population. Further studies comparing CD44+ CD24+ ESA+ cells and with CD44+ CD24+ ESA+ CD133+ cells may elucidate the functional role of this protein and further examine its role in drug resistance.

CXCR4

CXCR4 is a chemokine receptor that has been found to play a role in invasion and metastasis, as it was found to be elevated at the invasive edge of pancreatic tumors. In isolation, CXCR4 is not a marker of CSCs per se; however, it was shown to mark a subpopulation of $CD133^+$ pancreatic CSCs with a high propensity to metastasize [4]. CXCR4 is the receptor for stromal-derived factor-1 (SDF-1/CXCL12) and is important for hematopoietic stem cell homing to the bone marrow and metastasis and proliferation of cancer cells [29, 30]. Importantly, blocking $CD133^+/CXCR4^+$ cells prevented metastasis of tumor xenografts in mice. These data indicate that CXCR4 might serve as target for therapeutics designed to slow or prevent metastasis of pancreatic CSCs. Like $CD133^+/CXCR4^-$ cells, $CD133^+/CXCR4^+$ cells were resistant to cell death induced by gemcitabine, indicating the need for new approaches to effectively eliminate this cell population and prevent cancer relapse.

c-MET

The mesenchymal-epithelial transition factor gene *c-MET* is a membrane-bound receptor tyrosine kinase that has previously been identified on normal pancreatic stem and progenitor cells [31]. c-MET overexpression is associated with a stem

cell-like phenotype in a wide range of cancers, and the interaction of c-MET with its ligand hepatocyte growth factor (HGF) (also referred to as scatter factor) has been shown to promote malignancy and tumor drug resistance [32]. In the mutated or amplified form, c-MET generates and maintains the transformed phenotype and drives clonal evolution of tumorigenesis; however, the wild-type form of c-MET seems to contribute to the maintenance of the CSC phenotype [9, 33]. Li et al. examined pancreatic CSCs for the presence of c-MET and compared these subpopulations with other known pancreatic CSC markers such as $CD44^+/CD24^+/ESA^+$ and CD133+. Work in primary human pancreatic cancer cell populations demonstrated that cells expressing high levels of c-MET were as tumorigenic as $CD44^+/CD24^+/ESA^+$ cells and more tumorigenic than $CD133^+$ cells. Interestingly, $CD44^+/c\text{-}MET^{High}$ cells were the most tumorigenic of all populations, whereas $CD133^+/c\text{-}MET^{High}$ cells were comparatively less tumorigenic in vivo. Tumors formed in mice from $CD44^+/c\text{-}MET^{High}$ cells were identical to the original tumors from which they were derived. In addition, cells that express CD44+ and c-MET together were found to be more tumorigenic in mice than cells that express c-Met alone. Expression of c-MET also correlated with the ability of cells to form tumorspheres in vitro [19, 31]. It is possible that CD44 and c-Met may work in concert to promote a pancreatic CSC phenotype as CD44 is important for optimal HGF signaling via c-MET.

There is a unique appeal to c-MET as a pancreatic CSC target, as there are specific inhibitors of c-MET, unlike many other pancreatic CSC markers. Findings indicate that agents that disrupt c-MET activity might interfere with CSC activities in different tumor types, and experimental evidence suggested that c-MET plays a dual role in oncogenesis. Inhibition of c-MET activity with the kinase inhibitor XL184 (cabozantinib) reduced tumorsphere formation, growth of tumor xenografts, and metastasis in intracardiac injection models. XL184 also increased the efficacy of gemcitabine against subcutaneous and orthotopic xenograft tumors, further demonstrating its potential clinical utility [31]. The role of c-MET in CSC function was highlighted in a study showing that high expression of c-MET in glioblastoma cells correlated with increased formation of neurospheres in vitro, tumorigenesis in vivo, resistance to radiation, and expression of stem cell transcription factors, such as Nanog and SOX2 [34–36].

ALDH1

Aldehyde dehydrogenase 1 (ALDH1) has been shown to enrich for normal and malignant stem cell populations in multiple organ systems [37, 38]. Unlike the previous phenotypic markers discussed, ALDH1 is not found on the cell membrane but as it is an intracellular enzyme involved in retinoic acid metabolism. This distinct marker was first studied in CSC populations in hematological malignancies. Hess et al. demonstrated hematopoietic stem cell populations expressing that $ALDH^{high}$ and CD133+ were able to reconstitute the bone marrow with a tenfold greater capability compared to cells enriched for CD133+ expression alone [39]. Rasheed et al. demonstrated increased tumorigenic potential of

$ALDH^{high}/CD44^{+}/CD24^{+}$ and $CD44^{+}/CD24^{+}$ pancreatic cancer cell populations with ALDH expression correlating with a worse prognosis in early-stage pancreatic cancer patients [40]. Pancreatic cancer xenograft tumors exposed to gemcitabine become enriched for ALDH1+- and CD24+-positive cells, indicating that they can withstand chemotherapy [41]. Interestingly, these authors found minimal overlap between ALDH and $CD44^{+}/CD24^{+}$ cell populations (<0.1%), suggesting the existence of at least two distinct tumor-initiating populations within human pancreatic tumors.

Autofluorescence

In 2014, the unique CSC property of autofluorescence was discovered by Miranda-Lorenzo et al. in human pancreatic tumors [42]. This significant finding allowed identification of CSC independent of cell surface markers. The interest in this CSC biomarker stems from the fact that expression of cell surface markers is subject to change due to different tissue digestion protocols and isolation techniques. This alternate detection method is based on cellular autofluorescence following exposure to a standard blue laser which is thought to be a result of the accumulation of the fluorescent vitamin riboflavin in ABCG2-coated vesicles exclusively located within the cytoplasm of CSCs. Cells that possess this property demonstrated CSC features and phenotypes, such as self-renewal, exclusive long-term tumorigenicity, and invasiveness in vivo. This population was found to compose 0.04–6.38% of bulk pancreatic tumor cells. Autofluorescence allowed this rare population to be detected by flow cytometry and avoided some of the possible artifacts of surface markers. It was found that the CSC surface markers CD44, CD133, and CXCR4 were variably overexpressed in autofluorescent cells; however, none of these markers was exclusively restricted to autofluorescent cells, suggesting that these may represent a discrete subpopulation within the CSCs.

Other CSC Subpopulations

Work by Niess et al. in 2015 identified another potential measure of pancreatic CSCs that is independent of cell surface markers. The unique phenotype of these CSC cells is thought to partially depend on the ABCG2 transporter, which bears a similar mechanism to autofluorescence CSC populations. Putative CSCs referred to as "side populations" (SP) were isolated from bulk tumor cells based on their ability to efflux the Hoechst 33342 dye. Cells that are able to efflux Hoechst dye are thought to harbor cell membrane transporters, such as the ABCG2 transporter, giving cells the ability efflux chemotherapeutics which is thought to augment therapeutic resistance. SP cells have been previously identified in multiple CSC populations including hepatocellular carcinoma [43], melanoma [14], glioma [44], and esophageal and lung cancer [10, 15]. In this study, SP cells were isolated from the human pancreatic cancer cell line L3.6pl, and tumorigenicity was evaluated following orthotopic

injection of SP and non-SP cells into athymic mice. SP cells were found to comprise 0.9% of the population and demonstrated the ability to self-renew and differentiate into non-SP cells. Only SP-derived cells were found to have significantly formed tumors compared to non-SP and unsorted cells. In addition, all animals injected with SP cells presented with large metastases in the liver and lymph nodes, whereas animals injected with non-SP cells showed only one animal with liver metastases, and two out of ten animals presented with lymph node metastases. When L3.6pl cells are cultured with increasing concentrations of gemcitabine, the proportion of SP cells, ABCG2 transporter, and CD24 cells were significantly enriched. Some overlap was found between SP cells and CD24+ cells, a previously identified CSC marker; however, there was no overlap found with CD133+ cells [6]. Further work to examining overlap of SP cells with other CSC cell surface marker characteristics may help unite some of the distinct putative pancreatic CSCs being investigated.

Cell Signaling Pathways in CSCs

Defined genetic alterations have been identified in pancreatic cancer; the most notable is an activating mutation in K-ras in over 90% of cases [45]. In addition, a significant number of pancreatic tumors have lost tumor suppressor activity in $p16^{INK4A}$, SMAD4, and p53. Determining the involvement of these genes in the temporal development of premalignant and malignant pancreatic lesions is evolving with the use of genetically engineered mouse models of pancreatic cancer and microdissection of human PanIN lesions. At this time there is not a clear link between these genetic mutations and the phenotypic appearance and behavior of pancreatic cancer cells and CSCs, including their cell surface markers. Several studies have noted alterations in developmental cell signaling pathways that are associated with pancreatic cancer development and progression.

Sonic hedgehog (SHH) is a developmental morphogen in humans that has a critical role in embryogenesis, including normal pancreas development. It is well established from in vitro and in vivo evidence that the SHH signaling pathway is aberrantly reactivated in pancreatic cancer [46–51]. There are studies suggesting SHH is also one of the mediators in pancreatic CSCs [47, 51]. SHH signaling is initiated by the binding of its ligand, namely, SHH, Indian hedgehog, or Desert hedgehog to its receptor Patched which then interacts with Smoothened (SMO). This leads to an intracellular cascade that results in activation and nuclear translocation of the Gli family transcription factor Gli1. Gli transcription factors turn on genes in the nucleus that promote cellular proliferation, cellular survival, stemness, and cell fate determination in a variety of organs [48]. Recent evidence indicates that the Gli genes have a critical role in normal pancreas development and that this dysregulated SHH signaling plays some role in pancreatic cancer [49]. Reverse transcriptase polymerase chain reaction has found that SHH is increased 46-fold in CD44+ CD24 + ESA+ pancreatic CSCs compared with normal pancreatic epithelial cells [46]. Singh et al. [47] identified downstream targets of the Gli genes that regulate cellular

proliferation and survival in pancreatic CSCs by using a small molecule inhibitor of SHH signaling, GDC-0449. GDC-0449 induced significant cell death in pancreatic CSCs isolated from three pancreatic cancer cell lines and decreased expression of SHH signaling components Gli1, Gli2, Patched-1, Patched-2, SHH and Smoothened, Gli-DNA binding, and Gli-luciferase reporter activities. GDC-0449-induced changes in gene expression and apoptosis were blocked by Gli1 plus Gli2 shRNA, thus pointing a role of Gli for cellular proliferation and survival in human pancreatic CSCs [47].

Initially, there appeared to be a correlation between in vitro, in vivo, and clinical data in regard to SHH. Overexpression of SHH and its downstream effector, Gli1, is associated with a poor overall survival of pancreatic adenocarcinoma patients [52]. However, a pilot clinical trial with an SHH inhibitor alone or in combination with gemcitabine failed to improve clinical outcomes in pancreatic cancer patients [53]. Similarly, strategies that target signaling pathways overexpressed in more differentiated pancreatic cancer cells alone or in combination with conventional cancer therapeutics have disappointed in clinical trials [54]. It is clear that the SHH pathway plays a role in pancreatic CSC signaling; however, based on the above evidence, this pathway is not sufficient for maintenance of this cell population in isolation, and future therapeutic strategies need to simultaneously target additional regulatory pathways in differentiated cancer cells as well as pancreatic CSCs.

The Notch pathway controls important cellular processes including stemness, differentiation, proliferation, and survival [55]. In addition, Notch pathway activation is described for many human cancer types, including lung, colorectal, breast, and pancreatic cancer [56–58]. In mouse models for pancreatic cancer, the Notch signaling pathway has shown to be important, where inhibition of Notch signaling by a γ-secretase inhibitor (GSI) completely blocked tumor formation [58]. There is also evidence suggesting inappropriate activation of Notch signaling could be an early event leading to accumulation of undifferentiated precursor cells in pancreatic cancers and promotes survival of CSCs [59]. Using primary human pancreatic xenografts, Abel et al. (2014) demonstrated that the CSCs (CD44+ CD24+ ESA+) had upregulation of the Notch pathway components, including Notch 1–3, Hes1, Jag2, and DDL1. Inhibition of the Notch pathways with a gamma-secretase inhibitor R0492907 or Hes1 shRNA reduced the percentage of CSCs and tumorsphere formation. Furthermore, in vivo treatment of orthotopic pancreatic tumors in NOD/SCID mice with the gamma-secretase inhibitor MK-0752 also blocked tumor growth and reduced the CSC population in the tumors [60]. Similarly, Wang et al. found higher Notch1 expression in pancreatic CSC compared with the non-CSC population in L3.6pl cells [61]. Ji and colleagues reported that $CD44^{+}/CD133^{+}$ expressing pancreatic CSCs contain high levels of Notch1 and Notch2 and that restoration of miR-34 downregulates both receptors [62].

DLL4 is an important component of Notch-mediated stem cell self-renewal and vascular development. Yen et al. investigated the contributions of DLL4 in tumor cells and in the host vasculature and stroma in a panel of xenograft models derived

from pancreatic cancer patients by treating the mice with neutralizing antibodies against human and mouse DLL4. Anti-DLL4 was found to reduce CSC cell frequency as a single agent and in combination with gemcitabine. It was found that the effect on CSCs in xenograft experiments was due to targeting DLL4 expressed on human tumor cells and not mediated through inhibition of DLL4 in the host stroma and vasculature [63].

Ponnurangam et al. identified a pharmacological agent, Quinomycin, targeting the Notch signaling pathway in a mouse model of pancreatic cancer [64]. Nude mice carrying tumor xenografts were administered Quinomycin, and it was found that treatment with the compound significantly inhibited tumor xenograft growth, coupled with significant reduction in the expression of CSC markers and Notch signaling proteins. Moreover, Quinomycin affected pancreatosphere formation and decreased the expression of CSC marker proteins DCLK1, CD44, CD24, and EPCAM. Furthermore, levels of Notch 1–4 receptors; their ligands Jagged1, Jagged2, DLL1, DLL3, and DLL4; and the downstream target protein Hes-1 were reduced. Ectopic expression of the Notch intracellular domain (NICD) partially rescued the cells from Quinomycin-mediated growth suppression. Together, these data suggest that the Notch signaling pathway is an integral component of CSC survival in pancreatic cancer [64].

Bmi1 is a member of the Polycomb group family of proteins that has been has found to be important in oncogenesis in multiple solid tumors [65, 66]. It has also been shown to be important for maintenance and self-renewal of normal stem cells. Proctor et al. noted overexpression of Bmi1 in the cancer stem cell compartment in primary human pancreatic cancer xenografts and that tumorspheres demonstrate high levels of Bmi1 compared to bulk tumor cells [67]. Silencing of Bmi1 with shRNA in CSCs derived from primary human pancreatic cancer xenografts resulted in smaller tumor development in NOD/SCID mice and decreased CSCs self-renewal. This study suggests a role for Bmi1 in the regulation of pancreatic CSCs that warrants further investigation.

There is increasing interest in the role of microRNAs (miRs) in CSC biology in multiple tumor types, including pancreatic cancer [62, 68]. miRNAs are small noncoding RNAs involved in the regulation of gene expression at the posttranscriptional level by binding to the 3′-untranslated regions or the open reading frames of target genes, which then leads to either repression or degradation of mRNA [69]. miRs can be classified functionally as oncogenic, if they are upregulated in tumor cells, or tumor suppressor miR if they are downregulated in pancreatic cancer. There is some evidence to support miR contribution to initiation, propagation, and regulation of EMT in CSCs [70]. Clinically, miR-21 expression was shown to correlate with the clinical outcome of pancreatic cancer patients [71]. In addition, overexpression of miR-1246 was shown to be associated with chemoresistance and stemness in pancreatic cancer cells in vitro. In vivo it was found that miR-1246 could increase tumor-initiating potential and induced drug resistance [72]. As the role of miR in stem cell biology continues to evolve, future therapeutic strategies may focus on regulating the miRNA profile in CSCs (Fig. 2).

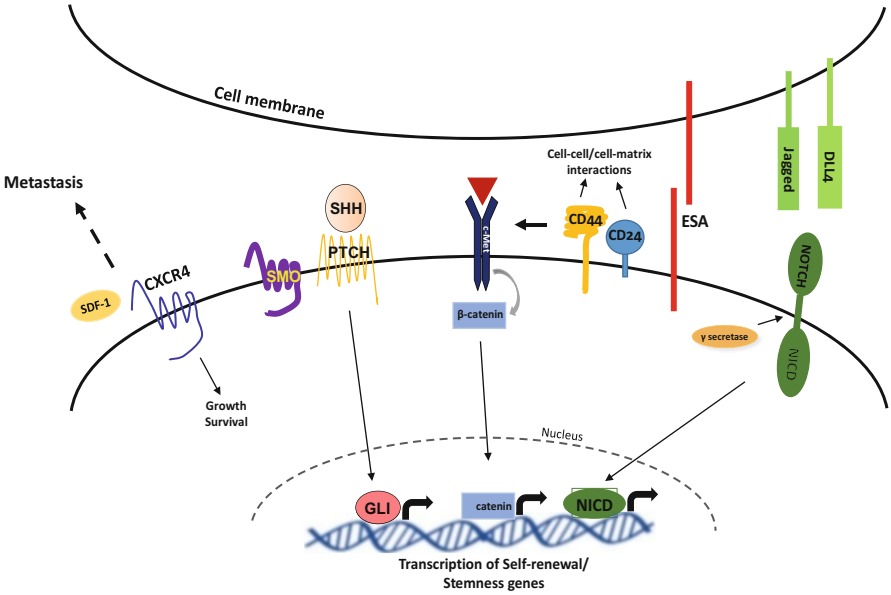

Fig. 2 Signaling pathways in pancreatic cancer stem cells. Cell surface markers ESA, CD24, and CD44 promote cell-cell or cell-matrix interactions, and CXCR4 and c-Met respond to secreted ligands to promote cancer cell migration, invasion, proliferation, and survival. Developmental pathways, such as β-catenin and Notch, are highly active in pancreatic CSCs and could be activated by canonical stimuli or oncogenes, such as c-Met. These pathways stimulate the expression of genes that regulate stem cell properties, such as self-renewal

Altered Metabolism of Pancreatic CSCs

The extensive desmoplasia that accounts for the bulk of the tumor in pancreatic cancer reduces availability of oxygen and nutrients, making pancreatic tumors one of the most hypoxic solid tumors. To maintain proliferation under these growth-restricting conditions, tumor cells undergo marked alterations in cellular metabolism. The oncogenic KRAS mutation is invariably present in most pancreatic tumors and increases glycolysis to generate macromolecules such as amino acids, nucleotides, and fatty acids. Oncogenic KRAS has also rewired glutamine metabolism and increase autophagy and micropinocytosis to provide nutrients for the rapidly proliferating tumor cells [73–77]. Additionally, intratumoral hypoxia also favors the stabilization of hypoxia-inducible factor 1 α (HIF1α) which favors the glycolytic phenotype of pancreatic cancers [78]. However, unlike their rapidly proliferating counterparts, pancreatic CSCs differ in their utilization of glucose and have increased dependence on mitochondrial metabolism and oxidative phosphorylation (OXPHOS). Recent work by Sancho et al. observed that $CD133^{+}$ pancreatic cancer stem cells have increased dependence on OXPHOS and hence have increased sensitivity to the mitochondrial complex I inhibitor, metformin [79]. However,

in vivo treatment of PDX mice with metformin subsequently generated tumors resistant to the drug. The authors further identified that this resistant population ($CD133^+$ $Mito^{low}$) had an intermediary metabolic phenotype with increased glycolysis while maintaining OXPHOS. Notably, these CSCs resembled CSC with MYC activation and PGC1α (peroxisome proliferator-activated receptor-γ coactivator 1) inhibition. The authors concluded that the interplay of MYC and PGC1α levels regulated the metabolic phenotype of CSC and sensitivity to metformin or PGC1α inhibition [79]. Interestingly, a previous study also observed an increase in CSCs ($CD133^+$, $CD44^+$) in pancreatic cancer cells with ablation of oncogenic KRAS signaling [80]. However, in the absence of oncogenic KRAS signaling, these cells lacked the intermediary population as reported by Sancho et al. [79]. Previous studies have elucidated that PGC1α mediates mitochondrial biogenesis, increased invasiveness, and OXPHOS in melanoma and breast cancers [81, 82]. Hence, in pancreatic cancer, increased PGC1α might not only contribute stemness, but it might also contribute to the high metastatic potential of these tumors.

It is important to note that understanding the metabolic phenotype of pancreatic CSCs is contingent upon the type of stem cell markers utilized to evaluate metabolism, the stage of tumor, and the period of study. Examining other established markers and tumor models will help delineate the precise metabolic heterogeneity in pancreatic CSC.

Therapeutic Targeting of Pancreatic CSCs

CSCs appear to explain many aspects of the neoplastic evolution of tumors, and there is also compelling evidence that they may account for therapeutic resistance. Knowledge of the central role that multidrug-resistant (MDR) transporters play in protecting normal stem cells has added insights that may partially explain treatment failure in cancer stem cells. It is known that MDR transporters protect normal and neoplastic cells, and, as such, it is thought that resting cancer stem cells, which are both the cancer-initiating cell and its source of replenishment under selective pressure, have innate drug resistance by virtue of their stem cell phenotype. Acquired drug resistance in more differentiated cancer cells may contribute to an aggressive phenotype, but it may not be the primary reason for cancer recurrence or spread after therapy [83]. In addition, cancer stem cell resistance to radiation therapy is thought to lie in the enhanced capacity of their DNA repair mechanisms. Bao et al. demonstrated that cancer stem cells contribute to radioresistance in gliomas through preferential activation of the DNA damage checkpoint response and an increase in DNA repair capacity [84]. It was shown that CD133+ cells were enriched after radiation in gliomas in both cell culture and immunocompromised mice. Interestingly, the radioresistance of CD133-positive glioma stem cells can be reversed with a specific inhibitor of the Chk1 and Chk2 checkpoint kinases. Further investigation in pancreatic cancer models will be interesting to determine whether a radioresistant population of pancreatic CSCs exists [84]. Current available therapies for patients work by eliminating bulk tumor cells, as targeting pancreatic CSC remains

investigational at this time. Eradication of CSCs is critical for long-term treatment success, as this subpopulation of cells is capable of reestablishing the tumor after the majority of the bulk tumor cells have been eliminated (Fig. 1). New approaches aimed at debulking existing tumors and eliminating CSCs will likely prevent relapse. A number of agents targeting the PCSC pathway have been shown to be effective against pancreatic CSCs in preclinical studies, and clinical trials utilizing some of these targeting approaches are currently underway.

Inhibition of c-Met with XL184 [31] or Alk-4 and Alk-7 with SB431542 [85] reduces the number of CSCs in tumors and had synergistic effects with gemcitabine to reduce the tumor burden in the mice. Maximum benefit was seen when gemcitabine and SB432542 were combined with the Smoothened inhibitor CUR199691 which works by disrupting the pancreatic CSC-stimulated stoma to increase drug delivery. Furthermore, CUR199691 synergized with gemcitabine and rapamycin to inhibit spheroid formation in vitro and tumor burden in mice [86]. The integral contribution of the Notch pathway to pancreatic CSCs was previously discussed, as it has multiple points to target for therapeutic intervention. Inhibition of Notch signaling in tumor xenografts with antibodies against the delta-like ligand4 (DLL4) reduced tumor regrowth in mice treated with gemcitabine, and it was also shown to decrease the proportion of CSCs in tumors. DDL4 inhibition also decreased tumorsphere formation [63]. Similarly, inhibition of the Notch signaling pathway with the gamma-secretase inhibitor MRK-003 in combination with gemcitabine in mice decreased tumor growth and CSC proportions [87].

Recently, it has been proposed that the c-Jun NH_2-terminal kinase (JNK) pathway is important for the self-renewal capacity of PCSCs. AS602801 is an orally administered inhibitor of the JNK pathway that is being tested for its immunomodulatory activity in phase II clinical trials examining endometriosis. Okada et al. examined the effects of AS602801 on bulk pancreatic tumor cells and subpopulations of CD133+ cells, as previous reports have implicated JNK in tumorigenesis [88]. In vitro, AS602801 exhibited cytotoxicity against both bulk tumor cells and CSCs derived from human pancreatic cancer, in addition to non-small cell lung cancer, ovarian cancer, and glioblastoma at concentrations that did not decrease the viability of normal human fibroblasts. AS602801 also inhibited the self-renewal and tumor-initiating capacity of cancer stem cells surviving the initial round of AS602801 treatment. Importantly, CSCs in established xenograft tumors were reduced by systemic administration of AS602801 at a dose that was not toxic to mice. These findings suggest AS602801 may be an anti-CSC agent and further investigation of the utility of AS602801 in the treatment of cancers [89] (Table 2).

Conclusion

The discovery of CSCs has enriched the field of cancer biology by introducing new and important concepts. It is clear that CSCs are a distinct subpopulation within bulk tumor cells that are capable of self-renewal and producing differentiated progeny. Only a select subset of cancer cells are tumorigenic, the CSCs, and these cells appear

Table 2 Agents that target pancreatic cancer stem cells

Agent	Mechanism	Tumor model	
XL184	c-Met inhibitor	O/SC/IC	Li, 2011 [31]
SB431542	Alk-4/Alk-7 inhibitor	O	Lonardo, 2011 [90]
Anti-DLL4	DLL4 blocking antibody	O/SC	Yen, 2012 [63]
MRK-003	γ-Secretase inhibitor	SC	Mizuma, 2012 [87]
CUR199691	Smoothened inhibitor	O/SC	Mueller, 2009 [86]
AS602801	JNK inhibitor	O	Okada, 2016 [89]

IC intracardiac metastasis assay, *O* orthotopic xenograft, *SC* subcutaneous xenograft

to be more resilient to standard anticancer treatment than bulk tumor cells. Pancreatic CSCs possess distinct markers, intracellular signaling, and metabolic features that distinguish them from the non-CSC tumor cells. However, more work needs to be done to more fully understand the molecular machinery that regulates self-renewal and therapeutic resistance. There are many promising new targets on the horizon to strategize how to inhibit the growth of pancreatic CSCs. However, questions remain to be answered in order to translate this knowledge into "actionable" treatments for patients. Targeted therapy against CSCs in conjunction with conventional tumor debulking chemotherapeutic agents is likely required for optimal outcomes in pancreatic cancer patients.

Apoptosis: Signaling Pathways in Pancreatic Cancer Pathogenesis

David J. McConkey and Woonyoung Choi

Contents

Abstract

Conventional and investigational cancer therapies have had little to no effect on the course of pancreatic cancer disease progression. Because apoptosis plays a major role in the effects of conventional chemo- and radiotherapy, it has been widely assumed that apoptotic pathways must be disrupted more frequently in pancreatic cancer than they are in other solid malignancies. However, comprehensive genomic characterizations of primary pancreatic cancers do not support this conclusion. Rather, it appears that one of the recently identified molecular subtypes of pancreatic cancer (quasimesenchymal/basal-like/squamous) that shares similarities with basal-like breast and bladder cancers contains tumors

that are most likely to be apoptosis sensitive and responsive to conventional chemotherapy. Otherwise it is not immediately obvious how the molecular and genomic properties of pancreatic cancers would be expected to impart apoptosis resistance, providing indirect but strong support for the conclusions that late diagnosis and the extent to which tumor-stromal interactions reinforce apoptosis resistance represent the truly unique challenges to effective clinical control of the disease. This book chapter will provide an update of what has been learned recently about the molecular control of apoptosis in pancreatic cancer and how the information might be exploited in the design of more effective therapeutic regimens.

Introduction

"Apoptosis" is a term that was coined by Andrew Wyllie, John Kerr, and Alistair Currie in 1972 to describe a series of stereotyped morphological alterations are associated with most physiological cell deaths, including programmed cell death during development [1]. These changes include chromatin condensation, nuclear and plasma membrane blebbing, cell shrinkage and detachment from neighboring cells, and specific recognition and engulfment by tissue macrophages. Subsequent biochemical studies demonstrated that apoptosis is usually associated with endogenous endonuclease activation, resulting in the formation of oligonucleosome-length DNA fragments ("DNA ladders") [2]. Parallel chemical mutagenesis experiments in *Caenorhabditis elegans* embryos revealed that developmentally programmed apoptosis in the organism requires two genes, termed *ced-3* and *ced-4* [3], and subsequent work revealed that *ced-3* encodes an aspartate-specific cysteine protease (the first "caspase") [4]. Caspases are also required for apoptosis in mammalian cells [5], and caspases are required for the DNA fragmentation associated with the response [6].

Major insights into the biochemical mechanisms involved in caspase activation came from studies with large volumes of HeLa cell extracts, where investigators isolated three proteins ("apoptosis protease activating factors" or Apafs) that could promote activation of recombinant procaspase-3 when the extracts were supplemented with ATP [7]. Microsequencing revealed that one of the proteins was another caspase (procaspase-9) and a second was the mitochondrial electron transport chain intermediate, cytochrome c. The third (termed Apaf-1) is the mammalian homolog of ced-4. Functional studies revealed that Apaf-1 functions as an adaptor protein, promoting the cytochrome c- and ATP-dependent oligomerization and activation of procaspase-9 [8]. Active caspase-9 then cleaves and activates caspases 3 and 7, the two major mammalian "effector" caspases that initiate cell death in mammalian cells.

These observations catalyzed an aggressive investigation of the biochemical mechanisms that control cytochrome c release from mitochondria during apoptosis. Work from several laboratories demonstrated that pro- and anti-apoptotic members of the BCL-2 family are centrally involved. BCL-2 was originally cloned as an oncogene that is located at the t(14;18) translocation that serves as the hallmark feature of follicular non-Hodgkin's B cell lymphomas [9, 10]. Subsequent work revealed that BCL-2 acts to suppress apoptosis [11] and that it is structurally and functionally related to another molecule (BCL-X_L) that also inhibits apoptosis [12]. Investigators showed that the protein localizes to mitochondria [13] and that it binds to structurally related polypeptides that promote cell death [14]. The BCL-2 family is now known to consist of multiple death inhibitors (i.e., BCL-2, BCL-X_L, MCL-1) and death promoters (Bax, Bak, Bad, Bid, Bim, etc.), and that the death promoting members of the BCL-2 family can be further divided into two subfamilies ("multidomain" and "BH3-only") based on the number of domains they share with BCL-2 and the other death inhibitors [15]. Cytochrome c release occurs when activation of a member of the BH3-only subfamily induces Bax and/or Bak to form pores in the outer mitochondrial membrane [16], and the anti-apoptotic members of the family inhibit pore formation by binding to and neutralizing pro-apoptotic members of the family [15]. Interestingly, BH3-only proteins are activated by different environmental cues, and specific BH3-only proteins bind preferentially to specific anti-apoptotic members of the BCL-2 family [17]. These properties of the BH3-only proteins allow for different cell types to display different sensitivities to upstream apoptotic regulators.

The inhibitor of apoptosis proteins (IAPs) make up a second family of polypeptides that play central roles in regulating caspase activation [18]. Originally identified in baculoviruses, the IAPs can directly bind to and inhibit certain caspases, thereby preventing cell death [18]. There is good consensus that X-linked inhibitor of apoptosis protein (XIAP) is the most potent direct inhibitor of caspases, although others (including survivin and the cIAPs) can also block cell death [18]. Parallel studies in *Drosophila* and mammalian cells showed that the death inhibitory activities of the IAPs are under the control of another family of proteins. These polypeptides, including Reaper, Hid, and Grim in *Drosophila* and Second Mitochondrial Activator of Caspases (SMAC) in mammals, directly bind to and neutralize the IAPs, releasing bound caspases to allow them to participate in induction of apoptosis [18]. The sequestration of SMAC within mitochondria places it under some of the same BCL-2 family-dependent mechanisms that control cytochrome c release.

Apoptosis is initiated by a variety of different kinds of intracellular stress and/or by aggregation of surface receptors known as "death receptors" – extrinsic pathway. The most familiar death receptors are the type 1 receptor for tumor necrosis factor, Fas, and the receptors for tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), which are known as death receptors 4 and 5 (DR4 and DR5). Following ligand-induced trimerization, death receptors recruit an adaptor protein known as Fas-associated death domain (FADD), which binds to and activates caspases 8 and 10 via oligomerization [19]. In lymphocytes caspase-8 activation is sufficient to cause downstream proteolytic processing and activation of effector caspases to cause

cell death. However, in most other cells (termed "type II" cells), the signal must be amplified via the mitochondria for cell death to proceed efficiently [20]. This amplification is also mediated by active caspase-8, which cleaves the BH3-only protein Bid, producing a functionally active form of the protein (tBid) that translocates to the mitochondria and promotes Bax/Bak activation and cytochrome c release [21]. It has been determined that XIAP dictates whether or not a given cell belong to the "type II" category [20]. Although its name implies otherwise, few cancer cells are actually sensitive to TNF-induced apoptosis because TNF usually activates pro- and anti-apoptotic signals simultaneously. The anti-apoptotic signal is dependent on the transcription factor nuclear factor kappa B (NFκB), and inhibitors of NFκB are powerful sensitizers to TNF-induced apoptosis [22].

Apoptosis is tightly linked to proliferation and the molecular mechanisms that control cell cycle progression. Studies focused on the Myc oncogene demonstrated that it promotes both cell cycle progression and apoptosis and that the outcome is determined in part by the presence or absence of exogenous tissue-specific growth factors that are required for maintenance of survival [23]. In normal cells, oncogene-associated apoptosis sensitization involves the tumor suppressor $p19^{ARF}$, which is upregulated by oncogenes and functions to promote accumulation of p53 by shuttling its physiological inhibitor (mdm2) to the nucleolus. TP53 is also required for DNA damage-induced apoptosis in immature thymocytes [24, 25] and oncogene-sensitized normal fibroblasts or epithelial cells [26], observations that served as the basis for the hypothesis that tumor-associated inactivating *TP53* mutations and deletions impart resistance to conventional chemo- and radiation therapy in cancer patients. However, subsequent work in patients with solid tumors have largely overturned this hypothesis. Rather, it appears that p53's more potent effects as an inhibitor of cell cycle progression override its ability to promote DNA damage-induced apoptosis in epithelial cancers. The strongest support for this idea has come from experiments in preclinical mouse models of breast cancer, where stable chemotherapy-induced tumor regressions were only observed in tumors that lacked wild-type p53 [27]. TP53 inactivation was also associated with more clinical benefit in breast cancer patients treated with neoadjuvant chemotherapy in the I-SPY clinical trial [28].

Cell-Autonomous Mechanisms of Apoptosis Resistance in Pancreatic Cancer

There is the sense that some human cancer cells are intrinsically more apoptosis sensitive than others, and if they could be identified prospectively, patients with apoptosis-sensitive tumors could be more aggressively managed with conventional therapies. Recent work has defined the mechanistic basis for intrinsic apoptosis sensitivity [29]. Cancer cells can be "primed for death" because one or more of the anti-apoptotic members of the BCL-2 family are bound constitutively to pro-apoptotic BH3 proteins [29]. This creates vulnerability to any further increase in BH3 protein availability, and this "primed" state has been linked to clinical

response to specific BCL-2 family small molecule inhibitors and conventional chemotherapy [30]. Developing methods to identify these vulnerabilities in pancreatic cancer could be used to identify the patients who will benefit the most from cytotoxic therapies. In addition, these approaches might also allow for the identification of the mechanisms that cause intrinsic resistance and strategies to overcome them. Active nuclear factor kappa B (NFκB) and epithelial-to-mesenchymal transition (EMT) are two such mechanisms that appear to play particularly important roles.

Role of NFκB

Although pathway analyses have implicated "apoptosis" as one of the pathways that is commonly disrupted in pancreatic cancers [31], recently completed comprehensive genomic characterizations of primary human pancreatic cancers have failed to identify high-frequency mutations or copy number alterations that would be expected to directly impart apoptosis resistance (like the t(14;18) chromosomal translocation does in non-Hodgkin's lymphomas) [32]. However, there are indirect apoptosis resistance mechanisms that appear to be particularly relevant to the disease. The one that has been studied the longest involves the inflammation-associated transcription factor, NFκB, which has been widely implicated in the maintenance of cell survival [33]. NFκB is constitutively active in a majority of human pancreatic cancer cell lines and primary tumors [34], and NFκB inhibitors sensitize pancreatic cancer cells to TRAIL- and chemotherapy-induced apoptosis [35, 36]. Several of the central regulators of apoptosis are direct transcriptional targets of NFκB, including BCL-X_L and XIAP [36]. *KRAS* mutations play major roles in driving NFκB activation [37] through direct effects and indirect effects on autocrine and paracrine cytokine production [38]. Constitutive PI3 kinase/AKT pathway activation is also involved [39].

The role of NFκB in maintaining chemoresistance has been examined using RNAi to knock down expression of NFκB's p65 subunit in human pancreatic cancer cell lines and xenografts [40]. This panel included cells that were sensitive (BxPC-3, L3.6pl, CFPAC-1) or resistant (mPANC96, Panc-1, MiaPaCa2) to gemcitabine-induced apoptosis at baseline [40]. Strikingly, p65 knockdown induced apoptosis and increased gemcitabine-induced cell death only in the cells that were sensitive to gemcitabine at baseline. In contrast, p65 knockdown had no effect on basal or gemcitabine-induced apoptosis in the gemcitabine-resistant cells in vitro or in vivo [40]. Therefore, while it is clear that NFκB controls the expression of important anti-apoptotic genes in pancreatic cancer cells, it is not clear that NFκB inhibition will be sufficient to overcome intrinsic apoptosis resistance.

Nevertheless, the preclinical observations implicating constitutive NFκB activation in pancreatic cancer have generated enthusiasm for evaluating NFκB inhibitors in pancreatic cancer therapy. Unfortunately, no potent and specific inhibitors are clinically available, but two "dirty" NFκB inhibitors have been evaluated. The first was the proteasome inhibitor bortezomib (Velcade, formerly known as PS-341),

which in preclinical studies PS-341 inhibited the growth of some [41] (but not all) [42] pancreatic cancer xenografts, effects that were associated with induction of apoptosis and inhibition of angiogenesis. However, combination therapy with bortezomib plus gemcitabine [43] or carboplatin (G. Varadhachary, personal communication) failed to produce any clinical benefit in the second line in patients. Aside from their effects on NFκB, proteasome inhibitors have strong cytostatic effects, and these effects may even interfere with apoptosis induced by conventional therapies.

Curcumin was the second inhibitor to enter clinical trials. It is a natural product NFκB inhibitor that also displayed promising activity in preclinical models of human pancreatic cancer [34]. Unfortunately, it appears that curcumin's low water solubility could be a barrier to clinical development. Even though the dose of oral curcumin selected for Phase II studies was high (8 g/day) [44–46], it displayed poor bioavailability [44, 45, 47]. These observations prompted the development of liposome-encapsulated [48] and lipid-mixed formulations [47], which are still undergoing clinical evaluation.

Role of EMT

Epithelial-to-mesenchymal transition (EMT) is an important developmental program that is often reactivated in epithelial tumors as they progress to become metastatic. The hallmark feature of EMT is loss of the homotypic adhesion due to down-regulation of E-cadherin, accompanied by other changes such as loss of cell polarity genes and increased motility and invasion [49]. These changes in global gene expression are mediated by two transcription factors (Zeb-1, Zeb-2) that recruit histone deacetylases to E-box elements within the E-cadherin promoter [49]. Members of the microRNA (miR) 200 family also play important roles in maintaining the "epithelial" phenotype by repressing Zeb-1 and Zeb-2. Recent work has also demonstrated that these transcription factors can drive some of the canonical epigenetic changes (DNA methylation) that are observed during the progression of solid tumors and cells that have undergone EMT share important properties with cancer stem cells [50].

To identify molecular mechanisms involved in gemcitabine sensitivity or resistance, baseline gene expression profiles were obtained with a panel of human pancreatic cancer cell lines selected on the basis of sensitivity or resistance to gemcitabine-induced apoptosis [51]. The results demonstrated that markers of EMT, and in particular expression of Zeb-1, closely correlated with gemcitabine resistance and cross-resistance to cisplatin and 5-fluorouracil. Knockdown of Zeb-1 not only restored E-cadherin expression but also sensitivity to all three drugs. EMT also generates resistance to EGFR inhibitors, as several studies showed that loss of E-cadherin was associated with resistance to the clinical EGFR inhibitors gefitinib and erlotinib in NSCLC, colon cancer, pancreatic cancer, and head and neck squamous cell carcinoma lines [52–56]. Subsequent work demonstrated that Zeb-1 expression was associated with intrinsic resistance to apoptosis [30], and even more

recent work demonstrated that EMT was not as important for pancreatic cancer metastasis as it was for drug resistance [57]. Other studies indicate that EMT can overcome Kras dependency [58, 59], which could have important implications for the development of Kras inhibitors for pancreatic cancer therapy.

Several clinically available inhibitors of chromatin-modifying enzymes reverse EMT in human cancer cells in vitro. Histone deacetylase (HDAC) inhibitors, including vorinostat, restore E-cadherin expression and enhance EGFR inhibitor sensitivity in "mesenchymal" tumor cells [60]. However, HDAC inhibitors also promote p21-associated cell cycle arrest, and this may not be desirable when these agents are combined with conventional chemotherapeutic agents that are more active in cycling cells. It may also be difficult to achieve biologically active concentrations of HDAC inhibitors without producing toxicity when they are combined with gemcitabine and other conventional chemotherapeutics in patients [61]. Inhibitors of the H3K27 histone methyltransferase EZH2 have also been reported to increase E-cadherin expression and gemcitabine sensitivity in vitro [62], and several of them are now being evaluated in clinical trials. It remains to be seen whether they can reverse EMT and promote sensitivity to chemotherapy at clinically achievable concentrations in patients.

The recent identification of molecular subtypes in primary human pancreatic cancers [32, 56, 63] has important implications for interpreting the impact of EMT on drug resistance in patients. One of the subtypes, termed "quasimesenchymal" [56], "basal-like" [63], or "squamous" [32], is similar to the basal subtypes found in breast and bladder cancers [63] and is enriched with EMT biomarkers [56] and gene expression signatures associated with Myc pathway activation [32]. Therefore, they exhibit biological properties associated with both apoptosis resistance (EMT) and sensitivity (Myc). Preliminary analyses of their clinical properties suggest that like their breast and bladder cancer counterparts, they are associated with shorter disease-specific survival in the absence of neoadjuvant chemotherapy [32], but they may also be more chemosensitive than the tumors that belong to the other subtypes [56, 63]. Prospective clinical studies should be designed to examine whether basal subtype membership is really linked to clinical benefit from neoadjuvant chemotherapy.

Tumor-Stromal Interactions and Drug Resistance

It appears that cell-extrinsic rather than cell-intrinsic mechanisms are largely responsible for the therapeutic resistance that is observed in preclinical models and pancreatic cancer patients. Pancreatic cancers are characterized by an extensive fibrotic stromal compartment that plays important roles in cancer biology. Over the last 15 years, investigators have developed better preclinical models that can be used to define the molecular mechanisms that give rise to the fibrotic stroma and mediate apoptosis resistance in the epithelial compartment of the tumor. In early studies, investigators developed strategies to isolate and culture the cancer-associated fibroblasts (CAFs, also known as "stellate cells") that are a major constituent of the

inflammatory stroma in pancreatic cancer [64]. In vitro co-culture experiments have shown that they promote resistance to gemcitabine and radiation in vitro and they enhance tumorigenicity when they are co-inoculated with human cancer cells in orthotopic xenografts in vivo [65]. Subsequent work in genetically engineered mouse models demonstrated that the fibrotic stroma in pancreatic cancers prevented cancer chemotherapeutic agents and potentially immune cells from even entering the tumors [66]. Many reports had documented that paracrine tumor-stromal interactions involving the sonic hedgehog (Shh) pathway are important in pancreatic cancers, and in the initial preclinical study, a Shh inhibitor promoted sensitivity to gemcitabine by reducing fibrosis and increasing drug delivery [66]. However, in subsequent clinical trials, combinations of gemcitabine plus Shh inhibitors did not produce increased drug accumulation, response rates, or survival in patients [67, 68]. This led to the design of more sophisticated preclinical studies in which stromal fibroblasts were conditionally eliminated either by ablating SHH [69] or by using the fibroblast-specific a-SMA promoter to drive thymidine kinase expression and sensitivity to the cytotoxic drug ganciclovir in CAFs [70]. In both cases, this produced more poorly differentiated and high-grade tumors that were associated with shorter disease-specific survival [69, 70]. In these models, CAF depletion either had no effect on gemcitabine sensitivity [70], or it even inhibited gemcitabine-induced tumor growth control [69], even though CAF ablation was associated with increased apoptosis [70]. These results prompted both groups to conclude that CAFs act to restrict (rather than promote) pancreatic cancer disease progression.

Perhaps not surprisingly, more recent studies demonstrated that even the tumor-associated stroma is heterogeneous in pancreatic cancers. One group used bioinformatics to isolate stroma signatures in public gene expression profiling datasets [63]. They concluded that pancreatic tumors contained either “normal” (stellate cell) or “activated” (CAF) signatures and that the latter were associated with more aggressive disease [63]. The stromal signatures were not associated with tumor molecular subtype (quasimesenchymal/basal vs. classical), but the presence of the “activated” CAF signature was associated with shorter disease-specific survival in both subtypes [63]. The concept of stromal heterogeneity was reinforced by another recent study, which showed that inactivation of the TGFβ pathway in tumor cells was associated with more stromal-epithelial tissue tension, STAT3 activation, and more aggressive disease [71]. Importantly, both studies demonstrated that increased tumor macrophage infiltration was also associated with more aggressive disease biology. Clearly future studies will need to focus on how other aspects of stromal heterogeneity, including differences in cell types and matrix proteins, contribute to the clinical characteristics of these tumors.

Although these observations seem to make the impact of stromal biology on apoptosis even more difficult to understand, some general conclusions and hypotheses can be advanced. As discussed above, apoptosis sensitivity is associated with cell cycle progression, and ablation of stromal fibroblasts generated more undifferentiated, high-grade tumors that proliferated more rapidly [69] and exhibited higher rates of spontaneous apoptosis [70]. Therefore, the results are consistent with the overall idea that the shorter disease-specific survival observed in these models

was not due to apoptosis resistance but rather to more rapid proliferation and progression. It seems likely that more aggressive combination chemotherapy (perhaps including a platinum agent with gemcitabine) would produce more benefit in the ablated tumors versus controls. It would also be interesting to know whether the presence of "activated" fibroblast signatures was associated with more or less benefit in patients with basal tumors (one would expect less). Larger studies are required to address this question.

Conclusions

The completion of large genomic studies and the development of new tools to visualize cancer at the single cell (and cell-free) levels provide an unprecedented opportunity to design new tools for the early detection and treatment of pancreatic cancers. The scientific approach to these problems is also changing, with more emphasis on whole genome as opposed to single gene or pathway analyses and the design of preclinical models (organoids, PDX models, GEMMs) that better capture crucial elements of human disease. It has become clear that apoptosis sensitivity and resistance are not binary states but represent a continuum and predicting therapeutic outcome will require not only knowledge of baseline tumor characteristics but also an understanding of how tumors adapt and evolve in response to cytotoxic stress. Both of the tumor-autonomous apoptosis resistance mechanisms highlighted in this chapter (NFκB activation and EMT) are induced by stress, so future studies must take inducible resistance into account. The tumor-associated stroma also adapts in response to stress, and it will be important to measure the dynamics of these changes in preclinical models and clinical trials in patients.

Progress can also be accelerated by exploiting neoadjuvant clinical trial designs. Past experience in patients treated with neoadjuvant chemotherapy for breast or bladder cancers demonstrated that pathological downstaging predicts for disease-specific survival, which means that candidate regimens can be screened for clinical activity much more rapidly in the neoadjuvant setting. Just as importantly, neoadjuvant studies allow for the collection of matched tumors before and after therapy, which enables the visualization of tumor adaptation. Preclinical models can be powerful tools for mechanistic interrogation but do not rival primary patient tumors as a resource for initial discovery.

Abstract

The epidermal growth factor receptor (EGFR/ErbB) signaling axis influences the development, maintenance, and disease of tissues throughout the body. Effects have been demonstrated on normal cell proliferation, migration, differentiation, adhesion, and apoptosis in pancreas as well as heart, muscle, nervous system, and a wide variety of organ epithelia. In addition, alterations in the epidermal growth factor (EGF) pathway, including overexpression of the ErbB family of receptor tyrosine kinases, mutations in downstream mediators (e.g., Ras), as well as aberrant signaling, are present in the vast majority of pancreatic and other solid tissue tumors. The importance of the ErbB signaling axis to cancer is illustrated by the number of articles and reviews published on this topic to date (>20,000 and >3000, respectively). In line with the importance of ErbB signaling to cancer, several anticancer therapies have been developed targeting various parts of the ErbB signaling axis and are currently in use, with more undergoing intense development and investigation. Presently, the NIH currently cites an extensive list of clinical studies of ErbB signaling in cancer.

Keywords

ErbB · Epidermal growth factor · EGF · EGFR · Signaling · Pancreatic cancer · Therapy · Molecular imaging

Introduction

Studies of EGF date back to the 1950s when its roles in gastrointestinal ulcers, and subsequently in cancer, were discovered [1, 2]. EGF is now known as the founding member of the EGF family of ligands. EGF ligands signal through the ErbB family of receptors to alter intracellular protein activity, gene transcription, and cell biological status with respect to proliferation, migration, differentiation, and more.

ErbB signaling has roles in numerous diseases, most notably cancer but also psoriasis, Alzheimer's disease, and schizophrenia [3]. ErbB1 is overexpressed in colorectal, gastric, ovarian, renal, prostate, cervical, brain (including glioblastoma multiforme, GBM), non-small cell lung cancer (NSCLC), and squamous cell head and neck cancer. ErbB2 is a potent inducer of neuroblastoma and metastatic mammary tumors in rats and is overexpressed or mutated in many human cancers including breast, brain (including GBM), and NSCLC. In mouse, an increase in ErbB signaling causes cancers of the pancreas, breast, lung, colon, stomach, ovary, brain, prostate, and kidney.

In the pancreas, ErbB signaling affects development and growth of both the endocrine and exocrine pancreas [4, 5], and its receptors influence the development and progression of pancreatic cancer. In fact, ErbB1, also known as EGFR, is overexpressed in 30–90% of pancreatic cancer [6] where neoplastic cells appear to enter the lymph node and establish metastasis to other organs [7]. EGFR has become

a model of translational research that raises the stature of basic science. This is a prime example of how a molecule discovered in the laboratory can transcend the bench and become a therapeutic proof of principle. Moreover, studies on ErbB family members have inspired the birth of other molecular-targeted areas, such as anti-VEGF, anti-TGF-β, anti-c-KIT, and others.

EGF Ligands

EGF ligands have different affinities for the different ErbB receptors [3, 8]. Seven ligands have high affinity for ErbB1 (amphiregulin (AREG), betacellulin (BTC), EGF, epigen, epiregulin (EREG), heparin-binding EGF-like growth factor (HBEGF), and TGF alpha). Of these, BTC, epigen, and EREG also bind ErbB4, as does neuregulin (NRG)-1, NRG-2, NRG-3, NRG-4, and tomoregulin. NRG-1 and NRG-2 also bind ErbB3, as does Neuroglycan C (Fig. 1).

All of the EGF ligands are single-transmembrane glycoproteins with an N-terminal extracellular region and C-terminal cytoplasmic tail [8]. A juxtamembrane extracellular EGF domain is common to all ligands. This EGF domain contains six conserved cysteines, which form three disulfide bonds providing a common secondary structure and allowing interaction with ErbB receptors. EGF is unique in that it has nine repeats of the EGF domain. The presence of AR, BTC, and EPR in syntenic regions of human chromosome 4 and mouse chromosome 5 suggests these ligands

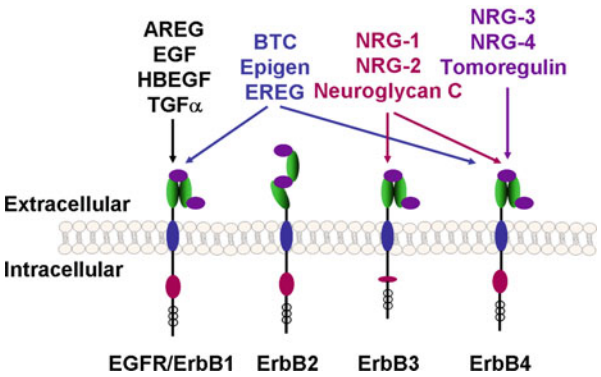

Fig. 1 ErbB receptors and their ligands. The four ErbB receptors with their corresponding high-affinity activating ligands are shown. All four receptors have an extracellular amino terminus with two cysteine-rich (*CR*) domains (*green*) containing the dimerization domain (*DD*) and two leucine-rich ligand-binding domains (*L*) (*purple*). Receptors all have a single-transmembrane domain (*blue*), an intracellular kinase domain (*pink*), and carboxy terminal tail with tyrosine phosphorylation sites (*open circle*). Receptors are shown here as inactivated monomers (*no ligand bound*). In the inactivated state of ErbB1, ErbB3, and ErbB4, the two CR domains are tethered by disulfide bonds (*shaded green*) sequestering the DD so that it is unavailable for dimerization. In contrast, ErbB2 does not bind ligand and has a constitutively exposed DD. ErbB3 is unique in that its kinase domain is inactive. Abbreviations for ligands are defined in the text

arose by a gene duplication event that preceded the divergence of human and mouse [8].

Ligands may signal while membrane bound or as a proteolytically cleaved, soluble, extracellular portion [8]. The cleaved form is generated in a process called ectodomain shedding by the activity of a sheddase (a protease of the matrix metalloprotease (MMP) or a disintegrin and metalloprotease (ADAM) family). The efficiency of cleavage is determined by the sequence at the site of cleavage, the length of the juxtamembrane domain, and availability of particular sheddases, which have preferential activity for specific ligands [9]. Following cleavage, signaling may be autocrine (on the same cell), juxtacrine (on an adjacent cell), paracrine (on a nearby cell), or endocrine (on a distant cell).

EGF Receptors

The receptor family consists of four single-transmembrane glycoproteins, ErbB1 (EGFR, HER1), ErbB2 (HER2, *neu* in rodents), ErbB3 (HER3), and ErbB4 (HER4). The four ErbB receptors share several common functional domains (Fig. 1). The extracellular domain includes the N-terminus, leucine-rich domain (LD) 1, cysteine-rich domain (CD) 1, LD2, and CD2. There is a dimerization domain (DD) in CD1, which is hidden in ErbB1, ErbB3, and ErbB4, but not ErbB2, due to disulfide bonds tethering CD1 and CD2 [3]. These bonds are absent in ErbB2, leaving the DD constitutively available. Intracellular domains include the juxtamembrane domain, tyrosine kinase domain, and C-terminal tail containing tyrosine phosphorylation sites. ErbB3 differs from the other ErbB receptors in that it has an inactive tyrosine kinase domain [3].

Classical activation of ErbB1, ErbB3, and ErbB4 results from binding of a single ligand to a single receptor monomer, inducing a conformational change exposing the dimerization domain within CD1 (Fig. 1) [3]. ErbB2 has no known ligand but does not need one for dimerization since its DD is constitutively exposed. Homo- and heterodimerization follow exposure of the dimerization domain (Fig. 2). Most ErbBs have the highest affinity for ErbB2 as a dimerization partner; however, dimer composition is ultimately a function of both affinity and levels of expression of receptor monomers [3]. Following dimerization, the tyrosine kinase domain of ErbB1, ErbB2, and ErbB4 phosphorylates the C-terminal tail of its dimerization partner [3]. Due to its inactive kinase domain, ErbB3 cannot phosphorylate another ErbB receptor, although another ErbB receptor can phosphorylate ErbB3. Together, these events, initiated by the dimerization of different ErbB family members, can be referred to as the ErbB canonical pathway.

Noncanonical pathways can also activate ErbB receptors. Any activation of ADAM family metalloproteinases, such as activation of G protein-coupled receptors by non-EGF ligands, including endothelin-1, bombesin, thrombin, lysophosphatidic acid, Wnt1, Wnt5, and angiotensin-II, can induce cleavage of EGF ligands and activation of ErbB receptors [3]. Integrins can increase the translation of ErbB2 and ErbB3 and form a complex with ErbB2 and Src resulting in ErbB2 phosphorylation

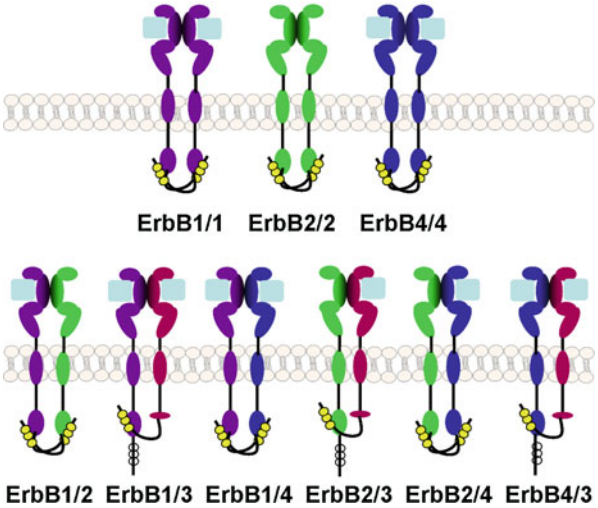

Fig. 2 ErbB Dimers. There are nine possible signaling ErbB dimer combinations. Monomers of ErbB1 (*purple*), ErbB3 (*pink*), and ErbB4 (*blue*) change conformation with ligand binding (*light blue*) such that the DD becomes available and the monomer forms a dimer. Upon dimerization with all ErbB monomers except ErbB3, tyrosines in the C-terminal tail become phosphorylated (*yellow*) by the dimerization partner. ErbB2 (*green*) does not bind ligand and has a constitutively available DD. The kinase domain of ErbB3 is inactive, thus ErbB3 cannot phosphorylate its dimerization partner; however, ErbB3 can be phosphorylated. The phosphorylated tyrosines bind and activate intracellular proteins with SH2 and PTB domains. Shown on top are the possible activated ErbB homodimers (ErbB1, ErbB2, and ErbB4) and on bottom the activated heterodimers

and activation. In addition, ECM proteins [10], cell adhesion proteins, proteins related to the immune response, and several poxviruses [11] utilize the ErbB signaling pathway. Understandably, the identification of noncanonical pathways has elicited significant excitement since several of them help explain processes that were obscure before their discovery.

Post-receptor EGF Signaling

Phosphotyrosines on activated ErbB receptors create binding sites for Grb2 and Src homology 2 (SH2) proteins, activating signaling of the RAS/RAF/MAPK, PLCγ1/PKC, PI3kinase/AKT, and STAT pathways (Fig. 3) [12]. An analysis of the affinity and specificity of ErbB receptors for signaling proteins showed that ErbB1 and ErbB2 are the most promiscuous, with ErbB3 following, and ErbB4 showing the most specificity [13]. Downstream signaling varies depending on the specific ligand bound and the monomer composition of the ErbB dimer [14, 15].

Following signaling, receptors may be dephosphorylated, cleaved, or endocytosed [3]. Dephosphorylation, which results from the activity of phosphatases such as density-enhanced phosphatase-1 (DEP1) and protein tyrosine phosphatase

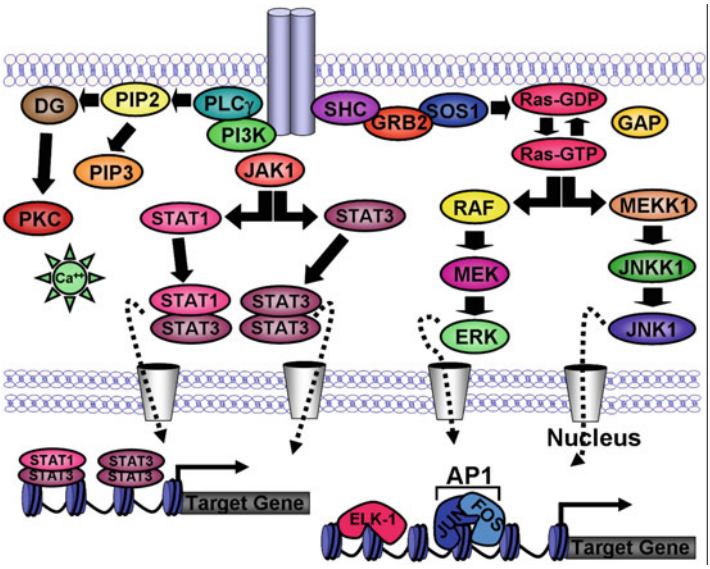

Fig. 3 ErbB signaling pathways. EGF receptor activation initiates a diverse array of cellular pathways via dimerization (represented by the *light blue cylinders* in the cell membrane). Each receptor dimer recruits different Src homology 2 (SH2)-containing effector proteins triggering distinct signaling pathways, culminating in cellular responses such as cell proliferation or apoptosis. The activated receptor complexes with the adaptor protein, GRB2, which is coupled to the guanine nucleotide-releasing factor, SOS1. This GRB2-SOS1 complex can either directly bind to receptor phosphotyrosine sites or indirectly through SHC. As a result of these interactions, SOS is localized in close proximity to RAS, allowing for Ras activation. Subsequently, the ERK and JNK signaling pathways are activated, which ultimately lead to the activation of transcription factors, such as c-fos, AP-1, and Elk-1, that promote gene expression and contribute to cell proliferation. In addition, in response to EGFR activation, JAK kinases activate STAT-1 and STAT-3 transcription factors, contributing to further proliferative signaling. Protein kinase C (PKC) is also activated via phosphatidylinositol signaling (PIP2➔PIP3) and calcium release, which serves as another node of EGF signaling. See text for further details

(PTP) 1B, stops signaling by removing sites for adaptor proteins to bind. Endocytosis may stop or promote signaling by promoting ligand dissociation, lysosomal degradation, and possibly nuclear targeting. Once in lysosomes, receptors remaining bound to ligand are more often degraded, while those dissociated from ligand are more often recycled to the membrane. This may provide a regulatory step to stop signaling preferentially of high-affinity ligand-receptor combinations. One notable exception is ErbB1/ErbB2 dimers, which preferentially escape degradation and are recycled, and thus tend to signal longer. ErbB1 signaling induces several proteins with a negative feedback effect, promoting its own degradation, such as Sprouty-2, LRIG-1, MIG-6/RALT, and suppressor of cytokine signaling-5 (SOC-5).

All ErbB receptors have been found in the nucleus where they may function as transcription factors or cofactors [3]. ErbB receptors contain three clusters of basic amino acids in the juxtamembrane domain with homology to known nuclear

localization sequences. Nuclear localization of ErbB1 causes the upregulation of several cancer-related genes, such as cyclinD1, B-myb, cyclooxygenase-2, and members of the iNOS/NO pathway [16]. ErbB4 undergoes a ligand-dependent proteolytic cleavage of the intracellular domain [9]. However, investigation on the nuclear role of ErbBs is still at its infancy in many organs and certainly underrepresented in the field of pancreatic cancer research. Therefore, this area of research offers a unique opportunity for potential fruitful discoveries that can advance our knowledge on this painful disease.

Signaling via the Canonical EGF-RAS-ERK Pathway

This pathway is of paramount importance for the pathobiology of pancreatic cancer since its alteration, at many levels, associates frequently with this disease [17]. Upon dimerization, the ErbB receptor becomes autophosphorylated at multiple tyrosines within its cytoplasmic domain (reviewed in [12]). The generation of a phosphorylated tyrosine acts as a docking site on this receptor for proteins containing domains similar to a portion of the Src oncogene and thus termed Src homology 2 domains (SH2 domains). The SH2 domain-containing protein, Grb2, binds to the receptor and subsequently recruits the guanine nucleotide exchange factor, SOS (Fig. 3). Another Src homology domain in Grb2, called an SH3 domain, is a proline-binding motif that interacts with many proteins. SOS acts as the guanine nucleotide exchange factor (GEF) for RAS which unloads GDP and binds GTP to become activated (Fig. 4). Inactivation of RAS requires the exchange of GTP for GDP again. This GTP hydrolysis can be accelerated by GTPase-activating proteins (GAPs). Noteworthy, the human genome encodes three *RAS* genes that give rise to four ubiquitously expressed gene products, though only one of them, *K-RAS*, is mutated in more than 90% of pancreatic tumors [17]. This family of proteins is composed of H-RAS, N-RAS, K-RAS A, and K-RAS B (K-RAS A and K-RAS B are splice variants of single gene). The *H-RAS* gene was named such due to its homology to the oncogene of the Harvey murine sarcoma virus, while the *K-RAS* acquired its name from homology to the oncogene of the Kirsten murine sarcoma virus. The *N-RAS* gene does not have a retroviral homolog, but it is identified this way because it was originally isolated from neuroblastoma cells.

The process of Ras activation involves the migration of GTP-bound RAS to the membrane where it recruits RAFs, a group of three serine/threonine kinases (A-RAF, B-RAF, C-RAF) whose regulation is complex and not completely understood. Membrane-localized RAF is activated by multiple phosphorylations and dephosphorylations. Subsequently, RAF phosphorylates two serine residues in the activation loop of MEK1/2 (Fig. 4). MEK is a dual specificity kinase that phosphorylates ERK on both the threonine and tyrosine within a conserved TEY motif in the activation loop. Two isoforms of this enzyme exist, ERK1 and ERK2, which share many functions, though independent knockouts of these proteins in mice suggest that sometimes they may have nonredundant functions in vivo. Activated ERK can phosphorylate more than 100 substrates at various locations in the cell, creating a

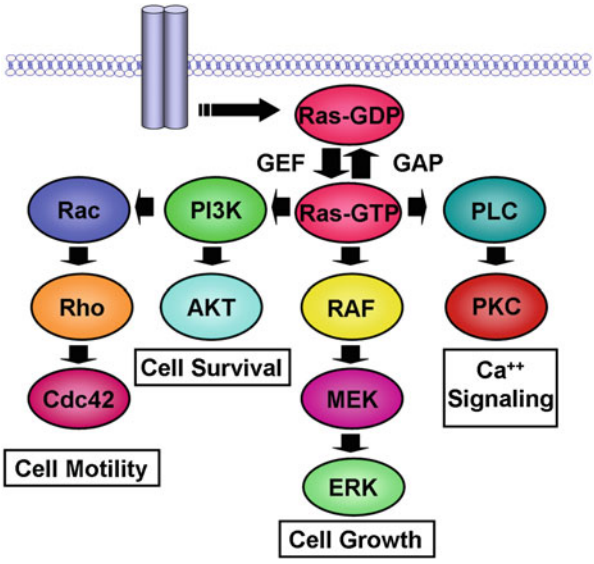

Fig. 4 Downstream RAS signaling. After receptor activation (represented by the *light blue cylinders* in the cell membrane), RAS activation is regulated by the cycle of hydrolysis of bound GTP. The activated receptor signals to a guanine nucleotide exchange factor, such as SOS1 (see Fig. 3), which then ejects GDP from RAS to allow RAS to bind free GTP to become active. Opposing this activation are the GTPase-activating proteins (GAPs), which stimulate the endogenous GTPase of RAS, thereby creating inactive RAS-GDP. Although PI3K can be activated via its recruitment to ErbB receptors, PI3K can also be activated by RAS directly. Activation of PI3K results in not only activation of AKT and its downstream effectors (see Fig. 6) to mediate cell survival but an increase in PtdIns(3,4,5)P3 at the plasma membrane as well. This leads to the activation of the Rho family of small GTPases, Rho, Rac1, and Cdc42 via recruitment of GEFs to the plasma membrane

multidimensional network. Specifically within the nucleus alone, the dimerized form of ERK actively translocates into the nucleus where it phosphorylates many substrates. These substrates include transcription factors that are regulated by MAP kinase phosphorylation, including Elk-1, c-Myc, c-Jun, c-Fos, and C/EBP β, among others. For instance, the phosphorylation of the ETS family of transcription factors, such as ELK-1, which modulate *c-fos* and *c-jun* expression, leads to activation of the AP-1 transcription factor, which is made up of a Fos-Jun heterodimer (Fig. 3). These regulators are able, among others, to regulate the expression of proteins, such as D-type cyclins, which instruct the cell to enter into the G1 phase of the cell cycle. Thus, the MAP kinase pathway represents signals originating from receptors at the cell surface to the nucleus that result in the regulation of gene expression.

Due to the diverse nature of the downstream substrates this pathway acts upon, normally, the process of activation must be tightly regulated. Thus, evidence for negative feedback loops is found at several levels. For example, ERK-mediated phosphorylation of MEK inactivates the pathway. ERK also activates the kinase RSK2, which can inhibit the ERK pathway by phosphorylating SOS. In contrast,

ERK phosphorylation of RAF appears to enhance activation of the ERK pathway. Finally, there are several phosphatases, including the dual specificity phosphatases (DUSPs), which can inactivate ERK either in the cytoplasm or the nucleus. Therefore, due to their incredible regulatory potential, this pathway relies on maintaining tight checks and balances, which, unsurprisingly, when altered, can easily contribute to the development and maintenance of the cancer phenotype.

EGF Signaling via Other Important, Noncanonical Intracellular Pathways

In addition to the MAPK pathway, ErbB can regulate many cancer-associated cell functions by activating other intracellular kinases and their signaling cascades. Although the detailed description of these cascades is beyond the scope of this article, a brief description of pathways will be provided that are among the most important in cancer-associated processes, such as PI3Ks, PDK, AKT, GSK3β, and mTOR. Phosphoinositide 3-kinases (PI3Ks) were originally discovered as enzymatic activities, which transduce signals downstream of several oncoproteins and growth factor receptors, thereby signaling to induce cell proliferation, survival, and migration. These proteins comprise a family of lipid kinases that are classified into three subfamilies according to structure and substrate specificity (reviewed in [18]). The class IA PI3Ks are of the most relevant to this article due to their clear involvement in cancer [18]. This class is divided into two subgroups. PI3K, which acts downstream of ErbB receptors, is composed of both a regulatory (85 kDa) and a catalytic subunit (110 kDa). There are three catalytic isoforms (p110α, p110β, and p110δ) and five regulatory isoforms (p85α, p85β, and p55γ encoded by separate genes and p55α and p50α that are produced via alternate splicing of the p85α gene).

Recruitment and activation of PI3K to Tyr-phosphorylated ErbB receptors occur via an SH2 domain within the regulatory subunit [19] (Fig. 5). Noteworthy, however, PI3K can also be activated by Ras directly (Fig. 4) [20]. ErbB-mediated activation of PI3K within the plasma membrane microenvironment phosphorylates phosphoinositides (PtdIns) at the 3′-OH position of the inositol ring. The most studied product of PI3K activity is PtdIns(3,4,5)P3 from the phosphorylation of PtdIns(4,5)P2. The PtdIns(3,4,5)P3 molecules bind to pleckstrin homology (PH) domains with one of the relevant PH domains in this context which is that of AKT, also known as protein kinase B (PKB). Through this mechanism, AKT localizes to the membrane, where it is activated by phosphorylation on Thr-308 by PDK1 (3-phosphoinositide-dependent protein kinase 1).

Interestingly, PDK1 contains a PH domain with higher affinity for PtdIns(3,4,5)P3 than AKT [21]. This PDK1 PH domain can, in addition, complex to PtdIns(3,4)P2 which is produced by hydrolysis of PtdIns(3,4,5)P3 in the membrane. This mechanism allows the existence of basal levels of activated PDK1; however phosphorylation of AKT at S473 is required for its full activation. This important step is mediated by mTOR (mammalian target of rapamycin) signaling complex 2 or mTORC2. After full activation, AKT phosphorylates several proteins that mediate

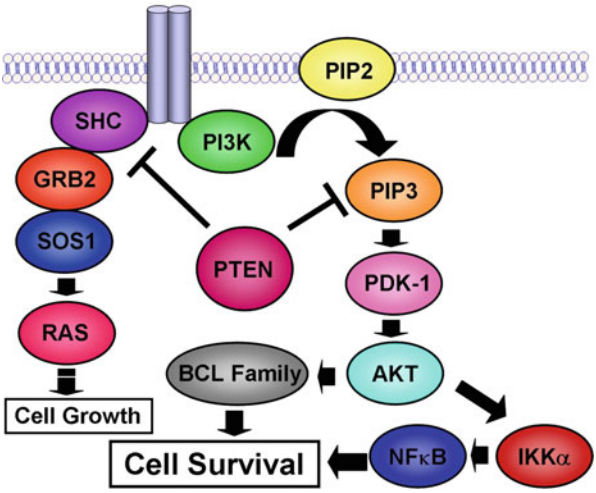

Fig. 5 PTEN regulation of phosphoinositide 3-kinase (PI3K) signaling. Upon activation via receptor signaling (represented by the *light blue cylinders* in the cell membrane), the main substrate of PI3K is phosphoinositide (4,5) bisphosphate (PIP2). Phosphorylation of PIP2 by PI3K generates PtdIns(3,4,5)P3 (PIP3). PIP3 and its 5′-dephosphorylation product, PIP2, are important second messengers that promote cell survival, cell growth, protein synthesis, mitosis, and motility. Cell survival, mitosis, and protein synthesis are all promoted via PI3K-dependent activation of the PDK-1/AKT pathway. Importantly, PTEN is a tumor suppressor gene that is able to dephosphorylate PIP3 in order to regulate this process. Since the activation of AKT is regulated via its phosphorylation by PDK-1, along with integrin-linked kinase (ILK), inactivation of PTEN permits constitutive and unregulated activation of the AKT pathway. In addition to regulating the AKT signaling pathway, PTEN also inhibits EGF-induced SHC phosphorylation to suppress the MAP kinase signaling cascade. Thus, inactivation of PTEN also facilitates the constitutive and unregulated signaling of MAP kinase, lending to an increase in cell growth

the cross talk to other pathways (Fig. 6), such as glycogen synthase kinase 3 (GS3K) and mTOR, regulates the activity of p70 ribosomal S6 kinase-1, and activates eukaryotic translation initiation factor 4E-binding protein-1. These steps are critical to mediate protein synthesis. Thus, together, these cascades of phosphorylations promote growth and survival in many different cell populations. For instance, the activation of PI3K and AKT, as well as the subsequent downstream signaling, promotes survival via a RAS/PIK3/AKT1/IKBKA(IκB kinase-α)/NFKB1 pathway that induces antiapoptotic gene transcription [22].

AKT is negatively regulated by the tumor suppressor PTEN (phosphatase and tensin homolog deleted on chromosome 10). PTEN is a lipid phosphatase that catalyzes the reverse reaction of PI3K, by dephosphorylating the D3 position of its lipid products and thereby inhibiting the activation of AKT [22]. Aberrant AKT/PTEN signaling, often found in different human cancers, plays an important role in cancer development, progression, and therapeutic resistance [22].

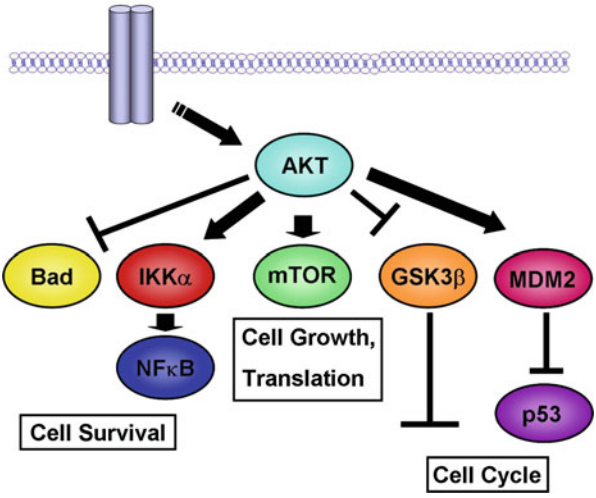

Fig. 6 AKT and its downstream effectors. As shown in Fig. 3, EGFR activation results in direct or indirect activation of PI3K. AKT is located downstream of PI3K and, therefore, functions as a key effector of ErbB signaling. Activated AKT promotes cell survival through inhibition of apoptosis by phosphorylating the Bad component of the Bad/Bcl-XL complex. This phosphorylation causes Bad to dissociate from the Bad/Bcl-XL complex through binding to 14-3-3. In addition, AKT triggers activation of IKK-α that ultimately leads to NFκB activation and cell survival. AKT also regulates cell growth through its effects on the mTOR pathway, as well as cell cycle and cell proliferation through its actions on GSK3β, resulting in inhibition of cyclin D1, and MDM2, thus indirectly inhibiting p53

ErbB can also signal via members of the Rho family of small GTPases, namely, Rho, Rac1, and Cdc42 (Fig. 4). Like Ras, these proteins are activated when bound to GTP and inactive in the GDP-bound state, steps that are mediated by specific GEFs and GAPs, respectively. As mentioned above, receptor activation stimulates PI3K, resulting in an increase in PtdIns(3,4,5)P3 at the plasma membrane. This increased in PtdIns(3,4,5)P3 recruits, via the PH domain members of the Vav family of proteins (Vav1, 2, and 3), which by acting as a GEFs, lead to the activation of Rho, Rac1, and more discriminately, Cdc42 [23]. Vav is not the exclusive GEF for this protein since, for example, several others GEFs, including Sos1, Sos2, and Tiam1, have been shown to transduce the growth signal from the EGF receptor to Rac1 [24]. Small GTPases of the Rho family are involved in a variety of functions in different cells, though they are notorious for their role in cytoskeletal reorganization and cell migration. For instance, Cdc42 controls the assembly of filopodia [25], Rac1 stimulates the formation of lamellipodia and membrane ruffles, and RhoA regulates the assembly of stress fibers [26].

The proteins Diaphanous 1 (Dia1) and ROCK signal the activation of some Rho GTPases to their action on the actin cytoskeleton [27]. Dia1 stimulates actin polymerization and actin bundle formation. ROCK activates myosin to cross-link actin bundles, and, as a result, the formation of actomyosin bridges to induce contractility.

Besides their role in motility, Rho GTPases are also emerging as important regulators of the Wnt-APC-beta-catenin signaling, which is of paramount importance for the regulation of cytoskeletal dynamics, cell adhesion, gene expression, and cell growth (reviewed in [28]). Interestingly, at least some part of this pathway appears to be necessary for pancreatic cancer, since it has been demonstrated that aberrant expression of Vav1 acts as a dominant oncogenic factor in these tumors and its levels correlate with patient survival [29]. Therefore, future studies in this area may uncover additional pathobiological mechanisms as well as therapeutic targets for pancreatic cancer.

Anti-ErbB-Mediated Therapy for Pancreatic Cancer

Therapeutic targeting of pancreatic cancer has proven to be a significant challenge both for researchers and clinicians due to the aggressive biology, resistance mechanisms, and insufficient knowledge in the molecular characterization of the disease. Due to the frequent activation of EGFR signaling in pancreatic cancer, considerable resources have been invested in the development and implementation of new therapies targeting this oncogenic molecule. Currently, the first line of treatment for patients with advanced or otherwise inoperable disease remains gemcitabine alone or in combination with the small molecule tyrosine kinase inhibitor erlotinib, fluoropyrimidine, or an albumin-bound form of paclitaxel, nab-paclitaxel [30, 31]. Two fairly recent phase III trials in highly selective patient populations have shown increased progression-free survival (PFS) and overall survival (OS). The FOLFIRINOX regimen (infusional 5-fluorouracil, folinic acid, irinotecan, and oxaliplatin) and nab-paclitaxel in combination with gemcitabine demonstrated a significant increase of treatment efficacy in comparison with gemcitabine alone [30]. Gemcitabine (difluorodeoxycytidine) is a nucleoside analog that inhibits ribonucleotide reductase, thereby decreasing the deoxynucleotide pool available for DNA synthesis, with resultant strand termination and eventual cellular apoptosis. This drug was explored for clinical advantage over the standard 5-FU because of its apparent antitumor effects. One study showed that gemcitabine was more effective and provided a modest survival advantage over 5-FU [32]. Despite its establishment as the standard for pancreatic cancer treatment for over a decade, the majority of patients still experienced tumor progression within 2.2–3.8 months with a median OS of 5–6.7 months [33]. For this reason, combinatorial treatment strategies are actively being pursued to improve patient PFS and OS. In this regard, since the EGFR pathway works as a well-established oncogenic stimulus for pancreatic cancer, it has rapidly become a good candidate as a target for combinatorial therapies.

There are two categories of ErbB-targeted therapies for cancer, receptor-targeting monoclonal antibodies (mAbs) and small molecule reversible/irreversible tyrosine kinase inhibitors (TKIs) [34]. Monoclonal antibodies bind to the extracellular domain of the receptor, preventing ligand-induced activation. Tyrosine kinase inhibitors bind to the intracellular kinase domain, inhibiting phosphorylation and

subsequent signaling. In general, the monoclonal antibodies developed to date are more specific than the tyrosine kinase inhibitors, yet they also may be immunogenic themselves. Inhibition of EGFR has also been shown to enhance molecular targeting by gemcitabine. In a phase III trial, treatment with gemcitabine plus erlotinib, an EGFR tyrosine kinase inhibitor, compared to gemcitabine alone in 569 randomly assigned patients with unresectable, locally advanced or metastatic pancreatic cancer, exhibited significantly longer OS in patients treated with the combination of gemcitabine and erlotinib [35]. Significant improvement with the combination of gemcitabine and erlotinib was also observed in 1 year survival rates of 23% and PFS with a median survival of 3.75 months in comparison with 17% and 3.55 months, respectively, in the gemcitabine alone group. In fact, the results of these studies prompted the FDA to approve erlotinib for use as a second-line therapy for recurrent, metastatic pancreatic cancer. Subsequently, a phase II study evaluating the combination of gemcitabine with erlotinib established a relationship between the presence of grade 2 or higher skin rash and longer overall survival in patients diagnosed with advanced PDAC [36]. Noteworthy, however, a multicenter phase II trial, known as RACHEL, concluded that dose escalation of erlotinib to the level of skin toxicity did not result in improved survival for patients with metastatic PDAC [37]. One randomized, prospective trial shed some light on gemcitabine alone or gemcitabine plus erlotinib treatment in pancreatic cancer patients with *EGFR* and/or *K-ras* mutations. The results of that study determined that PFS and OS rates were significantly higher in the combination therapy especially in patients with *EGFR* mutations, while *K-ras* mutation status did not play a role in treatment response or survival [38]. Unfortunately, to date, erlotinib has emerged as the only approved targeted therapy in PDAC despite a number of phase II and III trials [39]. Furthermore, most patients have intrinsic resistance to EGFR inhibitors, not responding to this type of therapy, and in those patients who experience tumor response to EGFR inhibitors, the majority will eventually acquire resistance and face disease progression. In fact, tumors have developed resistance mechanisms through the activation of EGFR-independent signaling pathways that are activated downstream of the ErbB family members so as to promote their survival [40]. However, advancing our understanding of specific cellular and molecular mechanisms that promote resistance to these therapies will help to design new strategies to improve this promising type of agents.

Notably, studies in other cancers have paved the way for their testing in PDAC. The majority of the therapeutic agents available for targeting the ErbB family members in PDAC have also demonstrated moderate efficacy in breast and NSCLC, among others [41]. For example, trastuzumab, approved by the FDA for use in breast and gastric cancers, is a humanized IgG_1 that functions by binding to juxtamembrane domain IV of ErbB2/HER2 to inhibit its ectodomain cleavage and ligand-independent dimerization [42]. This mAB against ErbB2 has exhibited antitumor effects in PDAC with high ErbB2 expression in vitro as well as in vivo xenograft models [43]. However, in a multicenter phase II trial using trastuzumab combined with capecitabine, an oral prodrug of 5-FU, PFS and OS did not function favorably compared with standard chemotherapy, even though the therapy was well tolerated [44]. Lapatinib, a small molecule, functions as a reversible,

ATP-competitive tyrosine kinase inhibitor of both EGFR and ErbB2 and received FDA approval in 2006 for advanced or metastatic breast cancer [42]. Interestingly, this TKI in combination with capecitabine has demonstrated the possibility as a tolerable regimen for patients with gemcitabine-refractory PDAC in a recent phase II trial [45]. While the number of enrolled patients was small (n = 17), a subset of these patients displayed clinical benefit from treatment, suggesting that this combination merits further study. Afatinib, another small molecule, irreversibly blocks signaling from EGFR, ErbB2, and ErbB4 by alkylating a single cysteine residue (Cys773 of EGFR, Cys 805 of ErbB2, and Cys 803 of ErbB4) within the ATP-binding pocket and permanently inactivating the kinase [46]. Afatinib received US FDA approval in July 2013 for the treatment of metastatic NSCLC, which has EGFR exon 19 deletions or exon 21 (L858R) substitution mutations [47]. Recently, studies in preclinical models for PDAC suggest that this drug may display activity, alone and in combination with radiotherapy, independent of *K-RAS* status [48]. The combination of mAbs and small molecule kinase inhibitors is expected to produce remarkable antitumor therapeutic efficacy for many cancers, with the optimism that this would include PDAC [49]. For instance, although the mechanism by which the combination of the EGFR-TKI afatinib and anti-EGFR antibody cetuximab confers potent antitumor activity in vivo has not been fully elucidated, the combination appears to have synergistic effects to inhibit phosphorylation of ErbB1/EGFR, ErbB2/HER2, ErbB3, as well as the downstream signaling molecules, Erk and Akt [50]. Furthermore, combinations of two inhibitors from the same category, such as mAbs, are also being explored. As one example, in a preclinical study, the combination of cetuximab and trastuzumab, both mAbs, was found more efficient as first- and second-line treatment than gemcitabine in human PDAC xenografts [51]. This was followed by a phase I/II trial combining cetuximab and trastuzumab in patients with metastatic pancreatic cancer after gemcitabine failure [52]. While 9 out of 39 patients had stabilized disease, the treatment was suspended due to cutaneous toxicities. However, further investigations are warranted to attempt to control some of these side effects. In addition, several of these therapies are also being combined with PI3K/Akt/mTOR inhibitors (e.g., sirolimus), SRC kinase inhibitors (e.g., dasatinib), Ras/Raf/MEK/ERK inhibitors (e.g., selumetinib), JAK/STAT inhibitors (e.g., ruxolitinib), VEGFR inhibitor (e.g., bevacizumab), and IGF-IR inhibitors (e.g., NVP-AEW541) [53], among others. Nevertheless, all of these studies demonstrate that, although not impressive, targeting ErbB family members alone or in combination displays some type of advantage, which, if enhanced through the rational design of future novel combinatorial agents, may be one of the potential therapeutic approaches to fight PDAC. In this regard, since pharmacological manipulation of epigenetic regulators is emerging as a tool that seeks to increase the efficacy of combinations or even antagonize drug resistance, the use of these molecules in combination with ErbB inhibitors is another promising avenue for future exploration.

Overall, more ErbB-targeted therapeutics remain under development and investigation. In fact, this is a difficult, but potentially fruitful area, where hard-core basic science research can generate a conceptual framework for novel drugs via interactions with other academicians in the fields of molecular modeling, crystallography, and synthetic chemistry, as well as pancreatic cancer diagnosis and management

teams. Thus, this pipeline of investigations to take drugs from the bench to the bedside, as demonstrated for EGFR inhibitors, is the paradigm that may be needed in order to defeat this dismal disease.

Several putative predictors of the efficacy of ErbB-targeted therapy have emerged [34]. The presence of skin toxicity (rash) is positively correlated with efficacy and may be indicative of blood or tissue anti-ErbB concentration. Interestingly, immunohistochemical labeling that shows increased ErbB expression is not a good predictor of response, and good responses have been observed in tumors that stain negative for ErbBs [54]. The presence of mutations in ErbBs seems to be a good indicator of efficacy, as well as an increase in *ErbB* copy number. Tumors with an activated K-RAS do not appear to respond well to anti-ErbB therapy [34]. This may explain the modest effects of anti-ErbB therapy in pancreatic cancer, as activated K-RAS in pancreatic cancer is almost universal. However, this type of therapy, for which development and testing remains active, can potentially be further improved by combining the anti-ErbB compounds with inhibitors of other signaling molecules and cascades involved in cross talk with the EGFR pathway, as described below, or additional downstream targets, against which several drugs have been developed, and many are currently in clinical trials.

Cross Talk between EGFR Signaling and Other Major Signaling Pathways and Their Potential Utility for Additional Therapeutic Strategies

The progression and aggressive behavior of many cancers, and in particular pancreatic malignancies, are caused by not only the deregulation of a single signaling pathway but rather the cooperation among several oncogenic and tumor suppressor signaling cascades. In fact, ErbB family members are readily involved in several cross talk events. For instance, in relationship to other tyrosine kinase receptors, EGFR and c-MET converge on the same downstream signaling cascades and, thereby, elicit similar cellular responses [55]. MET has also been shown to interact with EGFR [56], and their cross talk induces proliferation, invasion, and migration [57], all processes that contribute to carcinogenesis. Interestingly, studies in colon cancer demonstrate that activation of MET while treating cells with cetuximab to inhibit ErbB family members results in resistance to the inhibitory effects of this drug [58]. Similarly, activation of ErbB family members confers resistance to MET inhibition in some gastric cancer cells [59], reinforcing the influence of cross talk between these two pathways.

Reciprocal coprecipitation between EGFR and another tyrosine kinase receptor, namely, the IGF1R, has been detected several in cancer cell lines [60]. Congruently, EGFR knockdown decreases the levels of IGF1R via a mechanism that involves increased IGF1R ubiquitylation and degradation [60]. Furthermore, resistance to EGFR inhibitor drugs has been reported to occur, at least in part, through activation of IGF1R signaling [61]. Thus, although not yet shown in pancreatic cancer cells, due to the related GI origins, it would not be surprising that similar phenomena occur

in this malignancy. Therefore, any studies in this regard should take this existing data into consideration for experimental design and interpretation.

ErbB family members can also cross talk with signaling pathways mediated by serine/threonine receptors. Among these molecules, TGF-β receptor family members display both context-dependent tumor suppressive and tumor-promoting activity in pancreatic cancer [62]. Conventionally, signaling by TGF-β cytokines, namely, TGF-β1, TGF-β2, and TGF-β3, is classified by whether they work via Smad-dependent or Smad-independent pathways. A large amount of non-Smad proteins exist, which are known to mediate TGF-β signaling, but are also part of the EGFR signaling cascade, including several MAPK kinases, members of the ras family of proteins, and KLF transcription factors [63, 64]. Notably, it has been shown that TGF-β1 and TGF-β3 can cooperate with ErbB2/HER2 to stimulate cell motility and invasion [65]. Experimentally, for example, metastases are accelerated in a Neu (ErbB2)-induced mammary cancer model with overexpression of active TGF-β1 or the activated form of the type I TGF-β receptor in the mammary glands of bi-transgenic mice [66, 67]. Furthermore, the pro-migratory effect of TGF-β on cells overexpressing ErbB2 is abrogated by inhibition of ErbB2 with trastuzumab, an ErbB2 neutralizing antibody [68]. In regard to pancreatic cancer, experimental work has tested whether concomitant targeting of EGFR and TGF-β signaling pathways could offer a therapeutic advantage to treat this disease [69]. In this study, shRNA-mediated silencing of EGFR in combination with TGF-β sequestration by soluble TGF-β receptor II (TβRII) was utilized to evaluate the effects on colony formation, tumorigenicity in nude mice, and downstream signaling. In addition, any deleterious effects observed by targeting both EGFR and TGF-β in a pancreatic cell line harboring wild-type Smad4 could be counteracted by concomitant targeting of ErbB family members, TβRI activation, and the intracellular src kinase, suggesting a novel therapeutic approach for PDAC [69]. Thus, it is likely that the tumor-promoting activity of TGF-β appears to rely on either the cross talk with ErbB family members or signaling molecules that are shared in common between these two pathways, suggesting that a combinatorial therapy based on inhibiting these interactions may be either additive or synergistic to control tumor progression.

Transactivation of members of the ErbB family can also involve other types of receptors besides tyrosine and serine/threonine kinases, including sonic hedgehog (SHH), Wnt, Notch, and GPCRs. The Hedgehog ligands signal via two multi-transmembrane proteins, named Patched (PTC) and Smoothened (SMO), with PTC serving as the ligand-binding subunit and SMO as the signaling component [70]. The inhibitory effect that PTC has on SMO is released upon binding of the Hedgehog ligand to its receptor PTC, which allows SMO to trigger a signaling cascade that results in activation of GLI transcription factors. The first description of cross talk between EGFR signaling and the SHH pathway was inferred from the finding that these pathways synergize to induce malignant transformation of skin epithelial cells through activation of several members of the MAP kinase pathway [71]. From this original observation, other investigators have been able to demonstrate that this cross talk is also operational in pancreatic cancer cells, among others [72]. Subsequent studies have shown that the cross talk between these pathways can be integrated in the

nucleus, since the SHH-activated transcription factors, such as c-JUN/AP-1, are also co-regulated by EGF [73]. Not surprisingly, SHH-induced cell proliferation involves the cooperation with the EGFR and PKC signaling pathways [74]. Mechanistically, EGF likely influences SHH signaling through ERK-mediated phosphorylation and stabilization of its master transcription factor GLI1 [75], indicating that different bidirectional cross talk between EGFR and SHH signaling pathways may contribute to the malignant transformation of cancer cells. Through the use of mouse models, cooperation between SHH and Ras signaling has been observed during the earliest stages of PDAC formation [76]. Furthermore, inhibition of SHH signaling enhances the antiproliferative effect of the EGFR inhibitor, gefitinib, in pancreatic cancer cells [77]. Thus, the simultaneous targeting of both EGFR and SHH signaling cascades represents a potential treatment strategy for PDAC.

ErbB activation has also been associated in cross talk with Wnt, which binds to frizzled (Fz) receptors and leads to MMP-mediated release of soluble ErbB1 ligands to ultimately transactivate EGFR [78]. EGFR signaling enhances Wnt signaling through direct ERK MAP kinase-mediated phosphorylation of the WNT co-receptor LRP6, which dramatically increases the cellular response to WNT, as well as phosphorylation of β-catenin, which is known to increase cytoplasmic β-catenin concentration via release of β-catenin from membrane-bound complexes [79]. Another less direct yet efficient way to achieve this level of cross talk between both pathways is evidenced by EGFR pathway-mediated downregulation of caveolin-1, which causes a decrease in E-cadherin, transcriptional activation of β-catenin, and enhanced tumor invasiveness [80].

The Notch pathway is recognized to play essential roles during pancreatic development [81]. In the adult organ, Notch signaling is reactivated during pancreatic cancer initiation. However, recent studies have uncovered a role for Notch receptors in the inhibition of PanIN development, a discovery that suggests that in some contexts, these molecules can also work as tumor suppressors. Thus, it is likely that similar to TGF-β, Notch signaling behaves either as an oncogenic or a tumor suppressive stimulus due to the complexity of signaling with multiple receptors, ligands, and downstream mediators. Cross talk between the Notch and EGFR pathways has been observed in several cancer types. While independent inhibition of either EGFR or Notch signaling alone is not sufficient to suppress tumor cell survival and proliferation, simultaneous inhibition of both pathways proves to be an effective combination to eliminate tumor growth, revealing the existence of cross talk between these oncogenic pathways [82]. Notably, a direct relationship has been established between EGF receptor activation and Notch signaling in acinar-to-ductal metaplasia and PanIN formation, as precursor lesions for PDAC [83]. Moreover, Notch signaling synergizes pathways that work downstream of EGFR, such as K-ras, to promote rapid reprogramming of acinar cells to a duct-like phenotype and to induce the initiation of pancreatic carcinogenesis [84]. However, different groups have demonstrated that inhibition of Notch signaling enhances K-ras-mediated PanIN formation [85], again highlighting the context-dependent nature of Notch signaling. In addition, these studies have been done in animal models of pancreatic cancer, which are known to often give rise to contrasting results depending upon their genetic background as well

as the methodologies used to manipulate these pathways [86]. Lastly, while the available models have undoubtedly been technological achievements in the field, their ability to faithfully recapitulate human disease remains limited. Therefore, more work is needed to define whether inhibiting the interaction between the EGFR and Notch pathways would be beneficial or deleterious in humans.

G protein-coupled receptors (GPCRs), similar to ErbB receptors, regulate large signaling networks, which are involved in the development and progression of various cancers [87]. In addition, both of these types of receptors are also being actively studied as preferred pharmacological targets for the treatment of many cancers. Consequently, knowledge of their interaction is of importance, not only for better understanding pathobiological processes but also for learning how to intervene with them for therapeutic purposes. GPCRs are integral membrane proteins with seven transmembrane helices [88]. In humans, there are approximately 800 GPCRs, which are categorized into three main classes (A–C) based on their sequence similarity [88]. In contrast with ErbB receptors, GPCRs lack intrinsic enzymatic activity, but rather couple to heterotrimeric G proteins, which hydrolyze GTP and mediate downstream signaling [87]. In this regard, a sizable amount of publications has documented the interaction of GPCR-mediated signaling cascades and members of the ErbB family of receptors. Indeed, several GPCRs transmit oncogenic signals via the MAPK [89], thereby leading to the regulation of cell growth, cell migration, homing, and metastatic behavior [90]. The first study of this type in the pancreas involved the discovery of cross talk between cholecystokinin (CCK) receptors and EGFR-mediated pathways [91]. Similar to EGFR, CCK receptors are overexpressed in human pancreatic cancer, and their activation by the ligands, gastrin or CCK, stimulates cell proliferation [92]. Interestingly, while PanIN and PDAC development in the K-ras-mediated mouse model is dependent upon the presence and activation of EGFR [93], the pharmacological inhibition of CCK receptors also reduces the number of these lesions, suggesting that these pathways may synergize [94]. In addition to CCK, another neuropeptide, neurotensin, induces rapid and dose-dependent ERK1/2 activation with subsequent stimulation of DNA synthesis in PDAC cells [95]. Beyond these few examples, a plethora of studies have reported that other GPCRs known to cross talk with the EGFR signaling pathway, such as those activated by different GI peptides and chemokines, are expressed in PDAC cells and mediate cell growth and migration [90]. Therefore, potential combinatorial therapies that target GPCRs may enhance the therapeutic index of EGFR-inhibiting drugs and antibodies. Certainly, consideration of cross talk between ErbB family members and other signaling pathways as described will be essential for development of effective therapies.

ErbB-Mediated Molecular Imaging Modalities

ErbB targeting with the goal of generating molecular imaging modalities for tumors is another new area of investigation; however, a detailed description is beyond the scope of this chapter [96]. Briefly, radiopharmaceutical, in particular, labeled humanized

monoclonal antibodies, that specifically target cell surface proteins, including receptors, have been used with the goal of either neoplastic cell ablation (molecular-targeted chemotherapy) or for imaging (molecular imaging) in many tissues. Molecular medicine offers many modalities, including single photon computed tomography (SPCT) or positron emission tomography (PET), which, in combination with MRI and CT, have the potential to give a good definition, anatomical-functional map of a tumor. Several types of antibodies, either whole or as a fragment, are being currently tested against ErbB1 [34]. Some molecules of particular interest due to their potential higher biodistribution and more rapid clearance are the so-called anti-ErbB1 "affibodies." Affibodies are made from three bundle molecules based on 58 amino acids from IgG, and they can bind to their targets at low nanomolar concentration. For example, some of these molecules have been shown to bind to specific tumors in vivo. This is important if the therapy is dependent upon the expression of a distinct cell surface protein. As another approach, near-infrared (NIR) fluorescent labeling is being applied to a mAb against EGFR, cetuximab, as a new tool for fluorescence-guided surgery to visualize tumor margins, as well as metastatic sites in order to achieve precise surgical resection [97]. Molecular imaging techniques to survey other ErbB members, together with EGFR, are also being derived [98]. Furthermore, as these molecular imaging techniques are being actively expanded to other targets [99], this predicts that it could be possible to use a similar approach to cell surface markers that are expressed at the stage of carcinoma in situ (PanIN3) in hopes to push earlier limits of detection. Therefore, molecular imaging offers another wide-open field of study in pancreatic cancer research, and future development in this area has the potential to profoundly impact the diagnosis and therapy of this disease.

It is important to reflect on all of the theoretical frameworks underlying how these signaling cascades work and can be targeted. However, their expected results are "epithelium centric" and do not integrate the potential modulation of ErbB signaling that can occur with other molecules present in the tumor microenvironment. Pancreatic cancer is characterized by a robust desmoplastic reaction, which influences pancreatic cell growth. However, whether other pathways, which are active in the tumor microenvironment, modulate the outcome of ErbB signaling is an area of current investigation. For instance, the existence of cross talk between ErbB1 and integrin signaling has recently been demonstrated to be involved in carcinoma cell invasion and metastasis, which may explain, in part, how inhibitors of EGFR affect malignant disease [100]. However, studies on the role of the desmoplastic reaction in the tumor biology of pancreatic cancer is another rapidly evolving and very promising area of pancreatic cancer research, where most of the discoveries possessing the highest translational potential may occur in the very near future.

Conclusion

Given the central role of ErbB signaling in the regulation of proliferation, migration, and differentiation, it seems likely that therapeutically tapping into this high-level control mechanism can prove useful for pancreatic cancer treatment. It is interesting to

note that ErbB-targeted therapies developed thus far target an ErbB monomer and, as a result all dimers containing that monomer, thus potentially affecting ErbB signaling in complex ways. A more refined strategy with more specific targeting may prove to be significantly more effective. This may be at the level of targeting specific receptor dimers or specific downstream signaling events activated by tumorigenic dimers but not by dimers promoting healthy tissue differentiation. While anti-EGF inhibitors have elicited modest success in the treatment of pancreatic cancer, additional combinations of these agents with small drugs targeting other signaling molecules and cascades involved in cross talk with the EGFR pathway may have synergistic effects and thus offer better therapeutic options. Several important areas of investigation on factors that affect ErbB-mediated signaling, such as noncanonical pathways, the likely modulatory role of factors from the tumor microenvironment, how other cellular pathways are altered under the almost universal presence of oncogenic *K-ras* mutations, and the effects of nuclear ErbBs, remain among the less understood areas of basic research in pancreatic cancer with highly promising translational potential.

Box 1 Key Research Points

- Four ErbB isoforms are differentially expressed in human tissues. They form different types of dimers which then complex with distinct ligands, some found overexpressed in pancreatic cancer (ErbB2-EGF).
- A good understanding of the biochemistry and cell biological processes associated to these receptors is important, not only for the biology but also the pathobiology of pancreatic cancer. Unfortunately, besides ErbB1, little detailed information is available to reconstruct pathways that can be specific to the other isoforms.
- The knowledge of some of these ErbB-mediated pathways such as EGFR is among the best-understood signaling cascades in many organs. The role of ErbB proteins in pancreatic development and cell homeostasis remains an underrepresented area of biomedical research.

Box 2 Future Scientific Directions

- EGFR is the best-studied ErbB receptor isoform, and its contribution to pancreatic cancer, though still far from complete, is better understood. However, pancreatic cancer cells express other combinations of ErbB isoforms, for which the biology and signaling are less known but may be of significant biomedical relevance in this disease.
- More knowledge must be gained on how to modulate the response of anti-EGFR therapy in a manner that can be more beneficial to pancreatic cancer patients. Fortunately, there are numerous signaling nodes that have been identified during the last two decades, which can serve as targets for

(continued)

Box 2 Future Scientific Directions (continued)

combined therapeutic modalities designed to achieve this goal. Many of these targeted therapies have been or continue being developed for clinical use. Combination therapies that target different nodes in this pathway are under active investigation.

- The interaction of pancreatic cancer cells with the tumor microenvironment, which is full of growth factors that bind to ErbB receptors and extracellular matrix proteins that cross talk with these pathways, may provide the basis for future application of this important basic science knowledge to the design of therapy. Therefore, more basic science is needed in this area to inform the development of novel molecularly targeted drugs by focusing on several members of the EGF pathway.

Box 3 Clinical Implications

- Two types of ErbB-targeted therapies exist, which are receptor-targeting monoclonal antibodies (mAbs) and small molecule reversible/irreversible tyrosine kinase inhibitors (TKIs). Currently, erlotinib, an EGFR TKI, remains the only approved molecular-targeted therapy for PDAC.
- The role of EGFR and, in particular, other members of the ERB family of tyrosine kinase receptors, in normal pancreatic molecular cell biology, warrants further investigations. Their translational potential to human disease has not been fully realized. While this has been already an area of fruitful research, due to its translational potential, research on the ErbB pathway and cross talk with other pathways deserve to be further expanded.
- The area of molecular-targeted imaging has extensively benefited on investments on EGFR as a probe. Some of these techniques remain to be refined but represent promising areas of translational research as well as evidence-based medical care.

Hedgehog Signaling Plays a Dual Role in Pancreatic Carcinogenesis

Tara L. Hogenson, Rachel L. O. Olson, and Martin E. Fernandez-Zapico

Contents

Abstract

The hedgehog (Hh) pathway plays an important role in a wide variety of developmental processes including cellular differentiation and tissue patterning. While Hh signaling is a critical component of embryonic development, this pathway is not typically active in most adult tissues. Inappropriate Hh signaling has been associated with several types of malignancies including pancreatic ductal adenocarcinoma (PDAC). In PDAC, the Hh pathway is activated by two distinct mechanisms in the tumor epithelial and stromal compartments. In the stroma, the Hh pathway activity is induced by its ligands in a canonical fashion;

in tumor epithelial cells its activity is regulated in a ligand-independent manner by known PDAC oncogenic cascades including KRAS, TGFβ, and EGFR signaling. Initial preclinical studies demonstrated that the Hh pathway may be a promising therapeutic target for PDAC. However, Hh inhibition has not been successful in clinical trials of PDAC patients with advanced metastatic disease. Recent reports indicate the Hh pathway may play a dual role in carcinogenesis, acting as an oncogene in early tumorigenesis while switching to a tumor suppressor as the cancer progresses. Current research efforts are aimed at further understanding the role of the Hh pathway in all stages of carcinogenesis and defining the translational value of Hh inhibition in PDAC.

Introduction

The hedgehog (Hh) signaling pathway was first identified in *Drosophila melanogaster* in the late 1970s when Nusslein-Volhard and Wieschaus discovered certain genetic mutations resulted in short larva covered with denticles resembling a hedgehog [1]. An isolated mutation led to identification of the Hh gene coding for the ligand of the pathway. Homologous Hh genes have been identified in many vertebrates including mice and humans. These genes are critical during embryonic development of the neural tube, brain, gut, testis, and limb [2–4]. As a mediator of gastrointestinal development, the Hh pathway is active throughout the epithelial layer of the primitive gut, but it is largely excluded from the region where the pancreas develops [5]. Ectopic Hh expression within the pancreatic domain blocks normal pancreas development and leads to "intestinalization" of the pancreatic epithelium. Aberrant activation of the Hh pathway in the adult pancreas is associated with pancreatic diseases including pancreatitis and pancreatic ductal adenocarcinoma (PDAC) [6–11].

Overview of the Hedgehog Pathway

Hh signaling in mammals has three known ligands, sonic hedgehog (Shh), Indian hedgehog (Ihh), and desert hedgehog (Dhh). All three ligands bind the receptor Patched-1 (Ptch1), a 12-transmembrane receptor. Ptch1 and Smoothened (Smo), a 7-transmembrane (7TM) G-protein-coupled receptor (GPCR), are the core components of the Hh receptor complex. The current paradigm for Hh signaling places the primary cilia as the central cellular location for Hh pathway signal activation in vertebrates (Fig. 1) [12]. In the absence of Hh ligand, Ptch1 binds the shaft of the cilium and inhibits Smo from colocalizing [13, 14]. Localization of Ptch1 at the base of the cilia indicates it may play a role in regulation of proteins that are transported in and out of the primary

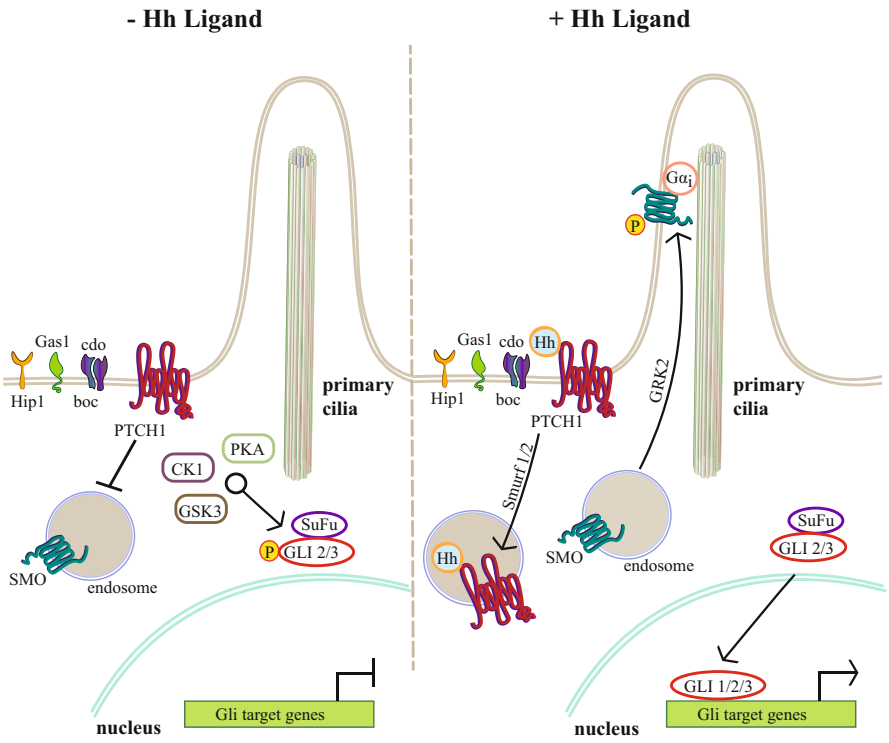

Fig. 1 Hh signaling pathway in the absence and presence of ligand. In the absence of Hh ligand, Ptch1 localizes to the base of primary cilia and inhibits Smo colocalization. Upon Hh ligand binding, Ptch1 is endocytosed through ubiquitination by the E3 ligases, Smurf1 and Smurf2, and subsequently degraded. Coreceptors Gas1, Cdo, and Boc enhance Hh signaling. Following activation, Smo accumulates at the primary cilia and activates downstream signaling of the Hh pathway through the $G\alpha_i$ protein. Smo is phosphorylated by GRK2. Next, β-arrestin 2 binds Smo and promotes its internalization. SuFu binds directly to GLI2/3 in the absence of ligand. PKA, GSK3, and CK1 phosphorylate GLI2/3 to its repressor form. Upon binding of Hh ligand, GLI localizes to the nucleus and binds Hh target genes to activate their transcription. SuFu is ubiquitinated and targeted for degradation

cilia, but the exact mechanism by which Ptch1 inhibits Smo trafficking remains unclear [15]. It was initially hypothesized that there is a direct interaction with Smo, where binding of ligand to Ptch1 induces a conformational change, allowing Smo to dissociate [16]. However, more recent research indicates that Ptch1 does not associate with Smo [17] and may regulate Smo localization through modulating the levels of oxysterol, an oxidized derivative of cholesterol [14], which directly binds Smo and allosterically promotes its localization in the cilium [18]. Upon Hh ligand binding to Ptch1, Ptch1 is endocytosed and ubiquitinated by the E3 ligases, Smurf1 and Smurf2, leading to its degradation [19]. Ptch1 removal from the cilia allows for cell surface accumulation of Smo in the organelle and induction of the Hh intracellular signaling cascade leading to activation of the GLI family of transcription factors, final effectors of the cascade [13].

The GLI family includes three separate zinc finger proteins, GLI1, GLI2, and GLI3. GLI1 and GLI2 are primarily transcriptional activators (although GLI2 has some repressor functions), while GLI3 acts mainly as a repressor of transcription [20]. In addition to its regulation by the Hh ligands, Ptch1 activity is modulated by cell surface proteins, including CAM-related/downregulated by oncogenes (Cdo), brother of Cdo (Boc), growth arrest specific 1 (Gas1), and hedgehog interaction protein 1 (Hip1). Cdo, Boc, and Gas1 enhance Hh signaling; Cdo and Boc bind Hh ligands and facilitate presentation of ligand to the Ptch1 receptor [21], while Gas1 increases the range of the Hh signal during embryogenesis, especially in tissues with low levels of the ligand [22, 23]. Hip1 negatively regulates signaling through sequestration of Hh ligand [24].

It has been demonstrated that G-proteins, β-arrestin, and suppressor of fused (SuFu) play a critical role in mediating Hh intracellular signal following Smo activation. The 7TM structure of Smo utilizes G-proteins for signal transduction, a property shared among most 7TM receptors. However, Smo lacks homology with other GPCRs, and it is missing several GPCR-like features such as the generation of secondary messengers typically associated with G-proteins, like cAMP or calcium [25, 26]. While classification of Smo as a GPCR remains somewhat controversial, Riobo et al. found that Smo activates the $G_{(i)}$ family of G-proteins and this signal is required for GLI activation [27]. However, Smo signaling through G-proteins alone is not sufficient to activate GLI transcription factors. A truncated form of Smo which includes the $G_{(i)}$-activating domain was not capable of activating the GLI reporter, indicating another region of Smo is required for GLI activation. Upon activation, Smo is phosphorylated by the G-protein-coupled receptor kinase 2 (GRK2) [28]. This phosphorylation prevents reassociation of G-proteins with their receptors. β-Arrestins are proteins located in the cytosol that bind phosphorylated 7TM receptors and promote their internalization. Phosphorylation of Smo by GRK2 and interaction with β-arrestin 2 leads to endocytosis of Smo, indicating these proteins play an important role in regulation of Smo signaling [28, 29]. SuFu is a negative regulator of the Hh pathway; its inactivation leads to constitutive Hh signaling [30]. SuFu binds directly to GLI2 and GLI3 proteins, preventing their translocation to the nucleus when no ligand is present [31, 32]. While GLI1 protein functions only as an activator, GLI2 and GLI3 proteins can be transcriptional activators or repressors. In the absence of ligand, protein kinase A (PKA), glycogen synthase kinase 3 (GSK3), and casein kinase 1 (CK1) phosphorylate full-length GLI2 and 3 [33, 34]. This phosphorylation leads to processing of GLI2 and GLI3 to their repressor form and inhibits localization of the GLI-SuFu complex to the nucleus [35]. The phosphoinositide 3-kinase (PI3K)/Akt pathway is an important regulator of PKA. Akt is required for inhibition of PKA-dependent GLI2 inactivation [36].

Upon Hh stimulation, Smo accumulation in the cilia leads to SuFu dissociation from GLI2 and GLI3 in part through the action of the kinesin motor protein, Kif7 [35, 37]. Following dissociation, SuFu is ubiquitinated and targeted for degradation, while GLI2 and GLI3 translocate to the nucleus [35, 38]. One study found that SuFu recruits SAP18, a component of the mSin3-histone deacetylase corepressor complex, to GLI1 promoters, indicating that SuFu may not be degraded and can translocate to the nucleus to act as a co-regulator of GLI [39]. In addition to SuFu

repression of GLI2 and GLI3 activation, the Hh pathway utilizes intraflagellar transport (IFT) to move GLI2 and GLI3 along the cilia toward the nucleus. Disruption of IFT proteins in the cilia prevents active GLI3 formation, indicating the importance of this specialized compartment in Hh signaling [40–42].

GLI proteins activate Hh target genes through binding specific consensus sequences located in the promoter region of these genes, which include molecules responsible for cell fate determination, tissue patterning, proliferation, and transformation as well as components of the pathway [43, 44]. For example, GLI2 transcriptionally activates GLI1, which in turn induces the expression of Ptch1 [45], and other targets of Hh-modulated cellular functions [46]. The kinase DYRK1A phosphorylates GLI1 at a general nuclear localization sequence ("SPS" motif), leading to enhanced nuclear localization [47]. Other protein kinases that have been shown to regulate Hh signaling include protein kinase C-δ (PKCδ) and mitogen-activated protein/extracellular signal-regulated kinase 1 (MEK-1) [48]. In addition, atypical protein kinase C ι/λ (aPKC-ι/λ) plays a role in phosphorylation and activation of GLI1 downstream of Smo. aPKC-ι/λ forms a complex with missing in metastasis (MIM), a centrosome-associated protein that positively regulates Hh signaling and ciliogenesis, and colocalizes to the basal body. Inhibition of aPKC-ι/λ blocks Hh signaling and represses cell growth [49].

Not all Hh pathway signaling is ligand dependent or proceeds through Ptch1/Smo to GLI activation. Subtypes of ligand- and GLI-independent pathways are known as noncanonical Hh signaling. Type 1 noncanonical Hh signaling is Smo and GLI independent. When Shh binds the Ptch1 receptor, Ptch1 may interact directly with cyclin B1 and caspases to inhibit proliferation and induce apoptosis [50]. Ptch1 receptor can also induce apoptosis in the absence of Hh ligand through the adapter protein, DRAL, and caspase-9 activation [51]. Type II noncanonical signaling is Smo dependent and GLI independent through the activation of a Rho signaling [52–54]. In addition, there are several known noncanonical mechanisms for GLI activation independent of Hh ligand in carcinogenesis. Hh ligand expression does not activate the Hh pathway in a large number of tumor epithelial cells, yet GLI1 is still expressed in these cells, indicating noncanonical activation of downstream components of the Hh pathway [55]. In fact, several studies have shown that GLI expression can be activated through Hh-independent mechanisms, particularly in the epithelial compartment through cross talk between GLI and other pathways such as KRAS, TFGβ, and EGFR [10, 43, 56, 57]. For additional details on noncanonical signaling, refer to the Sect. 4.1.

Role of Hedgehog Signaling in the Pathogenesis of Pancreatitis and Tissue Remodeling

In the adult pancreas, the Hh pathway is typically only active in endocrine cells within the islets of Langerhans where Hh signaling regulates insulin production and secretion [58]. However, evidence suggests this pathway is upregulated during exocrine regeneration of acinar tissue following injury in mice, where blockage of the Hh pathway

leads to impaired pancreatic regeneration [59–61]. During normal regeneration, Hh is upregulated and then becomes undetectable once regeneration is complete [59, 62]. Thus, dysregulation of the Hh pathway following repair may play a role in pancreatic diseases associated with tissue injury, such as chronic pancreatitis. As described in other sections of this book, chronic pancreatitis is an inflammatory condition that leads to tissue remodeling and fibrosis of the exocrine tissue. While normal adult exocrine and ductal cells do not express detectable levels of components of the Hh pathway, patients with fibrotic tissue associated with chronic pancreatitis show elevated expression of Shh, Ihh, and Ptch1 [6, 63, 64]. Chronic pancreatitis is a known risk factor for PDAC, indicating that deregulation of the Hh pathway in pancreatitis may play a role in tumorigenesis through reactivation of Hh-GLI target genes. Mathew et al. demonstrated that loss of one *Gli1* allele resulted in impaired tissue repair following pancreatitis leading to an altered stroma [65]. Mice with normal GLI1 expression fully resolved architecture and function in the pancreata after 1 week. Hemizygous loss of *Gli* in fibroblasts was also associated with lowered expression of several immune proteins that regulate immune function during tissue damage and repair, including IL-6, MCP-1, and IL-8, and factors that regulate immune cell migration including M-CSF [65]. In addition, loss of GLI1 was also associated with an increase in T cells and fewer myeloid cells, indicating GLI is an important modulator of the immune response in the pancreas.

Another event related to Hh pathway activation that may contribute to the pathogenesis of chronic pancreatitis includes loss of cilia in epithelial cells. The absence of cilia in pancreatic epithelial cells produces lesions similar to those seen in chronic pancreatitis [66]. Cilia are absent in pancreatic preneoplastic lesions (e.g., PanINs) and human PDAC cells, indicating loss of cilia occurs early during tumor development and is associated with cancer progression [67]. Seeley et al. demonstrated that activation of KRAS, an early event during PDAC initiation, blocks cilia assembly in PanINs and PDAC cells [67]. The authors propose oncogenic KRAS may lead to aberrant activation of the Hh signaling pathway in the absence of cilia. This was supported by the work of Cervantes and colleagues showing that the loss of cilia is associated with overexpression of Hh in the pancreatic epithelium and enhanced PDAC tumorigenesis [68]. Wong et al. suggests cilia may play a dual role in both suppressing and promoting tumorigenesis via the Hh pathway since human basal cell carcinomas are frequently ciliated [69]. The mechanism by which the tumor is initiated may determine the role cilia play in cancer progression. For example, removal of cilia in tumors initiated by Smo mutation inhibited tumor progression, while loss of cilia in tumors induced by GLI mutation increased tumorigenesis [69]. Since cilia are the central location for canonical hedgehog signaling, loss of cilia in tumor epithelial cells may play a role in the switch from canonical to noncanonical activation of the Hh pathway during PDAC tumorigenesis.

Hedgehog Signaling in PDAC Biology

One of the first indications the Hh pathway may be critical in PDAC was the discovery that PanIN lesions express Shh ligand [9, 70, 71]. This is important since components of the Hh pathway, especially the ligands, are undetectable in the normal human pancreas. In support of this notion, Shh overexpression in the developing pancreas of a transgenic mouse is sufficient to initiate PanIN-like precursor lesions [9, 72]. PDAC cells express GLI1 in the absence of ligand, indicating that ligand-independent activation of downstream components of the Hh pathway is occurring [55]. In fact, activation of the Hh pathway is unique in PDAC cells and the stroma, where activation of downstream components of the Hh pathway in the tumor epithelial cells occurs through noncanonical signaling while the surrounding stroma utilizes canonical Hh signaling. Cross talk between the tumor cells and the tumor microenvironment demonstrates a complex interplay that both promote cancer progression and tumor suppression as PDAC advances to the later stages of disease.

Role of Hedgehog Pathway in PDAC Cell Compartment

As mentioned above, activation of the GLI transcription factors in PDAC cells is ligand independent. Nolan-Stevaux et al. showed that deletion of the Smo receptor in pancreatic epithelium did not inhibit GLI expression in these cells, indicating that GLI is activated using a noncanonical mechanism [57]. This activation is mediated through cross talk with several other pathways including KRAS, TGFβ, and EGFR (Fig. 2).

GLI1 expression is a critical component of KRAS-driven PDAC. Using a mouse model with simultaneous activation of oncogenic KRAS and GLI1 in pancreatic epithelial cells, Rajurkar et al. showed that GLI1 promotes KRAS-driven PDAC precursor lesions [8]. Using a similar KRAS model, Mills and colleagues further demonstrated a key role for GLI1 in initiation of PDAC, where loss of GLI in the presence of oncogenic KRAS leads to a significant decrease in PanIN lesions and ablated PDAC formation [11]. Rajurkar et al. suggest the underlying mechanism of this promoting effect was GLI1-dependent regulation of I-kappa-B kinase epsilon (IKBKE), a major regulator of NF-κB pathway in PDAC cells [8], while Mills et al. identified cytokine IL-6 pancreatic fibroblasts as one of the mediators of GLI1-regulated PDAC initiation [11]. IL-6 expression in the stromal compartment induces activation of STAT3 in adjacent epithelial cells, leading to premalignant lesions in PDAC. Transgenic overexpression of GLI2 in the pancreatic epithelium did not induce PanIN lesion development, but a significant percentage of mice developed highly undifferentiated pancreatic tumors [7]. Interestingly, simultaneous overexpression of GLI2 and activation of KRAS cooperate to develop PanIN lesions, indicating interaction between Hh and KRAS plays a role in PDAC initiation [7]. GLI3 has also been shown to play a role in KRAS-regulated oncogenic functions, specifically autophagy. Evidence suggests that autophagy may promote tumor

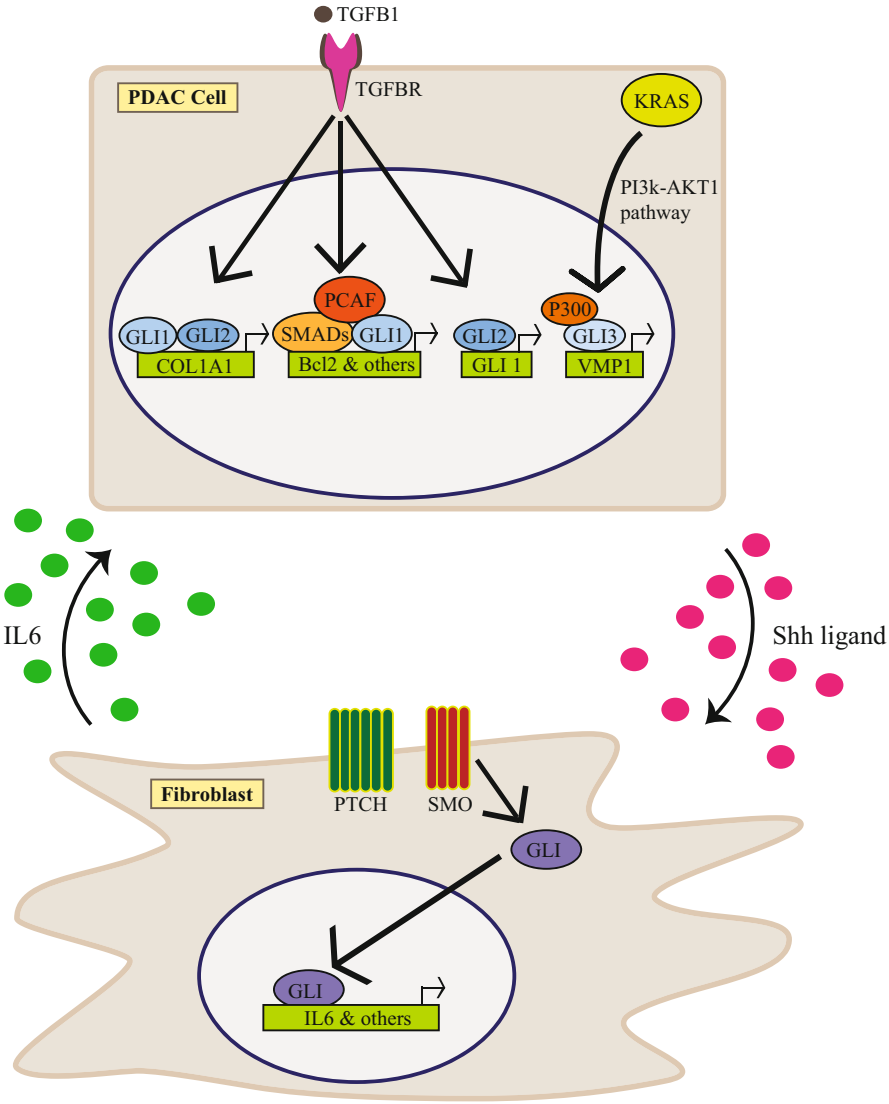

Fig. 2 Paracrine signaling between tumor epithelial cells and fibroblasts. Tumor epithelial cells employ noncanonical activation of GLI. Two mechanisms for ligand-independent activation include KRAS and TGFβ pathways. Oncogenic KRAS activates PI3K-AKT1 pathway to induce binding of GLI3 and p300 to the promoter of VMP1, leading to autophagosome formation. TGFβ induces COL1A1 expression through formation of a transcriptional complex of GLI1 and GLI2 (Martin E. Fernandez-Zapico unpublished observation). TGFβ also induces formation of the transcriptional complex of SMAD2, SMAD4, and PCAF to induce BCL2 transcription. In addition, TGFβ promotes GLI2 binding to GLI1 promoter and induces transcription. Shh ligand expressed by tumor cell initiates Hh signaling in neighboring stromal cells through paracrine signaling. Hh signaling in stromal cells promotes expression of GLI target genes including IL-6 and COL1A1, which stimulate neighboring cancer cells

progression by allowing cancer cells to escape low-nutrient conditions. KRAS-driven tumors display constitutively activated autophagy [73]. KRAS-induced autophagy in PDAC cells lines promotes binding of GLI3 and p300 through the KRAS-PI3K-AKT1 pathway to the promoter of the autophagy gene vacuole membrane protein 1 (VMP1), a pancreatitis-associated protein [74]. In this case GLI3 acts as an activator of transcription, stimulating expression of VMP1 and promoting autophagosome formation. Oncogenic KRAS has also been shown to inhibit autocrine signaling of ligand in PDAC cells, promoting paracrine signaling between the PDAC cells and the stroma [11, 55]. This shift from autocrine to paracrine signaling is through KRAS activation of the downstream effector dual specificity tyrosine phosphorylation-regulated kinase (DYRK1B), which inhibits GLI1 expression through expression of the repressor, GLI3 [75].

Similar to KRAS, transforming growth factor-β (TGFβ) induces ligand-independent activation of GLI proteins in different tumoral compartments including PDAC cells. TGFβ induces GLI2 expression in PDAC cells through Smad3, β-catenin, and LET-dependent upregulation of GLI2 transcription [43, 76]. Further analysis of this phenomenon showed that TGFβ can promote the formation of a new transcriptional complex of GLI1, SMAD2, SMAD4, and the histone acetyltransferase, PCAF, to regulate TGFβ-induced BLC2 gene expression in PDAC cells [77]. Activation of TGFβ is associated with epithelial to mesenchymal transition (EMT), metastasis, and tumor growth [78]. GLI1 seems to antagonize this effect through binding of the E-cadherin (CDH1) promoter [79]. E-cadherin is a transmembrane protein critical for cell adhesion, and lowered expression of E-cadherin leads to increased cell motility. Lowered expression of GLI1 in advanced PDAC was associated with a loss of E-cadherin and promotion of EMT, indicating that GLI expression in the later stages of PDAC may actually inhibit metastasis [79]. Conversely, GLI1 has also been shown to regulate mucin 5AC (MUC5AC) expression in PDAC [80]. Increased MUC5AC expression is associated with migration and invasion of PDAC through GLI1 attenuation of E-cadherin/β-catenin signaling. Inhibition of MUC5AC could potentially restore E-cadherin-mediated cellular adhesion and decrease β-catenin nuclear accumulation, lowering the migratory ability of PDAC cells [80]. This somehow discordant effect could be explained by the different models and experimental conditions used by these research groups [79, 80]. Other molecules controlling cell adhesion have been associated with active Hh signaling, including galectin-1 (Gal1). Gal1, a regulator of cell-cell and cell-ECM adhesion, is highly expressed in PDAC stroma and has been shown to regulate acinar to ductal metaplasia, thought to be a critical step in PDAC initiation where acinar cells take on the pancreatic duct cell phenotype, in part through promotion of Hh signaling [81].

Epidermal growth factor (EGFR) signaling is aberrantly activated in a large number of PDACs, and it has been shown to influence Hh signaling through stimulation of GLI target genes [10]. Eberl et al. identified a set of GLI-regulated genes with enhanced expression in the presence of an active EGFR signal including JUN, SOX9, SOX2, FGF19, and CXCR4 [10]. Both SOX2 and SOX9 are transcription factors involved in regulation of stem cells, indicating that HH-EGFR response

may play a critical role in cancer stem cell (CSC) maintenance though a GLI1-dependent mechanism. A number of groups have also demonstrated that canonical Hh pathway plays a critical role in maintenance of CSCs through regulation of genes associated with stemness [20, 82, 83]. Inhibition of Hh signaling has been shown to interfere with self-renewal of CSCs and may lead to chemosensitivity [84–86]. Gu et al. demonstrated that a combination of radiation with Hh inhibition leads to a significant decrease in EMT in PDAC [87].

Another Smo-independent mechanism for GLI1 activation includes the G-protein subunit, Gα. As previously mentioned, Smo is coupled with a heterotrimeric G-protein complex that activates the Hh intracellular signaling cascade. However, it is unclear if G-protein coupling of Smo occurs in carcinogenesis. Gα has been shown to affect activation of GLI1 independent of Smo [88]. A potential target of Smo-Gα includes the kinase DYRK1A, which acts as a positive regulator of GLI transcription, but may also function as an inhibitor of Hh signaling through indirect inhibition of the GLI transcriptional coactivator MKL1 (MAL) [89]. A MKL1 interactor, Jumonji domain-containing protein 1A (JMJD1A), is a histone demethylase that binds directly to GLI, inhibiting its degradation [89]. Similar to the epigenetic regulator JMJD1, He et al. demonstrated that GLI1 regulates the DNA methyltransferases, DNMT1 and DNMT3a, in PDAC through binding to the DNMT1 gene promoter [90]. GLI1-/DNMT1-mediated methylation may promote invasion and metastasis through activation of oncogenes. Through in vivo RNAi screen for epigenetic regulators regulating PDAC biology, Huang et al. identified BRD2 and BRD3, members of the BET family of chromatin readers, as regulators of PDAC growth in part through modulation of GLI transcription factors [91]. BET bromodomain inhibition led to a decrease in GLI activity in PDAC cells [91]. Huang et al. found the transcriptional activation of GLI1 and GLI2 is mediated through physical interaction with BET proteins. These data suggest the BET proteins may play an important role in regulation of the noncanonical Hh pathway and offers a new strategy for targeting this pathway.

Hedgehog Signaling in PDAC Tumor Microenvironment

As described in some of the chapters of this book, desmoplastic reaction (DR) is a typical feature of PDAC tumor microenvironment (TME). The TME is highly fibrotic and composed of different cell types including pancreatic stellate cells (PSCs), fibroblasts, endothelial cells, nerve cells, immune cells, and acellular components of the extracellular matrix (ECM). Interaction between the stromal cells and malignant epithelial cells appears to play a critical role in tumorigenesis in PDAC. At this point, it is not entirely clear whether the presence of stroma promotes or restrains cancer progression. Initial studies indicated stroma promotes cancer progression, where increased levels of stroma were correlated with a poor prognosis and depletion of stroma improved prognosis [92–94]. However, more recent studies have shown the stroma may actually work to restrain the growth of the tumor, indicating there is still more to learn regarding its role in PDAC [95–97].

Several reports demonstrate that activation of the Hh pathway in the stroma is ligand dependent, and it is usually initiated by signaling from neighboring PDAC cells, leading to an increase in growth factor and chemokine production in stroma, promoting DR in the TME (Fig. 2) [98, 99]. For example, Hh-activated PSCs are thought to play an important role in stromal production in response to pancreatic injury and inflammation [100–102]. PSCs are responsible for production of the many ECM proteins in the TME, including collagen types I, III, and IV and fibronectin [103, 104]. Collagen type I is encoded by two genes, COL1A1 and COL1A2, which are targets of the GLI proteins in PSCs and fibroblasts (Martin E. Fernandez-Zapico unpublished observation). As a result of the dense DR in PDAC, the TME is hypovascular and hypoxic [105, 106]. Hypoxia is associated with worse clinical outcome due to an increase in tumor growth rate and metastasis [107]. Tumor hypoxia leads to activation of hypoxia-inducible factor 1α (HIF-1α), a transcription factor that is overexpressed in PDAC and is associated with increased EMT and invasion [108, 109]. HIF-1α induces noncanonical activation of GLI1 in pancreatic cancer cells to promote Snail expression and EMT [109]. These studies show the critical role the TME plays in tumor progression through promotion of invasion and metastasis of PDAC.

As previously mentioned, chronic inflammation is a known risk factor for PDAC. Inflammatory cells are an important part of the stromal reaction associated with PDAC and may play a role in disease progression through upregulation of several pathways including Hh [110]. IL-6 and other proinflammatory markers are elevated in PDAC patients [111, 112]. As previously mentioned, IL-6, a target of GLI1, induces STAT3 activation in PDAC cells [11, 112], a transcription factor essential for the formation of PanIN lesions and their progression into tumors [113–115]. This indicates that Hh mediates the communication between the stroma and epithelial cells playing a critical role in tumor initiation.

Based on the tumor-promoting features of the stroma, Hh inhibition appears to be a promising target in PDAC treatment. In support of this theory, Olive et al. found that depletion of the stroma by co-administering the Hh inhibitor, IPI-926, with gemcitabine, led to disease stabilization through more efficient delivery of the drug to the tumor [93]. This successful result led to clinical trials with the Hh inhibitor, vismodegib (GDC-0449), for treating PDAC [116, 117]. Unfortunately, these studies showed patients treated with an Hh inhibitor either showed no improvement or had a higher rate of disease progression than placebo.

These failed clinical trials bring into question the prevailing paradigm that the stroma supports tumorigenesis in PDAC. In fact, more recent studies have shown the stroma may actually work to restrain the growth of the tumor [95–97]. Rhim et al. demonstrated that loss of stroma using an Hh inhibitor or genetic ablation of Shh leads to more aggressive tumors [95]. Also, a preclinical study found that Hh inhibition at the PanIN stage led to increased tumor progression, while Hh activation in advanced stages of PDAC slows down tumorigenesis [96]. Similarly Mills et al. showed loss of GLI1 in a PDAC model with activated KRAS, and concomitant loss of p53 led to accelerated progression [118]. In this study the authors suggested a significant decrease in expression of FAS/FASL as a potential

underlying mechanism for increased tumorigenesis in animals lacking GLI1. Decreased expression of FAS/FASL is associated with lower apoptosis and may lead to increased tumor progression. In addition, lowered expression of GLI1 in advanced PDAC was associated with a loss of E-cadherin and promotion of EMT [79]. These unexpected findings reveal an incomplete understanding of the role of the Hh pathway in all stages of PDAC. While Hh inhibition appears to be a potential target for PDAC treatment, it seems that increased Hh expression may actually have a tumor repressive effect in the latter stages of PDAC. A study by Fendrich et al. showed that Hh signaling promotes acinar differentiation, indicating increased GLI levels may actually promote differentiation and slow tumorigenesis [59].

One important caveat is that Hh inhibition in patients is unlikely to completely inactivate Hh signaling. As previously mentioned, Hh coreceptors Gas1, Boc, and Cdo bind Hh ligand and enhance Hh pathway signaling. These coreceptors are upregulated in PDAC and are required for Hh signal transduction [119]. Surprisingly, deletion of two coreceptors led to a more potent tumor compared to wild type. Deletion of all three receptors resulted in lower angiogenesis and decreased tumorigenesis, indicating HH signaling effects in PDAC are dose dependent [119]. These findings may explain the failure of Hh inhibitor clinical trials, where partial inhibition may actually increase tumorigenicity through increased angiogenesis.

Targeting Hedgehog Pathway in PDAC

As mentioned above, thus far, Smo inhibition of Hh pathway in PDAC has had disappointing results. One reason for this poor response may be that PDAC cells utilize Smo-independent activation of the Hh pathway. In addition, SMO is critical to several cellular functions, and loss of SMO could be deleterious to cells independent of Hh pathway activity. Finally, the stage of the PDAC plays a major role in the outcome of Hh inhibition. Based on this data, researchers are looking to target downstream components of Smo signaling, such as GLI inhibitors, as well as utilizing a more individualized approach when selecting a therapy that will work best for each patient. GLI inhibition would be a promising target since it would affect both the tumor and stromal cells. A small molecular inhibitor of GLI1 and GLI2, the Gli-*ANT*agonist (GANT61), acts in the nucleus to block GLI1- and GLI2-mediatied transcription [120]. GANT61 was discovered using a luciferase assay-based screen in HEK293 cells. Studies in mice showed that GANT61 induces strong tumor regression (120), may inhibit pancreatic CSC growth [121, 122], and induces autophagy, contributing to reduced viability [123]. While GANT61 is a potent GLI1 and GLI2 inhibitor, there are no clinical trials currently ongoing for this drug for any type of cancer. Arsenic trioxide (ATO), a popular chemotherapeutic agent, is FDA-approved for the treatment of acute promyelocytic leukemia (APL) where it degrades the PML-RAR fusion protein that drives the disease [124]. Arsenic can inhibit the Hh pathway through inhibition of GLI proteins by directly binding the

GLI zinc finger domain and blocking ciliary accumulation of GLI2 [125, 126]. This allows Hh pathway inhibition downstream of Smo. Combination of ATO and parthenolide (PTL), an herbal medicine, was shown to inhibit growth of pancreatic cancer cells through induction of apoptosis [127]. This study indicates ATO may be a promising target for GLI inhibition, but additional preclinical studies are needed to determine its effectiveness. In another study, Damhofer and colleagues investigated the potency of paracrine signaling of tumor cells in the neighboring stroma [128]. While Hh ligands are highly membrane-associated, they can only target cells diameters away. By inhibiting the release of Hh ligands from PDAC cells, Damhofer et al. found this increased the signaling range of the ligand to adjacent stromal cells. This indicates that endogenous Hh on the cancer cell surface increases signaling range and potency. Based on this theory, Hh-blocking antibodies may lower this activation and decrease the signaling range of PDAC tumors, which may have a different effect than complete ablation of the pathway.

In support of the above statement, Rihm et al. discovered that Shh-deficient tumors were more poorly differentiated, exhibited increased vascularity, and were more aggressive [95]. These results suggest inhibition of the HH/GLI1 axis may have a proangiogenic effect on the tumor. Shh-deficient mice showed increased tumor vasculature, leading the authors to investigate the effect of angiogenesis inhibition through administration of anti-VEGF receptor to tumor-bearing SHH-deficient mice [95]. Anti-VEGF receptor therapy led to a significant improvement in the overall survival of mice-bearing undifferentiated tumors. This indicates that the subset of PDAC patients with undifferentiated tumors with low levels of Hh activity may benefit from some form of anti-angiogenic therapy.

Some antifungal inhibitors have unexpectedly shown promise in PDAC treatment. A screen of FDA-approved drugs identified itraconazole (ITZ) as an Hh inhibitor, most likely through inhibition of Smo, but is distinct from other Smo antagonists [129]. ITZ is commonly administered orally for treatment of a broad range of fungal infections. In addition to inhibition of the Hh pathway, ITZ also inhibits angiogenesis and induces autophagy [130–132]. One case involving a patient with unresectable stage III PDAC showed a positive response to ITZ treatment [133]. Following ITZ treatment for 9 months, the patient's PDAC regressed and was able to be treated surgically. This makes ITZ an interesting candidate for PDAC treatment.

As an alternative to direct Hh inhibition, some chemopreventive "natural agents" (nutraceuticals) may also target PDAC CSCs through inhibition of self-renewal and early metastasis [85]. Consumption of fruits and vegetables is strongly correlated with a lower PDAC incidence [134]. These natural compounds prevent cancer through inhibition of multiple signaling pathways [135, 136]. For example, sulforaphane, found in cruciferous vegetables, has been found to inhibit self-renewal of CSCs through inhibition of downstream components of the Hh pathway, Nanog, and Oct-4, which are pluripotency maintaining factors [137]. In addition to sulforaphane, other nutraceuticals that inhibit the Hh pathway include epigallocatechin-3-gallate (EGCG), found in green tea polyphenols, and the

flavonoid, quercetin [85]. EGCG inhibits CSCs through inhibition of pluripotency transcription factors (Nanog and Oct-4), EMT markers (twist-1 and Zeb-1), and components of the Hh pathway. Quercetin shows a synergistic inhibitory effect on GLI and TCF/LEF transcriptional activity in CSCs when used in combination with EGCG [85].

Conclusion

The Hh pathway is highly complex and its mode of action is cell type dependent in PDAC. This complexity has made targeting the Hh pathway for treatment of PDAC difficult. While it is clear that the stroma contributes significantly to PDAC tumorigenesis, it is not known which components of the stroma are tumorigenic and which repress tumor growth. Delineating the role of each cell type in the stroma in PDAC will be critical when targeting stromal depletion as a drug therapy. In addition, the Hh pathway plays multiple roles in carcinogenesis by its involvement in both the cancer cells and stroma, where it contributes to tumor initiation and progression in early carcinogenesis but may switch to a tumor suppressor as the cancer progresses. This multifunctionality makes it critical to understand the role of the Hh pathway in all stages of cancer, particularly in the advanced stage when the cancer is most often detected. In addition, development of Hh inhibitors downstream of SMO offers promise as an effective treatment for advanced PDAC since this treatment would target both the cancer cells and the stroma.

While SMO inhibition was not successful for patients with advanced metastatic PDAC, there is some indication that this treatment may be beneficial before cancer develops, such as during chronic pancreatitis. As mentioned in this chapter, the Hh pathway is aberrantly activated in pancreatitis and preneoplastic lesions, and activation of this pathway during inflammation may drive the pancreas toward tumor formation. GLI acts a tumor promoter in early tumorigenesis, indicating that inhibition of GLI may block tumor initiation. Therefore, Smo inhibition in patients with a risk of developing PDAC may be a beneficial chemopreventive in both the early stages of inflammation and during tumor initiation when the Hh pathway is tumorigenic.

Finally, another area of research that should be further investigated is the mechanisms responsible for the transcriptional activation of GLI. Identification of coactivators of GLI may help researchers further elucidate GLI transcriptional regulation and identify new therapeutic targets for PDAC treatment. One potential coactivator of GLI includes the Zic family of proteins [138]. Similar to GLI, Zic proteins contain a zinc finger-binding domain. In addition, Zic and GLI proteins have a nearly identical binding sequence, although Zic binds GLI promoters with a lower binding affinity [138]. Zic proteins have been shown to interact with GLI through their DNA-binding domains to synergistically enhance gene expression, indicating Zic may act as a transcriptional coactivator of GLI [138, 139]. Further clarification of coactivators, such as Zic proteins, in GLI transcriptional activation may serve as a potential avenue to interrupt GLI signaling in PDAC.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is a deadly cancer with a 9% 5-year survival rate. For reasons that are not readily evident, *KRAS* is mutated in 90–95% of PDAC cases, and this truncal alteration is associated with a high frequency of mutations in crucially important tumor suppressor genes, most notably *CDKN2A* (~90%), a gene that encodes p16, *TP53* (~70%), and *SMAD4* (~50%). Concomitantly, there is overexpression of transforming growth factor beta (TGF-β) isoforms and of high-affinity tyrosine kinase receptors (TKRs) and their ligands. Enhanced cancer cell proliferation and migration mediated by TKRs, combined with loss of beneficial TGF-β-dependent pathways required to restrain uncontrolled cell proliferation, contributes to PDAC's biological aggressiveness. This chapter provides an overview of these issues and focuses on the role of alterations in Smad4 expression and function and aberrant TGF-β signaling that combine to promote pancreatic cancer growth through cell autonomous and paracrine actions, thereby contributing in an important manner to PDAC pathobiology.

Pancreatic Ductal Adenocarcinoma

Disease Description

Pancreatic ductal adenocarcinoma (PDAC) is the third leading cause of cancer mortality in the United States, with a 5-year survival of 8–9% [1]. Due to the increasing incidence of both type 2 diabetes mellitus and obesity as well as the aging of the population, all of which are recognized risk factors for PDAC [1–4], it is predicted that the incidence of PDAC will continue to increase in the United States. Moreover, improving survival rates in other cancers, such as breast cancer, will accentuate PDAC's impact as a therapy-recalcitrant cancer, and it is anticipated that

by 2020 or a few years beyond 2020 PDAC will become the second leading cause of cancer death in the United States [5].

Overview of Cardinal Features of PDAC

Cardinal features of PDAC include a propensity to be locally invasive as well as metastatic, and to exhibit resistance to chemotherapy or radiotherapy [6, 7]. Approximately 20% of patients with PDAC have a resectable cancer at clinical presentation. This low percentage of patients who are candidates for surgery is due to advanced stage at presentation in most cases, and the absence of biomarkers for early detection. As shown in Table 1, PDAC's biological aggressiveness is likely due to the presence of several high-frequency major driver mutations that include *KRAS* (90–95% mutation rate), *CDKN2A* (~90%), *TP53* (~70%), and *SMAD4* (~50%) in combination with many low-frequency driver mutations that add complexity to the altered genomic landscape and may interfere with attempts at targeted therapies [8]. Additionally, there is constitutive activation of pro-survival pathways including AKT, STAT3, and NFkB that combine to contribute to marked apoptosis resistance, excessive production of tyrosine kinase receptors (TKRs) and their ligands such as transforming growth factor alpha (TGF-α), fibroblast growth factors (FGFs), insulin-like growth factor 1 (IGF-1),

Table 1 Major driver mutations and targetable mutations in PDAC. Gene alteration frequency (%) function

Gene	Alteration	Frequency	Consequence
KRAS	Activating mutations	~92%	Mitogenic signaling that contributes to PDAC initiation, progression, and metastasis
CDKN2A	Inactivating mutations	~90%; ~10% is epigenetically silenced	Loss of ability to suppress cell cycle progression, causing enhanced proliferation
TP53	Inactivating mutations	~70%	Apoptosis resistance, chemoresistance, increased metastasis
SMAD4	Homozygous deletions or missense mutations	~24% deleted ~14% mutated ~6% multiple alterations	Perturbations in canonical TGF-β signaling
BRCA1	Amplification, mutation, and deletion	~5% amplified ~1% mutated ~1% deleted	Genomic instability due to loss of DNA damage repair capacity and inability to activate checkpoint mechanisms
BRCA2	Mutation and amplification	~4%mutated ~2% amplified	Loss of ability to perform homologous recombination
PALB2	Mutation and amplification	~4%mutated ~1% amplified	Loss of ability to perform homologous recombination

Data for frequency of gene alterations for *SMAD4*, *BRCA1*, *BRCA2*, and *PALB2* are from TCGA and cBioportal. Mutations in *BRCA1*, *BRCA2*, and *PALB2* define a subgroup of PDAC patients that can have a marked therapeutic response to platinum agents [17] and poly(ADP-ribose) polymerase (PARP) inhibitors

and hepatocyte growth factor (HGF), a dense stroma that impedes drug delivery, and suppression of cancer-directed immune mechanisms [6–10].

PDAC exhibits many features of the hallmarks of cancer, including self-sufficiency in growth signals, insensitivity to growth inhibitory pathways such as those that are usually activated by transforming growth factor beta (TGF-β), immune evasion, and a capacity to invade and metastasize [11]. These aberrant processes have been attributed to ~70 genetic alterations impacting many signaling pathways [12]. Subsequent deep whole genome sequencing and copy number variation studies suggest that PDAC has additional mutations in numerous genes, such as *ROBO2*, ARID2, *SLIT2*, *MAP2K4*, and *ATM*, and that in some PDACs there are deletions, rearrangements, and amplifications of large fragments of DNA and small regions of hypermutation termed kataegis [13, 14], underscoring the complex and heterogeneous nature of PDAC.

The TGF-β Superfamily of Ligands

TGF-β Superfamily

The TGF-β superfamily consists of growth factors that are expressed in all vertebrates, including humans, rodents, and *Xenopus*, and that has been subdivided into two main branches on the basis of sequence homologies [15]. Thus, one branch includes TGF-β isoforms, activins, and nodal, whereas the other branch includes such growth factors as muellerian inhibitory substance (MIS), growth and differentiation factors (GDFs), and bone morphogenetic proteins (BMPs) which has numerous members [15, 16]. The three mammalian TGF-β isoforms share ~70–80% amino acid sequence homology and are synthesized as precursors that are cleaved into biologically active 25 kDa dimers [17]. Differences in biological actions are dictated by temporal and spatial regulation of expression [18]. In general, TGF-βs enhance the proliferation of mesenchymal cells and inhibit the proliferation of epithelial cells. However, TGF-βs are multifunctional and can exert numerous additional biological actions in a context-dependent manner, such as induce differentiation and apoptosis, modulate the expression of integrins, alter extracellular matrix deposition, and direct the traffic of inflammatory cells [15–18].

Canonical TGF-β Signaling

As depicted in Fig. 1, TGF-β actions are initiated following ligand binding the type II TGF-β receptor (TβRII) homodimer [19, 20]. TGF-β itself also binds as a homodimer, and the resulting complex associates with a type I TGF-β receptor (TβRI) homodimer that is thereby phosphorylated within a SGSGSG sequence and activated as a serine-threonine kinase [19, 20]. Activated TβRI phosphorylates Smad2 and Smad3 but not Smad4. That is because phosphorylation occurs on the last two serine amino acids of the C-terminal SSXS residues of Smad2 and Smad3, located in their mad homology

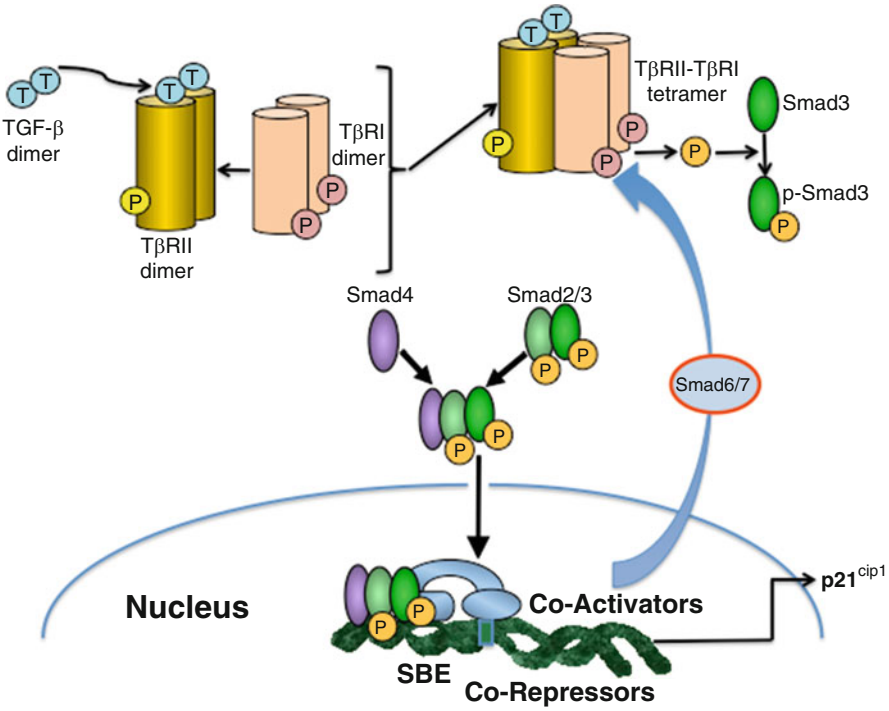

Fig. 1 Canonical TGF-β signaling. Following binding of a TGF-β dimer to the TβRII dimer, the TβRI dimer is recruited to form a heterotramer with TβRII, and the kinase activity of TβRI is thereby activated. The serine-threonine kinase activity of TβRI in turn leads to the phosphorylation of Smad2 and Smad3. The figure depicts the phosphorylation of Smad3. These receptor-activated phospho-Smads (p-Smad2 and p-Smad3) form complexes with Smad4 and translocate to the nucleus where they associated with coactivators and corepressors to interact with specific Smad-binding elements (*SBE*) in the DNA. In the example shown, interaction with coactivators leads to the induction of $p21^{cip1}$. In addition, inhibitory Smad6 and Smad7 are induced by TGF-β, leading to negative feedback effects on Smad2/3 phosphorylation and actions as explained in the text

2 (MH2) domain, and this motif is absent in Smad4 [19–21]. In addition, the Smad anchor for receptor activation (SARA) restrains Smad2 and Smad3 near the cell membrane, thereby enhancing TβRI's ability to access Smad2/3 to [22]. Once phosphorylated, Smad2 and Smad3 oligomerize with Smad4 and the resulting complexes translocate to the nucleus to regulate gene transcription in conjunction with corepressors and coactivators [19–23]. In general, activins also act by inducing the phosphorylation of Smad2/3 whereas BMP signaling induces phosphorylation of Smad1, 5, and 8 [24]; in both pathways receptor-activated Smads associate with Smad4.

Smad Cytoplasmic-Nuclear Shuttling

Smad2 and Smad3 are endowed with an intrinsic capacity to keep shuttling between the cytoplasm and nucleus [25]. However, under basal condition, Smad2 and Smad3

are mostly localized in the cytoplasm, in part due to SARA's ability to tether both ligand-activated transcription factors near the cell membrane and to mask the nuclear import signal in the MH2 domain [22]. This domain also mediates Smad2/3 oligomerization, transcriptional activity, and protein-protein interactions [19–21]. By contrast, the amino-terminal MH1 domain facilitates Smad2/3 binding to DNA [21].

Smad Nuclear Retention

Smad2/3 transcriptional regulatory actions in the nucleus are dependent on nuclear retention of these complexes. Although Smad4 is not required for retention of Smad complexes in the nucleus, it contributes in an important manner to the formation of active transcriptional complexes [21]. Thus, following nuclear translocation, Smad4 binds to a CAGAC motif and Smad-interacting DNA-binding proteins that function as coactivators or corepressors, and that include such proteins as p300/CBP, AP-1, FAST-1, Milk, and OAZ, enabling the Smad complexes to modulate gene transcription [26, 27]. Moreover, recent studies indicate that Smad transcriptional actions are modulated by cell-specific transcription factors and chromatin machinery, and by transcription factors activated by cross-interacting signaling pathways, all of which combine to markedly refine gene expression output [27].

The above complex regulatory actions require the presence of Smad2/3 complexes and Smad4 in the nucleus, and the nuclear localization of these Smads is also finely orchestrated to allow for effective modulation of gene expression. For example, TGF-β signals to attenuate Smad2 exit from the nucleus [28], thereby promoting the nuclear retention of p-Smad2. Conversely, nuclear phospho-Smad2/3 can be dephosphorylated by phosphatases and once stripped of their phosphate, Smad2/3 moieties shuttle out of the nucleus and into the cytoplasm aided by Ran-binding protein 3 (RanBP3), a Ran-binding protein that resides in the nucleus [29]. Ran is a ras-related nuclear protein that interacts with regulator of chromosome condensation 1 (RCC1) and binds GTP [29]. RanBP3 associates with Ran, nuclear pore proteins, RCC1, and Exportin 1 that is also known as Chromosomal Maintenance 1, or CRM1. Consequently, RanBP3 is able to drive dephosphorylated Smad2/3 from the nucleus, through the nuclear pores, and into the cytoplasm [29], thereby inhibiting Smad2/3 transcriptional actions. By contrast, Smad4 contains a nuclear export signal that impedes nuclear localization when TβRI is inactive, and Smad4 exit from the nucleus into the cytoplasm is directly mediated by CRM1 [30].

TGF-β-Mediated Autoinhibition

TGF-β signaling cascades eventually lead to the activation of autoinhibitory pathways. Thus, TGF-β induces the expression of two inhibitory Smads, Smad6 and Smad7, that are components of a negative feedback loop that deactivates TGF-β signaling [31]. Inhibitory Smads bind to the activated TβRI and inhibit the phosphorylation of Smad2/3 [31]. In addition, Smad7 recruits Smurf1 (Smad-

ubiquitilation regulatory factor 1 (Smur1) and Smurf2 to the receptor complex, leading to the ubiquitilation and degradation of TβRI [32, 33]. Ubiquitilation can be reversed through the actions of the USP15 deubiquitilation enzyme, which prevents TβRI degradation and promotes continued signaling [34]. Conversely, Smad7 associating proteins, including STRAP, GADD34/PP1c, and the Yes-Associated Protein 65 (YAP65), enhance the inhibitory actions of Smad7 to attenuate TGF-β signaling through a variety of mechanisms [35]. For example, PP1c is the catalytic subunit of protein phosphatase 1, and it inhibits TGF-β signaling by dephosphorylating TβRI [35].

Modulation of TGF-β Actions

TGF-β actions can be modulated through additional mechanisms, underscoring the importance of negative feedback loops in the regulation of this important pathway. For example, the BMP and activin membrane-bound inhibitor (BAMBI) is a negative regulator of TGF-β/BMP/activin signaling [36]. BAMBI disrupts TGF-β and BMP effects on transcription, inhibits TGF-β action on Smad2/3 phosphorylation, and antagonizes TGF-β's antiproliferative actions [36]. BAMBI acts by interfering with formation of the TβRII-TβRI heterotetramer, and by associating with Smad7 and TβRI to abrogate TβRI-Smad3 interaction, thereby specifically blocking Smad3-mediated effects [36]. Another example of negative feedback regulation is represented by the actions of SnoN and c-Ski, each of which contains a Smad4-binding domain and both SnoN and c-Ski are able to interact with Smad4 as well as Smads2/3, thereby preventing Smad complexes from activating gene transcription [37]. A third example is represented by Smad3's propensity to undergo ADP-ribosylation as a result of the actions of poly (ADP-ribose) polymerase-1 (PARP-1), which results in Smad complex separation from DNA and decreased transcriptional responses [38].

Suppression of TGF-β-Mediated Autoinhibition

Pathways that inhibit TGF-β actions are also negatively regulated, assuring a fine-tuning of the spectrum of downstream signaling cascades. Thus, Smad7, c-Ski, and SnoN are all negatively regulated by the RING-type E3 ubiquitin ligase Arkadia that is encoded by the *RNF111* gene [37]. Arkadia induces ubiquitin-dependent degradation of Smad7, c-Ski, and SnoN [37]. Moreover, transcription can be enhanced when Smad2/3 become acetylated by TGF-β-induced association with CBP/p300 [39].

There are also indirect mechanisms to interfere with TGF-β-mediated autoinhibition. One interesting example is the ability of activated TβRI to become covalently linked to the SUMO polypeptide, a process called sumoylation [40]. Once sumoylated, TβRI-mediated activation of Smad2/Smad3 is enhanced as a consequence of an improved association of the Smad complex to the receptor

[40]. Thus, sumoylation of TβRI leads to enhanced transcriptional activity by TGF-β.

TGF-β Actions in the Normal Pancreas

The normal pancreas expresses wild-type Smad4 and its various cell types are presumed to be able to respond to TGF-β present in the circulation in a physiological manner. In addition, there are low levels of TGF-β that are synthesized and expressed in the exocrine and endocrine cells of the pancreas [41]. By immunostaining, all three TGF-β isoforms are more abundant in the endocrine islet cells than in either the acinar or ductal cells [42]. The potential physiological importance of TGF-βs in the normal pancreas is evidenced by the observation that mice expressing a dominant-negative form of TβRII (to attenuate TGF-β signaling) in the pancreas exhibit increased acinar cell proliferation and decreased differentiation [42], indicating that TGF-β restrains mitogenesis and promotes differentiation in acinar cells. Interestingly, activation of the pancreatic cholecystokinin (CCK) receptor by caerulein in mice expressing a dominant-negative form of TβRII is associated with a decreased inflammatory response when compared with wild type mice [43]. Thus, some components of TGF-β signaling may modulate immune events in the pancreas and may contribute to caerulein-induced pancreatitis.

TGF-β and Pancreatic Cancer

Loss of TGF-β-Mediated Growth Inhibition in Cancer

In many cell types where TGF-β inhibits proliferation, TGF-β suppresses the G1 phase of the cell cycle by upregulating cyclin-dependent kinase (CDK) inhibitors such as $p21^{Cip1}$, $p15^{Ink4b}$, $p27^{Kip1}$, and p16 and by downregulating drivers of the cell cycle, including Cdc25A, CDK2/CDK4, cyclin A, cyclin E, and p34cdc2 [44]. In culture, PCCs exhibit attenuated growth-inhibitory responses to TGF-β or altogether fail to be growth inhibited [45] in standard two-dimensional cell cultures.

In general, loss of TGF-β-mediated growth inhibition may be due to decreased expression or mutation of TβRII or TβRI. Mutations within relatively unique repeat sequences in TβRII may occur in cancers that exhibit defective mismatch repair and microsatellite instability; these mutations occur within an adenine mononucleotide repeat human TβRII cDNA, due to deletions or insertions of adenines at nucleotides 709–718. For example, mutations in the *TGFBR2* gene may occur in colorectal cancers (CRCs) as microsatellite instability [46]. However, CRCs may also harbor *TGFBR2* mutations in microsatellite stable colorectal cancers [47]. In addition, expression of TβRII may be lost due to other mechanisms such as mutations in the *TGFBR2* gene promoter. In PDAC, it was previously reported that *TGFBR1* and *TGFBR2* are only mutated in ~1% and ~4% of PDAC cases, respectively

[48]. Moreover, three of four of the *TGFBR2* mutations were of the type associated with microsatellite instability [48].

Lessons from The Cancer Genome Atlas

SMAD4, originally identified as a gene deleted in pancreatic carcinoma locus 4 (*DPC4*) on chromosome 18q [49], exhibits allelic loss in ~90% of PDACs, with homozygous deletion occurring in ~30%. Moreover, analysis of this gene has revealed the presence of inactivating mutations in ~20% of PDACs, most commonly occurring within the DNA binding MH1 domain or transcriptional activation MH2 domain. In addition, in some PDACs, there are frame-shift and nonsense mutations in the *SMAD4* gene that result in loss of Smad4 function, as well as missense mutations within the MH2 domain that markedly attenuate Smad dimerization efficiency and may lead to rapid ubiquitilation and degradation of the protein [50]. Consequently, cells harboring such alterations are afflicted with multiple functional perturbations, including dysregulated TGF-β signaling, transcription, and metabolism and adhesion.

As shown in Table 2, in addition to the above well-established alterations, recent advances in sequencing technology have yielded new information in regard to gene mutations in PDAC. Thus, results available in The Cancer Genome Atlas (TCGA) and other sites that can be readily searched on cBioportal (www.cbioportal.org/) indicate that there is a 6% overall alteration rate in the *TGFBR1* gene with 6 of nearly 150 PDACs harboring putative passenger mutations and three harboring deep deletions. Moreover, as indicated in cBioportal, there is an 8% overall alteration rate in the *TGFBR2* gene with two deep deletions, three truncating mutations, four putative passenger mutations, and one putative missense driver mutation. Additionally, the *SMAD2* gene is deleted in 19% of PDACs and mutated in 1% of PDACs, whereas *SMAD3* is amplified in 4% and mutated in 3% of PDACs, *SMAD6* is amplified in 5% and mutated in 1% of PDACs, and *SMAD7* is deleted in 18% and amplified in 1% of PDACs.

As expected based on published data on Smad4 mutations [49, 50], cBioportal indicates that *SMAD4* is deleted in 24% of PDACs, mutated in 14%, and harbors multiple alterations in 6% of PDACs. Deletions, amplifications, or mutations at 1 to 3% frequency range are also observed with BMPR1A, BMPR1B, and BMPR2 that transmit bone morphogenetic protein (BMP) signals, and ACVR2A and ACVR2B that mediate activin signals. Together, these mutations represent an important component of the spectrum of perturbations in TGF-β pathways that contribute to PDAC pathobiology [12] and that include Smad6 or Smad7 overexpression [51, 52], and retinoblastoma protein (pRb) dysfunction [53], which combine with other mechanisms to convert TGF-β from a tumor suppressor to a PCC mitogen [54, 55].

Smad4 and MicroRNAs

MicroRNAs (miRNAs) are short noncoding RNAs, generally 18–25 nucleotides long, that regulate numerous cell functions by targeting specific mRNAs for

Table 2 Mutations in PDAC directly affecting TGF-β signaling components

Gene	Alteration	Frequency	Consequences
SMAD2	Mutation and deletion	~19% mutated ~1% deleted	Perturbations in canonical TGF-β signaling
SMAD3	Amplification and mutation	~4% amplified ~3% mutated	Perturbations in canonical TGF-β signaling
SMAD6	Amplification and mutation	~5% amplified ~1% mutated	Perturbations in negative feedback regulation
SMAD7	Amplification and mutation	~18% deleted ~1% amplified	Perturbations in negative feedback regulation
TGFBR1	Mutation and deletion	~4% mutated ~2% deleted	Loss of negative growth constraints on proliferation
TGFBR2	Mutation, deletion, and amplification	~5% mutated ~1% deleted ~1% amplified	Loss of negative growth constraints on proliferation
TGFBR3	Deletion and amplification	~4% deleted ~2% amplified	Loss of negative growth constraints on proliferation

The high frequency of *SMAD2 mutations* and *SMAD7* deletions underscores the important role of aberrant Smad signaling in PDAC pathobiology

degradation and/or translational repression [56, 57]. Multiple miRNAs have been implicated in PDAC pathobiology based on their altered expression in PDAC and evidence for biological actions, and several miRNAs are known to exert their effects by acting on Smad4. For example, miRNA-182-5p targets Smad4 and RECK in human bladder cancer [58], miRNA-199a attenuates canonical TGF-β signaling by targeting Smad4 in gastric cancer cells [59], and miRNA-224 enhances proliferation of hepatocellular carcinoma cells [60]. In PDAC, Smad4 is targeted by miRNA-421, miRNA-483-3p, and miRNA-301a-3p [61–63]. Conversely, loss of Smad4 in PDAC is associated with decreased miR-494 expression, allowing for FOXM1 to be upregulated and thus leading to increased nuclear translocation of β-catenin, enhanced PCC proliferation and invasion, and decreased response to gemcitabine [64].

TGF-β can also induce the expression of miRNAs and act by exerting posttranscriptional effects. For example, TGF-β is known to induce miRNA-21 expression through a Smad3-Smad4 pathway [65]. In addition, TGF-β enhances miRNA-21 expression in a Smad4-independent manner by promoting pri-miRNA-21 processing into pre-miRNA-21, which is then converted to mature miRNA-21 [66]. Importantly, PDACs are known to overexpress miRNA-21 [67], and this miRNA has oncogenic properties and is therefore considered as an oncomir [68]. In this context, TGF-β's ability to increase miRNA-21 levels in a Smad4-independent manner may enhance its capacity to act as a tumor promoter in a cell-autonomous manner even when Smad4 is mutated or deleted.

Smad4 and Polysomes and Long-Noncoding RNAs

TGF-β has also been shown to increase polysome formation, induce a global increase in translation by activating mTOR, modulate the distribution of mRNA moieties in the cytoplasm and nucleus, and dictate their distribution into polysosmes [69], and these effects are Smad4-dependent. Moreover, long noncoding RNAs (LncRNAs), which are longer than 200 nucleotides and do not encode proteins, have also been implicated in cancer in general and TGF-β actions [70]. Thus, lncRNA-Activated by TGF-β (lncRNA-ATB) is induced by TGF-β in a Smad4-independent manner and sequesters miRNA-200 family members, leading to the upregulation of ZEB1 and ZEB2 and induction of epithelial-mesenchymal transition (EMT) and enhanced metastasis [71]. Together, these actions by TGF-β underscore its ability to exert diverse effects by modulating the expression and function of coding as well as noncoding RNAs.

Smad4 and Mouse Models

Studies with mouse models have revealed that *Smad4* heterozygote mice are viable but develop gastric polyps and eventually invasive gastric cancer in the antrum [72]. By contrast, mutant mice with a homozygous deletion of *Smad4* die by fetal day 7.5 with an abnormal visceral endoderm [73], underscoring the importance of Smad4 for visceral endoderm differentiation. Moreover, rescue experiments have yielded embryos with anterior truncations, indicating that Smad4 regulates anterior patterning during embryogenesis [73].

In a subcutaneous model using severe-combined immunodeficient (SCID) mice, adenoviral-mediated forced expression of *SMAD4* in several PCCs that are devoid of *SMAD4* resulted in suppressed tumor growth in conjunction with decreased expression of vascular endothelial growth factor (VEGF) and gelatinases [74]. In subcutaneous nude mouse models of PDAC, reexpression of *SMAD4* in Hs766T PCCs confirmed that tumor growth was attenuated and angiogenesis was decreased due to attenuated VEGF expression [75], whereas in BxPC3 PCCs tumor growth was

attenuated as a consequence of decreased PCC proliferation without evidence for decreased angiogenesis [76]. Moreover, with time, BxPC3 cells were able to escape TGF-β's growth suppressive effects resulting in accelerated growth [76]. Inasmuch as all three studies used a subcutaneous model, their results must be interpreted with caution, since subcutaneous mouse models of PDAC are known to be very vascular and are not believed to represent PDAC in humans.

A vastly improved genetically engineered mouse model (GEMM) of PDAC was reported in 2003 that recapitulates many features of human PDAC. Thus, activation of oncogenic *Kras* transcription occurs through its endogenous promoter when mice carrying a *LoxP-Stop-LoxP* element (*LSL*) upstream of the silenced transcriptional start site of the $Kras^{G12D}$ allele are crossed with mice carrying a pancreas-specific promoter that drives Cre recombinase to excise the *LSL* site [77]. Generation of the KC GEMM, which expresses oncogenic *Kras* driven by Cre recombinase, yields animals that develops pancreatic intraepithelial neoplasia (PanIN) and acinar to ductal metaplasia (ADM) lesions by 2 months of age, and PDAC at variable penetrance by 8 to 12 months of age [77]. PanIN are seen in both human PDAC and GEMMs of PDAC and progress at variable rates from PanIN-1 to PanIN-2 and -3 [77, 78]. Progression to PDAC is accelerated when the KC GEMM is modified by conditional loss of tumor suppressor genes such as *Ink4a* or *Trp53* [78]. For example, *Pdx1-Cre*;*LSL-*$Kras^{G12D}$;$Ink4a^{lox/lox}$ mice harbor oncogenic $Kras^{G12D}$ and a homozygous deletion of the *Ink4a* locus, resulting in large, highly invasive ductal adenocarcinomas with frequent EMT changes by 7–11 weeks of age [78]. By contrast, *Pdx1-Cre*;*LSL-*$Kras^{G12D}$;$Smad4^{lox/lox}$ mice exhibit acceleration of tumor progression [79], but these tumors resemble intraductal papillary mucinous neoplasia (IPMNs). *Smad4* deficiency also accelerated PDAC development in *Pdx1-Cre*; *LSL-*$Kras^{G12D}$;$Ink4a^{lox/+}$ mice but the cancer cells appeared to be better differentiated than the corresponding GEMM with wild-type Smad4 [79]. Importantly, some PCC lines established from the *Pdx1-Cre*;*LSL-*$Kras^{G12D}$;$Ink4a^{lox/+}$ mice expressing wild-type *Smad4* exhibited enhanced proliferation in response to TGF-β [79], underscoring TGF-β's potential to act as a mitogen in some PCCs.

GEMMs have transformed our knowledge of PDAC pathobiology. For example, studies with GEMMs in which EGFR deletion in the pancreas abrogated cancer formation in oncogenic Kras-driven models [80] underscored the importance of EGFR family members in PDAC pathobiology in spite of the presence of *Kras* mutations in these models. Specifically in regards to the *Pdx1-Cre*;*LSL-*$Kras^{G12D}$; $Smad4^{lox/lox}$ mice, it was shown that loss of expression of the Anterior gradient 2 (*Agr2*) gene delays PanIN initiation and progression to PDAC [81], suggesting that loss of *Smad4* may convert TGF-β from a tumor suppressor that can decrease AGR2 expression to a tumor promoter that upregulates AGR2 expression [81].

Smad7 and MicroRNAs

In a feed-forward loop, TGF-β enhances miRNA-21 expression that, in turn, leads to more sustained TGF-β signaling by downregulating the levels of inhibitory Smad7

[82]. Moreover, miRNA-106b and miRNA-182b also target Smad7 [83, 84], suggesting that downregulation of Smad7 may be an important mechanism for enhancing TGF-β's tumor promoting actions. In support of this possibility, oncomirs, such as miRNA-372, and miRNA-302 attenuate TGF-β signaling by targeting TβRII [85], suggesting that suppression of TGF-β actions is a widespread mechanism in oncogenesis. However, it is not clear at what step during neoplastic transformation TGF-β converts from a tumor suppressor to a tumor promoter. Moreover, hypoxia, tumor necrosis factor alpha (TNF-α), interferon gamma (IFNγ), and mitogenic growth factors such as epidermal growth factor (EGF) act to upregulate Smad7 expression [86], and this upregulation occurs in the context of established tumors, when TGF-β functions as a tumor promoter.

The above observations raise the possibility that Smad7 actions in vivo may be context-dependent and may contribute to tumor progression. Indeed, in vivo studies indicate that Smad7 actions in tumors are more complex than in cultured cell lines. Thus, in human colon adenocarcinoma cells Smad7 attenuates TGF-β-induced G1 arrest and Akt phosphorylation while increasing TGF-β effects on c-Jun phosphorylation, and promoting anchorage-independent growth and tumorigenicity in nude mice [86]. Concomitantly, Smad7 inhibits p21 expression and apoptosis, as well as TGF-β-mediated suppression of Cyclin D1 and CDK4 [87]. In addition, Smad7 prevents TGF-β from maintaining pRb in an active, hypophosphorylated state [87].

In PCCs engineered to overexpress Smad7 there is an increase in thioredoxin levels, as well as enhanced anchorage-independent growth and tumor growth in vivo [88]. Moreover, laser capture microdissection followed by quantitative reverse-transcriptase PCR of RNA isolated from cancer cells in human PDAC samples revealed that thioredoxin and Smad7 are concomitantly overexpressed in PCCs in vivo, suggesting that thioredoxin is downstream of Smad7 in a pathway that promotes pancreatic cancer growth [88]. In support of this conclusion, Smad7 overexpression, by interfering with pRb functions in PCCs, derepresses E2F and enables TGF-β to promote tumor growth while blocking its growth inhibitory effects [54, 55]. These observations suggest that the in vivo consequences of the complex regulatory networks governing TGF-β-Smad4-Smad7 interactions are context-dependent and require further elucidation through the use of in vivo autochthonous models.

Paracrine Growth-Promoting Actions of TGF-β in PDAC

PDAC is associated with increased expression of all three TGF-β isoforms, and this overexpression in treatment-naïve patients who have undergone resection without receiving postoperative adjuvant therapy has been correlated with decreased patient survival [89]. It has been proposed that together with the loss of the tumor suppressor functions of TGF-β, its overexpression by PCCs in vivo drives PDAC progression by exerting paracrine actions in the tumor microenvironment (TME) that include alterations in the components of the extracellular matrix, enhanced stroma

formation, stimulation of aberrant angiogenesis, suppression of cancer-directed immune pathways, enhanced EMT, and a greater propensity for cancer cell to invade and metastasize.

An example of the complex paracrine actions by TGF-β is represented by its ability to induce stroma formation and to promote the expression of connective tissue growth factor (CTGF), a factor that also enhances stroma formation in PDAC. The importance of this TGF-β-CTGF axis in PDAC is underscored by the observations that blocking CTGF by an antibody (e.g., FG-3019) reduces tumor growth, metastasis, and angiogenesis in an orthotopic mouse model of PDAC [90] and in a genetically engineered mouse model (GEMM) of PDAC [91].

Direct Mitogenic Actions of TGF-β in Pancreatic Cancer Cells

As described earlier, TGF-β-mediated growth inhibition is dependent on the upregulation of CDK inhibitors such as $p21^{Cip1}$. The final common pathway downstream of these growth-inhibitory signals leads to the activation of pRb by maintaining it in a hypophosphorylated state. However, overexpression of Smad7 occurs in about 50% of PDACs, and this overexpression prevents TGF-β from inhibiting proliferation [88]. Moreover, the PCCs in PDAC tissues exhibit strong phospho-pRb, Ki67, and phospho-Smad3 immunoreactivity but low level of $p21^{Cip1}$ [55], suggesting that activation of TGF-β pathways is not associated with $p21^{Cip1}$ upregulation and fails to inhibit PCC proliferation in PDAC in vivo. Low levels of $p21^{Cip1}$ in conjunction with loss of pRb function are also associated with enhanced PCC proliferation in spite of the expression of markers generally associated with senescence [54]. In theory, the senescence response prevents the proliferation of dysfunctional cells that have the potential to undergo malignant transformation, and the cells exhibit β-galactosidase activity at pH 6.0 in contrast to being active at pH 4.0 as observed in lysosomes. Enhanced proliferative capacity occurring in this context has been termed senescence bypass.

The mechanisms whereby TGF-β can exert direct mitogenic effects on PCCs was elucidated in a study in which PCCs were isolated from a GEMM of PDAC that was generated by using mice that express *Rb* with a floxed STOP codon in exon 19 that were crossed with mice carrying *LSL-Kras*^{G12D} and *Pdx1-Cre* [54, 55]. This breeding strategy yielded compound mutant mice expressing *Kras*^{G12D} in the context of loss of pRb. PCCs established from this KRC GEMM express senescence markers but are hyperproliferative due to the loss of pRb and low $p21^{Cip1}$ levels, indicting that they have undergone senescence bypass [55]. Moreover, these changes occur in conjunction with a robust senescence-associated secretory phenotype with production of multiple cytokines and elevated TGF-β levels [54, 55].

Importantly, TGF-β enhances proliferation in PCCs derived from the KRC GEMM, and this effect is especially pronounced when the cells are grown in three-dimensional (3D) cultures [55].

Noncanonical TGF-β Actions in Pancreatic Cancer

TGF-β's direct mitogenic effects in PCCs that are devoid of pRb are mediated by the activation of noncanonical TGF-β pathways, such as extracellular signal regulating kinase (ERK), AKT, and Src [55]. Moreover, restoring wild-type pRb expression in these cells, but not mutated pRb, eliminates TGF-β's growth stimulatory actions [55], suggesting that the altered transcriptome that occurs as a consequence of the derepression of the E2F family of proteins preferentially redirects TGF-β signaling toward it's noncanonical pathways.

Noncanonical signaling can be activated by TGF-β through a variety of mechanisms (Fig. 2). For example, TGF-β can induce TβRII autophosphorylation on tyrosine residues 259, 336, and 424 [92], and can directly phosphorylate tyrosine residues on TβRI as well as serine and tyrosine residues on SchA [93]. Importantly, SchA phosphorylation results in the formation of ShcA/Grb2/Sos complex that can activate Ras and multiple downstream signaling cascades that promote tumorigenicity [93].

An altogether different mechanism is demonstrated by the actions of TGF-β-activated kinase 1 (TAK1) since it activates mitogen-activated kinase kinase

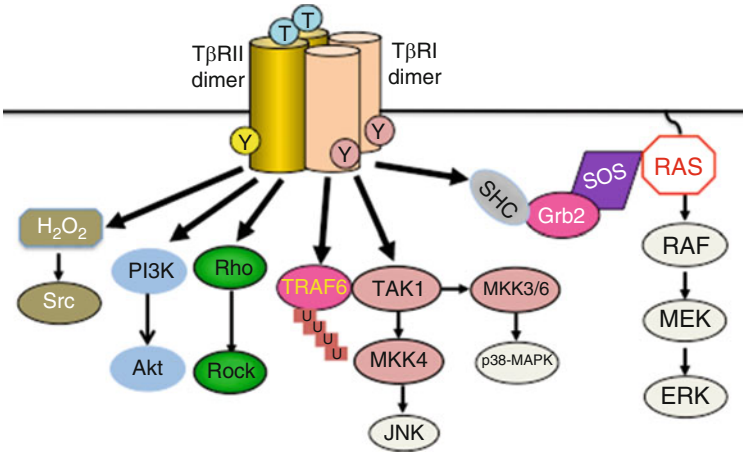

Fig. 2 Noncanonical TGF-β signaling. Both TβRII and TβRI can be phosphorylated on tyrosine residues, enabling the p85 regulatory subunit of PI3K to associate with either receptor, leading to the activation of PI3K and Akt. TGF-β also directly phosphorylates serine and tyrosine residues on SchA. SchA phosphorylation generates ShcA/Grb2/Sos complexes that activate Ras and multiple downstream signaling cascades. In addition, TGF-β-activated kinase 1 (*TAK1*) is activated as a result of its association with K63-linked poly-ubiquitilation (shown as a chain of small boxes labeled u for ubiquitin) TRAF6 (TNF receptor-associated factor 6). TAK1 then activates mitogen-activated kinase kinase 6 (*MKK6*) and MKK3, which then activate p38-MAPK. TAK1 also activates mitogen-activated kinase kinase 4 (*MKK4*) that activates Jun kinase (*JNK*). TGF-β also activates Rho GTPase, thereby activating its downstream effector Rock. Moreover, TGF-β activates NADPH oxidase, thereby generating H_2O_2 (hydrogen peroxide) leading to the activation of Src

6 (MKK6) and MKK3, which then activate p38-MAPK, thereby leading to enhanced phosphorylation of Smad2 [94]. TAK1 also activates mitogen-activated kinase kinase 4 (MKK4) that activates Jun kinase (JNK), and JNK is known to promote mitogenesis [94]. Moreover, the activation of TAK1 requires the presence of a modified form of TNF receptor-associated factor 6 (TRAF6) that must initially associate to active TβRI and undergo K63-linked poly-ubiquitilation chains on TRAF6 prior to being capable of recruiting of TAK1 [94]. Intriguingly, p38-MAPK immunoreactivity in PDAC has been correlated with better prognosis [95]. Taken together, these observations underscore the complex nature of the TAK1 noncanonical pathway.

There are several additional noncanonical pathways, which include activation of PI3K, Rho GTPase, and Rho-like GTPases such as Rac and Cdc42 [28]. Moreover, as a consequence of its ability to activate NADPH oxidases, TGF-β has been shown to increase hydrogen peroxide (H_2O_2) generation and thereby lead to the activation of Src [96], as depicted in Fig. 2.

Therapeutic Implications

Reagents for Targeting TGF-β

Multiple strategies have been proposed to suppress TGF-β deleterious effects in cancer. Some have worked in cell culture systems and subsequently in preclinical models. Moreover, some have moved into clinical trials, but a great deal of work remains to be done to find the right strategy that successfully treats a cancer and does not cause major side effects.

At the ligand level, approaches for targeting TGF-β have ranged from the use of anti-TGF-β neutralizing antibodies to impede TGF-β actions [97], antisense mRNAs or antisense oligonucleotides to inhibit TGF-β synthesis [98], a dominant-negative form of the TGF-β1 precursor to inhibit TGF-β isoform processing [99] soluble TβRII and TβRIII that act to sequester TGF-βs [100], and monoclonal antibodies that target all three TGF-β isoforms [101]. At the receptor level, a variety of screening strategies generated numerous small molecule inhibitors of the kinase activity of TβRI (206–214). At the postreceptor level, a variety of strategies have been shown to target components of downstream signaling pathways.

Preclinical Studies of Targeted TGF-β Therapy in PDAC

Expressing a soluble TβRII (sTβRII) construct in PCCs led to attenuated tumor growth in a subcutaneous nude mouse model as well as attenuated tumor growth, metastasis, and malignant ascites formation in an orthotopic mouse model of PDAC [101]. Expression of sTβRII also attenuated tumor angiogenesis and lowered the levels of mRNA moieties encoding plasminogen activator inhibitor 1 and urokinase plasminogen activator, both of which have been implicated in tumor growth and

metastasis [101]. Moreover, the small molecule inhibitor LY2109761, which targets both TβRI and TβRII, was shown to suppress pancreatic cancer metastasis in an orthotopic model [102]. Orthotopic mouse models have therefore helped to demonstrate the potential benefits of targeting TGF-β in PDAC.

By contrast to the findings in orthotopic models, in a GEMM of PDAC in which oncogenic *Kras* was combined with heterozygous loss of *Tp53*, TGF-β targeting using a monoclonal antibody that inhibits the actions of all three TGF-β isoforms (1D11), resulted in enhanced PDAC progression [103], casting doubt on the potential benefit of targeting TGF-β in PDAC. The same study also demonstrated that the integrin αvβ6 may contribute to TGF-β's tumor suppressor function and that targeting αvβ6 with a highly specific monoclonal antibody also accelerates PDAC progression in this GEMM [103]. However, with both strategies, accelerated tumor growth was dependent on the presence of wild-type *Smad4* [103], and 1D11 has been shown to inhibit pulmonary metastases in a murine mammary cancer model while also promoting antitumor immune mechanisms by enhancing the activity of CD8+ T cells [102]. Furthermore, it has been recently demonstrated that TGF-β can induce both EMT and apoptosis in PCCs that express wild-type Smad4, but promote tumor progression in PCCs devoid of Smad4 [104], underscoring the context-dependence of potential responses to TGF-β-targeted therapies.

TGF-β and Angiogenesis in PDAC

PDACs are generally hypovascular and desmoplatic. However, PDACs are also heterogeneous and may exhibit regions of readily detectable microvasculature. Thus, in addition to being hypoxic, PDACs can have blood flow and obtain necessary nutrients from the arterial blood supply while discharging waste into their venous drainage.

Using TCGA-derived RNA-seq data it was determined that ~35% of PDACs expressed a strong pro-angiogenesis gene signature, and the same PDACs expressed a transcriptome indicative of active TGF-β and pro-inflammatory signaling pathways that was similar to that observed in the KRC GEMM [105]. Expression of Smad4 correlated with the presence of a TGF-β gene signature in these samples [105]. An additional 47% of PDACs exhibited a moderate pro-angiogenic gene signature that was similar to that observed in the KRC GEMM [105]. Only ~18% of the PDACs expressed very few pro-angiogenic genes, and this signature was very similar to the gene signature seen in the highly desmoplastic and hypovascular KPC tumors. Taken together, these observations suggest that PDACs exhibit marked heterogeneity in relation to tumor angiogenesis, and TGF-β may exert multiple paracrine actions on the TME in PDAC (Fig. 3), by promoting aberrant angiogenesis and desmoplasia, suppressing cancer-directed immune mechanisms, and directly enhancing PCC survival and proliferation. Therefore, proposed therapeutic approaches need to consider these multifaceted actions of TGF-β when designing clinical trials.

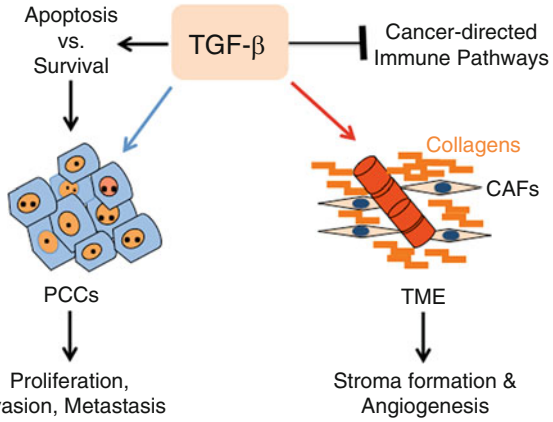

Fig. 3 Paracrine TGF-β actions in PDAC. PDAC overexpresses all three human TGF-β isoforms all of which are released into the tumor microenvironment where they promote the proliferation of cancer-associated fibroblasts (*CAFs*), induce deposition of collagen and fibronectin to help generate PDAC-associated desmoplasia, and stimulate tumor micro-angiogenesis. In addition, TGF-βs can promote the survival and proliferation of pancreatic cancer cells (*PCCs*), and enhance their invasiveness and metastatic potential, while suppressing cancer-directed immune mechanisms

Future Directions for Targeting TGF-β in PDAC

The explosive generation of new data thanks to novel technologies and "omics" ranging from genomics, to proteomics, metabolomics, lipidomics, epigenomics (as just some examples) combined with powerful informatics tools and supercomputing, high-throughput screening strategies, and novel drug packaging and delivery methodologies will allow for novel combinatorial therapies with fewer side effects, dramatic improvements in efforts at delivering effective precision medicine. In addition, novel strategies for early diagnosis and improvements in our understanding of why immune checkpoint inhibitors have not been as successful in PDAC as in some other solid tumors will allow for earlier and more successful immune- and vaccine-based interventions that will dramatically increase cure rates. In this regard, it is important to understand that TGF-β is both a tumor suppressor and a tumor promoter, depending on the stage of PDAC development. Moreover, recognizing that TGF-β plays a pivotal role in immune modulation, it will be important to continue to advance our knowledge regarding TGF-β-mediated cell-autonomous and paracrine actions, and to improve our understanding of the intersections of these pathways with other canonical and noncanonical signaling cascades, the immune system, and noncoding RNAs.

Conclusion

TGF-β exerts important regulatory actions in the normal pancreas where it functions as a tumor suppressor. However, TGF-β actions are context dependent. Thus, in the presence of major driver mutations that are common in PDAC, such *KRAS*, *TP53*,

and *SMAD4* mutations, TGF-β converts from a tumor suppressor to a tumor promoter, exerting deleterious paracrine actions on the tumor microenvironment and promoting immune evasion. In addition, TGF-β can exert direct mitogenic effects on pancreatic cancer cells by activation of noncanonical signaling pathways, and the capacity to exert these effects is enhanced as a result of the functional inactivation of pRb caused by excessive mitogenic signaling, *KRAS* mutations, loss of *CDKN2A*, and Smad7 overexpression. TGF-β also interacts with signaling pathways that are downstream of other members of the TGF-β superfamily and/or downstream of tyrosine kinase receptors. Consequently, strategies designed to suppress TGF-β signaling in PDAC need to consider the mutational landscape and specific signaling nodes that are active within a given tumor in order to allow for safe and effective combinatorial therapies.

Key Research Points

TGF-β signaling is complex, context-dependent, and regulated by positive and negative signaling inputs.

TGF-β signaling is mediated via canonical and noncanonical pathways.

In the normal pancreas, TGF-β acts as a tumor suppressor and functions to maintain acinar cell homeostasis.

In PDAC, TGF-β exerts paracrine effects on the tumor microenvironment to enhance PDAC growth and metastasis, but it can also exert direct mitogenic effects on pancreatic cancer cells.

Future Scientific Directions

There is a need for improved understanding of TGF-β signaling and its cross-talk pathways.

There is a need for improved understanding of TGF-β-mediated suppression of cancer-directed immune mechanisms and how this might impact attempts at immunotherapy.

It is important to gain a better understanding of the direct mitogenic effects of TGF-β on pancreatic cancer cells in order to improve therapeutic strategies.

Clinical Implications

Effective therapies aimed at targeting TGF-β pathways require precision medicine tools in order to avoid loss of TGF-β's tumor suppressor functions.

Combinatorial therapies that target TGF-β pathways and other deleterious pathways may restore cancer-directed immune mechanisms and improve immune checkpoint inhibition therapies.

It is crucial to understand tumor heterogeneity issues in relation to TGF-β actions in order to effectively target deleterious TGF-β pathways without enhancing progression of precancerous lesions.

Notch Signaling in Pancreatic Morphogenesis and Pancreatic Cancer Pathogenesis

Gwen Lomberk and Raul Urrutia

Contents

Abstract

Notch signaling is the focus of investigation in a large number of laboratories around the world due to its pleiotropic effect in regulating normal development and alterations in cancer. During the last few decades, the scientific community studying this pathway has made significant contributions to our understanding of the cellular role of Notch signaling in regulating proliferation, differentiation,

apoptosis, migration, branching morphogenesis, and angiogenesis. Similar to observations with other signaling cascades, such as TGBβ, besides its role in morphogenesis, Notch signaling becomes dysregulated in adult tissue and contributes to the development and maintenance of the cancer phenotype. Elegant studies in this field of research have led to not only the better understanding of the molecules within the pathway but, as a consequence, rational design of drugs that can inhibit Notch signaling with promising results. The study of Notch signaling in the pancreas has dawned on solid ground and has progressed to a better understanding of the pathway at the mechanistic level along with the development of some promising pharmacological antagonists. Thus, investigations in this field are predicted to continue to advance the field of pancreatic cancer research in a significant manner for decades to come.

Notch · Morphogenesis · Development · Signaling · Pancreatic cancer · γ-Secretase

Introduction

Since the discovery of mutant Notch phenotypes in the fly wing over 100 years ago [1], Notch signaling has continually elicited significant attention from the basic science community because of its ability to regulate normal morphogenesis in a conserved manner from flies to human. This remarkable conservation throughout the animal kingdom suggests that evolution has exercised a strong pressure for maintaining this morphogenetic cascade for millions of years, thus underscoring its importance for life. Almost seven decades after the first observation of the notched wing phenotype, the Artavanis-Tsakonas and Young labs independently cloned the Notch receptor, finally attributing this phenotype to gene haploinsufficiency [2, 3]. From this work, studies on the Notch pathway have propagated a revolution in a large number of fields, including developmental and stem cell biology, neuroscience, as well as cancer biology [4]. Developmentally, Notch signaling became first known as a robust mediator of lateral inhibition, a key patterning process that organizes the regular spacing of different cell types within tissues, including branching morphogenesis of a similar type as that observed in the pancreas [5–8]. In fact, several molecules from the Notch signaling pathway are potent regulators of normal pancreas organogenesis and/or neoplastic transformation in this organ. Initially, the interest of Notch signaling as a modulator of disease states developed from studies of its role in hereditary diseases that result from abnormal morphogenesis, such as Alagille syndrome, spondylocostal dysostosis, and several cancers, all of which display aberrant ligand expression [9–11]. However, in the adult pancreas, Notch has also been shown to recapitulate some of its developmental functions, thus aiding in both regeneration [12] and the acquisition of the neoplastic phenotype [6, 8, 13]. As a result, the current concept is that Notch signaling is associated not only with pancreatic morphogenesis but also with the development and/or maintenance of the pancreatic cancer cell phenotype.

The attractiveness of studying this pathway for pancreatic cancer investigators is due to an increased need to better understand the pathobiological role of this type of signaling in pancreatic cancer along with the relative ease that exists for pharmacologically targeting this pathway, which has led all the way to clinical trials. This increased understanding on how Notch signaling regulates an aggressive cancer phenotype in this organ, at the fine cellular and molecular level, is very promising to derive potential "biomolecular-based therapeutic modalities" that can be combined with the currently existing therapies to fight this disease. Thus, in this chapter, the current knowledge in the field of Notch signaling research is updated, and a theoretical framework that covers the molecular to the pathobiological role of this biochemical cascade in pancreatic cells is discussed.

Notch Receptor

Receptors of the Notch family are cell-surface type I transmembrane proteins, consisting of four members (Notch −1, −2, −3, and −4). Upon ligand binding, Notch receptors undergo successive proteolytic cleavages that lead to the release of the Notch intra-cellular domain (NICD) (Fig. 1) [6, 14]. This cleaved Notch intracellular domain is the active form of the receptor. In fact, several studies have shown that this pathway can be activated, in a ligand-independent manner, by simply overexpressing the NICD.

In order to better understand the mechanism of Notch signaling, it is important to remember the domain composition of this receptor since its interaction with other proteins, including ligands, depends upon this structural composition and domain organization [14]. Most notably, the extracellular domain of Notch is composed of 36 EGF repeats in vertebrates, though their number varies according to the organism being considered (Fig. 2). Another important motif includes three Lin12/Notch repeats. Careful biochemical analysis has demonstrated that the repeats 11 and 12 EGF function as binding sites for Delta and Serrate [15]. The Notch intracellular domain includes six ankyrin repeats and two classically basic residue-charged nuclear localization signals. The positions of the S1–S4 cleavage sites are crucial, since cleavage at these sites, which is achieved by the γ-secretase enzyme, releases the intracellular domain [16]. In turn, the intracellular domain subsequently migrates to the nucleus to function as a transcriptional regulator. Thus, this system appears to have evolved to mediate the characteristic long-term transcriptional response that is necessary to trigger a hierarchical cascade of gene expression, responsible of regulating cell differentiation, tissue remodeling, and morphogenesis.

Notch Ligand

Initially, most of the mechanistic information gained about the Notch signaling pathway was gathered from experiments in *Drosophila melanogaster* [17]. The two ligands found as results of these experiments, Delta and Serrate, and

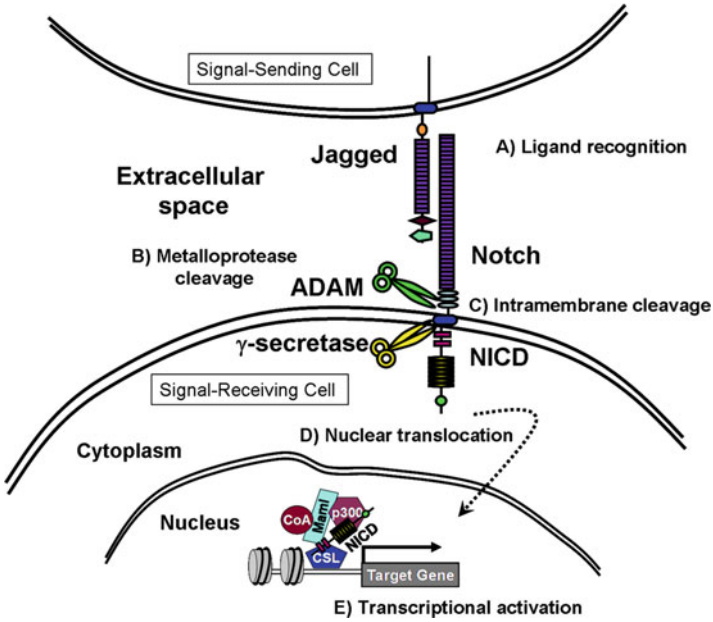

Fig. 1 **The Notch signaling pathway**. The figure illustrates the key events in the Notch signaling pathway. Ligands of the delta and jagged families expressed on an adjacent signal-sending cell initiate the signal through Notch receptor recognition on the signal-receiving cell (**a**). This interaction between receptor and ligand leads to a cascade of proteolytic cleavages of the Notch receptor, beginning with metalloprotease cleavage just outside the membrane (**b**). This proteolytic step facilitates the subsequent intramembrane cleavage of Notch by the γ-secretase complex (**c**) to release the Notch intracellular domain (*NICD*) from the membrane. The NICD then translocates to the nucleus (**d**) and enters into a transcriptional activation complex with the transcription factor CSL along with coactivators, including Mastermind-like proteins (Maml) and CBP/p300, thereby activating transcription of target genes (**e**)

Lag2, another molecule with similar domains, are known today as the canonical DSL (Delta, Serrate, Lag2) ligands, which are believed to be responsible for most Notch functions [15]. Noteworthy, however, noncanonical ligands have also been shown to activate Notch, though little is known about these pathways [18].

Similar to the Notch receptor, the canonical ligands are also type 1 cell-surface proteins containing tandem epidermal growth factor (EGF) repeats in their extracellular domains (Fig. 3). The DSL domain, the N-terminal (NT) domain, as well as the first two EGF repeats are required for binding of these ligands to Notch [19, 20]. The mammalian canonical ligands are identified by their homology to the two *Drosophila* ligands, Delta and Serrate, and are designated as either Delta-like (Dll1, Dll3, and Dll4) or Serrate-like (Jagged1 and Jagged2) [15]. The intracellular domain of DSL ligands contains a C-terminal PDZ motif [21], which is required for signaling and interactions with the cytoskeleton. The currently accepted model for Notch signaling activation is initiated at the cell membrane by the DSL ligand expressed in one cell (signal-sending cell) and a Notch receptor

(Notch1–4) expressed on another cell in close proximity (signal receiving cell). Consequently, since cell-to-cell contact is necessary to activate this pathway, a Notch-bearing cell would be regulated by its neighboring cells expressing the Delta and Serrate ligands to achieve lateral inhibition. Lateral inhibition, as it has been classically described for early neuroblast differentiation, is a process in which Notch mediates reciprocal inhibitory signaling between neuroblasts that otherwise have a similar potential for cell phenotype determination [22]. In order to present Notch to ligand, these molecules form heterodimer produced as a result of processing by a furin-like protease during transit to the plasma membrane [23]. Ligand binding initiates additional cleavages of Notch, first by a disintegrin and metalloproteases (ADAM) within the juxtamembrane region, followed by γ-secretase within the transmembrane domain, thereby resulting in the release of the Notch intracellular domain (Fig. 1) [6, 24]. γ-Secretase is made of four subunits, namely presenilin (PS), APH-1, nicastrin, and PEN-2. PS is the catalytic peptide, which provides the aspartyl protease activity to the entire complex [25]. Therefore, pharmacologically inhibiting this process, as is commonly done using γ-secretase via pharmacological inhibitors [26], can disrupt Notch signaling, raising the possibilities that tools of this type can be used to manipulate the

pathway for therapeutic purposes, though its disruption is not necessarily cell specific and may have unwanted consequences.

Intracellular Signaling Molecules for the Notch Pathway: The first intracellular signaling peptide that must be considered the beginning of the Notch signaling pathway is the NICD, which is produced by proteolytic cleavages of the receptors. This peptide translocates to the nucleus and associates with the CSL (CBF1/Su(H)/Lag-1) family of transcription factor complexes (Fig. 1), resulting in subsequent activation of Notch target genes, such as *Myc*, *p21*, and HES, and Hey family members, via the mastermind-like transcriptional coactivators [27, 28]. *Hes* and *Hey* genes are the mammalian counterparts of the Hairy and Enhancer-of-split type of genes in *Drosophila,* and they represent the primary targets of the Delta-Notch signaling pathway [24, 29]. In this review, the primary focus is to describe the role of Hes proteins as Notch signaling molecules because of their role in pancreatic morphogenesis [30, 31]. In mammals, there are seven members in the Hes family (Hes1–7), although Hes4 is absent in the mouse genome.

Crosstalk with Other Signaling Cascades

Continuous tissue remodeling during embryogenesis requires coordinated regulation among many signaling pathways to maintain the balance between proliferation and differentiation, stem cells and immature progenitor cells. Canonical Notch signaling has long been regarded as a signaling cascade that is sufficient for morphogenesis. However, recent studies have shown that Notch signaling can establish a crosstalk with other cascades in order to achieve its pleiotrophic effects [32–35]. Some of these pathways include Hedgehog, TGFβ, BMP, VEGF, and Wnt signaling. Following, the crosstalk between Notch with TGFβ and VEGF signaling is described for two very important reasons: namely, these pathways are the best known Notch interactors and they both play an important role in cancer-related functions, such as angiogenesis.

Interestingly, most of the data regarding the role of Notch in angiogenesis has been derived from experiments in animal models. For instance, mice in which *Notch1* has been disrupted in the whole animal, by homologous recombination, are lethal at E10.5 because the primary vascular plexi in the yolk sac and brain undergo aberrant remodeling [36]. In addition, this phenotype also includes alterations in large vessels. Supporting the validity of this data, experiments performed using a vascular-specific knockout of *Notch1* displays remarkably similar defects [36]. Alterations in vascular biology have also been observed in genetically engineered animals expressing genes encoding proteins from the Notch signaling pathway [37]. For instance, knockout of a single allele of *dll4* leads to lethality at E9.5 also due to a failure in remodeling the primary vascular plexus. This phenotype is also recapitulated in jagged1-deficient mice and RBP-J–deficient mice. Additional experiments using a gain-of-function paradigm based on expressing the NICD have shown alterations in angiogenesis [38]. Thus, the role of Notch signaling in endothelial cell biology and angiogenesis is well established.

Notch-TGFβ Interactions

As mentioned above, under defined circumstances, Notch signaling has been found to interact with TGFβ signaling. Members of the TGFβ family of cytokines form distinct signaling subfamilies, including TGFβ, BMPs, Activin, and Inhibin, among others. Signaling via these cytokines begins at the cell surface by activating distinct serine/threonine kinases, which in turn transduce the intracellular signal to the nucleus through either Smad-dependent or independent mechanisms [39]. In endothelial cells, TGFβ induces cell migration while arresting proliferation [40]. In addition, many members of the TGFβ family of cytokines not only have the ability to display similar effects on endothelial cells but also stimulate pericytes, which are critical for vessel formation [41]. Therefore, the role of these cytokines in angiogenesis is recognized.

In the past several years, emerging evidence supports a role for an interaction among these pathways in angiogenesis. For instance, TGFβ induces endothelial cell migration in a manner dependent upon a pathway that involves Jagged-1-Notch-Hey-1-Smad3 [42]. TGFβ-mediated arrest of cell proliferation has been found to require Notch signaling [33]. Many TGFβ-inducible genes require an additional stimulation with Notch to achieve full expression. Knockout of the Notch ligand, Jagged-1, leads to a reduction of TGFβ-mediated induction of p21 and rescues the cell cycle arrest that is characteristic of this pathway [43]. Lastly, signaling via the intracellular domain of certain Notch receptors has been found to interact with Smads from the BMP pathway and appear to participate in signaling by this cytokine [42, 44].

Notch-VEGF Interactions

Basic evidence for an interaction between angiogenic factors and Notch signaling has been gathered by the observation that VEGF induces both Notch receptor and ligand [45]. For instance, notch1 and dll4 are upregulated by VEGF, via both VEGFR1 and VEGFR2, in human arterial cells [46]. This upregulation in Notch requires signaling through phosphatidylinositol 3-kinase/Akt, but not MAPK/ERK or src kinases. Interestingly, similar results have been found in the mouse retina, where VEGF induction of dll4 was demonstrated [47]. Administration of VEGF in mouse retinas increases expression of dll4, whereas injection of the VEGF antagonist, VEGF-Trap, downregulates the expression of this molecule. Noteworthy, however, Dll4 in this situation forms part of a negative feedback loop where Notch signaling upregulates HESR1 (HEY1), which then functionally interacts with SP1 sites to silence *VEGFR2* gene expression. At the cellular level, the *dll4*+/− phenotype increases filopodia and branching angiogenesis, which can be antagonized, at least partially, by reducing VEGF levels with sFlt1 (soluble VEGFR1 extracellular domain) or by blocking VEGFR2 using specific antibodies. These studies on dll4 in developing retina indicate that, in the presence of Notch signaling, cells may migrate toward a VEGF gradient in order to facilitate the initial steps of angiogenesis. Remarkably, subsequent downregulation of these signals correlate with subsequent steps in angiogenesis, such as anastomoses, tube formation, and vessel maturation. Lastly, the VEGF-Notch signaling interaction has been validated using zebrafish, *Danio rerio*, as an in vivo animal model [45]. In zebrafish, this pathway appears to underlie arteriovenous specification. In VEGF morphants, the dorsal aorta loses arterial markers, such as ephrin B2, and ectopically expresses the vein marker, Flt4. The aberrant arterial phenotype is rescued by activated Notch in VEGF morphants, but not conversely, by VEGF in Notch mutants. These experiments are extremely informative because, together, they locate Notch downstream of VEGF in zebrafish arterial specification.

The Notch-Hes Pathway in Pancreatic Morphogenesis

Through the analyses of many experiments performed in various organisms ranging from *Drosophila melanogaster* to human, Notch has been found to play several functions that are important for development, normal physiology, and diseases. These functions include but are not limited to cell proliferation, cell differentiation, apoptosis, cell migration, angiogenesis, and branching morphogenesis. Having this concept in mind, in fact, allows us to understand how Notch is of significant importance for both pancreatic development and carcinogenesis [6].

During development, the pancreas originates from the endodermal foregut epithelium as two primordial parts of the organ, namely the dorsal and ventral pancreatic buds, which fuse to form the entire gland. In both pancreatic buds, the epithelium gives rise to exocrine and endocrine cells: exocrine progenitors become acinar cells, which secrete digestive enzymes, whereas endocrine cells emigrate from the epithelium to form islets. The liver and biliary systems also originate from the endodermal epithelium of the foregut. Together, this data indicate that both systems share a pattern of branch morphogenesis, which is not only needed under physiological conditions, but during cancer development the biliary and pancreatic ducts give rise to similar type of cancers, both with extremely aggressive behavior. Therefore, it can be predicted that these malignancies may, at least in part, overlap in the molecular mechanisms that give rise to and maintain their cancer phenotype.

At the molecular level, in the developing pancreas, the Ptf1a transcription factor promotes exocrine cell differentiation [48], whereas the bHLH gene, *Ngn3*, mediates the differentiation of all types of endocrine cells [49], including α (glucagon-producing), β (insulin-producing), δ (somatostatin-producing), and PP (pancreatic polypeptide-producing) cells. The role of the Notch pathway in this phenomenon can be better understood via its relationship with Ngn3. The inactivation of the murine *Hes1* by homologous recombination triggers an upregulation of *Ngn3*, creating a bias toward endocrine cell differentiation and severe hypoplasia of the gland [50]. Further supporting a critical role of Notch in pancreatic development is the fact that similar phenotypes are observed after either knocking out the delta-like 1 (*Dll1*) ligand or the transcription factor that is an effector of Notch, namely RBP-J (recombination signal sequence-binding protein) [8, 51] showing accelerated differentiation of pancreatic endocrine cells, as well as by the overexpression of either *Ngn3* or the intracellular form of Notch3 (repressor of Notch signaling) [52]. Together, this data strongly suggests that the Dll1-Notch-RBP-J-Hes1 pathway inhibits premature endocrine differentiation.

Hes1 also antagonizes the function of Ptf1a, the master regulator of exocrine cell differentiation, by directly targeting the *Ptf1a* promoter and silencing its expression [5]. Moreover, expression of the intracellular domain of Notch inhibits acinar cell differentiation by antagonizing the function of Ptf1a [7, 30]. Thus, in summary, Notch-Hes1 signaling promotes the maintenance of pancreatic progenitor cells by antagonizing Ptf1a and Ngn3. However, in *Hes1*-null mice, Ptf1a and Ngn3 are

ectopically expressed in the common bile duct, leading to the formation of an ectopic pancreas [50]. Thus, this observation emphasizes that the biliary tree has similarity with the pancreatic buds at the molecular level, at least enough as to adopt a pancreas phenotype when key pancreas-specific regulators are expressed in these cells. This is not a trivial finding since this type of transdifferentiation is not a common event in every tissue type. Thus, both the biliary and the pancreas epithelium appear to go through a phase of "capacitation," in which the expression of key Notch-induced transcription factors is able to push their phenotype either way. The potential contribution of this concept to better understanding normal bile and pancreatic duct morphogenesis and their cancers is potentially very insightful, though it remains an underrepresented area of research.

Elegant studies in zebrafish have also been very useful for learning the role of Notch in pancreatic morphogenesis. For instance, activated Notch and Notch target genes impair zebrafish acinar cell differentiation [30]. In fact, strong evidence supporting a role for Notch in regulating exocrine pancreatic differentiation has been derived from this work on zebrafish embryos, in which Notch signaling is disrupted (homozygous *mindbomb* mutations) [30]. Mutant embryos appear to have accelerated exocrine pancreatic differentiation as compared with wild-type controls. Similar alterations were also observed after expressing a dominant negative *Suppressor of Hairless* [*Su(H)*]. Mechanistic studies, using transient transfection assays in COS7 cells involving a Ptf1-responsive reporter gene, demonstrated that Notch and Notch/Su(H) target genes directly inhibit Ptf1 activity. Thus, since Ptf1 is a critical regulator of acinar cell differentiation and zymogen gene expression, this work in zebrafish has not only defined a role for Notch in acinar cell differentiation but also provides at least one mechanism by which this pathway functions.

Notch and Pancreatic Cancer

While the Notch signaling pathway is required for the expansion of pancreatic progenitor cells, Notch signaling is mostly suppressed in the adult pancreas [52]. At this stage, active Notch signaling is confined to centroacinar cells, which is substantiated by Hes1 staining of human and mouse pancreas [53, 54], as well as a Notch-responsive reporter strain [55]. This same reporter strain allowed the detection of active Notch signaling in preneoplastic lesions, known as pancreatic intraepithelial neoplasia (PanIN), and tumor cells of pancreatic ductal adenocarcinoma (PDAC)-bearing mice. As the case with many embryonic pathways, functions that Notch performs during embryonic development are recapitulated, to some extent, during cancer. Consequently, after organogenesis, it is critical that this signaling pathway undergoes tight regulation in order to prevent aberrant signaling, which has the potential to lead to neoplastic transformation, as described in other organs. Initially discovered to play a role in T cell lymphoblastic leukemia due to the identification of a recurrent chromosomal translocation [56], Notch signaling has been demonstrated to be involved in the development of many hematopoietic and solid malignancies, including pancreatic cancer [57].

Early and continuing interest in the role of the Notch pathway in PDAC come from studies indicating that expression levels of members of the Notch signaling pathway, including receptors, ligands, and downstream targets, were increased in human pancreatic cancer compared to normal human pancreas by microarray and qPCR or normal pancreatic ductal epithelium by IHC, suggesting that the Notch pathway is active in PDAC [54, 58]. In a large, integrated genomic analysis study, performed in 2016, of 456 PDAC samples to define molecular subtypes of pancreatic cancer, 32 recurrently mutated genes from 10 pathways were identified; one of which was the Notch pathway [59]. Central to the most commonly mutated oncogene in PDAC, *KRAS*, Notch signaling is required for Ras-induced transformation of fibroblasts [60], as well as the related Hras-driven tumorigenesis in a mouse mammary tumor model [61]. Interestingly, through the use of genetically engineered mice (GEM), analysis of precursor PanIN lesions from the *Pdx1-Cre; LSL-KRAS*^{G12D} mouse model of PDAC initiation recapitulated Notch pathway activation, as evidenced by strong nuclear expression, accompanied by faint cytoplasmic expression of Hes1. Notably, nuclear expression was not observed in the normal ducts or islet cells of these animals, nor in these compartments in control animals [62]. Similar results were obtained in a zebrafish model of PDAC with eGFP-*KRAS*^{G12D} expression specifically driven to the pancreas, in which live imaging analysis of the exocrine pancreatic tissue revealed not only *KRAS*-positive cells but progressive activation of TGFβ and Notch pathways [63]. Furthermore, inhibition of Notch signaling in the *Pdx1-Cre*; *LSL-KRAS*^{G12D}; *p53*$^{lox/+}$ mouse model, which advances to PDAC with distant metastases, was shown to attenuate the progression of PanIN to PDAC, mainly through a reduction in the proliferation rate of premalignant cells [55].

Notch is also a mediator of cell transdifferentiation, similarly known as metaplasia [13, 50]. Its role in this process is essential for the field, since frank PDAC is thought to progress in a multistep fashion from ductular-like preneoplastic PanIN lesions with metaplastic components by the accumulation of distinct mutations in oncogenes and tumor suppressor genes. Mice overexpressing TGFα, as driven by the *Elastase I* promoter/enhancer in acinar cells, undergo a massive metaplasia where the pancreas is often replaced by ductular-like structures, known as acinar-to-ductal metaplasia (ADM), which have lost most of the acinar phenotype and are surrounded by a robust desmoplastic reaction [54]. These lesions undergo neoplastic transformation, a process that can be significantly accelerated by crossing the mice with *p53* null animals [64]. In these GEM models, the expression levels of Notch receptors, ligands, and target genes were higher in metaplastic ducts than in adjacent normal appearing tissue *in vivo* and in organ explants exposed to TGFα [54]. Thus, together, the evidence gathered from mice and human studies propose that postnatal expression of Notch signaling molecules occurs in the metaplastic pancreatic epithelium, which is a phenomenon that correlates with cancer development.

Nevertheless, additional studies utilizing GEM models have revealed both oncogenic and tumor suppressive roles for Notch signaling in PDAC development. For instance, in studies utilizing a Cre-dependent *Notch1* gain-of-function transgene, *Rosa26*$^{Notch1IC\text{-}IRES\text{-}GFP}$ with the *Kras*^{G12D} and a tamoxifen-inducible *Pdx1-Cre*^{ERT},

dual activation of Notch1 and mutant Kras significantly increased PanIN formation in these animals in comparison to mice with only mutant Kras activation [13]. In addition, activation of *Kras*^{G12D} in fully differentiated adult acinar cells with the *Elastase1-Cre*^{ERT2} model formed PanIN lesions, which was also enhanced in the presence of *Notch1* activation. However, using the *Pdx1-Cre*-driven mouse model in which oncogenic *Kras* is activated simultaneously with deletion of *Notch1* in the pancreas, the loss of *Notch1* resulted in increased tumor incidence and progression, implying that *Notch1* can function as a tumor suppressor gene in PDAC [65]. Studies focused on both Notch 1 and 2 in a similar model of *Kras*^{G12D}-driven pancreatic carcinogenesis (*Ptf1a*$^{+/Cre(ex1)}$) indicated that mice with loss of *Notch2*, but not *Notch1*, survived significantly longer, only very rarely developed PDAC with ductal differentiation, and presented with a switch of phenotype toward anaplastic pancreatic cancer with epithelial-mesenchymal transition [66]. This key role of Notch2 in PanIN progression and malignant transformation was associated with its regulation of Myc signaling. In wild type and *Kras*^{G12D} animals, *Notch1* and *Notch2* were prominently expressed in whole-tissue mRNA, whereas *Notch3* and *Notch4* had comparatively low expression [66]. Furthermore, increased expression of *Notch2* and the Notch target gene, *Hes1*, but not *Notch1* was observed in *Kras*^{G12D} animals at an age when only a few PanIN1 lesions are notable, which corroborated prior reports [54]. In experiments aimed at assessing Notch1 as a regulator of *Kras*^{G12D}-driven ADM, utilizing both the *Pdx1-Cre* and *Elastase1-Cre*^{ERT2} models, oncogenic Kras was sufficient to drive ADM both in vitro and in vivo, but loss of *Notch1* has almost no impact on this process [67]. Similar to the studies from Hanlon, et al. [65], the number, but not the severity, of *Kras*^{G12D}-induced PanIN lesions was higher in mice with *Notch1* deletion [67]. Thus, in these contexts, *Notch1* deletion appears to make acinar cells more susceptible to formation of PanINs. Interestingly, knockout of *Hes1* in the *Ptf1a*$^{+/Cre(ex1)}$*; LSL-KRAS*^{G12D} model resembles features of the *Notch2* knockout animal reported by Mazur, et al. [66], with enhanced ADM formation and tumor development, but inhibition of high-grade PanIN formation [68]. When the *Ptf1a*$^{+/Cre(ex1)}$*; LSL-KRAS*^{G12D} model was crossed to mice carrying a dominant negative form of the Mastermind-like 1 gene, *MAML*, an essential coactivator of canonical Notch signaling-mediated transcription independent of which Notch receptor is activated, epithelial Notch signaling was inhibited and delayed PanIN initiation, but this effect was lost with age [69]. Collectively, these studies emphasize the importance of Notch signaling levels in the exocrine pancreas to maintain homeostasis, and the various observed cell-type and context-dependent effects of this pathway upon genetic manipulation should be considered when evaluating Notch inhibition for PDAC therapies.

The modes of action of Notch signaling pose an obvious mechanistic relevance of this pathway for tumor–stromal interactions. As mentioned in a previous section, the mechanism whereby Notch is expressed in a cell population in a manner that regulates cell fate is known as lateral inhibition. Therefore, the expression of Notch and its ligands can influence expression in neighboring cells. Notch also influences lineage decisions in more differentiated states in a manner that two daughter cells undergo asymmetric inheritance of ligands. Furthermore, Notch

ligands and receptors are expressed on different cell types, such that Notch can only be activated in the receptor-bearing cell in a mechanism of inductive signaling. This type of signaling, which can serve as a boundary between two groups of cells, has been modeled in tumor and stromal cell interactions. The unrelenting chemoresistance seen in PDAC is simultaneously influenced by tumor parenchymal and stromal factors. In studies evaluating critical pathways in tumor-stromal interactions, Fujita et al. found that direct coculture of pancreatic cancer cells and pancreatic stellate cells (PSCs) dramatically increased the mRNA levels of *Hes1* in both cell types, suggesting that direct cell contacts activated Notch signaling [70]. Another report from Cao and colleagues determined that a Notch pathway inhibitor or *Hes1* siRNA reversed the chemoresistance induced by PSCs and that high Hes1 levels are associated with poor prognosis in patients with PDAC [71]. Overactivation of the Notch pathway via the ligand Delta-like 4 (DLL4) enhanced the expression of genes associated with the epithelial–mesenchymal transition (EMT) and cancer stem cell (CSC) phenotypes, as well as induced multi-chemoresistance *in vitro* and inefficient chemo-drug delivery *in vivo* [72]. Therefore, therapy targeting the Notch signaling pathway has the potential to reverse chemoresistance and improve survival in patients with pancreatic cancer.

The Notch pathway has been found to play a role in additional mechanisms related to chemoresistance, such as elevated cancer stem cells (CSCs). Representing a small subpopulation of pancreatic cancer cells, CSCs are associated with an aggressive tumor behavior. The Notch pathway has been found to be further upregulated in CSCs compared to bulk pancreatic cancer cells [73]. Functionally, inhibition of the Notch pathway by a γ-secretase inhibitor or *Hes1* shRNA results in a reduction of pancreatic CSC self-renewal and tumorigenicity [73]. In contrast, use of an exogenous Notch peptide ligand to activate the pathway enhanced the percentage of CSCs and tumorsphere formation. Treatment of orthotopic PDAC tumors with a γ-secretase inhibitor not only inhibited tumor growth but also reduced the number of CSCs in these tumors [73]. Further studies have suggested that contributing factors to the failure of treatment in PDAC may be an increase in number of CSCs, as well as activation of the Notch pathway [74]. The evidence supporting a role of the Notch pathway in CSCs provides an additional rationale for targeting this pathway as a potential therapy for PDAC.

The key role of Notch signaling during pancreatic carcinogenesis has elicited interest in finding molecules capable of downregulating this pathway to normal levels, as potentially useful in the therapy of pancreatic cancer. Several suitable molecules have long existed from studies on the biology of Notch signaling, such as γ-secretase inhibitors, though new agents are under investigation, as discussed further in the following section. For instance, reports using cultured pancreatic cancer cells have shown that in BxPC-3, HPAC, and PANC-1 pancreatic cancer cells, Notch-1 downregulation causes the upregulation of NF-κB, a potential downstream target of this pathway and induces apoptosis [75]. In this work, the authors found that naturally occurring molecules (substances of great interest to the field of chemoprevention), such as genistein, are efficient in downregulating Notch signaling, thus adding to the arsenal of compounds that may serve as the foundation for

developing several generations of new drugs, which can be tested for either the chemoprevention of pancreatic cancer at the PanIN stage or even later when a frank tumor develops.

Targeting the Notch Pathway

Different types of small drugs, such as ADAM inhibitors, Notch antisense, anti-Notch monoclonal antibodies, RNA interference, and natural products, such as genistein and curcumin, have been proposed for inhibiting Notch. Currently, several classes of Notch pathway inhibitors, targeting different components of the pathway with various mechanisms of action, are not only under development, but are in clinical trials. The most promising and widely-tested manner of inhibiting Notch signaling is through γ-Secretase Inhibitors (GSIs), as the first class of Notch inhibitors to enter clinical testing for cancer [76]. Again, before Notch becomes competent for signaling, it is processed by two important enzymes, furin-like activity and γ-secretase [24]. Thus, in theory, any manipulation that interferes with Notch processing in adult tissue should impair signaling by this pathway. Originally, the idea of generating GSI was derived from the Alzheimer's field [77]. Multiple GSIs have been in various phases of clinical trials for PDAC patients, including BMS-906024, PF-030840, MK-0752, and RO4929097 [76]; however, few are being used as single agents in these trials. For example, patients with previously treated metastatic PDAC were entered into a two-stage, single-arm Phase II trial for RO4929097, an oral GSI [78]. In this study, 25% (3 of 12) evaluable patients achieved stable disease, but further enrollment during stage 2 was suspended due to the sponsor's discontinuation of RO4929097. Preclinical studies with PF-03084014 found greater efficacy in PDAC to induce apoptosis, as well as inhibit tumor cell proliferation and angiogenesis, which resulted in a reduction not only in primary tumor growth but also in metastatic dissemination, compared to gemcitabine alone [79]. According to ClinicalTrials.gov, however, any trials with PF-03084014 have been terminated or withdrawn due to change in strategy of the development of this drug. A Phase I/IIa trial has been completed for MK-0752, a potent non-competitive oral GSI, in combination with gemcitabine for the treatment of patients with surgically unresectable stage III/IV PDAC [80]. Results presented at the 2016 EORTC-NCI-AACR International Conference on Molecular Targets and Cancer Therapeutics from a phase I study indicated that LY3039478, also a GSI, is modestly effective against a range of advanced or metastatic cancers [81]. Similarly, a first-in-human phase I trial of the GSI LY900009 demonstrated the drug was tolerable, with no unexpected safety concerns and rapidly absorbed, but antitumor activity was limited [82]. None of the enrolled patients presented with a complete or partial response. While 5 of 35 patients (14%) demonstrated stable disease, these tumor types included papillary adenocarcinoma, non-small-cell lung carcinoma, ureter carcinoma, rectal carcinoma, and leiomyosarcoma, and not the 3 cases of pancreatic cancer enrolled in the study. Overall, the dose-limiting toxicity of GSI use in humans has been primarily due to secretory diarrhea, which is likely from goblet-cell

metaplasia of the small-intestinal epithelium as a result of Notch1 and Notch2 inhibition [80]. Other side effects have included skin disorders, such as erythema, rash, and pruritus, additional gastrointestinal toxicities to cause nausea and vomiting, fatigue, hypophosphatemia, and headache [80]. In order to limit these toxic side effects, regimens that employ intermittent GSI administration, such as 3-days-on-4-days-off or once a week, have been investigated based on the pharmacokinetics of specific drugs [76]. GSIs, as part of potential PDAC therapies, possess advantages that involve cost efficiency, simple administration, pan-Notch inhibition, and generally favorable tissue penetration [83, 84]. However, systemic toxicity and off-target effects remain as drawbacks. GSIs have the potential to inhibit additional γ-secretase substrates, which are more than 90 in addition to Notch receptors, and, thus, must be taken into consideration as studies evolve. The regimens for GSIs will have to be managed appropriately to not only most effectively reduce toxicity but, equally important, maintain the beneficial therapeutic effect on tumors and CSCs.

Another class of Notch pathway inhibitors that are actively under clinical development is of the monoclonal antibody (mAb) type, against either Notch receptors or Notch ligands. OMP-59R5, also known as tarextumab, is a human antibody against Notch2 and Notch3, which demonstrated reduced growth of PDAC patient-derived xenografts in combination with gemcitabine plus nab-paclitaxel [85]. In April 2016, a Phase Ib/II study of OMP-59R5 was completed in combination with nab-paclitaxel and gemcitabine in untreated patients with metastatic PDAC (ClinicalTrials.gov). Results from the phase Ib trial indicated that a 15-mg/kg dose of tarextumab combined with standard doses of gemcitabine and nab-paclitaxel was well tolerated with significant activity, in particular in patients with high Notch3 expressing tumors [86]. Another humanized mAb, OMP-21M18 or demcizumab, is against the ligand, DLL4, to block its interaction with Notch1 and Notch4. OMP-21M18 is being tested in combination with standard-of-care gemcitabine as a phase Ib trial in patients with advanced pancreatic cancer [84]. Thus far, fatigue and hypertension seem to be the most common drug-related toxicities, as reported by a phase Ib trial in patients with non-small cell lung cancer [87]. The optimism for this type of agent (mAbs) is the potential to reduce or eliminate some of the toxicities associated with GSI-based pan-Notch inhibition.

Other classes of agents under investigation to target the Notch pathway that are worth mention include "stapled peptides," decoys, and natural compounds. Stapling is a key technique for stabilizing peptides in an α-helical structure, which gives rise to a stapled peptide that is able to compete efficiently to interfere with protein–protein interactions that are mediated by α-helices. Such as the interaction of MAML with the Notch intracellular domain. A synthetic, cell-permeable, stabilized α-helical, hydrocarbon-stapled peptide derived from MAML1 has been produced, called SAHM1, which demonstrated the ability to directly bind preassembled Notch1–CSL complexes and competitively inhibit MAML1 coactivator binding [88]. Peptides such as SAHM1 have several advantages, including relatively small size, high structural compatibility with target proteins, and the ability to disrupt specific protein–protein interfaces [83]. Their utility in humans will depend on their pharmacokinetics. Decoys are soluble forms of the extracellular domain of Notch

receptors or Notch ligands, which then act as a "decoy" to compete with their endogenous cell surface-bound counterparts and eliminate Notch signaling. Although decoys of the Notch pathway have not been used in the context of pancreatic cancer yet, a Notch1 decoy has been reported that functions as ligand-dependent Notch antagonist to reduce Notch1 activity and interfere with Dll1, Dll4, and Jagged1 activities to effectively block Notch signaling in endothelial cells and thereby inhibit tumor neoangiogenesis and growth [89]. Notch signaling has also been effectively inhibited through soluble forms of the DSL type ligands Dll1 and Jagged1 [83]. Pharmacokinetics and biodistribution will be key aspects of the potential efficacy of these decoys as therapeutic options. Finally, several natural compounds appear to target Notch signaling. As mentioned earlier, genistein, which is found in soy products, inhibits Notch signaling, decreases cell proliferation, and induces apoptosis in PDAC cells, which is mediated by downregulation of NF-κB activity [75]. Sulforaphane, a natural compound derived from cruciferous vegetables, has been found to reduce the growth of CSC-xenografts derived from pancreatic tumors [90]. Similarly, quercetin, which is a major polyphenol and flavonoid commonly found in many fruits and vegetables, also inhibited growth of CSC-enriched xenografts and prevented expression of proteins involved in the EMT phenotype [91]. Certainly, the favorable concept of natural products is their relatively low toxicity, and persistent, limited Notch inhibition by natural products could be attractive for potential chemoprevention.

Although the majority of therapies against the Notch pathway are of the GSI type, the utility of others, including mAbs, stapled peptides, decoys, and natural products, warrant further investigation. Since the Notch pathway is integral for embryonic and CSC pathways, biology will be essential for managing the development of Notch inhibitors. Furthermore, monitoring Notch activity and its inhibition through biomarkers will be beneficial for measuring successful targeting. The potential challenges, however, do not outweigh the remarkable therapeutic promise offered by a pathway that is critical for proliferation and survival of cancer cells, angiogenesis, and CSC maintenance.

Conclusion

Over 100 years since the discovery of the Notch pathway, evidence has mounted in the past couple decades to implicate Notch signaling in cancer, maintenance of CSCs, and angiogenesis in a context-dependent manner. Studies initiated in model organisms such as the fruit fly provided a detailed understanding on how this pathway works at the biochemical level. Notch signaling has been associated with both normal morphogenesis and neoplastic transformation. Complementary studies in zebrafish and mice have revealed the significant relevance of this pathway in normal pancreatic morphogenesis, as well as pancreatic cancer. Moreover, alterations in this pathway have been detected in human tissue. Thus, together, these studies place Notch signaling at the center of the signaling cascades that are important to study in the pancreas and have rendered the Notch pathway an attractive

target for therapy. Importantly, developmental pathways, such as Notch, typically function together with other pathways to direct cell fate. Therefore, the most scientifically sound approach to target this pathway would be to develop mechanism-based combinations. The scientific community has reached a point where the Notch signaling pathway is largely understood at the basic molecular level. Although evidence has existed for almost two decades that Notch signaling plays a key role in cancer, there remains much to investigate. With the recent and ongoing development of agents to effectively target this pathway, this field will only continue to grow, and the promise of drugs or drug combinations that can specifically modify Notch signaling, while avoiding harmful side effects and improving both survival and quality of life for PDAC patients, remains extraordinary.

Box 1 Key Research Points

- Notch signaling is a master regulator of embryonic development in many cells and organisms. It is involved in the process of lateral inhibition where cell-to-cell contact between a signaling and a receiving cell determine fate outcome. In the exocrine pancreas, Notch is involved in acinar cell differentiation.
- Notch signaling interacts with key exocrine pancreatic transcription factors, like PTF-1, thus providing at least one mechanism by which this pathway specifies cell fate in this organ.
- Alterations in Notch signaling are a cause of several diseases, including certain malignancies. Notch is altered during the metaplastic progression that leads to pancreatic cancer and ductal adenocarcinoma. These findings make Notch a potential therapeutic target for therapeutic interventions.

Box 2 Future Scientific Directions

- Notch is involved in both pancreatic morphogenesis and pancreatic cancer. Fortunately, different types of animal models and model organisms exist to better understand the mechanism by which this pathway instructs these processes.
- Studies on crosstalk between Notch signaling with other cascades in pancreatic cells is very well-established for a few pathways. Therefore, expanding this area of research will provide a better understanding of pancreatic physiology and pathobiology.
- Historically, some of the knowledge on the Notch pathway that has been derived from studies in nonpancreatic cell systems has been directly applied to normal and neoplastic pancreatic cell biology. However, recent studies, which indicate that well-known mediators of the Notch pathway regulate pancreatic morphogenesis in a Notch independent manner, require a careful extrapolation of data from the literature and in depth molecular experimentation in the pancreas itself.

Box 3 Clinical Implications

- Fortunately, prototype drugs have been derived from the knowledge gained on the biochemistry of Notch signaling. Currently, several classes of Notch pathway inhibitors, which target different components of the pathway by various mechanisms of action, are not only under development but are in clinical trials. These

include several protease inhibitors, in particular, the γ-secretase inhibitors (GSIs), which have been the first class of Notch inhibitors to enter the clinic.

- GSIs, which are the major tool for manipulating Notch signaling, are among the most advanced drugs. However, these drugs are not very specific, as γ-secretase cleaves numerous substrates besides Notch. Therefore, side effects are common. The development of additional types of Notch pathway inhibitors, including monoclonal antibodies (mAbs), stapled peptides, and decoys, offers promise to diminish side effects and improve the therapeutic index.
- Since Notch deregulation appears to already occur at the preneoplastic stage (PanINs) and these lesions are very frequent in normal and pancreatitis patients, it remains to be explored if natural compounds that target this pathway, such as genistein, sulforaphane, and quercetin, are beneficial for the chemoprevention of pancreatic cancer.

Contents

Abstract

Pancreatic ductal adenocarcinoma is the most severe form of pancreatic cancer because of pronounced inflammation and desmoplasia leading to hypoxia, metabolic reprogramming, and immune suppression that ultimately promote tumor

growth and metastasis. The conventional wisdom is that patient survival is hobbled by the inability of currently available therapies to penetrate the tumor and its dense stromal microenvironment. The pancreatic cancer stromal microenvironment is a heterogeneous population of cancer cells, immune cells, cancer-associated fibroblasts, vascular endothelial cells, and neurons. While a detailed understanding of the cells, mediators, and receptors influencing stromal dynamism continues to emerge, interactions between these cells influence tumor suppression as well as tumor promotion. The specific roles for the inflamed stroma in pancreatic cancer immune evasion, progression, metastasis, and therapeutic resistance likely depend on stage of tumor development and distinct biophysical features within the dynamic cellular micro-niches of the tumor. Uncovering the stromal mechanisms of tumor development and progression should prompt the discovery of key windows of opportunity for multimodal therapies in pancreatic cancer.

Introduction

The most common form of pancreatic cancer, pancreatic ductal adenocarcinoma (PDA), originates from epithelial cells lining the exocrine ducts of the pancreas. Despite Herculean efforts and numerous diverse clinical trials, death rates from PDA remain nearly equal to incidence rates. This is largely due to the relatively unique biology of PDA, namely, the dissemination of tumor cells to distant sites (liver, peritoneum, lung) very early following malignant transformation at the primary site in the pancreas. Therefore, despite tremendous advances in therapeutic opportunities, durable disease control (cure) remains elusive even though survival durations have increased with the application of more effective multimodality therapy [1]. However, overall survival time remains inferior to other solid tumors, and a major reason for this is the inaccessibility of currently available therapies to penetrate the tumor and its dense stromal microenvironment. PDA, relative to other solid tumor malignancies, is characterized by a prominent desmoplasia, with 80–90% of the tumor parenchyma comprised of dense fibrotic stroma enveloping the cancer cells (Fig. 1).The intense fibrosis of the PDA stroma results in pronounced tumor hypoxia and a unique form of hypovascularity that restricts the effectiveness of radiotherapy and impedes the delivery of chemotherapeutic drugs [2, 3]. Thus, therapies to specifically target the stroma were implemented in an effort to sensitize PDA to radiation and chemotherapy. However, clinical trials with stromal-targeted therapies have shown minimal efficacy [4]. Concomitant with those results from the clinic, accumulating evidence from preclinical PDA animal models revealed that

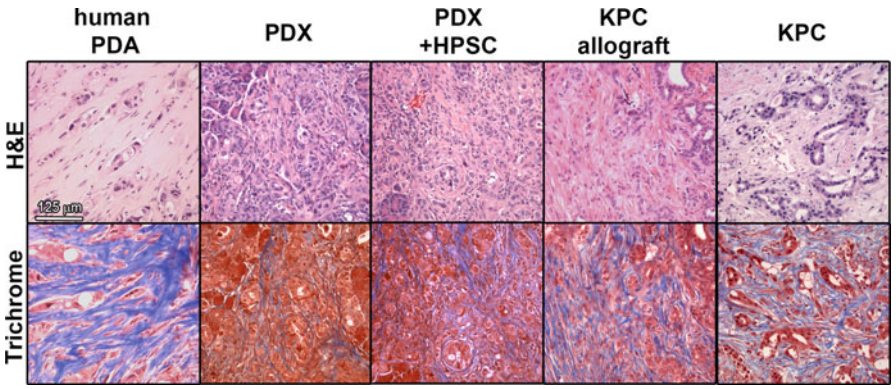

Fig. 1 Histopathology of the stromal compartment in human and murine models of pancreatic cancer. Photomicrographs of hematoxylin and eosin (H&E; *top*) or Masson's trichrome (*bottom*) stained clinical and preclinical primary exocrine pancreatic ductal adenocarcinoma (PDA) tumor tissue. Staining reveals abundant remodeling and deposition of collagen (*blue trichrome staining*) in human patient tumors (PDA) and the genetically engineered KPC mouse model. Primary tumors from xenografted patient-derived cells (PDX) show little collagen deposition or fibrosis. Mixing patient-derived cells with human pancreatic stellate cells (HPSC) leads to slightly more collagen and stromal remodeling. Allografting murine KPC PDA cancer cells into syngeneic mice resulted in higher levels of fibrosis relative to the PDX immune-incompetent model systems

complete ablation of the cellular stromal compartment, surprisingly, led to even more aggressive tumor biology [5, 6]. These findings suggest the stroma is a dynamic tissue whose effects on tumor progression cannot simply be viewed as positive or negative. Cumulatively, the emerging literature indicates that a more nuanced clinical and research approach is required to better understand the role of the stroma in the development, progression, and therapeutic resistance of PDA.

PDA develops through the dysregulation of cancer cell-autonomous and non-cancer cell-autonomous signaling pathways that parallel defined morphological changes in the pancreas. These structural modifications within the pancreas arise from acinar-to-ductal metaplasia that progress into pancreatic intraepithelial neoplasia (PanIN 1–3) leading to invasive carcinoma [7]. PanIN formation is characterized by changes in ductal architecture as well as an influx of innate myeloid and adaptive lymphoid immune cells [8]. The predominant molecular changes within the ductal epithelium are activating mutations in KRas, a critical event found in >90% of PDA patients. Subsequent changes in tumor suppressor genes, p16 and p53, and Smad4, also known as Deleted in Pancreatic Cancer-4 (DPC4), are associated with the transformation of ductal epithelial cells into invasive carcinoma. These cancer cell-autonomous changes parallel profound remodeling of the stromal matrix surrounding the transformed epithelium. Desmoplasia, the deposition and/or remodeling of connective tissue, around the malignant duct in PDA is the result of a fibrotic stromal reaction by diverse fibroblasts and immune cells and their secreted products. The cellular constituents of the stroma consist of pancreatic stellate cells (PSC),

fibroblasts, vascular endothelial cells, immune cells, and cancer cells. Cells within the tumor parenchyma also produce a dynamic array of acellular components such as collagen, fibronectin, hyaluronan, and other glycosaminoglycans, as well as cytokines, growth factors, and proteases that lead to the production and deposition of new extracellular matrix. Ultimately, these molecular constituents establish the biophysical properties of PDA tumors thought to be critically important to the characteristic aggressive biology associated with disease.

Within the normal pancreas, resident fibroblasts, PSCs, and their associated connective tissue components, along with leukocytes, and vascular endothelial cells act to homeostatically repair tissue and coordinate wound repair. Akin to many mucosal tissues, during pancreatic injury or tissue damage, ductal epithelial cells upregulate a pro-inflammatory gene program resulting in the secretion of cytokines, growth factors, and proteases, as well as production of reactive oxygen and nitrogen species [9]. These soluble mediators impact the diverse array of cells present within the pancreatic mucosa. The cumulative effect of this inflammatory influx is to synthesize and remodel the extracellular matrix, neovascularize the tissue, coordinate normal innate and adaptive immune surveillance mechanisms, and stimulate epithelial wound closure to repair the injured pancreas. However, in the setting of premalignant and malignant tissue, transformed epithelial cells bearing oncogenic mutations alter the normal wound repair processes ultimately resulting in the desmoplasia and stromal remodeling indicative of PDA. The extreme concentration of cellular infiltrates together with the presence of acellular components establishes an immune repressive, hypoxic, nutrient-deprived, and avascular microenvironment novel among solid tumors.

Inflammation and Activated Stromal Cells

In normal wound healing, activated fibroblasts play key roles in the secretion of cytokines and chemokines, recruitment of immune cells, and the deposition and remodeling of the extracellular matrix (ECM). Cancer-associated fibroblasts (CAFs) constitute the cellular majority within the evolving PanIN to invasive PDA carcinoma. CAFs synthesize and secrete extracellular matrix proteins, participate in the recruitment of suppressive leukocytes, and stimulate the proliferation and dissemination of transformed cancer epithelial cells. CAFs are activated fibroblasts derived predominantly from resident quiescent PSCs but can evolve from resident fibroblasts, bone marrow-derived mesenchymal cells, and/or the epithelial-to-mesenchymal transition (EMT) of normal epithelial cells (Fig. 2). The primary identifiable cellular marker for CAFs is α-smooth muscle actin (α-SMA), a cytoskeletal protein closely associated with smooth muscle cells which led to their further classification as myofibroblasts. Additional identifiers of CAFs include fibroblast activation protein, fibroblast specific protein 1, vimentin, and platelet-derived growth factor (PDGF) receptors. This repertoire of CAF markers reflects the diversity and heterogeneity of these cells, a finding that is only beginning to be understood [10]. CAFs dynamically secrete a broad array of molecules to contribute to and remodel the

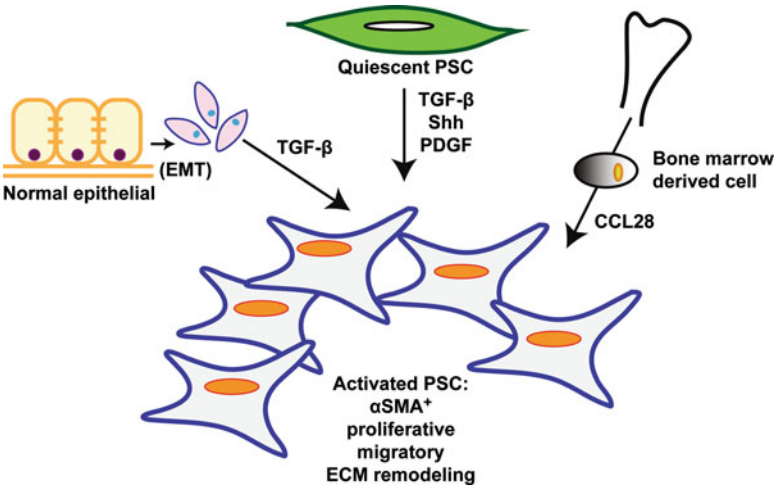

Fig. 2 Derivation of cancer-associated fibroblasts in pancreatic cancer. Activated pancreatic stellate cells (PSC) are abundant and drive much of the stromal remodeling and deposition in pancreatic ductal adenocarcinoma (PDA). Activated PSCs are characterized by elevated α-smooth muscle actin (α-SMA) expression, as well as proliferative, migratory, and enhanced ECM-producing capacity. Increased levels of activated PSCs are thought to result from transforming growth factor (TGF)-β, Sonic hedgehog (Shh), and platelet-derived growth factor (PDGF) stimulation of quiescent PSC present within the normal pancreas. Recent reports suggest activated PSC levels reflect recruitment of mesenchymal bone marrow-derived stem cells, perhaps through inflammatory chemokines such as CCL28 produced by cancer epithelial cells. Activated PSC may also be derived from a subpopulation of epithelial cells that have undergone TGF-β-mediated epithelial-to-mesenchymal transition (EMT)

ECM. Further, CAFs contribute to cytokine, chemokine, and growth factor production in the inflammatory stromal reaction that ultimately influence the establishment of the immunosuppressive PDA milieu (Fig. 3) [11].

The major source of CAFs in the PDA stroma is the resident quiescent PSC. In the normal pancreas, quiescent PSCs make up approximately 4% of the total cellular composition of the organ distributed in connective tissues and localized predominantly near ducts, blood vessels, nerves, and pancreatic lobules [12]. Their function, under homeostatic conditions, is thought to be related to the storage of vitamin A and the production of proteases needed to remodel the mucosa and submucosa of the exocrine pancreas. During tumorigenesis, progression from quiescent to activated PSCs stimulates the loss of vitamin A containing lipid vacuoles, induces expression of α-SMA (myofibroblast-like), and increases PSC proliferation and migration. The precise mechanism(s) behind the conversion from quiescent to activated PSC remains poorly understood. The prevailing theory is that the transition is triggered by environmental cues, largely inflammatory in nature, such as alcohol and its metabolites, reactive oxygen species produced during oxidative stress, as well as the release of transforming growth factor-β (TGF-β), PDGF, or Sonic hedgehog by epithelia cancer cells [13].

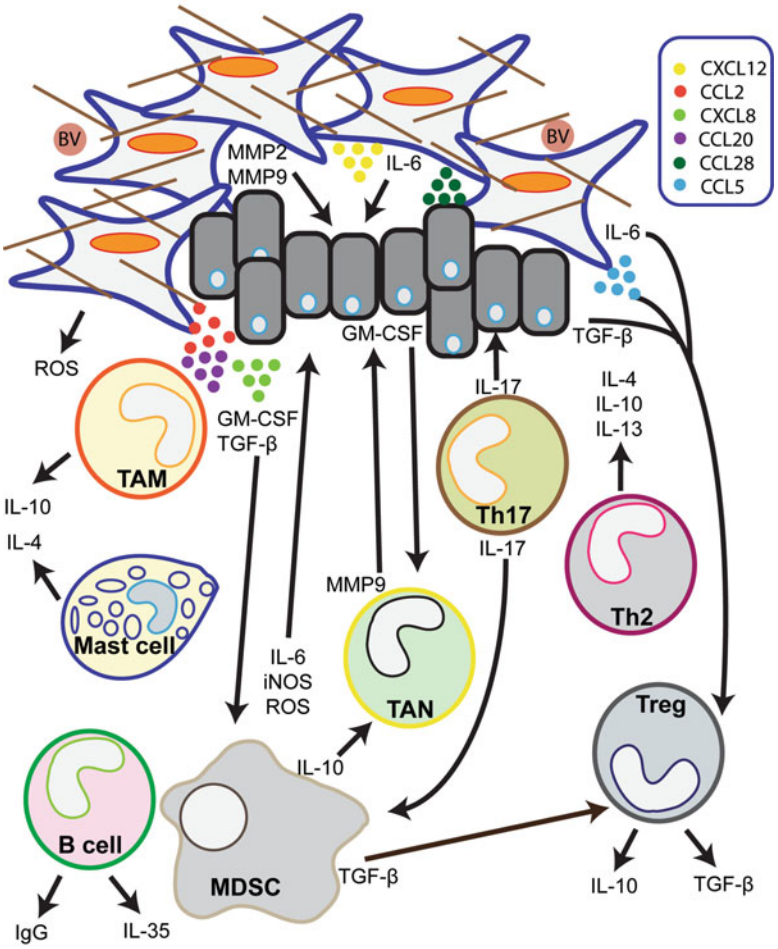

Fig. 3 Stromal inflammatory cells and mediators in the pancreatic cancer microenvironment. The complex tumor microenvironment of pancreatic ductal adenocarcinoma (PDA) reflects a collection of activated pancreatic stellate cells (PSC), blood vessels (BV), and innate and adaptive immune cells surrounding the transformed cancer epithelial cells. Secreted mediators produced by these varying cell types influence the recruitment and activation of tumor-associated macrophages (TAM), tumor-associated neutrophils (TAN), mast cells, B cells, and T helper cells (Th2 and Th17) as well as immune-suppressive myeloid-derived suppressor cells (MDSC) and regulatory T cells (Treg)

In addition to quiescent PSCs, bone marrow-derived mesenchymal cells may comprise a precursor cellular source for CAFs. Several groups have employed sex-mismatched murine transplantation/cell reseeding models to demonstrate that tagged mesenchymal stem cells reseeded to recipient mice expand and contribute to both the quiescent and activated PSC/CAF populations, as marked by the expression of desmin and α-SMA. While these bone marrow-derived mesenchymal cells appear

to be in the minority of the total tumor stromal cell population (<5%), their presence and function require further examination as they may have cell-specific spatial and/or temporal functions in the inflamed stroma.

During EMT, transformed epithelial cells of the exocrine duct lose expression of epithelial markers, notably β-catenin and E-cadherin, while acquiring expression of the mesenchymal markers vimentin and N-cadherin. The cumulative effects of the genetic and epigenetic changes leading to EMT of PDA cells result in the transition from stable epithelial cell-cell junctions typical of a normal exocrine duct to more non-adherent transformed cells with mesenchymal properties. Coculturing tumor epithelial cells with activated PSCs resulted in epithelial cell acquisition of fibroblast markers and fibroblast morphology in response to TGF-β produced by activated PSCs/CAFs. Thus, tumor epithelial cells may acquire phenotypic features and functional properties of CAFs during the EMT process that disrupt the homeostatic host defense immune response and contribute to tumorigenesis.

Inflammation and Stromal Immune Cells

Leukocytes, as well as surveilling lymphocytes, residing within the normal exocrine pancreas mucosa protect the organ from infectious agents and remove and repair damaged epithelium. These cells are actively antitumor early in the development of PDA. However, over time within the hypoxic fibrotic tumor mass encasing the transformed epithelium, these leukocytes differentiate into the more immune-suppressive tumor-promoting subsets. Thus, immunologically, the developing tumor shifts from a protective inflammatory environment into a non-protective immune evading milieu that suppresses both innate and adaptive arms of the immune system. The convergence of immunosuppressive M2-type macrophages, N2-type neutrophils, regulatory T cells, as well as myeloid-derived suppressor cells cumulatively dampens the ability of tumor-reactive cytotoxic T lymphocytes or helper T cells to remove the malignant cancer cells. The sum effect of this transition from pro-inflammatory to immune evasion is enhanced desmoplasia and the development of invasive carcinoma (Fig. 3).

Macrophages are vital innate immune responders that phagocytose dead or dying cells, facilitate wound healing, and regulate tissue homeostasis. Macrophages can differentiate into distinct lineages in response to stimuli within the surrounding tissue microenvironment. The M1 lineage is predominantly associated with pro-inflammatory host defense, while the M2 lineage is more closely involved with immune dampening. Monocytes recruited to, and that differentiate within, the tumor mass are most often the immunosuppressive M2 tumor-associated macrophage (TAM). The combination of the oncogenic KRas driver mutation within the transformed duct cells, with the secretion of inflammatory cytokines and growth factors by PSCs in the inflamed stroma, notably, TGF-β,interleukin (IL)-4, IL-10, IL-13, and epidermal growth factor (EGF), participates in TAM reprogramming into the M2 lineage. Chemokines, namely, CCL5 and CCL20, direct the recruitment, trafficking, and spatial organization of TAMs within the developing tumor, while

activated integrins and focal adhesion kinase signaling coordinate TAM adherence to stromal matrix proteins. M2-TAMs have multiple, wide-ranging effects in the stromal microenvironment, which cumulatively function to establish and maintain immune dampening and fibrosis via secretion of numerous immunosuppressive mediators, notably TGF-β, inducible nitric oxide synthase, arginase-1, indoleamine 2,3-dioxygenase, and the cytokine IL-10. M2-TAMs in the inflamed microenvironment promote aspects of tissue remodeling and wound healing. In particular, M2-TAMs aid in the digestion of extracellular matrix through production of matrix metalloproteinases (MMPs) and promote angiogenesis via vascular endothelial growth factor (VEGF) production [14]. Analysis of human PDA tissues revealed a correlation between high levels of infiltrating M2-TAMs, identified using the markers CD68, CD163, and CD204, with an increase in lymph node metastasis. TAMs also secrete cytidine deaminase, a pyrimidine salvaging enzyme capable of digesting and inactivating gemcitabine, contributing to immune-mediated chemotherapy resistance. The M1/M2 lineage model provides a useful, if simplified, framework to consider macrophage functions in tumorigenesis. However, there is increasing appreciation that macrophages exist in a continuum of phenotypes, fulfilling distinct functional roles in the inflamed stroma of solid tumors. In total, TAMs modify nearly every aspect of a tumor's development, from cancer cell proliferation and motility to invasiveness, angiogenesis, immunosuppression, extracellular matrix reorganization, and treatment resistance.

While M2-TAMs have a critical role in the development of PDA and the initial establishment of immune suppression, a separate monocyte lineage, the myeloid-derived suppressor cells (MDSC), appears to be a key contributor of the immune constraining microenvironment in late stages of tumor progression. MDSCs potently inhibit T cell proliferation, migration, and effector lymphocyte functions, blunt the antitumor cytotoxic effects of Natural Killer (NK) cells, and expand the suppressive regulatory T cell population. MDSCs originate from bone marrow hematopoietic stem cells and are a heterogeneous population of immature immune cells with angiogenic and immune-suppressive functions [15]. They can be derived from either a monocytic, m-MDSC, precursor lineage, or a granulocytic, gr-MDSC, precursor lineage. The chemokines CCL2 and CCL5 recruit newly derived MDSCs from the bone marrow to the established tumor. Secretion of various cellular mediators from M2-TAMs (arginase), CAFs (IL-6), and cancer cells (GM-CSF) play a pivotal role in MDSC expansion and migration which cumulatively promote continued immunosuppression in the tumor microenvironment [16]. Clinically, high levels of MDSCs are associated with reduced overall survival.

In addition to these myeloid innate immune cells, granulocytic cells also play a role in stromal inflammation in PDA. While levels of circulating neutrophils are elevated in patients with PDA, significant numbers of infiltrating neutrophils are uncommon within the tumor itself. Despite limited numbers infiltrating the tumor, a poor clinical outcome is correlated with increased levels of neutrophils in the tumor tissue in comparison with adjacent pancreas, supporting prior reports indicating neutrophils play a role in inflammation-driven tumorigenesis [17]. Tumor-associated neutrophils (TANs) arise from two lineages: N2-type neutrophils are

pro-tumorigenic and result from high localized concentrations of TGF-β, while N1-type neutrophils which are anti-tumorigenic and stem from elevated levels of IFN-γ. The pro-neoplastic phenotype of N2-TANs reflects their contribution to ECM degradation, promotion of neovascularization, and immunosuppression in the developing tumor. Infiltration of TANs into the tumor is largely influenced by CXCL8 and CXCL16 chemokine gradients produced by tumor epithelial cells. These same neutrophil populations secrete other chemokines, including CCL2, CCL3, CCL19, and CCL20, promoting recruitment of monocytes and dendritic cells to the tumor. TANs also participate in the inflammatory reaction and stromal remodeling by secreting a variety of pro-tumorigenic factors, including IL-2, IL-6, IL-10, TNF, and VEGF, matrix remodeling serine-proteases MMP-8 and MMP-9, and production of reactive oxygen species (ROS).

Mast cells are a myeloid granulocyte traditionally associated with allergy and anaphylactic reactions. However, mast cell numbers have been shown to be elevated in PDA and correlated with the presence of metastatic disease, higher tumor grade, and worse prognosis [18, 19]. Accumulating evidence supports a role for mast cells as tumor-promoting immune cells. Intratumoral mast cells were observed in genetically engineered mouse models of pancreas cancer, consistent with observations in human tissues. Mast cell secreted IL-13 promoted PSC proliferation and TGF-β expression, while conditioned medium from mast cells also stimulated growth of PDA cell lines. Additional studies in mast cell-deficient mice demonstrate reduced tumor growth. PSCs produce IL-33, a known pro-inflammatory molecule and activator of mast cells. Inhibition of the chemokine receptor CXCR4 using an FDA-approved small molecule antagonist blocked mast cell migration into PDA primary tumors and limited tumor expansion in a syngeneic mouse allograft model. In contrast, a newly described inducible genetically engineered mouse model suggests mast cells possess minimal, if any, effect on PDA progression [20]. Thus, more research is needed to clarify mast cell involvement in the cellular and extracellular dynamics of the stromal and immune microenvironment in PDA.

While innate immune cell subsets are critically important in inflammatory host defense responses, T lymphocytes of the adaptive immune system play roles in removal of cell-associated antigens or pathogens and are vital in the killing of cancer cells. T cell infiltrates, detected using the general T cell marker CD3, have been reported in both human and murine PDA tissue [21]. $CD3^+$ T cells can be further subdivided into cytotoxic T lymphocytes that form the first line of defense against tumors, as well as helper T cells which support antitumor responses. Natural killer cells (NK cells) are a separate subclass of lymphocytes, distinct from T or B cells, which play key roles in innate immune responses to lyse microbially infected cells or cancer cells. NK cells also produce the cytokine IFN-γ and can thus participate in the adaptive immune responses. There are three predominant helper T lymphocyte subtypes, each identifiable by the expression of the CD4 coreceptor and further defined by the type of cytokines produced. Helper T cells (Th) are classified as either Th1 cells that produce IFN-γ; Th2 cells secreting IL-4, IL-5, IL-13, and IL-10; or Th17 cells which secrete IL-17 and IL-22 cytokines. Th1 cells promote inflammation and participate in host defense to bacterial and viral pathogens. Th2 cells

contribute to allergic hypersensitivity and participate in host defense against extracellular antigens or helminth parasites. Th2 cells also negatively regulate Th1 cells by inhibiting their effector functions. Th17 cells function prominently at mucosal surfaces and trigger pro-inflammatory danger signals to promote neutrophil mobilization and the expression of host defense mediators. IL-17 and IL-22 secreted by Th17 cells promote NF-κB-dependent and JAK/STAT3 transcription factor signaling, respectively, which promote the early inflammatory cascade, and bridge the innate and adaptive immune processes.Th2 and Th17 cells secrete cytokines that stimulate a tumor-favorable, growth-enhancing, microenvironment. In contrast, $CD8^+$cytotoxic T cell functions are supported by $CD4^+$ Th1 cells through the production of proliferative IL-2 and regulatory IFN-γ cytokines histopathologically correlated with small PDA tumors. The functional role of $CD4^+$ T cell subsets was examined employing genetically engineered mouse models that express KRas in a tissue-specific and inducible manner [22, 23]. For example, when an inducible KRas murine PDA model was crossed with CD4 knockout mice, inflammation-associated tumor progression was abrogated [23]. The inability to establish a tumor-promoting environment in the absence of $CD4^+$ cells was attributed to the increased number of tumor-infiltrating antitumor $CD8^+$ T cells. In another approach, an inducible PDA/pancreatitis model resulted in pro-inflammatory Th17 cell recruitment to the tumor that synergistically increased tumor progression, suggesting that pro-inflammatory helper T cell subsets promote PDA development.

Regulatory T cells (Treg), defined by cell surface and cytoplasmic $CD4^+$, $FoxP3^+$, and $CD25^{high}$ markers, are critical effectors of peripheral immune tolerance, suppressing effector T cells through the secretion of the immune dampening mediators IL-10 and TGF-β and cell surface receptors CTLA-4 and PD-1 [24]. The combination of these secreted cytokines and receptor proteins potently inhibits the antitumor functions of $CD4^+$ Th1 cells and $CD8^+$ cytotoxic T cells, as well as NK cells. Accordingly, given the immune suppression in PDA, there is an elevated number of Treg cells in the tumor that is correlated with poor patient survival [25]. Infiltration of Treg cells into the desmoplastic stroma is mediated by activated PSCs and cancer epithelial cell secretion of chemokines such as CCL5, as well as altered expression of adhesion molecules on tumor-associated vascular endothelial cells. Further, TGF-β produced by CAFs can initiate the conversion of conventional effector $CD4^+$ T cells into a population of "induced" Treg cells [26, 27]. Depletion of Tregs increased the levels of tumor-reactive T cells and was correlated with smaller murine PDA tumors. Information from clinical trials indicate that gemcitabine, a common chemotherapeutic in PDA, reduced levels of gr-MDSC and Treg cells and was correlated with improved number of effector $CD8^+$ effector T cells in patients.

While evidence for humoral immunity in PDA has been relatively scarce, emerging data implicate B cells in important roles within the stromal environment of pancreatic cancer. Histopathologic analyses indicate B cells localized in proximity to neoplastic regions in both murine and human pancreatic cancer [28]. PDA murine models revealed that B cells were recruited to the tumor microenvironment via the chemokine CXCL13, which was itself produced and secreted by activated PSCs.

Once within the tumor microenvironment, B cells appear to play a pro-tumorigenic role through the secretion of IL-35, a positive effector of tumor cell proliferation. A pro-tumorigenic role for B cells was also identified through their production of IgG, which led to macrophage reprogramming into M2-TAMs through FcγR signaling. Pancreas-specific knockout of the hypoxia-inducible factor (HIF)-1α transcription factor revealed a significant increase in effector B cells into the pancreas and exacerbation of disease in a murine model. Treatment of HIF-1α-deficient mice with a B cell-depleting anti-CD20 monoclonal antibody relieved PanIN progression associated with more aggressive disease phenotype, suggesting humoral immunity has a role early in PDA development. Although roles for key factors in the inflammatory stroma have been implicated in B cell tumor responses, roles for helper T cells in the development of humoral tumor immunity, or B cell involvement in immune suppression or epithelial transformation and development and progression from PanIN to PDA, have yet to be defined.

In sum, the creation of a tumor-permissive environment results from an imbalance of antitumor versus pro-tumor immune cell populations (Fig. 3). The cells that are notably absent from pancreatic tumors include immune effector cells such as $CD8^+$ T cells, dendritic cells, and NK cells, which are actively excluded from the tumor by suppressor factors within the microenvironment. Similarly, the balance of $CD4^+$ helper T cells is skewed to have an increased proportion of immune-suppressive Th2 with a minimal infiltration of the Th1 effector arm. Coincident with these changes is the elevation in Treg cells that dampen the antitumor effector functions of activated lymphocytes and whose trafficking is regulated by other chemoattractants.

Inflammatory Mediators

Communication within the normal exocrine pancreas mucosa is mediated by an array of cytokines and growth factors produced by non-transformed and transformed epithelial cells, resident fibroblasts, and quiescent PSCs, together with macrophages and neutrophils of the innate immune response. Communication with the PDA microenvironment is bidirectional as transformed pancreatic cancer cells produce pro-inflammatory mediators, immunoregulatory cytokines and chemokines, as well as growth factors that act in a paracrine fashion on PSCs, CAFs, and leukocytes. Growth factor secretion by CAFs is indispensable in promoting tumor progression and metastasis. The resultant genetic and epigenetic changes evoked by cytokine and growth factor signaling within the tumor microenvironment act to increase cancer cell proliferation, mobility and dissemination, as well as activation and reprogramming of CAFs, TAMs, and T cells.

High serum levels of the pro-inflammatory cytokine IL-6 have been reported in patients with PDA and shown to promote a tumor-associated inflammatory environment in murine models [29, 30]. Activated PSC/CAFs are the primary source of pro-inflammatory IL-6. Secreted IL-6 binds to and triggers the IL-6 receptor, a member of the class I cytokine receptor family, to activate STAT3. The STAT3

signaling pathway has been implicated in several key aspects of PDA progression. Initial reports demonstrated roles for IL-6-mediated differentiation of peripheral naive $CD4^+$ T helper cells into Th17 cells and expansion of MDSCs [22]. IL-6 may also drive EMT of pancreatic cancer cells, suggesting a nonimmune pro-tumorigenic role for this pro-inflammatory molecule. IL-6 activation of STAT3 in pancreatic cancer cells may also upregulate DNA methyltransferase enzymes that participate in epigenetic changes in the tumor, perhaps silencing key genes involved in malignant progression [31, 32]. Thus, there is a well-documented role for IL-6 in PDA progression, proliferation, migration, and angiogenesis. In agreement with these broad effects, inhibition of IL-6 or STAT3 signaling has been shown to blunt tumor progression in preclinical models of pancreatic cancer.

Production of IL-17 and IL-22 by Th17 cells mediates pro-inflammatory host defense responses to extracellular pathogens and repair of mucosal tissues. IL-17 binds to the IL-17 receptor, a class I cytokine receptor that signals through the TRAF6 and NF-κB transcription factors. The resultant functional effects of IL-17 signaling are the synergistic expansion of TNF and IL-1 cytokine effects to recruit monocytes and neutrophils to the site of inflammation. IL-17 is also involved in the progression of PanINs and their transition to invasive pancreatic cancer [22]. Consistent with the plasticity of helper T cell subsets, IL-17 appears to be pro-tumorigenic, particularly early in tumor development. Anti-tumorigenic effects of Th17 cells appear later in tumor progression, with cells restricted to the peripheral margins of the established tumor [33]. Understanding the role of IL-17 in the progression of PDA was facilitated by genetic overexpression or genetic depletion studies in murine model systems. Overexpression of IL-17 accelerated PanIN development and progression, while loss of IL-17 was associated with decreased MDSC infiltration, perhaps reflecting reduced myelopoietic GM-CSF cytokine levels, as well as decreased IL-6 production. Further, the effects of IL-17 were not restricted to immune cells, as signaling through the IL-17 receptor expressed on KRas-activated epithelial cells was shown to promote carcinogenesis.

Isoforms of the pro-inflammatory IL-1 cytokine are elevated in PDA and appear to have discrete effects on tumor progression. IL-1 is the first of a large and expanding family of cytokines with distinct, cell-type-specific pro- or anti-inflammatory properties. Originally named lymphocyte-activating factor and subsequently identified as IL-1, it has mitogenic and pyrogenic properties and is among the earliest mediators of an inflammatory response. Within the malignant pancreas, high IL-1α levels are associated with poor patient prognosis [34, 35]. IL-1α produced by CAFs and TAMs regulates integrin expression impacting the development and migration potential of invasive cancer epithelial cells. IL-1β produced by CAFs and leukocytes influences macrophage recruitment, CAF activation, and the promotion of metastasis. Cell culture experiments and PDA murine models demonstrated that IL-1's biological effects signal through its canonical activation of the NF-κB transcription factor, which can be abrogated therapeutically using the anakinra IL-1 receptor antagonist.

Tumor necrosis factor (TNF), a master regulator of inflammation produced by macrophages and stromal fibroblasts, was originally called cachectin and

characterized as a regulator of myeloid antitumor cytotoxicity [36]. However, in a departure from its originally defined antitumor properties, TNF within the developing PDA tumor drives the production of numerous other cytokines and chemokines. This cytokine storm aids in establishing the immune-suppressive microenvironment and promoting tumor proliferation and migration. Indeed, in mouse models, overexpression of TNF correlates with progression from PanINs to invasive carcinoma. As expected from a cytokine with pleiotropic effects, TNF influences expression of mediators of hedgehog signaling, which plays a key role in stromal matrix remodeling, and the NF-κB-dependent upregulation of chemokine such as CCL2, CXCL1, and CXCL8 that drive macrophage and neutrophil trafficking and tumor infiltration. TNF may therefore play a key role in establishing or expanding the early inflammatory microenvironment. Over longer periods of time and as concentrations remain elevated, TNF's biological effects in established late-stage malignant PDA tumors likely reflect its more systemic roles in cachexia.

Reactive oxygen species (ROS) are free radicals produced during oxidative stress that cause damage to lipids, proteins, and DNA. Oxidative stress is characterized by a shift in the equilibrium between ROS levels and antioxidant compounds that mitigate its effects. Interestingly, cancer cells have adapted to tonically maintain levels of ROS at a lower threshold in order to avoid cell death. In PDA, oncogenic KRas-induced expression of both NADPH-oxidase stimulated formation of ROS and upregulated levels of detoxifying antioxidant signaling pathways. The concomitant production of ROS with antioxidant molecules acts to maintain a tonic level of pro-tumorigenic ROS which ultimately promotes tumor progression through a combination of signaling pathways in cancer cells [37]. As ROS is membrane diffusible, it may also act as a mediator with effects on CAF or immune cells within the tumor microenvironment. In the developing PDA tumor, ROS is also produced by monocytes in response to pro-inflammatory cytokine signaling. Leukocyte-produced ROS participates in the activation of quiescent PSCs, an effect exacerbated by epithelial PDGF. CAF-produced ROS has been shown to induce the polarization of monocytes into M2-TAMs, demonstrating that cancer cells are not the sole source of ROS in the PDA tumor microenvironment. It is therefore likely that ROS production by epithelial cells, as well as the surrounding stromal and immune cells within the inflamed tumor, cumulatively amplifies tumorigenic stimuli and promotes stromal desmoplasia.

TGF-β plays a complicated role in directing the epithelial cancer cell-autonomous, tumor microenvironmental, and systemic responses that cumulatively regulate the initiation, progression, and malignancy of numerous human cancers. TGF-β has a similarly complicated regulatory role in the human immune system. This complexity holds true in PDA, with TGF-β and its receptor-mediated activation of Smad4 playing a major role in the stromal inflammatory microenvironment and tumorigenesis. TGF-β serves as a tumor suppressor early in tumor development and progression inhibiting epithelial cell proliferation and accelerating apoptosis of metaplastic cells. However, elevated levels of TGF-β increasingly promote tumorigenesis through cancer epithelial cell migration and invasion, angiogenesis, as well as suppression of the antitumor immune system in later stages of tumor progression.

TGF-β is secreted by a collection of cells including macrophages, lymphocytes, CAFs/PSCs, epithelial cells, and platelets. Within the developing pancreatic tumor, TGF-β produced by cancer cells and PSCs stimulates EMT of ductal epithelia, VEGF-mediated neovascularization, and PSC activation and inhibits cytotoxic $CD8^+$ T cells, M1 macrophages, dendritic cells, and NK cells. Normally, TGF-β signaling through Smad4 promotes the induction of angiogenesis and immune suppression; however, this tumor-suppressive function is lost in PDA upon the inactivation/loss of *Smad4/Dpc4* by cancer epithelial cells [38]. Smad4 is a signal transducer activated by TGF-β that regulates expression of integrins, E-cadherin, and collagen, all of which are repressed in over 50% of invasive pancreatic adenocarcinomas. Genetically engineered mouse models have established the critical role for TGF-β in the development and exacerbation of PDA. When combined with oncogenic KRas mice, *Smad4* deletion, or knockout of the receptor, *Tgfbr2*, activated by the cytokine, accelerated the progression of KRas-initiated tumors. These in vivo data suggest that Smad4 mediates the tumor inhibitory action of TGF-β signaling at early stages of tumor development. Consistent with the pleiotropic nature of the cytokine, increased TGF-β levels as well as Smad4 loss/inactivation are associated with poor prognosis in patients.

IL-10 is an immunosuppressive cytokine overrepresented in tissue and serum from patients with unresectable PDA. Within the PDA tumor microenvironment, IL-10 is largely produced by Th2 cells, Tregs, and M2-TAMs. IL-10-mediated immune suppression within the pancreatic cancer tumor microenvironment correlates with reduced antitumor NK cell functions, reduced dendritic cell activity, as well as a demonstrative shift toward Th2 cell cytokine production. Consistent with its inhibitory effects, IL-10 also limits expansion and functional effects of Th1 cells. Histopathological analyses of human PDA specimens indicate IL-10 is produced by M2-TAMs located at the tumor periphery, which would be expected to limit entry and antitumor effects of cytotoxic T cells.

Chemokines, or chemotactic cytokines, represent a large family of more than 50 secreted proteins with a wide range of function in normal physiology. Chemokine functions include direction of immune cell trafficking, angiogenesis, and wound healing. As secreted molecules, chemokines travel in the circulation, diffuse through the parenchyma and extracellular matrix of tissues, and bind and activate their cognate receptors expressed on target cells. Much like other cytokines, chemokine expression is highly regulated during specific disease states. A variety of chemokines have been linked, either through histopathologic analyses of human specimens or using mouse models, with stromal inflammation and biologic effects on pancreatic cancer cells.

CXCL12, originally termed stromal-derived factor 1 based on its discovery in bone marrow stromal cells, and its cognate receptor CXCR4 are homeostatic chemokines with key roles in lymphocyte circulation. Data from knockout animals indicate the requirement of CXCL12 and CXCR4 signaling in neural development, vasculogenesis and lymphopoiesis/myelopoiesis. Conventional wisdom has been that the metastatic homing of cancer cells reflects CXCL12 produced by distant target tissues [39, 40]. However, CAFs are a tumor-proximal source of CXCL12 as epithelial expression of the *Cxcl12* gene is epigenetically repressed in transformed

PDA cancer cells [40]. Genetic reexpression of *Cxcl12* in pancreatic cancer cells reduced their proliferation and migration, suggesting that CXCL12 may have tumor-suppressive properties [40]. Subsequent reports demonstrate key antitumor effects of recombinant CXCL12 administered as a biologic therapy, with decreased metastasis and growth of primary tumors [31, 41]. The discordant effects of CXCL12 resulted in part from the concentration-dependent oligomerization of the chemokine ligand, with native protein or engineered monomeric variants providing a pro-tumorigenic signal, while elevated wild-type chemokine or mutant dimerized protein repressed tumor progression [31, 42]. The biologic effects of CXCL12 are mediated by CXCR4 whose expression is elevated in PDA and participates in cancer cell proliferation and migration [40]. CXCR4 is also expressed by the innate and adaptive immune cells localized within and surrounding the tumor. Combined chemotherapy to block immune suppression in conjunction with CXCR4 receptor antagonists blunted PDA growth in a preclinical mouse model and led subsequently to a clinical trial [NCT02179970] [43]. Stromal CXCL12 may influence the spatial organization and retention of $CXCR4^{+}$cytotoxic $CD8^{+}$ T cells in the juxta-tumoral stromal compartments, preventing access of these effector cells into the tumor mass.

CCL2 is a key regulator of monocyte/macrophage infiltration into the pancreatic cancer tumor via the engagement of the receptor CCR2. CCL2 secretion by pancreatic tumor cells is amplified in response to pro-inflammatory IFN-γ, TNF, and IL-1β cytokine stimulation [44]. Further, consistent with tissue damage and inflammation, CCL2 levels were markedly elevated following radiotherapy. CCL2 and CCR2 levels are enhanced in tumor tissue from an orthotopic murine pancreatic cancer model that was established to mimic the inflammatory milieu of human disease. Elevated serum levels of CCL2 in patients with pancreatic cancer correlated with a poor prognosis. A phase 1b single-center, open-label, non-randomized clinical trial was performed to judge the efficacy of supplementing FOLFIRINOX chemotherapy with the CCR2 inhibitor PF-04136309 [45]. While efficacy data is not yet available, the results of this study suggest that the combination treatment of the CCR2 inhibitor with FOLFIRINOX is safe and tolerable.

CXCR2 is activated by the ELR-motif CXC chemokines CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, and CXCL8 to promote the chemotaxis and bone marrow mobilization of neutrophils and gr-MDSC to sites of inflammation in the tumor [46]. CXCR2 signaling is upregulated in both MDSCs and TANs within the neoplastic pancreas, while tumor cells and CAFs have limited CXCR2 expression. In the PDA murine model, gr-MDSCs and neutrophils are the most prominent CXCR2-expressing cells [46]. Genetic or immune depletion of CXCR2 in the PDA murine model revealed a role for CXCR2 in distal metastasis, whereas growth and proliferation of the primary tumor were slowed but not prevented. In agreement with its expression by gr-MDSC, the loss or inhibition of CXCR2 greatly improved T cell infiltration into the tumor, and the combination of CXCR2 inhibitors with PD1 checkpoint blockade significantly extended survival.

The inflammatory chemokine CCL20 mediates its effects through its sole cognate receptor CCR6. As in colon cancer, both CCL20 and CCR6 are overrepresented in pancreatic tumor compared to normal pancreas [47]. In addition, M2-TAMs produce

CCL20 to functionally mediate the chemotactic migration and invasion of $CCR6^+$ tumor cells. Both cell culture and preclinical mouse model systems demonstrated the role for CCL20 and CCR6 in promoting tumor cell proliferation and migration in vitro and growth and metastasis to the liver in vivo. Consistent with reports implicating CCR6 in the pathogenesis of autoimmune psoriasis and colitis, pro-inflammatory Th17 cells infiltrate the tumor in response to PDA CCL20 production. Thus, CCL20 likely has an underappreciated role in pancreatic cancer.

Trafficking of lymphocytes and dendritic cells into lymph nodes is controlled largely through the chemokine receptor CCR7 [48]. Stimulation of CCR7-expressing PDA tumor cells by the chemokine CCL19 upregulates expression of the transcription factor Twist, which, by signaling through ERK and PI3K/AKT, facilitates EMT of cancer cells. CCR7-expressing pancreatic cancer stemlike cells expressing CD133 were also responsive to CCL21, which stimulated migration, survival, and EMT. Consistent with its known role in lymphoid tissue trafficking of immune cells, expression of CCR7 by pancreatic cancer cells resulted in an increased frequency of metastatic tumor cells within lymph nodes [49]. Intratumoral injection of CCL21 abrogated tumor progression by blunting lymph node trafficking of pancreatic cancer cells and was associated with higher numbers of tumor-reactive T cells in the primary tumor.

The chemokine CCL5, previously termed RANTES, coordinates the recruitment of CCR1-, CCR3-, and/or CCR5-expressing monocytes and T cells [50]. Pancreatic cancer cells that produce elevated levels of CCL5 actively recruit $FoxP3^+$ Tregs to the tumor microenvironment. Notably, interruption of CCL5 signaling reduced Treg levels within the tumor coincident with a decrease in primary tumor size. Another potential source of CCL5 is mesenchymal-derived stromal cells. These stromal cells have been shown to upregulate CCL5 when cocultured with cancer epithelial cells through engagement of the insulin-like growth factor (IGF) with its cognate receptor.

The chemokine CCL28 is an established mediator of mucosal-directed immune cell trafficking. CCL28 signaling through its cognate receptor, CCR10, promote migration of activated PSCs [51]. An RT-PCR screen of chemokine receptors uncovered the abundant expression of CCR10 and its ligand CCL28 in PDA cell lines. Immunohistochemical analyses of human primary PDA tissues revealed the expression of the ligand was restricted to cancer cells, while the receptor was abundant on both quiescent and activated PSCs as well as cancer epithelial cells. Inflammatory conditions upregulated the expression of CCL28 by pancreatic cancer cells and mediated migration of CCR10-expressing PSCs without altering their activation state. Thus, pro-inflammatory cancer epithelial cell-produced CCL28 chemokine may influence recruitment and localization of newly activated PSCs or bone marrow-derived mesenchymal cells to the PDA stroma.

Inflammation and Matrix Components

The extracellular matrix (ECM) is an essential noncellular component of all tissues and organs. The ECM serves not only as a molecular scaffold to organize soluble constituents but also acts as a biochemical and biomechanical mediator of tissue

morphogenesis, differentiation, and homeostasis. The role of the ECM in the stromal microenvironment is to provide crucial interactions that guide tumorigenesis, cell migration, invasion, and metastasis [52]. Although the ECM is composed primarily of water, proteins, proteoglycans, and polysaccharides, it is dynamic and heterogeneous and is constantly under a state of remodeling due to nonenzymatic and enzymatic modifications. Tumor cells and CAFs actively contribute to the remodeling of the ECM via an array of growth factors, such as fibroblast growth factor-2, TGF-β, and PDGF, influential proteolytic enzymes, and by de novo matrix or glycosaminoglycan deposition [12]. Activated PSCs secrete an array of ECM proteins that ultimately form the signature fibrotic scar seen histologically in PDA. The accumulation and elevation of these connective tissue components are posited to distort the normal ductal architecture leading to a compression of vascularization, poor transvascular permeability, and, in turn, hypoxia within the tumor [53, 54]. The fibrosis and stromal remodeling characteristic of PDA exacerbates tumor progression and renders the tumor resistant to chemotherapy and radiologic intervention.

The PDA stroma is enriched with various glycoproteins including collagens, fibronectin, and tenascin C, the clear majority of which is produced and deposited by activated PSC/CAFs within the tumor. While the primary collagens associated with PDA are types I and III, CAFs in culture may also produce collagen types I, III, IV, and V. Collagen provides tensile strength and rigidity to the tumor and contributes to the chemotactic migration of cancer epithelial cells, PSC/CAFs, and leukocytes. By exerting tension on the matrix, fibroblasts organize and align collagen fibrils into sheets and cables. Normal quiescent fibroblasts in the pancreas secrete collagen in a random isotropic manner, whereas an organized anisotropic arrangement of relatively straight collagen fibers is indicative of tumor-associated desmoplasia. Anisotropic collagen patterning can serve as a highway for cancer epithelial cell migration during invasion and metastasis. CAF-produced fibronectin is intimately involved in directing the organization of the interstitial ECM and, like collagen, has a crucial role in mediating cancer epithelial cell attachment, migration, and tumor metastasis. Consistent with EMT in many solid tumors, there are shifts in the matrix constituents, with elevated fibronectin and collagen I levels observed in human PDA tissue specimens. Genetically engineered mouse models of PDA constructed to selectively abolish α-SMA-expressing CAFs abrogated collagen and fibronectin deposition and stromal remodeling in PDA tumors [5]. Depletion of α-SMA myofibroblasts and their associated soluble mediators early during PanIN formation, or later in overt PDA, resulted in the development of significantly more invasive, undifferentiated, and hypoxic tumors compared to control mice, suggesting that stromal CAFs and/or the desmoplasia and inflammatory factors they produced beneficially curtailed tumor progression.

Sonic hedgehog (Shh), a member of the hedgehog family of genes involved in mammalian organogenesis, is aberrantly overexpressed in 70% of human PDA tissue specimens [55]. Shh binding to and activation of its receptor, Patched, which is expressed on CAFs, stimulate the membrane translocation of the Smoothened signaling protein, which subsequently activates downstream signaling pathways regulating gene expression. Activation of Smoothened target transcription

factors such as Gli led to changes in the pancreatic extracellular matrix and cytokine release, including Wnt and insulin-like growth factor (IGF), which promoted tumor growth [56]. Shh produced by tumor epithelial cells may function through autocrine signaling, regulating cancer epithelial cell proliferation and differentiation, and may function in a paracrine manner on neighboring PSC/CAFs to mediate pancreatic fibrosis. Co-activation of Shh and oncogenic KRas in a transgenic mouse model rapidly induced PanIN formation and shortened survival of tumor-bearing mice. A preclinical study using a Smoothened inhibitor, in combination with gemcitabine, markedly improved vascularization of PDA and survival in a preclinical model [53]. However, clinical trials using a commercially available hedgehog inhibitor were unsuccessful, with phase II studies showing limited benefit or, in some instances, being terminated early due to increased mortality [57]. Similarly, deletion of Shh from the stromal environment using genetically engineered mouse models resulted in cancers that were more aggressive, more proliferative, and presented with reorganized stroma notable for its increased vasculature [6]. The therapeutic efficacy of this genetic approach was replicated using an anti-stromal chemotherapy approach using a hedgehog inhibitor [58]. Evaluation of three genetically modified mouse strains further confirmed that inhibiting hedgehog signaling accelerates tumor progression. Suppressing stromal desmoplasia accelerated growth of the PanIN epithelium, while hedgehog activation caused stromal hyperplasia and reduced epithelial proliferation. Taken together, there is accumulating evidence from clinical trials and preclinical models supporting key protective roles for the stroma in PDA progression.

Mucins are a large family of high molecular weight O-glycosylated polypeptides typically expressed by epithelia cells to maintain and protect the normal pancreas mucosa from invading pathogens. Based on their diverse physiological and structural characteristics, mucins have been classified into a transmembrane subfamily and a secreted subfamily. Secreted mucins form the protective mucus layer on the apical surface of mucosal epithelia of the gastrointestinal, respiratory, and reproductive tracts. While the normal exocrine pancreas expresses low levels of MUC1, the expression of both transmembrane (MUC1, MUC3, MUC4, MUC7, MUC13, MUC16, and MUC17) and secretory mucins (MUC5AC, MUC5B, and MUC6) is aberrantly overexpressed in PanIN and PDA and has been linked to disease progression, poor prognosis, and chemoresistance. This likely reflects the ability of mucins to contribute to the immune-suppressive environment, alter signaling through receptor tyrosine kinases directly on cancer cells, or regulate cancer cell detachment, invasion, and metastasis [59]. Tumor epithelia are not the sole producers of mucins as MUC1 expression by Treg cells enhances their proliferation and cytokine production. Pancreatic cancer cells may become cross-linked to M2-TAMs or dendritic cells via mucins leading to increased production of immune-suppressive IL-10 and decreased secretion of the T cell chemoattractant CCL3. Given their aberrant expression early in tumor development, mucins have made an attractive target for diagnosis. The mucin polypeptide backbone is predominantly coated with O-linked carbohydrates. The sialyl Lewis carbohydrate CA19–9 prevalent on MUC1 is the most common FDA-approved prognostic marker for pancreatic cancer, but it can

also be elevated in colon and biliary cancers, when liver function is abnormal, and in a variety of benign conditions especially involving the lungs. In addition, Lewis antigen-negative patients do not produce CA19–9 and will not demonstrate marker elevation regardless of the extent of disease. At present, there is no reliable blood test for the early diagnosis of pancreatic cancer in asymptomatic individuals without a high-risk syndrome.

Hyaluronan (hyaluronic acid) is a large linear anionic non-sulfated glycosaminoglycan that retains water to provide elasticity to connective tissue. Under normal conditions hyaluronan is a key constituent in epithelial wound repair, inflammation, angiogenesis, and immune, epithelial, and fibroblast cell migration. Hyaluronan levels are tightly balanced by controlling its synthesis (hyaluronan synthases) and degradation (hyaluronidases). Hyaluronan is physiologically increased during an inflammatory response, likely in response to cytokines such as IL-1 and TNF upregulating hyaluronan synthase enzymes. Extracellular hyaluronan binds to its major receptor CD44 expressed largely on lymphocytes with a subset expressed on pancreatic cancer cells [60, 61]. In PDA, hyaluronan levels can be overabundant and correlate with increased tumor growth and migration. Abundance of hyaluronan is thought to be a major factor in PDA chemoresistance since it is the main contributor to the elevated interstitial fluid pressure, vascular collapse, and decreased vascular permeability associated with impaired drug delivery. However, hyaluronan signaling through CD44 promotes immune-suppressive signaling, M2-TAM reprogramming, and Treg localization, suggesting additional roles in tumorigenesis by modulating the immune microenvironment of PDA. De-bulking the tumor stroma by enzymatic digestion of hyaluronan was tested in preclinical models using PEGylated hyaluronidase PH20 (PEGPH20). Treatment of established murine PDA tumors with PEGPH20 relieved the elevated interstitial fluid pressure and re-expanded the stromal microvasculature of the tumor, ultimately sensitizing the cancer cells to gemcitabine treatment and extending overall survival [54]. Based on the strength of these preclinical studies, PEGPH20, in combination with chemotherapeutic interventions, has advanced to clinical trials [NCT01453153; NCT01839487; NCT01959139] and showed promise for improved drug efficacy, especially in those patients whose tumors demonstrate a greater level of staining (percent of the tumor tissue) with a hyaluronidase-binding protein [62].

Periostin and syndecans are additional ECM proteins or heparan-sulfate proteoglycans, respectively, with roles in PDA stromal remodeling and disease progression. Periostin, a CAF-secreted ECM protein, has been shown to be upregulated in PDA tissue compared to normal pancreas and was correlated with poor patient survival. Elevated levels of periostin can participate in a feedback loop that increases CAF fibrogenic activity while supporting tumor growth under serum and oxygen starvation characteristic of PDA tumors. Periostin binds to integrins on tumor cells activating EGFR-mediated intracellular signaling pathways, inducing EMT, and increasing tumor cell survival, invasion, and metastasis. Syndecan-1 and syndecan-2 have been shown to be upregulated in pancreatic cancer. The role for syndecans in PDA metastasis, especially related to tumor growth and movement along perineural fibers, has been observed [63].

Matrix metalloproteases (MMP) are members of a large family of calcium-dependent zinc-containing enzymes responsible for degrading and organizing the ECM. MMPs act on a variety of structural ECM components including collagens, fibronectin, and tenascin C enriched in PDA tumors. Immunohistochemical analysis of human PDA specimens revealed elevation of MMP-2, MMP-7, and MMP-9 primarily by cancer epithelial cells. Genetic ablation of epithelial MMP-9 resulted in increased levels of IL-6 production which subsequently promotes tumor cell growth and metastasis through the activation of STAT3 signaling in cancer epithelial cells [64]. Thus, MMP-9 may function as a tumor suppressor. Conversely, MMP-7 may act as a tumor-promoting factor since its downregulation abrogated PDA cancer cell proliferation [65]. Indeed, MMP-7 was shown to activate Notch signaling and, in turn, the dedifferentiation of exocrine duct epithelial cells. Notch signaling is a key mechanism of tumor progression that could be targeted therapeutically using γ-secretase inhibitors. MMPs also inactivate chemokines through amino-terminal proteolysis and may therefore play a role in sculpting chemokine inflammatory communication within the tumor microenvironment.

Tissue inhibitors of metalloproteases (TIMP) are the natural inhibitors of MMPs, and the balance between MMP and TIMP expression is an important variable in metastatic tumor progression. TIMP sterically and reversibly bind to the MMP catalytic zinc domain in a 1:1 stoichiometric ratio that, if unbalanced, can greatly influence the composition of the ECM within the tumor microenvironment. Cancer epithelial cell TIMP1 expression and secretion are increased in human tumor specimens and in tissues from PDA mouse models. However, it is still unknown if elevated levels of TIMP1 are a secondary response to increased tumor cell-derived MMPs or if TIMP1 itself is pro-tumorigenic. Taken together, a collection of differentially expressed proteolytically active MMPs and inhibitory TIMP enzymes contribute to tumor development and progression through their ability to selectively degrade components of the extracellular matrix that surrounds PDA.

Dynamic Inflammatory Stroma Milieu

These cellular and acellular mediators communicate in a dynamic interplay in the tumor microenvironment of preneoplastic and metaplastic PDA lesions (Fig. 4). The precise role(s) of the unique PDA cells and matrix stromal components in tumor progression and treatment remains incompletely understood but is an active area of research. The conventional wisdom that the stroma has tumor-promoting, tumor-protective, roles is increasingly in flux, with a tumor-suppressive, host-protective, role for the inflammatory stroma emerging. Indeed, complete ablation of desmoplastic stroma has been viewed as a therapeutic approach to limit tumor growth. Paradoxically, evidence from mouse models indicates that complete ablation of the stroma results in tumors that became more aggressive with an accelerated rate of tumorigenesis. By contrast, the idea of chronically "normalizing" activated stroma by reprogramming desmoplasia from a tumor-promoting to a tumor-restrictive state has been suggested to hold therapeutic promise [66, 67]. The identification of a

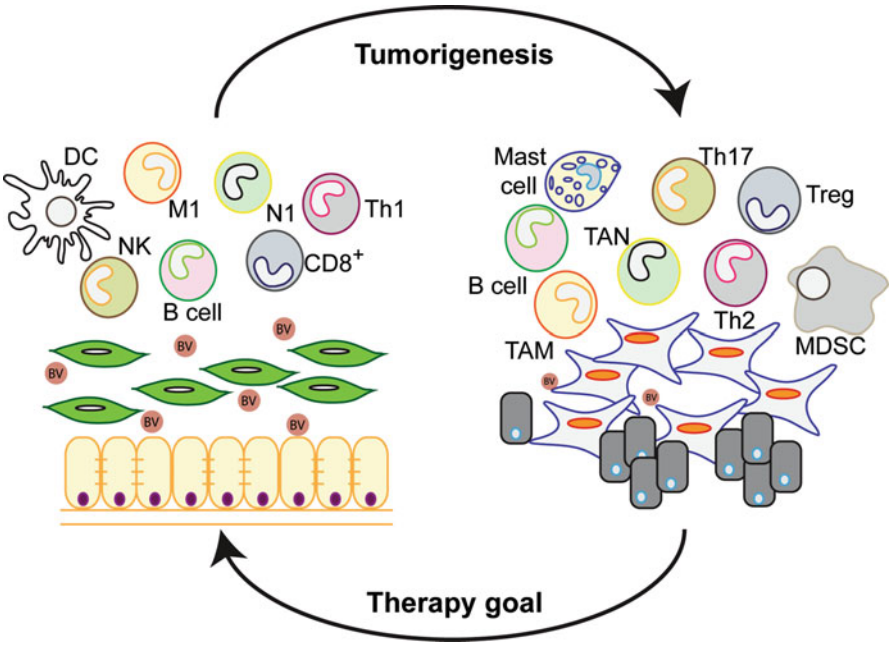

Fig. 4 Schematic overview of the dynamic balance between stromal and cancer cells within the pancreatic cancer milieu. In the normal pancreas (*left*) resident fibroblasts, quiescent pancreatic stellate cells (*green*), leukocytes, and vascular endothelial cells (BV) reside in close proximity to an intact ductal epithelium. Collectively these cells, and their mediators, coordinate wound repair and promote host defense to pathogens. Pancreatic injury or tissue damage upregulates a pro-inflammatory gene program that following oncogenic epithelial duct transformation (*right*) results in the secretion of cytokines, growth factors, reactive oxygen and nitrogen species, and proteases that remodel the stroma, reprogram and suppress immune cells, and play an essential role to promote tumor formation, growth, progression, and metastasis

clinically applicable way to revert desmoplastic stroma to normal is of considerable interest. To better categorize the heterogeneous PDA stroma, image analysis software to facilitate histopathology assessment of the discrete localization of various stromal markers has been developed [68]. Additional exploration of the secretome and cell surface marker expression profiles illustrated that CAFs are a highly heterogeneous population of cells that is made up of several subpopulations that are differentially regulated both spatially and temporally. Thus, it is possible that the conflicting reports on the tumor-promoting or tumor-suppressive properties of the inflamed stroma reflect the cellular heterogeneity within the microenvironment, with each of the varying components playing key temporal roles in tumor formation and malignant progression.

The fibrotic PDA stroma directs the formation of a hypovascular and hypoxic microenvironment, both of which likely contribute to the failure of anti-angiogenic, antiproliferative, and, to some degree, radiation therapies. In response to tissue hypoxia, pancreatic cancer cells and PSCs potently increase their expression of the

transcription factor HIF-1α [69]. The constriction and restriction of vascular growth in the PDA stroma are a conundrum in that uncontrolled tumor cell growth often requires an increased demand for oxygen and nutrients, a need that is usually compensated for through angiogenesis. Human PDA tissues are poorly vascularized and have fewer larger diameter (>10 μm) blood vessels compared to normal exocrine pancreas [53, 54]. While activated PSCs are more potent than pancreatic cancer cells in secreting pro-angiogenic substances such as VEGF in culture, both cell types exert an anti-angiogenic phenotype in the hypoxic tumor through the sustained and elevated deposition of new ECM proteins and secretion of cytokines and growth factors. Similarly, angiogenic factors produced by PSCs resulted in localized foci of angiogenesis localized to the tumor periphery. Given that hypoxia is typically a late event in tumor development, the cytokines produced likely provide positive feedback that exacerbates the remodeling and fibrosis initiated in the earliest stages of metaplasia, subsequently counteracting the pro-angiogenic factors.

Poor diffusion of oxygen and nutrients as well as blood vessel constriction by the dense stroma within pancreatic tumors results in cancer cell metabolic reprogramming in favor of glycolysis (Warburg effect) and activation of pro-survival stress responses. In fact, poor perfusion, hypoxia, and accompanying metabolic changes have been correlated with tumor aggressiveness [70]. Possible mechanisms for metabolic reprogramming in PDA during microenvironmental stress include those that are HIF-1α dependent and/or selection for mutations in oncogenes and tumor suppressors. Glucose deprivation also promotes KRas mutation in tumors, presumably by creating a selective pressure for such genetic aberrations [71]. Conversely, oncogenic KRas signaling can drive expression of GLUT1 glucose transporter and/or other metabolic factors that contribute to the reprogramming of bioenergetic metabolism.

Pro-survival stress responses including the integrated stress response and endoplasmic reticular stress (ER stress) response, also known as the unfolded protein response, are also induced by chemotherapy in PDA. This can lead to resistance to genotoxic tumor killing [72]. Induction of key regulators of the unfolded protein response such as GRP78 participated in resistance to chemotherapeutic agents in PDA by activating survival signaling factors including Akt. CRR9, a surface-expressed protein induced by ER stress and elevated in tumors, encoded by the cancer susceptibility gene candidate CLPTM1L, promoted pancreatic tumor cell survival under ER stress as well as chemoresistance [73]. CRR9 may exert this function through interaction with GRP78 at the plasma membrane and mediation of downstream survival signaling. Other tumor cell survival proteins such as dual-specificity phosphatase 1 are activated by oxidative, hypoxic, metabolic, and chemotherapeutic stresses resulting in chemoresistance.

The induction of autophagy in response to metabolic stresses is well known. Autophagy, "self-eating," appears to be an underlying stress-induced mechanism of PDA cancer epithelial cell survival, including that induced by chemotherapy [74]. Additional evidence suggests that autophagy may provide a pool of chemotherapeutic resistant quiescent cancer stem cells capable of becoming reactivated and in turn facilitating disease recurrence [75]. High expression of

autophagy and cancer stem cell markers was identified on human pancreatic tumors and was associated with poor survival. Further, autophagy appears to be upregulated in activated PSCs, with autophagy inhibitors inducing lipid droplet acquisition coincident with decreased IL-6 secretion and ECM production. While there is some debate on whether enhancement of autophagy-mediated killing or autophagy inhibition therapy should be pursued, emerging data support a role for autophagy cancer stemness, tumor progression, chemoresistance, and poor clinical outcome in patients with PDA.

Conclusions

The tumor microenvironment is a dynamic three-dimensional structure that supports epithelial ductal carcinoma formation and propagation through an altered extracellular matrix and is maintained by diffusible paracrine growth factors and cytokines. The inflammatory stroma in pancreatic cancer is a heterogeneous population of cancer cells, immunocytes, CAFs, vascular endothelial cells, and, as increasingly recognized, unmyelinated neurons. Cross talk between cells present within the tumor microenvironment plays an essential role in the development of an environment to promote tumor formation, growth, progression, and metastasis. The interaction between cells through direct contact or the release of cytokines, growth factors, and chemokines acting in an autocrine and/or paracrine fashion plays an essential role in controlling tumor growth. Increasingly it is recognized that the stromal microenvironment has tumor-suppressive as well as tumor-promoting properties. The distinct roles for the stroma likely depend on stage of tumor development, localization within the overall tumor mass, and distinct biophysical features within the micro-niches of the tumor. A detailed understanding of these features, including the cells, mediators, and receptors influencing stromal dynamism, continues to emerge. The sum effect of this complex stroma is that elevated chemokine production recruits inflammatory cells into the developing tumor that are ultimately reprogrammed by cytokines, growth factors, and other mediators from pro-inflammatory host defense leukocytes into immune-evading suppressor cells. Uncovering the precise target and depth of anti-stromal interventions should foster the discovery of key windows of opportunity for combinatorial therapies which may include immune checkpoint blockade, metabolic inhibitors, and cytotoxic compounds. The potential for stroma-based therapies to effectively target the tumor microenvironment and result in clinically meaningful improvements in patient survival will be based on the continued basic understanding of pancreatic cancer biology (Fig. 4).

radiotherapy, exists despite tremendous advances in our understanding of the molecular and cellular basis of PDA pathogenesis. Therefore, there is an urgent need to find molecular targets that can help to develop novel therapeutic approaches to improve the diagnosis and survival of PDA patients. The use of genetically engineered mouse models (GEMMs) of pancreatic cancer, as described here, have enabled a comprehensive investigation of the genetics and biology of the disease, opening new avenues to elucidate the molecular mechanisms involved in the pathogenesis of pancreatic cancer as well as the response to different therapeutic intervention strategies.

Keywords
Pancreatic cancer · Genetically engineered mouse models (GEMMs) · KRAS · Tumor genetics · Gene validation · Preclinical platform

Introduction

Pancreatic ductal adenocarcinoma (PDA) remains as an almost uniformly lethal disease with an overall 5-year survival rate of ~6% [1]. In 2012, approximately 338,000 new cases of PDA were diagnosed worldwide, and over 331,000 patients died from this disease, making it the seventh most common cause of cancer death (*GLOBOCAN, 2012*). Dismally, it is expected that PDA will become the second cause of cancer-related death by 2030 [2]. This dire clinical situation exists despite extensive efforts conducted over the last two decades to understand the genetics and biology of PDA, and is mainly due to both its early metastatic potential and its innate resistance to systemic chemotherapy and radiotherapy. This outcome highlights the urgent need to find new routes to combat PDA. Over the past three decades, the continuous improvement in gene targeting technologies has allowed the generation of refined genetically engineered mouse models (GEMMs) of pancreatic cancer that has closely mimicked the pathogenesis of the human disease. How GEMMs have supported the investigation of PDA pathogenesis, helping to unveil cancer promoting mechanisms and potential therapeutic targets, will be discussed in this chapter.

Pathogenesis of Human PDA

PDA is the most frequent and most lethal pancreatic neoplasia, representing >85% of all pancreatic neoplasias. Histologically, PDA emerges through a well-established sequence of microscopic preinvasive lesions (Pancreatic Intraepithelial Neoplasia; PanIN), associated with a relatively small number of frequently altered key genes. PanINs are classified from stages I (low grade) to III (high grade), with accumulative degrees of cytologic and architectural atypia through stages II and III. High grade PanINs eventually transform into frank PDA with areas of growth beyond the basement membrane [3, 4] (Fig. 1).

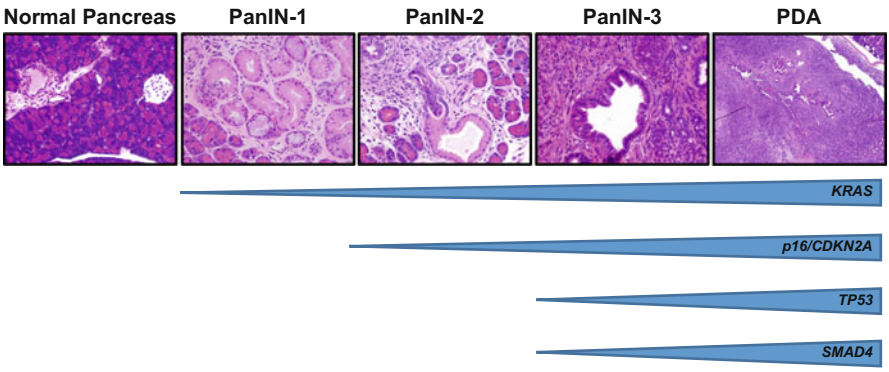

Fig. 1 PanIN to PDA progression model. Activating mutations in the oncogene KRAS are considered the initial mutational step in pancreatic cancer and induce the generation of PanIN-1 lesions. The progression from low-grade PanIN-1 to high-grade PanIN-3 lesions is associated with the accumulation of specific genetic alterations that include inactivation of *p16/CDKN2A* at an intermediate stage, and the inactivation of *TP53* or *SMAD4* at later stages

Early molecular profiling studies performed in the 1990s supported a pancreatic cancer progression model through the identification of genetic alterations that were accumulated in higher grade PanINs [5]. Activating mutations in *KRAS*, mainly at codons 12, 13, and 61, are detected in >90% of pancreatic cancer specimens [6]. Since *KRAS* mutations were detected in 36% of low grade PanINs and 87% of high grade PanINs [7], they are considered to be the initial molecular mutational step of PDA. Oncogenic RAS isoforms are refractory to GAP activity and conserve their active Ras-GTP conformation, allowing their interaction with multiple downstream effectors to trigger diverse cellular responses [8]. Among these effectors, RAF-MEK-MAPK, phosphatidylinositol 3-kinase (PI3K)-AKT, and Ral guanine nucleotide exchange factor (RalGEF) are the most extensively studied RAS effector pathways [9–11]. Oncogenic KRAS induces low-grade PanINs that progress to PDA following the acquisition of additional genetic and epigenetic alterations. Among them, the most relevant alterations include inactivation or point mutation of *p16/CDKN2A* (>95%), *TP53* (70%–75%), and the transforming growth factor (TGF)-β pathway components *DPC4/SMAD4* (55%), *TGFβRI* (<5%), and *TGFβRII* (<5%) [12–15] (Fig. 1). However, and despite massive efforts, these targets remain undruggable. Additionally, this relatively consistent mutational spectrum does not explain neither the strong resistance of PDA to chemotherapy and radiotherapy nor one of the most lethal features of PDA, the ability of the PDA tumor cell to invade the surrounding tissue and metastasize in other organs. It is hypothesized that the major molecular and cellular mechanisms involved in resistance to therapies and cellular dissemination of the PDA cell remain to be identified.

Besides PanIN lesions, the commonest pancreatic preneoplasia, two other pancreatic precursors, Intraductal Papillary Mucinous Neoplasia (IPMN) and Mucinous Cystic Neoplasia (MCN) [16] have received increasing clinical attention in the last few years. These preneoplastic pancreatic cystic lesions, less characterized

molecularly than PanINs, have the capability to progress to frank PDA. Therefore, unveiling the molecular basis underlying the development of the cystic lesions is critical for understanding the pathogenesis of pancreatic cancer. Notably, GEMMs of pancreatic cancer have accelerated our understanding of the genetic events involved in the development of the different pancreatic precursors, and in the progression of these preneoplastic lesions to invasive and metastatic PDA.

During the last decade, the extensive development of whole genome analysis approaches has confirmed the relevance of genes identified in the initial genetic studies performed in the 1990s, including KRAS, *p16/CDKN2A*, *TP53*, and *DPC4/SMAD4*. Additionally, these studies have identified a plethora of new potential key players, dramatically improving our knowledge of the genetic abnormalities that characterize PDA development and confirming that pancreatic cancers harbor a substantial genomic heterogeneity. A seminal study by Jones et al. [17] performed whole exome sequencing and copy number analyses of 24 human PDA tumors. This study identified more than 1000 somatic mutations, with an average of 63 genetic alterations per tumor. These alterations were grouped within 12 key signaling pathways that were each altered in at least 67% of the tumors, with apoptosis, KRAS signaling, G1/S regulation, Hedgehog signaling, TGFβ signaling, and Wnt/Notch signaling affected in 100% of the tumors [17].

More recently, Andrew Biankin and Sean Grimmond, employing integrated genomic approaches, have unveiled major biological pathways involved in the pathogenesis of pancreatic cancer. Using next-generation exome sequencing and single nucleotide polymorphism profiling analysis of paired normal-tumor DNA samples from 99 PDA patients, they have provided new insights into the molecular pathways dysregulated during pancreatic cancer progression. This approach identified 2,016 nonsilent mutations, with 16 genes extensively mutated, including known PDA driver genes (such as *KRAS*, *TP53*, *CDKN2A*, *SMAD4*, or *ARID1A*). Additionally, novel PDA candidate genes involved in chromatin modification (*EPC1* and *ARID2*) or DNA damage repair (*ATM*) were identified. Interestingly, this study also unveiled a critical role for axon guidance regulators (SLIT/ROBO signaling) in PDA development [18]. Importantly, two *Sleeping Beauty* transposon-mediated PDA mouse models delivered unbiased genetic evidence supporting the potential involvement of axon guidance genes in pancreatic carcinogenesis [19, 20]. These models, which will be discussed below in this chapter, have provided valuable examples of how GEMMs of pancreatic cancer can be used to understand the molecular basis of PDA pathogenesis. A subsequent analysis of 100 PDA specimens identified new candidate drivers of PDA including *KDM6A* and *PREX2*. This study also defined, based on chromosomal structural rearrangements, four subtypes of PDA with potential clinical value: stable (20% of total PDAs), locally rearranged (30%), scattered (36%), and unstable (14%). The unstable group was associated with the inactivation of genes involved in the maintenance of DNA integrity, including *BRCA1*, *BRCA2*, and *PALB2*. Importantly, four out of five patients with unstable genomes and/or a high *BRCA* mutational signature responded to platinum therapy, while none of three patients without these characteristics responded. This finding strongly suggests that whole-genome sequencing approaches may be used to define specific subgroups of patients and to tailor therapy accordingly [21].

Finally, the most comprehensive analysis to date (456 pancreatic cancer specimens) involving a combination of whole-genome and deep-exome sequencing, with gene copy number analysis, identified 32 persistently mutated genes and molecular pathways grouped into 10 signaling pathways and biological processes: *KRAS, TGF-β, WNT, NOTCH, ROBO/SLIT* signaling, *G1/S* transition, *SWI-SNF*, chromatin modification, DNA repair, and RNA processing. Additionally, RNA expression profiles of 232 pancreatic cancers defined four subtypes of pancreatic tumors: [1] squamous, [2] pancreatic progenitor, [3] immunogenic, and [4] aberrantly differentiated endocrine exocrine. The subtypes are associated with distinct genetic and epigenetic alterations, histopathological features, and survival rates [22].

Altogether, these studies have highlighted the complex genomic landscape of pancreatic cancer. Therefore, determining the role of the mutated genes in PDA initiation, progression, and maintenance, as well as the mechanisms of chemoresistance, is of paramount importance to uncover new therapeutic approaches. In this arduous task, mouse models of pancreatic cancer are playing a leading role and are helping to complement the genomic, transcriptomic, proteomic, and biological approaches employed to analyze human pancreatic cancer specimens.

Genetically Engineered Mouse Models as a Tool to Study Pancreatic Cancer Pathogenesis

The laboratory mouse, *Mus musculus*, owns characteristics that make it an ideal model system for cancer research including a small size, rapid reproduction, a relatively short lifespan of 3 years, and feasibility to recapitulate well the physiological and molecular features of human cancer. Additionally, its genome has been entirely sequenced, which has facilitated the extensive manipulation of the genome to generate genetically engineered mouse models (GEMMs) that express genetic alterations found in the human disease. GEMMs permit the ectopic expression of oncogenes (transgenic model), ablation of endogenous tumor suppressor genes (*knock-out* model), and physiological expression of oncogenes and negative dominant isoforms of tumor suppressor genes (*knock-in* model), in a spatiotemporal manner during tumor evolution to assess the role that specific genes and molecular pathways play during pancreatic cancer pathogenesis [23]. In the next sections of this chapter, the most relevant approaches to generate GEMMs of pancreatic cancer will be uncovered.

Ectopic Mouse Models of Pancreatic Cancer. Tumor Initiation and Cell of Origin

Early Transgenic Mouse Models

Pioneering approaches to generate mouse models of pancreatic cancer date back to the 1980s. Ornitz et al. [24] generated three transgenic lines that expressed the transforming *SV40 T-antigen* cDNA under the control of the rat *Elastase I* (*Ela-1*) promoter and enhancer, which drives the expression of exogenous cDNAs to the

pancreatic acinar cells from embryonic day E14. Newborn *Ela-1-SV40 T-antigen* transgenic mice showed hyperplastic pancreas at 2 weeks of age, and numerous pancreatic nodules at 10 weeks that rapidly progressed to exocrine pancreatic tumors, with mice from the three lines showing a median survival of 12.6–18.5 months [24].

A similar approach was used by Quaife et al. [25] to assess the oncogenic potential of $HRAS^{G12V}$ and *c-Myc*. *Ela-1-*$HRAS^{G12V}$ mice showed a dramatic development of pancreatic neoplasias including a massive acinar hyperplasia at embryonic day E14 that progressed to pancreatic dysplasia at E16 and acinar pancreatic tumor at E20. They monitored a cohort of 19 transgenic mice, finding that 14 out of 19 animals developed pancreatic cancer as newborns, with the remaining five mice developing pancreatic neoplasias as adults [25]. In contrast, none of the *Ela-1-c-Myc* mice developed pancreatic abnormalities [25]. Subsequently, Sandgren et al. [26] generated a slightly different *Ela-1-c-Myc* strain, in which the 3' noncoding region of the *c-Myc* gene, which is associated with mRNA instability [27], was replaced by the 3' noncoding region from the human *Growth Hormone* gene (*hGH*) that encodes a more stable mRNA. Interestingly, this strain developed mixed acinar/ductal pancreatic adenocarcinomas between 2 and 7 months of age [26]. The lack of oncogenicity of the *Ela-1-c-Myc* strain generated by Quaife et al. [25] was attributed to the low levels of expression of c-Myc. Finally, two groups showed that transgenic mice expressing the *Ela-1-TGFα* transgene developed hyperplasia, fibrosis, and pancreatic metaplasia with ductal-like features, with malignant transformation arising in mice older than 180 days at a low penetrance (<10%). These tumors, histologically classified as mixed cystic-papillary pancreatic tumors, originated from dysplastic tubular complexes. Furthermore, the tumors displayed an increased *EGFR* expression, strongly suggesting a robust influence of the TGFα/EGFR signaling pathway in pancreatic cancer development [28, 29].

Altogether, these early mouse models confirmed that pancreatic cancer pathogenesis is highly influenced by the oncogenic pathways activated. Thus, while expression in the pancreatic exocrine compartment of *SV40 T-antigen* and $HRAS^{G12V}$ induced acinar neoplasias, *c-Myc* and *TGFα* expression in acinar cells led to the development of pancreatic neoplasias with ductal features, strongly suggesting that pancreatic cancer could have an acinar origin. However, none of these mouse models described above were able to recapitulate the PanIN to PDA evolution observed in the human disease.

Kras Transgenic Mouse Models

Since oncogenic mutations in *KRAS* are found in over 90% of PDAs [6], and they are considered to be the earliest genetic event in pancreatic cancer development [3, 4], transgenic approaches were developed to generate mice expressing oncogenic *KRAS* in the pancreatic compartment with the hope of generating a mouse model that truly recapitulated the main features of PDA evolution. Grippo et al. [30] generated 10 transgenic lines carrying a transgene that expressed the human $KRAS^{G12D}$

cDNA under the control of the *Ela-1* promoter (*Ela-1-KRAS*^{G12D}). They found that mice from eight of those lines were smaller than control littermates at birth and displayed distended abdomens. Pancreata were found to be nodular or polycystic, and displayed a wide stromal reaction adjacent to a dysplastic epithelium with a glandular or papillary organization, and absence of normal ducts. Remarkably, mice from the remaining two transgenic lines showed a normal phenotype at birth and exhibited a nearly normal pancreatic histology, which was assumed to be the consequence of a reduced transgene expression and/or the site of transgene integration. As these mice aged, pancreata developed multifocal acinar hyperplasia, associated with focal dysplasia, fibrosis, and lymphocytic infiltration at 1–2 months of age. Older mice (6–18 months of age) developed acinar to ductal metaplasia (ADM) lesions, which are considered to be the precursor lesions of PDA [31]. However, none of the mice developed advanced pancreatic cancer, supporting the concept that genetic alterations were required for the progression of preinvasive lesions to frank malignancy. Importantly, this study indicated that the targeted activation of KRAS in the pancreatic acinar compartment is able to initiate pancreatic neoplasias with ductal features by inducing transdifferentiation of acinar cells.

In an effort to elucidate the cell of origin for PDA, Brembeck et al. [32] generated a transgenic strain that expressed the *KRAS*^{G12V} oncogene under the control of the *Cytokeratin-19* (*K19*) promoter, which is active in pancreatic ductal cells but not in other cell types of the pancreas. Importantly, *K19-KRAS*^{G12V} mice showed increased RAS activity in whole pancreatic extracts with lymphocytic infiltration observed around pancreatic ducts. However, expression of oncogenic *KRAS* in pancreatic ductal cells failed to initiate pancreatic neoplasias, introducing controversy about whether PanINs, in spite of the ductal-like properties, arise from mature pancreatic ductal cells.

Mist-Kras$^{G12D/+}$ *Knock-In* Mouse Model

A subsequent study by Tuveson et al. [33] shed light on the origin of the cancer-initiating cell in PDA. They generated a *knock-in* strain by cloning a *Kras*^{G12D} cDNA into the *Mist1* locus. Mist1 is a transcription factor that is expressed during pancreatic development after embryonic day E10.5 and required for correct pancreatic acinar organization. Pancreata from *Mist1-Kras*$^{G12D/+}$ mice displayed acinar and ductal metaplasia, and dysplasia. Acinar adenomas of solid or cystic nature were observed at 2 months of age, with invasive and metastatic pancreatic cancer developed after 3 months of age. Histologically, tumors were predominantly classified as cystic papillary neoplasms with acinar differentiation, with several specimens of mixed carcinomas with acinar and ductal features. However, glandular ductal adenocarcinomas were uncommon in this model. Interestingly, tumors recurrently developed the typical desmoplastic reaction present in human PDA including a rich collagenous stroma with accompanying fibroblasts. Moreover, the inactivation of the tumor suppressor gene *Trp53* cooperated with *Kras*^{G12D} to accelerate tumorigenesis (median survival of 6.5 months of the *Mist1-Kras*$^{G12D/+}$; *Trp53*$^{+/-}$ cohort

versus 10.8 months of the *Mist1-Kras*$^{G12D/+}$ cohort), confirming that PDA progression is supported by an accumulation of genomic alterations involving the activation of oncogenes and inactivation of tumor suppressor genes [3, 4]. This study strongly suggested that a pancreatic progenitor cell Mist1 positive represents a potential pancreatic cancer-initiating cell.

Overall, the ectopic mouse models described above have complemented histopathological analysis performed in human PDA specimens, providing vital information for understanding pancreatic cancer initiation. They have confirmed that oncogenic KRAS is able to initiate pancreatic neoplasias and have given insights into the cell of origin of PDA. However, a major limitation of these models is that none of them are able to recapitulate the main features of human PDA progression, with initial formation of PanIN lesions that progress to invasive and metastatic PDA. These drawbacks have been bypassed with the generation of more refined mouse models.

Conditional Kras Models of PanIN to PDA Progression. Cell of Origin

The remarkable development of gene targeting methods in embryonic stem cells during the last two decades have facilitated the physiological expression of oncogenes and inactivation of tumor suppressor genes in a spatiotemporal manner, leading to the generation of more sophisticated compound mutant mice that have closely recapitulated the features of human PDA. The generation of GEMMs harboring different sets of mutations have reinforced the genetic basis of the pancreatic cancer progression model defined by Hruban et al. [3, 4], allowing the study of diverse aspects of the genetics and biology of PDA.

The first GEMM that faithfully resembled the human disease was generated in 2003 by David Tuveson's laboratory [34]. Tuveson's laboratory used the *LSL-Kras*$^{G12D/+}$ *knock-in* mouse strain [35] to generate compound mutant mice that conditionally expressed oncogenic *Kras*^{G12D} in pancreatic progenitor cells. The *LSL-Kras*$^{G12D/+}$ strain harbors an endogenous *Kras*^{G12D} mutant allele transcriptionally silenced by a STOP cassette flanked by LoxP sites (LoxP-Stop-LoxP, LSL) cloned upstream of the targeted *Kras*^{G12D} Exon1. After *Cre* recombinase expression, the LSL cassette is removed thereby allowing the expression of oncogenic *Kras*^{G12D} in a spatiotemporal manner (Fig. 2). *LSL-Kras*$^{G12D/+}$ mice were interbred with two mouse models that expressed *Cre* recombinase during the embryonic development leading to the expression of *Kras*^{G12D} in all pancreatic lineages: the *Pdx1-Cre* transgenic strain (which expresses *Cre* in the prepancreatic endoderm from E8**.**5) and the *Ptf1a/P48-Cre knock-in* strain (which expresses *Cre* in the prepancreatic endoderm from E9.5). Compound mutant mice *LSL-Kras*$^{G12D/+}$*; Pdx1-Cre* and *LSL-Kras*$^{G12D/+}$; *Ptf1a/P48-Cre* (known as *KC*) developed preinvasive neoplasias, catalogued as PanIN lesions, with complete penetrance [34]. Remarkably, *KC* mice recapitulated the full spectrum of lesions seen in the human disease, starting with the development of PanIN-1 lesions in young mice that progressed through

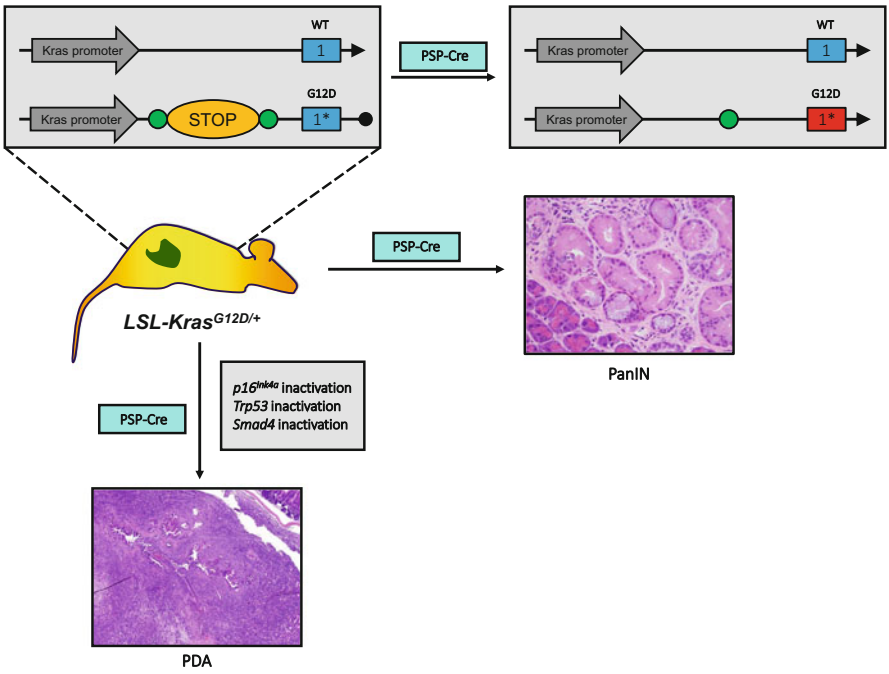

Fig. 2 Conditional GEMMs of pancreatic cancer. The *LSL-Kras*$^{G12D/+}$ *knock-in* strain carries a *Kras*^{G12D} allele transcriptionally silenced by a STOP cassette flanked by LoxP sites (*green circles*). *Cre* recombinase expression driven by pancreas specific promoters (PSP) removes the LoxP-STOP-LoxP cassette, thereby allowing *Kras*^{G12D} expression in the pancreas compartment, which in turn induces the development of PanINs. PanINs can progress to frank malignancy after inactivation of tumor suppressor genes, including *p16*^{Ink4a}, *Trp53*, or *Smad4*

PanIN-2 and PanIN-3 in older mice, with a subset of mice developing frank PDA usually not before 12 months of age [34]. Further cellular and molecular characterization revealed that murine PanIN, as human PanIN, expressed high levels of mucins and the epithelial ductal cell marker Cytokeratin-19 [34], supporting the idea that PDA derived from normal ductal cells or their precursors. However, and as mentioned above, the transgenic expression of the *Kras*^{G12V} oncogene from the *K19* promoter failed to induce PanIN or PDA [32], introducing controversy about whether PanIN, despite presenting ductal-like properties, arise from a mature ductal cell or from a progenitor cell of any lineage.

A few years later, Carriere et al. [36] gave additional insights into the cellular origin of PanIN. They generated *LSL-Kras*$^{G12D/+}$*; Nestin-Cre* mice, where *Cre* recombinase expression was directed to a population of pancreatic exocrine progenitors that express *Nestin* during embryonic days E10.5–12.5. They found that young *LSL-Kras*$^{G12D/+}$*; Nestin-Cre* mice (<6 months) developed PanIN-1 lesions at a similar frequency as observed in *LSL-Kras*$^{G12D/+}$*; Pdx1-Cre* mice, which expressed *Kras*^{G12D} in all pancreatic lineages. None of the *LSL-Kras*$^{G12D/+}$*;*

Nestin-Cre mice developed high-grade PanIN or PDA lesions due to the Nestin-mediated $Kras^{G12D}$ expression in the central nervous system that led to dramatic lethality after 6 months due to neurological problems. This study has supported that an exocrine progenitor lineage, rather than mature pancreatic ductal or acinar cells, may be the cell origin of pancreatic cancer.

Importantly, a different PanIN to PDA progression mouse model generated by Mariano Barbacid's laboratory [37] supported a nonductal origin of PDA. This model was based on the use of the *LSL-*$Kras^{G12Vgeo/+}$ mouse strain [38], which harbors a conditional $Kras^{G12V}$ and *β-geo* bicistronic allele transcriptionally silenced by a LSL cassette. *LSL-*$Kras^{G12Vgeo/+}$ mice were interbred with *Elastase-tTA* and *tetO-Cre* mice to generate the compound mutant strain *LSL-*$Kras^{G12Vgeo/+}$*; Elastase-tTA; tetO-Cre* [37]. The *Elastase-tTA* strain expresses the tTA transactivator in the pancreatic acinar/centroacinar compartment, thereby allowing the expression of *Cre* recombinase from the *tetO-Cre* allele when doxycycline was not supplemented in the drinking water. This model showed that *Cre*-mediated $Kras^{G12V}$ expression in pancreatic acinar/centroacinar cells of embryos or newborns, but not adult mice, faithfully mimicked the development of ADM lesions, PanIN lesions, and invasive PDA observed in the *LSL-*$Kras^{G12D/+}$*; Pdx1-Cre* and *LSL-*$Kras^{G12D/+}$; *Ptf1a/P48-Cre* models, which expressed the $Kras^{G12D}$ oncogene in all pancreatic lineages [34]. Interestingly, PanIN to PDA progression was dramatically accelerated after caerulein-induced chronic pancreatitis, confirming that inflammation synergizes with oncogenic Kras to promote pancreatic cancer. Overall, this study strongly suggests that PDA initiates by differentiation of acinar/centroacinar cells, or their precursors, into ductal-like cells [37].

Collectively, PanIN to PDA progression mouse models have supported a non-ductal origin of pancreatic cancer. Instead, PanINs seem to be originated either from pancreatic progenitor cells [34] or transdifferentiating acinar cell [31, 37, 39–41], which would support observations proposing that ADM might be the earliest pancreatic lesion and, as such, the precursor of PanIN-1 lesions [31, 39, 40].

Accelerated Mouse Models of PDA Progression. Confirmation of the Genetic Progression Model

GEMMs expressing endogenous levels of Kras oncogenes in the pancreatic compartment have supported the PDA progression model proposed by Hruban et al. [3, 4], which postulates that oncogenic mutations in the *KRAS* gene are the initiating genetic event in PDA development and induce low-grade PanIN lesions that progress to PDA following the acquisition of additional epigenetic and genetic alterations (Fig. 1). The genetic basis of this progression model has been further validated by the generation of GEMMs that combined the activation of Kras oncogenes with inactivation of known tumor suppressor genes in the pancreatic compartment (Fig. 2). In the framework of this chapter, the most relevant GEMMs of pancreatic cancer generated during the last decade will be discussed (Table 1).

Table 1 Endogenous GEMMs of pancreatic cancer

GEMM	Pancreatic phenotype	Metastasis	Survival (S)/tumor latency (L)	Comments	References
LSL-Kras$^{G12D/+}$; Pdx1-Cre	PanIN, PDA	>50%	>12 months (S)	Slow PanIN to PDA progression	[34]
LSL-Kras$^{G12D/+}$; Ptf1a/P48-Cre	PanIN, PDA	>50%	>12 months (S)	Slow PanIN to PDA progression	[34]
LSL-Kras$^{G12D/+}$; Nestin-Cre	PanIN	No	~6 months (S)	Lethality due to Cre expression in brain	[36]
LSL-Kras$^{G12Vgeo/+}$; Elastase-tTA; tetO-Cre	PanIN, PDA	No	>12 months (S)	Slow PanIN to PDA progression	[37]
LSL-Kras$^{G12D/+}$; Ink4a/Arf$^{flox/flox}$; Pdx1-Cre	PanIN, PDA	11%	8.5 weeks (L)	Micrometastasis only	[47, 48]
LSL-Kras$^{G12D/+}$; Ink4a/Arf$^{flox/+}$; Pdx1-Cre	PanIN, PDA	69%	34.2 weeks (L)		[47]
LSL-Kras$^{G12D/+}$; Trp53$^{flox/flox}$; Pdx1-Cre	PanIN, PDA	No	6.2 weeks (L)		[48]
LSL-Kras$^{G12D/+}$; Trp53$^{flox/+}$; Pdx1-Cre	PanIN, PDA	33%	21.8 weeks (L)		[48]
LSL-Kras$^{G12D/+}$; Trp53$^{flox/+}$; p16Ink4a$^{+/-}$; Pdx1-Cre	PanIN, PDA	25%	14.7 weeks (L)		[48]
LSL-Kras$^{G12D/+}$; Trp53$^{flox/+}$; p16Ink4a$^{-/-}$; Pdx1-Cre	PanIN, PDA	25%	13.1 weeks (L)		[48]
LSL-Kras$^{G12D/+}$; LSL-Trp53$^{R172H/+}$; Pdx1-Cre	PanIN, PDA	63%	5 months (S)		[51]
LSL-Kras$^{G12D/+}$; Tgfbr2$^{flox/+}$; Ptf1a/P48-Cre	PanIN, PDA	50%	33.6 weeks (S)		[56]
LSL-Kras$^{G12D/+}$; Tgfbr2$^{flox/flox}$; Ptf1a/P48-Cre	PanIN, PDA	12%	59 days (S)	Only long survivors develop metastasis	[56]
LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Pdx1-Cre	PanIN, IPMN	No	13.1 weeks (L)		[57]

(*continued*)

Table 1 (continued)

GEMM	Pancreatic phenotype	Metastasis	Survival (S)/tumor latency (L)	Comments	References
LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ptf1a/P48-Cre	PanIN, IPMN, PDA	No	15.7 weeks (L)	IPMN to PDA progression	[57]
LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ink4a/Arf$^{flox/+}$; Ptf1a/P48-Cre	PanIN, IPMN, PDA	37.5%	14 weeks (L)	IPMN to PDA progression	[57]
LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ink4a/Arf$^{flox/+}$; Pdx1-Cre	PanIN, IPMN, PDA		12.6 weeks (L)	IPMN to PDA progression	[57]
LSL-Kras$^{G12D/+}$; Smad4$^{flox/+}$; Pdx1-Cre	PanIN, cystic lesion	No	8 months (S)	Lethality due to gastric carcinomas	[60]
LSL-Kras$^{G12D/+}$; Smad4$^{flox/+}$; Ptf1a/P48-Cre	PanIN, MCN, PDA	41%	15 months (S)	MCN to PDA progression	[60]
LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ptf1a/P48-Cre	PanIN, MCN, PDA	18%	8 months (S)	Accelerated MCN to PDA progression	[60]
LSL-Kras$^{G12D/+}$; Elastase-TGFa; Ptf1a/P48-Cre	PanIN, IPMN, PDA	50%	7 months (S)	IPMN to PDA progression	[62]
LSL-Kras$^{G12D/+}$; Tif1γ$^{flox/flox}$; Pdx1-Cre	IPMN	No	ND		[63]

PDA Pancreatic Ductal Adenocarcinoma, *PanIN* Pancreatic Intraepithelial Neoplasia, *IPMN* Intraductal Papillary Mucinous Neoplasia *MCN* Mucinous Cystic Neoplasia, *ND* Not determined

Information of other mouse models that have helped to delineate the pathogenesis of PDA can be found in recent reviews [11, 42, 43].

Oncogenic Kras and *Ink4a/Arf* Inactivation

The *INK4A/ARF* (*CDKN2A*) locus encodes for the tumor suppressors $p16^{INK4A}$ and $p14^{ARF}$ ($p19^{ARF}$ in mice) [44, 45]. Genetic or epigenetic inactivation of the cyclin-dependent kinase inhibitor $p16^{INK4A}$ is a relatively early event in PDA development, and occurs in over 95% of human PDA samples (Fig. 1). Additionally, homozygous deletions of the *INK4A/ARF* locus, affecting both $p16^{INK4A}$ and the TP53 activator $p14^{ARF}$, happen in 40% of pancreatic cancers [46]. Early efforts to delineate the role of the *INK4A/ARF* locus during PDA development were performed by Ronald Depinho's laboratory. In an initial study, they interbred the *LSL-Kras$^{G12D/+}$* strain

with conditional *knock-out* mice harboring a $p16^{Ink4a}/p19^{Arf}$ allele with exons 2–3 flanked by LoxP sites. They generated *LSL-*$Kras^{G12D/+}$*; Ink4a/*$Arf^{flox/flox}$; *Pdx1-Cre* mice and found that the biallelic ablation of $p16^{Ink4a}/p19^{Arf}$ driven by the *Pdx1-Cre* allele cooperated with $kras^{G12D}$ to accelerate PanIN to PDA progression. Mice developed PanIN-1 lesions as early as 3 weeks of age that rapidly progressed through PanIN-2/3 lesions to a highly aggressive locally invasive PDA associated with the formation of micrometastasis in 11% of the mice [47, 48]. In a subsequent study, they generated *LSL-*$Kras^{G12D/+}$*; Ink4a/*$Arf^{flox/+}$; *Pdx1-Cre* mice and showed that monoallelic ablation of the $p16^{Ink4a}/p19^{Arf}$ locus and concomitant expression of $Kras^{G12D}$ led to the development of PDA with a longer latency compared with *LSL-*$Kras^{G12D/+}$*; Ink4a/*$Arf^{flox/flox}$; *Pdx1-Cre* mice (34.2 vs. 8.5 weeks, respectively). Additionally, $Kras^{G12D}$*; Ink4a/Arf* heterozygous PDAs showed enhanced metastatic potential compared with $Kras^{G12D}$*; Ink4a/Arf* null PDAs (69% vs. 11% mice showing metastasis, respectively) [47]. This invasive phenotype was associated with longer survival of the heterozygous *Ink4a/Arf* mice.

Oncogenic Kras and *Trp53* Inactivation

The tumor suppressor TP53 is considered the main guardian of the genome, and it is implicated in pivotal biological processes, including cell cycle arrest, DNA repair, and apoptosis [49]. Inactivation of the transcription factor TP53 (encoded by the human gene *TP53*) is a common genetic event in PDA, and it is strongly associated with PDA progression. Missense mutations in *TP53* are frequently associated with loss of the second wild-type allele, and they are found in 70–76% human PDA samples [13, 50] (Fig. 1).

Mutations in the *TP53* gene are distributed along the coding sequence with a strong prevalence in exons 4–9, which encode the DNA-binding domain of the protein. The three main mutation hotspots in the *TP53* gene found in human PDA are within this DNA-binding domain, and affect the residues R175, R248, and R273 (http://p53.free.fr). Over a decade ago, Hingorani et al. [51] investigated the impact of mutations in the mouse Trp53 DNA-binding domain in PDA development. They engineered a *knock-in* mouse strain harboring a conditional mouse ortholog of the human $TP53^{R175H}$ gene, *LSL-*$Trp53^{R172H/+}$. They generated *LSL-*$Kras^{G12D/+}$*;* *LSL-*$Trp53^{R172H/+}$*; Pdx1-Cre* (*KPC*) mice and found that the physiological expression in the pancreatic compartment of $Trp53^{R172H}$ in the context of $Kras^{G12D}$ led to the development of early PanIN lesion at 4 weeks of age that progressed to invasive PDA with mice showing a median survival of 5 months. Furthermore, 63% of *KPC* mice developed metastasis, with 59% of mice developing ascites [51]. Remarkably, PDA cell lines established from KPC tumors displayed aneuploidy and chromosomal instability, mirroring one of the main hallmarks of human PDA and strongly supporting the pivotal role of TP53 inactivation in PDA development.

The implication of the Trp53 inactivation during the pathogenesis of PDA was further decoded by combining the expression of $Kras^{G12D}$ with the heterozygous (*LSL-*$Kras^{G12D/+}$*; Trp53*$^{flox/+}$*; Pdx1-Cre*, $KP^{f/+}C$) or homozygous (*LSL-*$Kras^{G12D/+}$*;*

Trp53$^{flox/flox}$*; Pdx1-Cre*, *KP*$^{f/f}$*C*) deletion of *Trp53*. While *LSL-Kras*$^{G12D/+}$*; Pdx1-Cre* mice showed a tumor latency of 57 months, both heterozygous and homozygous inactivation of *Trp53* significantly accelerated PDA development with tumor latencies of 21.8 and 6.2 months, respectively [47]. Interestingly, and in contrast to the expression of mutant *Trp53*^{R172H} [51], Trp53 null PDAs displayed low metastatic potential. Indeed, only 33% of *KP*$^{f/+}$*C* mice developed metastasis, while none of the *KP*$^{f/f}$*C* showed metastatic deposits [47]. This behavior was confirmed in an independent study by Morton et al. [52]. They generated and monitored *KP*$^{f/+}$*C* and *KPC* compound mutant mice. While both strains showed a similar median survival (113 vs. 123 days, respectively), the incidence of metastasis was significantly higher in PDAs expressing *Trp53*^{R172H} (65%) compared with Trp53 null PDA (0%) [52]. Interestingly, Weissmueller et al. [53] have recently reported that mutant Trp53-mediated platelet-derived growth factor receptor beta (PDGFRβ) induction plays a critical role in the metastatic behavior of PDA harboring *Trp53* missense mutations. The authors showed that the inhibition of the p73/NF-Y complex by mutant Trp53 leads to the upregulation of PDGFRβ, which is strongly correlated with metastatic potential of PDA cells, unveiling one mechanism by which the gain-of-function activity of mutant Trp53 promotes invasion and metastasis in PDA [53].

Rozenblum et al. [50] showed that a significant number of PDAs, 25 out of 38, harbor inactivating mutations of both *p16*^{INK4A} and *TP53*, suggesting that the ablation of both tumor suppressors could be cooperating events during PDA progression. Bardeesy et al. [47] investigated the functional interaction of the dual *Trp53* and *p16*^{Ink4a} inactivation in PDA development. They interbred *LSL-Kras*$^{G12D/+}$*; Pdx1-Cre* mice with mice harboring homozygous or heterozygous *Trp53*^{flox} and/or *p16*$^{Ink4a\text{-}KO}$ alleles, and found that the inactivation, either alone or in combination, of *Trp53* and/or *p16*^{Ink4a} cooperated with *Kras*^{G12D} to accelerate PDA development. Additionally, they found that in the context of *Kras*^{G12D} and *Trp53* heterozygosity, both the heterozygous and homozygous deletion of *p16*^{Ink4a} dramatically shortened tumor latency (21.8 months (p16^{Ink4a} wild-type) versus 14.7 months (p16$^{Ink4a\text{-}KO}$ heterozygous) and 13.1 months (p16$^{Ink4a\text{-}KO}$ homozygous)), suggesting that inactivating mutations in *Trp53* and *p16*^{Ink4a} cooperate during PDA development. Furthermore, while in a *Kras*^{G12D} and Trp53 null background, inactivation of *p16*^{Ink4a} does not impact significantly tumor latency; the heterozygous or homozygous deletion of *Trp53* drastically reduces tumor latency in a *Kras*^{G12D} and *p16*^{Ink4a} null background, strongly suggesting that Trp53 functions as a more powerful barrier to PDA development [47].

Oncogenic Kras and TGFβ Signaling Inactivation. Role of the TGFβ Pathway in the Development of Cystic Neoplasias

The fourth most common genetic event involved in human PDA development is the inactivation of members of the Transforming Growth Factor beta (TGFβ) pathway, including *DPC4/SMAD4* (found mutated in over 50% of PDA specimens), *TGFβRI* (<5%), and *TGFβRII* (<5%) [14, 15]. Inactivation of the TGFβ pathway is believed

to occur in high-grade PanIN lesions [5] (Fig. 1), and it is associated with a highly invasive phenotype [54]. The TGFβ signaling pathway is involved in many cellular processes including cell growth, cell differentiation, and apoptosis. In normal and premalignant cells, TGFβ signaling preserves cellular homeostasis and exerts a tumor suppressor role. However, neoplastic cells are able to evade the TGFβ tumor-suppressive properties, instead using TGFβ to enhance transformation, invasion, and tumor dissemination [55].

GEMMs have been employed to understand the role of the TGFβ signaling pathway in the pathogenesis of PDA. Ijichi et al. [56] conditionally inactivated *Tgfbr2* in pancreatic progenitor cells by interbreeding mice carrying a *Tgfbr2* conditional *knock-out* allele, which harbored an exon 2 flanked by LoxP sites, with *Ptf1a/P48-Cre* mice. *Tgfbr2$^{flox/flox}$; Ptf1a/P48-Cre* mice developed normally and did not show any pancreatic abnormality, suggesting that Tgfbr2 does not play a critical role in pancreatic homeostasis. When the ablation of *Tgfbr2* was combined with the expression of *Kras^{G12D}*, mice showed a dramatic acceleration of PDA development. *LSL-Kras$^{G12D/+}$; Tgfbr2$^{flox/flox}$; Ptf1a/P48-Cre* mice exhibited abdominal distension associated with ascites and pancreatic tumors at ~6–7 weeks of age, and a median survival of 59 days. Most of the mice from this cohort were sacrificed at 7–10 weeks of age and did not show any distant metastasis. However, three mice that survived up to 24–27 weeks developed distant metastases in the liver, lungs, and diaphragm, as well as duodenal invasion and peritoneal dissemination. These findings confirmed the highly metastatic potential conferred by the inactivation of the TGFβ signaling pathway, and suggested that the low number of metastases detected in *LSL-Kras$^{G12D/+}$; Tgfbr2$^{flox/flox}$; Ptf1a/P48-Cre* mice may be due to their early lethality. To verify this hypothesis, the authors generated a cohort that combined *Kras^{G12D}* expression with the heterozygous inactivation of *Tgfbr2*. Interestingly, *LSL-Kras$^{G12D/+}$; Tgfbr2$^{flox/+}$; Ptf1a/P48-Cre* mice showed a median survival of 33.6 weeks and, importantly, 50% of the mice developed distant metastases mainly in the liver and lungs. Remarkably, heterozygous *Tgfbr2* mice retained the *Tgfbr2* wild-type allele confirming that *Tgfbr2* haploinsufficiency, in the context of oncogenic *Kras* expression, leads to PDA progression [56].

Additional insights into the significance of the TGFβ pathway in pancreatic cancer emerged from a study performed by Bardeesy et al. [57]. They generated a *Smad4* conditional *knock-out* allele, which harbored exons 8–9 flanked by LoxP sites. The analysis of *Smad4$^{flox/flox}$; Pdx1-Cre* and *Smad4$^{flox/flox}$; Ptf1a/p48-Cre* compound mutant mice revealed that the inactivation of *Smad4* did not impact in the normal development of the pancreas, supporting previous findings showing that *Tgfbr2* disruption did not affect pancreatic development [56]. When *Smad4* ablation was concomitant with *Kras^{G12D}* activation in pancreatic progenitor cells, *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Pdx1-Cre* and *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ptf1a/P48-Cre* mice showed rapid tumor progression, with an increase in the number and size of low-grade PanIN lesions, at 4 weeks of age, compared with mice expressing *Smad4*. Pancreatic lesions rapidly progressed to extensive IPMN and advanced PanIN lesions by 8 weeks of age. Overall, *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ptf1a/P48-Cre* mice showed a median survival of 15.7 weeks, with 100% of the

mice (n = 12) exhibiting IPMN and two out of twelve also presenting PDA. Furthermore, *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Pdx1-Cre* mice showed a median survival of 13.1 weeks, with five out of eight mice developing IPMN, and five mice also presenting gastric cancer due to the expression of Pdx1 in the foregut. None of the *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Pdx1-Cre* mice displayed PDA. These findings supported the role of Smad4 as a barrier for the progression of Kras^{G12D}-initiated PanINs to pancreatic cancer. Furthermore, the development of IPMN indicates that Smad4 may have a critical role in the formation of pancreatic cystic neoplasias.

Further genetic studies incorporating an *Ink4a/Arf^{flox}* conditional allele [57] revealed that Smad4 deficiency altered the tumor spectrum associated with the combined expression of *Kras^{G12D}* and *Ink4a/Arf* heterozygosity (60% of mice presenting PDA (n = 10) and a tumor-free survival of 38 weeks) or *Ink4a/Arf* homozygosity (100% of mice presenting PDA (n = 6) and a tumor-free survival of 8.6 weeks). Accordingly, *Ink4a/Arf* heterozygosity cooperated with *Kras^{G12D}* and *Smad4* ablation to accelerate pancreatic tumor progression. Thus, *Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ink4a/Arf$^{flox/+}$*; *Ptf1a/P48-Cre* mice showed a tumor-free survival of 14 weeks associated with the development of IPMN (1 out of 13 mice), PDA (12 out of 13 mice), and both IPMN and PDA (4 out of 13 mice). Furthermore, *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ink4a/Arf$^{flox/+}$*; *Pdx1-Cre* mice showed a tumor-free survival of 12.6 weeks, with mice presenting IPMN (4 out of 12), PDA (4 out of 12), and gastric cancer (8 out of 12). On the other hand, the homozygous inactivation of *Ink4a/Arf* did not significantly affect tumor-free survival. Thus, *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ink4a/Arf$^{flox/flox}$*; *Ptf1a/P48-Cre* mice showed tumor-free survival of 8.8 weeks associated with the development of PDA (4 out of 4 mice). Furthermore, *LSL-Kras$^{G12D/+}$; Smad4$^{flox/flox}$; Ink4a/Arf$^{flox/flox}$*; *Pdx1-Cre* mice displayed a tumor-free survival of 7.4 weeks, with 3 out of 10 developing IPMN, while 9 out of 10 presented PDA. Again, a considerable number of these mice from the Pdx1 cohort (50%) developed gastric cancer due to the activity of the *Pdx1* promoter in the foregut [57] .

Collectively, this study showed that *Smad4* deficiency leads to the development of IPMN in a *Kras^{G12D}* context (17/20 mice), with a low proportion of mice (2/20) presenting frank PDA. Interestingly, the inactivation of the tumor suppressor *Ink4a/Arf* in a *Kras^{G12D}* and *Smad4* null background dramatically increased PDA incidence, with 64% of heterozygous and 92% of homozygous mice developing PDA. These findings clearly confirm that the genetic landscape strongly determines tumor evolution.

Strikingly, mutations in *SMAD4* are infrequent in human IPMN, and are instead more common in human MCN [58, 59]. Genetic approaches using GEMMs have supported the human studies, delineating the role of the TGFβ pathway in the pathogenesis of MCN. Izeradjene et al. [60] interbred a *Smad4* conditional *knock-out* strain harboring an exon 8 flanked by LoxP sites [61] with *LSL-Kras$^{G12D/+}$*; *Pdx1-Cre* mice. Pancreata from *LSL-Kras$^{G12D/+}$; Smad4$^{flox/+}$; Pdx1-Cre* mice revealed the development of PanINs and macroscopic cystic lesions, although the early lethality of this cohort due to the development of gastric carcinomas (median

survival of approximately 8 months) precluded the analysis of late stages of the disease. To overcome the lethality induced by the expression of Pdx1 in the gastric epithelium, they performed a subsequent study in a *Ptf1a/p48-Cre* background, which restrains the expression of *Cre* recombinase to the pancreas compartment. Mice with heterozygous *Smad4* inactivation combined with $Kras^{G12D}$ activation, $LSL\text{-}Kras^{G12D/+}$; $Smad4^{flox/+}$; *Ptf1a/P48-Cre*, showed similar median survival to $LSL\text{-}Kras^{G12D/+}$; *Ptf1a/P48-Cre* mice. Remarkably, pancreata examination of heterozygous *Smad4* mice revealed the development of palpable abdominal masses in the body and tail that corresponded with large mucinous cystic lesions classified as MCN. PanIN lesions were also observed, although they usually were of a lower grade compared with those found in age-matched *Smad4* wild-type control littermates. Mice with homozygous *Smad4* ablation, $LSL\text{-}Kras^{G12D/+}$; $Smad4^{flox/flox}$; *Ptf1a/P48-Cre*, showed reduced median survival compared with heterozygous counterparts (8 vs. 15 months, respectively) associated with accelerated development of MCN. Interestingly, $LSL\text{-}Kras^{G12D/+}$; $Smad4^{flox/+}$; *Ptf1a/P48-Cre* and $LSL\text{-}Kras^{G12D/+}$; $Smad4^{flox/flox}$; *Ptf1a/P48-Cre* mice showed reduced metastatic behavior compared to the KPC mice, which correlated with the less aggressive phenotype showed by the cystic pancreatic neoplasias compared with PDA in humans [61].

Other GEMMs have provided additional insights into the molecular basis of pancreatic cystic neoplasia development. Siveke et al. [62] interbred *Elastase-Tgfα* transgenic mice with $LSL\text{-}Kras^{G12D/+}$; *Ptf1a/P48-Cre* mice. They found that concomitant expression of *Tgfα* and $Kras^{G12D}$ led to the development of cystic papillary neoplasias with resemblance to IPMNs that rapidly progressed to invasive and metastatic PDA [62]. Moreover, Vincent et al. [63] investigated the role of the TGFβ signaling regulator Transcriptional Intermediary Factor 1 gamma (Tif1γ) in pancreatic cancer development. They generated $LSL\text{-}Kras^{G12D/+}$; $Tif1\gamma^{flox/flox}$; *Pdx1-Cre* mice and found that the deletion of *Tif1γ* in pancreatic progenitor cells cooperated with $Kras^{G12D}$ to induce pancreatic tumors reminiscent of human IPMNs [63].

Taken together, the mouse models described above have helped to understand the genetics and biology of pancreatic cancer, establishing that aberrations in the TGFα and TGFβ pathways play a critical role in the generation of both PanINs and cystic neoplasias, including IPMNs and MCNs [16], that eventually progress to invasive PDA.

Mouse Models to Study the Role of Oncogenic Kras in PDA Maintenance

Activating mutations in *KRAS* are required for PDA development. Given that PDA is detected virtually only once the tumor is established, understanding of the role of oncogenic KRAS in PDA maintenance is of utmost importance to unveil molecular pathways with therapeutic relevance to tackle this disease. During the last few years, a new generation of GEMMs have helped to delineate the role of oncogenic Kras in PDA progression and maintenance. The Pasca di Magliano laboratory [64]

engineered a *tetO-Kras*^{G12D} regulatable transgenic allele which allows the expression of *Kras*^{G12D} when doxycycline is supplemented in the diet. They interbred *tetO-Kras*^{G12D} mice with *Ptf1a/P48-Cre* and *Rosa26-LSL-rtTA-IRES-EGFP* mice to generate the compound mutant strain *tetO-Kras*^{G12D}; *Rosa26-LSL-rtTA-IRES-EGFP*; *Ptf1a/P48-Cre* (known as *iKras**). *iKras** mice express *Cre* recombinase in the pancreas compartment from E9.5 that, in turn, removes the LSL cassette of the *Rosa26-LSL-rtTA-IRES-EGFP* allele allowing the expression of both the *rtTA* transactivator and the *EGFP* reporter in pancreatic progenitor cells. Once doxycycline is administrated in the drinking water, rtTA is activated, leading to *Kras*^{G12D} expression from the *tetO-Kras*^{G12D} allele. Importantly, upon doxycycline withdrawal *Kras*^{G12D} expression is reversed [64] (Fig. 3).

iKras* models have provided a valuable tool for understanding the role of oncogenic Kras in PDA maintenance. When *Kras*^{G12D} was abrogated in PanIN lesions established in **iKras* mice, preinvasive lesions reverted both with and without induction of acute pancreatitis, confirming that oncogenic Kras is required for PanIN maintenance [64]. Furthermore, the authors used this system to investigate advanced PDA. Thus, the *iKras** strain was introduced in a *Trp53*$^{+/-}$ background. Interestingly, both PanINs and PDA lesions established in *iKras*-p53*$^{+/-}$ mice regressed after *Kras*^{G12D} inactivation. This regression was associated with MAPK downregulation, although unlike iKras* PanIN lesions, pancreata did not fully recover their normal histology, and areas of metaplasia surrounded by fibrosis remained in the pancreatic parenchyma after *Kras*^{G12D} ablation [64].

In a parallel study, Ying et al. [65] engineered a *tetO_Lox-Stop-Lox-Kras*^{G12D} transgenic strain that was interbred with *Rosa26-LSL-rtTA-IRES-GFP* and *Ptf1a/P48-Cre* mice to generate *tetO_Lox-Stop-Lox-Kras*^{G12D}; *Rosa26-LSL-rtTA-IRES-GFP*; *Ptf1a/P48-Cre* compound mutant mice (known as *iKras*). Significantly, tumor regression was observed after *Kras*^{G12D} inactivation in both the *iKras* and *iKras-Trp53*$^{+/-}$models, supporting previous findings using the *iKras** model [64]. Strikingly, the authors showed that oncogenic Kras promotes metabolic reprogramming in neoplastic cells to sustain tumorigenesis. Indeed, they found that *Kras*^{G12D} inactivation led to inhibition of glucose uptake with a decrease in glycolytic intermediates [65].

Overall, oncogenic Kras regulatable mouse models have established that pancreatic cancer is strictly dependent on *Kras*^{G12D} expression, providing an unbiased genetic model to understand the molecular mechanisms involved in PDA progression and maintenance with the aim of identifying molecular targets for therapeutic interventions.

Mouse Models to Identify and Validate Human Pancreatic Cancer Genes

Pancreatic cancer evolves as a consequence of genetic alterations acquired during the progression of the disease. Indeed, whole-genome sequencing approaches performed in human pancreatic cancer specimens have exposed the complexity and heterogeneity of the tumor genomes, unveiling a significant number of novel candidates involved in the pathogenesis of pancreatic cancer [17, 18, 21, 22]. This

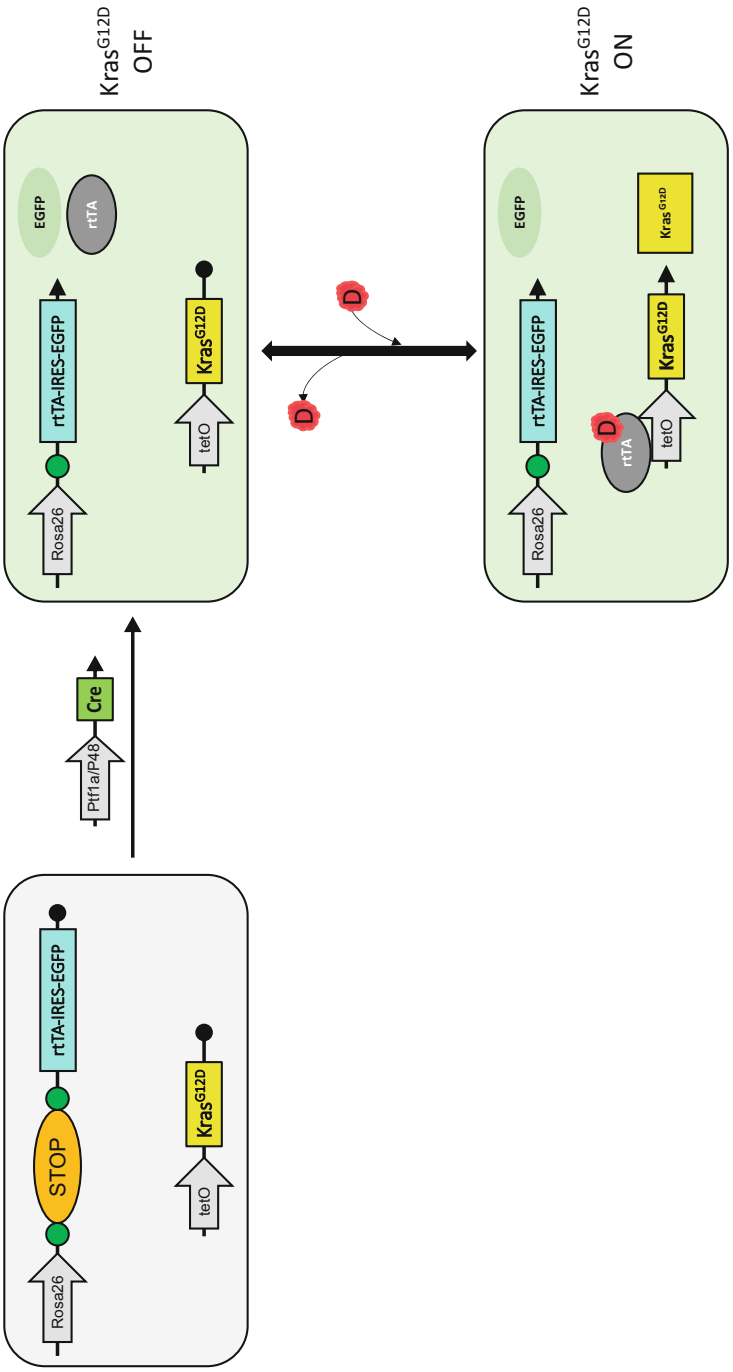

Fig. 3 ***iKras* mouse model.** *Ptf1a/P48*-driven *Cre* expression removes the LoxP-STOP-LoxP cassette from the *Rosa26-LSL-rtTA-IRES-EGFP* allele, thereby allowing the expression of the *rtTA* transactivator and the green fluorescent protein (*EGFP*). When doxycycline (D) is administrated, rtTA binds to the tetracycline operator (tetO) inducing the expression of $Kras^{G12D}$. When doxycycline is removed, rtTA is inactivated and $Kras^{G12D}$ expression eversed

complex genomic landscape is undoubtedly limiting our capability to act therapeutically to block the progression of the disease. Therefore, understanding the contribution of each genetic alteration to the pancreatic cancer development is of paramount importance to improve diagnosis and therapy.

The generation of mouse strains harboring the components of DNA transposon system have permitted in vivo insertional mutagenesis screens that have led to the identification of a plethora of novel cancer driver genes [66–69]. Transposon-based GEMMs harbor a transposon concatemer as the primary source of transposons, and a transposase to mobilize the transposons within the host genome. Importantly, transposon-based mutagenesis systems in mice have provided a valuable tool to reveal molecular pathways involved in different stages of PDA development in an unbiased manner.

Sleeping Beauty (SB) and *piggyBac* (PB) transposons are DNA transposable elements flanked by inverted repeat/direct repeat (IR/DR) sequences. Transposons harbor a strong promoter regulatory element to ectopically activate the expression of potential proto-oncogenes or dominant-negative tumor suppressor genes (gain-of-function activity), and bidirectional polyadenylation signals to trap upstream exons and inactivate potential tumor suppressor genes (loss-of-function activity) (Fig. 4). The mobilization of the transposons along the genome is mediated, using a non-replicative "cut-and-paste" mechanism, by site-specific transposases that specifically recognize the inverted terminal repeats. When transposons integrate in the genome, they regulate gene expression nearby the integration site [66].

In the last few years, transposon-based GEMMs have been used to identify new genes and molecular pathways that cooperate with $Kras^{G12D}$ during PanIN to PDA progression [19, 20, 70]. We generated a *Sleeping Beauty* (SB) conditional *knock-in* mouse model, *Rosa26-LSL-SB13*, that harbors a hyperactive *SB13* transposase under the control of the *Rosa26* promoter. Upstream of the *SB13* cDNA, a floxed transcriptional stop cassette (LoxP-STOP-LoxP, LSL) allowed the spatiotemporal control of *SB13* expression. The LSL cassette was removed in the pancreas by *Pdx1*-driven *Cre* recombinase expression (Fig. 4). We monitored a cohort of *LSL-*$Kras^{G12D/+}$*; Pdx1-Cre; T2/Onc; Rosa26-LSL-SB13* (*KCTSB13*) mice and found that SB13-mediated mobilization of a *T2/Onc* transposon concatemer in pancreatic progenitor cells led to a dramatic decrease in median survival due to the development of PDA and invasive cystic neoplasias (172 vs. 257 days of mice that do not harbor the *T2/Onc* and/or *Rosa26-LSL-SB13* alleles). The analysis of common insertion sites of the transposon in tumors obtained from *KCTSB13* mice revealed genes previously associated with human PDA including $p16^{Ink4a}$, *Rb*, components of the TGFβ signaling pathway, *Acvr1b, Arid1a, Stk11,* or *Pten*, confirming the biological significance of this approach. Additionally, the screen provided novel information of molecular pathways involved in PDA progression. The deubiquitinase *Usp9x* was the gene most commonly found to be inactivated in this screen, with over 50% of the KCTSB13 tumors (101 out of 198) showing inactivation of the *Usp9x* locus. Strikingly, we confirmed using in vitro approaches that *Usp9x* downregulation enhanced transformation of PDA cells. Furthermore, we generated *LSL-*$Kras^{G12D/+}$*;* $Usp9x^{flox/flox}$*; Pdx1-Cre* mice and found that *Usp9x* inactivation in the pancreas

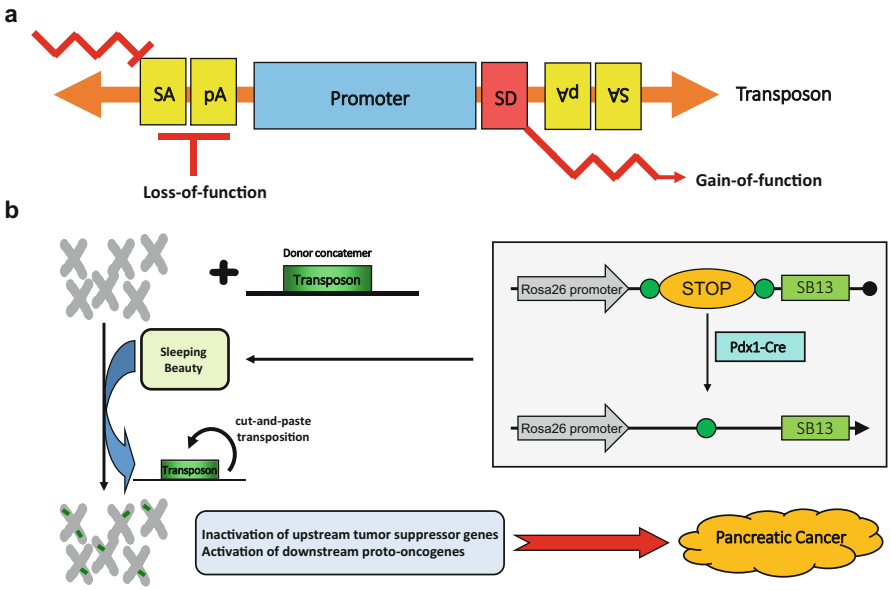

Fig. 4 Insertional mutagenesis screen in PDA. (**a**) Transposons harbor bidirectional polyadenylation sequences to trap upstream exons and inactivate potential tumor suppressor genes (loss-of-function activity), and a strong promoter to activate potential proto-oncogenes downstream of the integration site (gain-of-function activity). (**b**) *Pdx1-Cre*-mediated expression of *SB13* induces the mobilization of a transposon concatemer in the pancreas compartment leading to mutations that accelerate PDA progression

cooperated with $Kras^{G12D}$ to accelerate pancreatic cancer development. Significantly, data found in these GEMMs were corroborated clinically; *USP9x* was found to be downregulated in human PDA, and low *USP9X* levels correlated with poor prognosis and higher metastatic burden [19]. Overall, this study identified a novel tumor suppressor gene with prognostic and therapeutic relevance in PDA. Significantly, an independent study performed by Mann et al. [20] confirmed these findings. Using a similar approach, they found that SB11-mediated mobilization of the *T2/Onc2* or *T2/Onc3* transposon concatemers produced similar outcomes, a dramatic acceleration in pancreatic cancer progression and recurrent inactivation of *Pten* and *Usp9x* [20]. Strikingly, these two SB-mediated insertional mutagenesis screens unveiled mutations in axon guidance regulators, giving unbiased genetic evidence of the critical role of the SLIT/ROBO signaling in PDA development and supporting the genomic studies performed in clinical samples [18].

Finally, Rad et al. [70] performed a PB-mediated insertional mutagenesis screen in the pancreas. The authors generated *LSL-*$Kras^{G12D/+}$*; Pdx1-Cre; ATP1-S2; Rosa26-LSL-PB* mice, where the *ATP1-S2* transposon concatemer was mobilized by the PB transposase. These mice presented accelerated PanIN to PDA progression, with the development of classical pancreatic ductal adenocarcinomas and adenocarcinomas with hepatoid differentiation. The analysis of genes mutated by

PB transposons revealed novel driver candidates involved in pancreatic cancer progression, including gain-of-function mutations in *FoxP1* and *Fign* [70]. Remarkably, the top candidate genes diverged between the SB and PB screens. This was most likely due to the different integration preferences of SB and PB transposons, and confirmed that both transposon systems are complementary to study the pathogenesis of cancer.

Collectively, forward genetic screens have provided a valuable tool to identify mutations that promote pancreatic cancer progression, permitting an unbiased selection of pancreatic cancer driver genes among the candidate genes identified in genomic studies performed in human specimens. Additionally, these successful approaches support the use of GEMMs of pancreatic cancer to complement clinical studies and warrant the employment of transposon-based GEMMs for the identification of molecular mechanisms involved in drug resistance.

Mouse Models as a Tool to Develop Therapeutic Strategies to Fight Pancreatic Cancer: Understanding the Role of the Stroma in Chemoresistance

As described above, a collection of GEMMs of pancreatic cancer carrying diverse combinations of mutations have been generated. Importantly, the targeting of different molecular pathways has resulted in the development of tumors with distinct clinical and histopathological features that have led to a better understanding of the biology of pancreatic cancer. Taking advantage of this ability to recapitulate key clinical features of the human disease, GEMMs have been employed as a preclinical platform to develop new therapeutic intervention strategies and to understand the mechanisms of chemoresistance.

The use of mouse models of pancreatic cancer for preclinical studies was pioneered by the group of David Tuveson. They extensively employed the *LSL-Kras*$^{G12D/+}$*; LSL-Trp53*$^{R172H/+}$; *Pdx1-cre* (*KPC*) model that was shown to tightly recapitulate the biology of human PDA including an abundant desmoplastic stromal reaction associated with poorly vascularized tumors [71]. Supportively, *KPC* mice were found to be highly resistant to treatment with gemcitabine, mimicking human PDA chemoresistance and suggesting that the hypovascular and desmoplastic nature of PDA may be critical determinants for therapeutic response [71]. This hypothesis has been successfully proved by a number of studies that have used the *KPC* model as a preclinical model to evaluate how the depletion of the stroma impacts therapeutic response. Olive et al. [71] found that stroma depletion in established PDA using IPI-926, an inhibitor of the Hedgehog pathway effector Smoothened, led to an increase in tumor vascularization, enhanced gemcitabine delivery, and extended survival, suggesting that the tumoral stroma was a barrier for efficient drug delivery [71]. Discouragingly and surprisingly in view of the promising data from a Phase 1b trial, a Phase II trial showed a reduced median survival in patients on the gemcitabine + IPI-926 arm versus patients on the gemcitabine arm. This disappointing outcome

indicates that careful analyses are required to understand how GEMMs can be maximized for preclinical studies.

Interestingly, two recent reports have introduced controversies about the role of the stroma in PDA development. In the first study, Ozdemir et al. [72] ablated α-SMA+ myofibroblasts using an elegant genetic approach. They generated *LSL-Kras*$^{G12D/+}$*; Tgfbr2*$^{flox/flox}$*; Ptf1a/P48-Cre; α-SMA-tk*, and *LSL-Kras*$^{G12D/+}$*; LSL-Trp53*$^{R172H/+}$*; Pdx1-cre; α-SMA-tk* mice. Both cohorts expressed thymidine kinase (tk), an enzyme that transforms ganciclovir into a toxic product that selectively kills cells expressing *tk*, in α-SMA+ cells. Unexpectedly, myofibroblast ablation after treatment with ganciclovir led to the development of undifferentiated and invasive tumors and reduced overall survival compared with mice that did not receive ganciclovir. Importantly, these findings were supported by the analysis of clinical specimens. Indeed, patients with PDA and reduced numbers of myofibroblasts exhibited a shorter median survival. In line with these findings, Rhim et al. [73] deleted Shh in the pancreas compartment by generating *Shh*$^{flox/flox}$; *LSL-Kras*$^{G12D/+}$*; Trp53*$^{flox/+}$; *Pdx1-cre; LSL-Rosa26-YFP* (*ShhKP*$^{flox/+}$*CY*) mice. Significantly, *ShhKP*$^{flox/+}$*CY* mice showed accelerated tumor development compared with *KP*$^{flox/+}$*CY* mice. Furthermore, tumors displayed increased metastatic potential and exhibited a poorly differentiated histology accompanied by reduced stromal desmoplasia and increased angiogenesis. Significantly, this phenotype was recapitulated after chronic Smoothened inhibition using IPI-926. Taken together, these studies strongly suggested that at least some component of the stroma may be stopping tumor spread.

A number of additional studies have assessed different therapeutic approaches to target the PDA stroma. Two different groups have used PEGylated human recombinant PH20 hyaluronidase (PEGPH20) to evaluate the effect of targeting Hyaluronic Acid (HA), one of the major component of the extracellular matrix [74, 75]. PEGPH20 treatment reduced the interstitial fluid pressure generated by the high desmoplastic reaction and reexpanded the tumor vasculature, thereby increasing the delivery of gemcitabine. Importantly, PEGPH20 and gemcitabine combination nearly doubled overall survival of *KPC* mice over gemcitabine monotherapy. Significantly, a Phase Ib study has revealed that PEGPH20, in combination with gemcitabine, may benefit patients with advanced PDA, predominantly those with high HA tumors [76].

KPC mice have also helped to understand the antitumor activity of the nanoparticle albumin-bound (nab)-paclitaxel, which binds to SPARC (secreted protein acidic and rich cysteine) to promote stromal depletion. In immunodeficient mice with human pancreatic cancer xenografts, the nab-paclitaxel plus gemcitabine combination reduced tumor stroma, induced angiogeneisis, and increased intratumoral gemcitabine levels after 28 days of treatment [77]. A subsequent study by Frese et al. [78] showed that nab-paclitaxel and gemcitabine led to tumor regression and metastasis reduction in *KPC* mice after 8 days of treatment. Mechanistically, it was shown that nab-paclitaxel elevated intratumoral levels of gemcitabine through decreasing the levels of the gemcitabine-metabolizing enzyme cytidine deaminase, which resulted in the enhanced stabilization of gemcitabine. However, they did not

observe the depletion of stroma, likely due to the unfeasibility to treat *KPC* mice for 28 days due to the development of an acquired immune response to the human albumin component of nab-paclitaxel.

Another significant study showed that the tumor stroma limits antitumor immune response. Beatty et al. [79] showed that the combination of gemcitabine plus an agonist CD40 antibody, which activates T cell immunity, exhibited tumor regression in some patients with surgically incurable PDA. Interestingly, this treatment was recapitulated in *KPC* mice, although in this system the antitumor effect was not mediated by T cells, but on the CD40-activated macrophages, which promoted the depletion of tumor stroma [79].

Very recently, a significant study has shown that fibroblast drug scavenging may contribute to the clinical failure of gemcitabine in desmoplastic PDA. Hessmann et al. [80] showed that gemcitabine accumulation was considerably augmented in fibroblast-rich tumors. Importantly, primary PDA tumors show an increased number of α-SMA+ cells compared with matched liver metastases, suggesting that cancer-associated fibroblast (CAFs) may accumulate active gemcitabine intracellularly thus limiting the availability of the drug for cancer cells. Notably, gemcitabine treatment in KPC mice, although this did not extend overall survival, strongly reduced the number of liver metastases. Mechanistically, the authors demonstrated that metabolic enzymes involved in gemcitabine inactivation, including Nt5c1A and Nt5c3, were expressed at low levels in CAFs. Overall, this study unveils the metabolic targeting of CAFs as a potential promising strategy to enhance the antitumor activity of gemcitabine.

Collectively, preclinical studies using GEMMs of PDA have supported the development of novel therapeutic intervention strategies and also provided insights for understanding the molecular and cellular basis of chemoresistance in PDA. Information on additional preclinical studies can be found in [81, 82].

Conclusion

The improvement of gene-targeting approaches together with an increased understanding of the molecular basis of pancreatic cancer have led to the generation of GEMMs that faithfully reproduce the biology and histological evolution of pancreatic cancer. GEMMs of pancreatic cancer have been used not only to understand the molecular and cellular basis underlying pancreatic tumorigenesis, but also to unveil mechanisms of chemoresistance that have led to better therapeutic strategies. Nevertheless, current GEMMs have some limitations, and new approaches to modeling pancreatic cancer in mice are being developed.

The most accepted model for human pancreatic cancer development follows a stepwise genetic progression beginning with the activation of KRAS followed by the sequential inactivation of tumor suppressors during the progression of the disease [3, 4] (Fig. 1). Current mouse models are based on the use of a single recombinase, the Cre-LoxP or Flp-FRT systems. Accordingly, in these single recombinase-based GEMMs the activation of KRAS and inactivation of tumor suppressor genes happen

simultaneously in the same cell type, precluding the recapitulation of the genetic PDA progression model. Recently, Dieter Saur's laboratory have generated a dual-recombinase model for time- and host-specific targeting of pancreatic cancer by combining the Cre-LoxP and Flp-FRT systems, in which oncogenic Kras activation is mediated by the Flp-FRT system while the Cre-LoxP system enables the spatio-temporal regulation of a second genetic event [83]. This genetic approach permits a sequential genetic manipulation, facilitating the analysis of cooperating genetic events during PanIN to PDA progression, selective targeting of specific components of the tumor microenvironment, and genetic validation of therapeutic targets [83].

Current approaches to generate complex compound mutant strains are based on crossing individually targeted strains, which is extremely slow and highly costly. Therefore, new methods for a rapid generation of tailored GEMMs are greatly required. During the last few years, several approaches have been developed to accelerate in vivo studies:

1. Saborowski et al. [84] developed an embryonic stem cell (ESC)-based GEMM system to generate multiallelic chimeric mice. They established 2 ESC lines harboring four mutant alleles. Firstly, *LSL-Kras*$^{G12D/+}$ and *Pdx1-Cre* (or *Ptf1a/P48-Cre*) alleles to initiate PDA. Additionally, a recombinase-mediated cassette exchange (RMCE) targeted in the *col1a1* locus to facilitate high-efficiency targeting with tetracycline-regulatable shRNAs or cDNAs. Finally, a *CAGs-LSL-rtTA3-IRES-mKate2* allele drives *Cre*-mediated *rtTA3* (tetracycline trans-activator) and fluorescent *mKate2* protein expression in pancreatic progenitor cells. When doxycycline is administrated, rtTA3 induces the expression of the shRNA or cDNA cloned in the *col1a1-RMCE* allele. As proof of concept, the authors showed that *Pten* knock-down cooperated with *Kras*^{G12D} to accelerate PDA development, while *c-Myc* downregulation compromised PDA development.
2. Another approach was developed by Dieter Saur's laboratory [85]. They used RCAS-TVA-mediated retroviral gene transfer to downregulate or overexpress target genes in pancreatic cells that express the retroviral receptor TVA. They generated *LSL-Kras*$^{G12D/+}$*; Ptf1a/P48-Cre; Rosa26-LSL-TVA-lacZ* mice to direct TVA expression to pancreatic cells after Cre-mediated excision of the LSL cassette. TVA-mediated infection of pancreatic cells expressing *Kras*^{G12D} with retroviruses carrying a shRNA against *Trp53* dramatically enhanced PDA development, confirming that this system can be used to target neoplastic cells in vivo.
3. Finally, two groups have showed that CRISPR/Cas9 technology can be used to study cooperating events in PDA. Chiou et al. [86] showed that the lentiviral delivery of *Cre* recombinase and *sgLkb1* in pancreata of *LSL-Kras*$^{G12D/+}$*; Rosa26-LSL-Tomato; H11-LSL-Cas9* mice led to PDA development associated with *Kras*^{G12D} activation and *Lkb1* ablation. A second group showed that transfection-based multiplexed delivery of CRISPR/Cas9 to the pancreata of *LSL-Kras*$^{G12D/+}$*; Ptf1a/P48-Cre* mice permits important applications, including combinatorial gene-network analysis, synthetic lethality screening, and chromosome engineering [87].

In conclusion, GEMMs have provided an invaluable tool for understanding pancreatic cancer pathogenesis, complementing clinical studies and improving our capability to develop new therapeutic intervention strategies. It is expected that refinement of the current GEMMs will provide new avenues to enhance our knowledge of this lethal disease.

Abstract

Pancreatic cancer tumor microenvironment (TME), simply defined as the non-cancerous desmoplastic reaction, is considered a key player in all aspects of tumor growth, and progression. The dismal prognosis of pancreatic cancer and disappointing clinical trials has drawn our attention to the TME, particularly to the tumor-stromal interactions. While a myriad of molecular, pathological, and clinical features contribute to the lethality of pancreatic cancer, local invasiveness and distant metastases is a hallmark and leading cause of mortality and morbidity in this ominous cancer. Cancer-associated stromal cells including stellate cells have been implicated in epithelial mesenchymal transition (EMT), a process involved in invasion and metastases. In addition, the pre-metastatic niche, immune evasion, and enhancement of angiogenesis have been attributed to these cells. Interactions of the tumor stromal complex operate as a command and logistics center for pancreatic cancer cells, triggering and maintaining invasiveness and metastases. Understanding and modulating these interactions is a promising strategy to tame one of the most aggressive human cancers to date.

Pancreatic cancer · Tumor microenvironment · Cancer-associated fibroblast · Pancreatic cancer stellate cells · Tumor-cell interaction · Metastasis

Introduction

Pancreatic cancer (PC) is the third leading cause of cancer related-deaths in the world and is predicted to be second by 2030 [1]. It is an early asymptomatic and aggressive disease with a 5-year survival rate of 8% [2]. Upon diagnosis, only 10–15% are resectable with the remaining being metastatic [3]. Even in the completely resected primary tumor, the cause of death is local or systemic recurrence [4, 5]. The dismal prognoses of looming mortality is due to the propensity for early metastatic spread coupled to ineffective treatments [6]. Improvements to surgical resection are ongoing, and neoadjuvant and adjuvant systemic therapy and antimetastatic agents are gaining popularity. Even with these enhancements, metastasis in pancreatic cancer is inevitable [6]. Pancreatic cancer is characterized by its tumor microenvironment (TME) and its implication in tumor progression [7, 8]. The cellular environment and all of its components for which the tumor exists collaboratively promotes primary tumor growth and metastasis [9, 10]. The cellular and noncellular components of pancreatic cancer can drive host immune evasion, epithelial to mesenchymal transition, and invasiveness [11–13]. Moreover, they can be responsible for the resistance to chemotherapy and radiotherapy of pancreatic tumoral cells [14, 15].

Cellular and Noncellular Components of Pancreatic Tumor Microenvironment

Pancreatic cancer is not merely an isolated mass of malignant cells but a complex interaction of different cell types and noncellular elements [16, 17]. The cellular components of pancreatic TME are numerous. Of these components, stroma may account for greater than 80% of the total tumor volume of which cancer-associated fibroblasts (CAFs) are the most numerous stromal cell together with pancreatic stellate cells (PSC) [9, 18]. These secretory cells promote tumor growth and proliferation; modulate cancer cell metabolism, immunosuppression, extracellular matrix (ECM) remodeling; and increase metastatic processes [18, 19]. The phenotypic and functional heterogeneity observed in CAFs can be partially explained through their diverse cellular origins ranging from resident tissue mesenchymal cells (e.g., pancreatic stellate cells), bone marrow-derived mesenchymal stem cells, hematopoietic stem cells to epithelial and endothelial cells [20, 21] (Fig. 1). Resting PSC account for 4% of the normal pancreatic tissue and are spindle-shaped cells with a prominent rough endoplasmic reticulum, collage fibrils, and lipid droplets with expressions of desmin and glial fibrillary acid protein (GFAP) and vimentin on the cytoplasmic membrane [8]. Upon injury and inflammation the resting PSC loses its vitamin A storage and acquires a star-shaped morphology, expresses α-SMA, migrates and proliferates while secreting copious amounts of ECM, growth factors, and cytokines [8, 16]. Because of this, activated PSCs are often considered the "architect" cells of PC stroma and are an attractive therapeutic target and will be the focus of the next section.

Pancreatic tumors contain copious immune cells, yet are frequently immunosuppressive [22]. PC tumors are T-lymphocyte rich; CD8+ T-cells are associated with a promising prognosis whereas T-regulatory (Treg) cells are immunosuppressive and favor tumor growth [12, 23]. In advanced stages of PC B-lymphocytes have been found to promote cancer through polarization and immunosuppression of macrophage activity. Macrophage recruitment promotes angiogenesis, immunosuppression, and ECM remodeling enhancing tumorogenesis [24]. Myeloid-derived suppresser cells (MDSCs) are recruited in mass and inhibit the activity of T-cells in the pancreatic cancer TME [25, 26]. The immune-suppressive environment of PC serves as potential therapeutic targets and is influenced through communication with neighboring stromal and tumorgenic cells.

The noncellular components of the TME typically refers to the makeup of the extracellular matrix (ECM). Here, the ECM not only serves as a scaffold to house cellular components but functions in the evolution and metastasis of pancreatic cancer. For example, secreted protein acidic and rich in cysteine (SPARC) is a major noncellular element of the ECM in remodeling tissues and enhances intratumoral drug delivery [22]. Other elements such as tenascin C, periostin, and proteases contribute to enhanced tumor proliferation, aggressiveness, invasiveness, and migration whereas osteopontin stromal content correlates with better survival

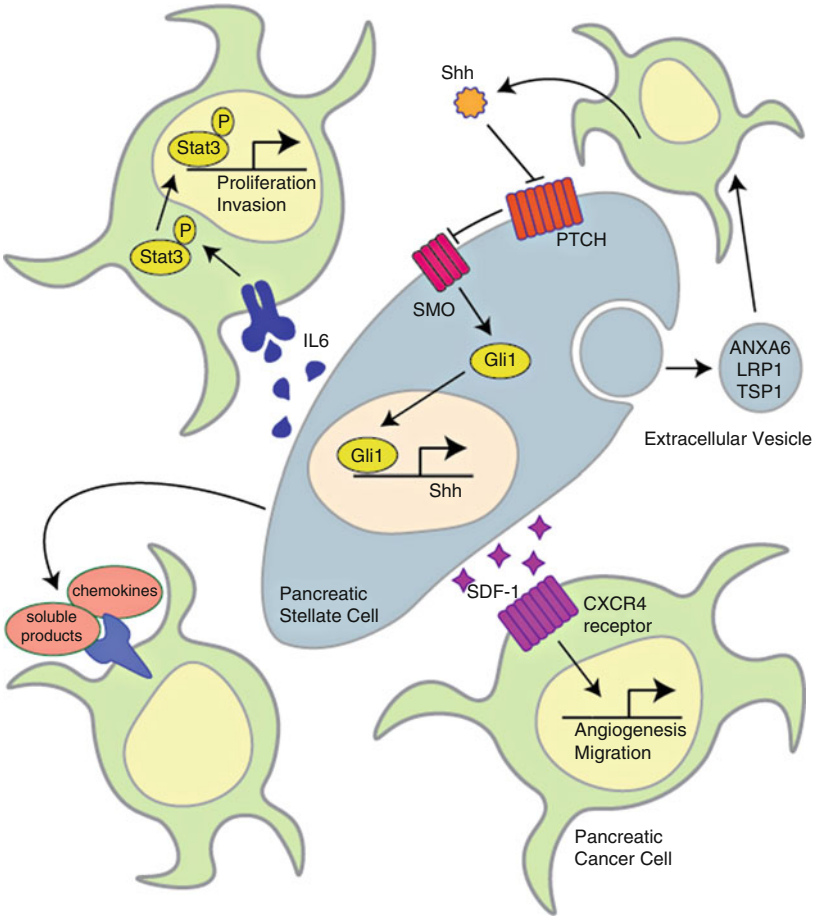

Fig. 1 Cancer-stroma cross-talk involves cellular communication between the tumor and the cellular environment for which the tumor exists. Activated PSCs are implicated in most all PCC processes and secrete copious amounts of IL-6 which activates STAT3 signaling in PCCs and promotes tumor cell proliferation and invasion. SDF-1 expression from PSCs promotes tumor angiogenesis and migration through the SDF-1/CXCR4 receptor ligand axis. Extracellular vesicle proteins ANXA6, LRP1, and TSP1 are secreted from PSCs and alter TME conditions, enhance PC invasion, survival, and aggressiveness. Various interleukins involved in paracrine signaling including chemokines and soluble products are secreted into the ECM from PSCs and act as mediators for tumorigenic invasion. PSC activation is enhanced through PCC secretion of Hedgehog and subsequent transcriptional activation mediated through GLI family transcription factors; overexpression of GLI1 and Hedgehog proteins are closely associated with PC. These interactions of the tumor-stromal complex initiate and maintain invasiveness and metastases of pancreatic cancer

rates [22]. The ECM serves as a conduit for communication between pancreatic cancer cells (PCCs) and noncancer cells and contributes to metastatic properties. PCCs alter the extracellular matrix through asserting direction via secretion of growth factors and chemokines into the ECM [27].

Due to the importance of the extracellular matrix (ECM) in cell behavior any alteration in the composition or structure of the ECM network can alter tissue architecture promoting the loss of normal function generating diseases, such as cancer [28]. The extracellular matrix is a noncellular well-organized network in which cells reside. In the pancreas the ECM influences a wide range of cellular processes; these include pancreatic islet cell development, survival, proliferation, and differentiation, as well as β-cells insulin secretion. Pancreatic human extracellular matrix consists of two parts: basement membranes (BM), which are found closely associated to islet cells, and an external thin layered interstitial matrix. The basement membrane, also known as peri-islet BM, is principally formed by collagens and layers of laminins (LN) [29]. Collagens provide a scaffold for embedded cells while laminins are essential to promote signal transduction mediated by interactions with cell surface receptors such as integrins. Basement membranes also contain fibronectin (FN) [30]. Heparin sulfate (HS) is a negatively charged glycosaminoglycans (GAGs) attached to core proteins, and favors bindings with different molecules including cytokines, growth factors, and chemokines [31]. Through these interactions signal transduction is promoted which leads to cell behavior control. Cells interact with ECM components through their surface receptors: integrins, discoidin domain receptors (DDRs), transmembrane proteoglycans such as syndecans, and the hyaluroan (HA) receptor CD44 [30]. Here the ECM influences cell behavior and gene expression through specific signal transduction as well as changes in interstitial fluid pressure which can be a barrier to perfusion, diffusion, and convection of small molecules therapeutics.

Tumor-Stromal Interactions in Pancreatic Cancer

Cancer-stroma "cross-talk" involves cellular communication between the tumor and the cellular environment for which the tumor exists [32]. For example, activated PSCs are implicated in a large number of PCC processes including intracellular signaling, carcinogenesis, growth, induction of EMT, invasion, migration, metastases, and even therapeutic resistance [33]. The molecular pathways that drive pancreatic cancer are comprised of oncogenes, tumor suppressor genes, and developmental signaling pathways [34]. These molecular alterations show varying incidence and exhibit a temporal order with cancer progression and correlate with the morphological, histopathological, and clinical context [34, 35].

Pancreatic Cancer Cells Hijack Immune Cells

PCCs modulate the innate and adaptive immune system through recruitment and potentiation of immunosuppressive cells [36]. In many cases, PC is initiated by oncogenic KRAS, which has been shown to recruit macrophages in addition to driving neoplasia [37]. The classic antitumor role of the immune system is

represented by cytotoxic CD8+ and Th1 cells infiltrating the stroma, bone marrow, and blood [12]. The noncanonical role of the immune system enhances tumor survival. Activated PSC induce Stat-3 differentiation of myeloid-derived suppressor cells (MDSCs) [38], mast cell proliferation, T-cell apoptosis, and inhibition of further T-cell tumor infiltration [39, 40]. In the context of innate immunity, the most prominent immune cell associated with PC stroma is the tumor-associated macrophage (TAM) or CD11b + macrophage [22]. Tumor invasion is enhanced through TAM recruitment from blood monocytes or resident tissue macrophages which suppress the antitumor T-cell response [22]. PCCs mediate macrophage differentiation [41] and other tumor-infiltrating immune cells to promote cancer growth and progression by TGF-β and IL-4 [42]. Macrophages chemo-protect PCCs through upregulation of enzymatic degradation of the chemotherapeutic agent gemcitabine and enhance tumor invasion [15, 41]. The PCC-PSC-mast cell communication recruit and activate mast cells, and reciprocally, mast cells contribute to stromal proliferation through IL-13 and tryptase resulting in cancer progression by TGF-β/Smad2 axis [43]. In addition, PCCs mobilize myeloid-derived suppressor cells (MDSCs) and mediate activation by Stat-3, and in return MDSC and other TME immune cells such as TAM [44] enhance the self-renewing therapy-resistant cancer stem cells (CSCs) [45].

L1CAM (CD171) an adhesion molecule, involved in the adaptive immune response, is overexpressed in PC and promotes the migration and infiltration of regulatory T cells (Treg cells) [36, 46]. PCCs stimulated by T cell gamma-interferon (INF) upregulate the immune inhibitory checkpoint PD-1 which reduces the late inflammatory reaction in the TME [47]. Contrary to this, CTLA-4 hinders the amplitude of early T cell activation [47]. Myeloid-derived suppressor cells (MDSC) infiltrate not only the tumor stroma but also bone marrow, the spleen, and blood stream; MDSCs induce regulatory Treg cells and attenuate antigen-specific T-cell response [22, 25]. In PC Treg cells are immunosuppressive through an induction of IL-10 and TGF-b blocking T-cell antigen responses [22]. These immune cell networks create an immune suppressive environment. Here, mast cells are recruited by PCCs and activated. Activation of mast cells enhance PSC proliferation and deposition of ECM [48]. Furthermore, activated PSC express Galectin-1, a β-galactoside binding lectin [49], that inhibits T cell activation, proliferation and promotes T cell apoptosis [50]. Knocking down Galectin-1 boosted the viability of CD4+ and CD8+ T cells [39, 50]. Targeting of Galectin-1 and PSC-IL-6-Stat3 pathway could neutralize the PSC-mediated immunosuppression [50, 51]. PC is immunotherapy resistant whereas other immune-active tumors such as melanoma are effectively treated with single immune-therapeutics targeting immune-inhibitory checkpoints such as anti-PD1 and anti-CTLA-4 [52, 53]. Converting PC to an immunogenic tumor is the key to overcoming this immunotherapy resistance [54]. Preclinical and clinical trials using combination immune therapy including a cancer vaccine and an immune checkpoint inhibitor have shown synergism [47, 54].

Stromal Cells Promote PCC Epithelial-Mesenchymal Transition

Cellular plasticity gained through epithelial-mesenchymal transition (EMT) contributes to stress adaptation and facilitates cancer progression and dissemination [6, 55]. EMT involves molecular processes engaged in reprogramming phenotypic and functional epithelial cells into motile and supportive mesenchymal cells [55]. The trigger(s) of EMT in PC remains elusive, yet, a myriad of growth factors, cytokines, intracellular pathways, and epigenetic cascades are known to participate in this process [56]. PSCs have been implicated in the promotion of EMT through modulation of the levels of mesenchymal genes including vimentin, Snail, and beta-catenin in PCCs morphology and enhances expression of mesenchymal markers vimentin, Snail, and beta-catenin [57, 58] Inflammation-healing are linked to EMT through molecular processes involving the activation of Notch, Hedgehog-GLI, TGF-β, and PDGF signaling (Fig. 1) [13, 14, 59, 60].

Epithelial cells metamorphosing into phenotypic and functional mesenchymal cells is characterized by the loss of E-cadherin and acquisition of N-cadherin and vimentin, markers of epithelial and mesenchymal cells, respectively [61]. EMT associates with cytoskeletal alternation, basement membrane invasion, venous infiltration, nodal metastases, and poor survival [61–63]. PCCs undergoing EMT have stem-cell-like properties and are integral in the development of metastatic PC [64, 65]. Circulating mesenchymal cells in blood of pancreatic cancer patients due to EMT are detectable prior to primary tumor diagnosis [64]. These findings indicate PC development is associated with EMT and that within the molecular pathways governing EMT there exists potential therapeutic targets. Of note, CAF/PSC-induced EMT is inhibited by retinoic acid through suppression of IL-6 secretion, and thus representing a novel therapeutic target for the treatment of advanced PC [66].

The TGF-β signaling pathway is implicated in epithelial cell arrest and tumor suppression [67]. However, it can also promote tumor growth by inducing EMT. For examples, TGF-β ligand is most abundant in PC stroma where it activates PSCs and upregulates ECM proteins fibronectin and collagen type I [68]. The role of TGF-β as guardian turned aggressor is in part explained by the dual function of the pathway and the imbalance between SMAD4 dependent and independent TGF-β pathways [67]. Loss of SMAD4 and consequent loss of the SMAD4-dependent TGF-β signaling abolishes tumor suppressor function of TGF-β. SMAD4 loss has been correlated with mesenchyme histological features, portal vein, lymph vessel, and perineural invasion as well as disease-specific and disease-free survivals [69]. SMAD4, a tumor suppressor molecule, mediates the shift of TGF-β function from tumor prevention to tumor promotion via boosting its invasive and metastatic potentials [67, 70]. In addition, an antibody blockade of TGFβ not only modulates tumor stroma to a less immunosuppressive and more antitumor profile but results in a greater epithelial phenotype with less metastatic potential [71]. In contrast, intact SMAD4 in PCCs correlate with TGF-β related proliferation, indicating that wild-type SMAD4 can be more responsive to TGFβ inhibition [71]. The overexpression

of TGF-β in pancreatic cancer skews the balance towards tumor promotion via the SMAD4-independent pathways as PI3KAKT, ERK, and p38 MAPK, NFκB/PTEN and STAT3 [67]. Together, the pro-cancer and pro-metastatic role of TGF-β late in the disease context suggests that SMAD4 status may be used to segregate the patient group that may benefit from TGF-β blockade.

Pancreatic Stellate Cells Enhance Pancreatic Cancer Invasiveness

PSCs boost PCCs infiltrative affinity by at least three distinct avenues. PSCs secrete various interleukins involved in paracrine signaling including chemokines and soluble products which act as mediators for invasion. Importantly, activation of IL-6 with its downstream signaling mediator STAT3 promote intraepithelial neoplasia to invasive cancer (Fig. 1) [72–74]. In vitro studies demonstrate that PCC invasiveness was influenced by expression of CCR9 and DSF1 expression through contributing to diminished cell-to-cell contact [75, 76]. SDF-1 belongs to the CXC chemotactic family that is related to the SDF-1/CXCR4 axis, which is of paramount importance to the mechanism and prevention of HIV-1 infection (Fig. 1). This suggests a metastatic potential in other solid cancers such as breast, lung, prostate, ovarian, and stomach cancers [76]. Of interest, PSCs and not PCCs express SDF-1 which activate the CXCR4 axis in cancer cells promoting migration and invasion. Moreover, PSCs supernatant enhances the migration of cancer cells in a dose-dependent manner through collagen-I the most abundant ECM component [76].

Extracellular vesicles (EV) have been identified to influence PSC/CAF-related cancer invasion [38, 63, 77]. Eleven stromal-specific proteins were identified to form a complex and may play a role in PC invasion. Among these proteins, ANXA6, LRP1, and TSP1 are of interest as they are associated with membrane-related events and cell-to-cell contact [31, 77]. These three proteins are secreted from PSCs/CAFs and alter TME conditions including hypoxia, lipid deprivation, and macrophage presence (TAM). In addition, ANXA6, LRP1, and TSP1 are not only enclosed in extracellular vesicles but are imperative for PC invasion, survival, and aggressiveness [77]. Of interest, higher ANXA6 levels in circulating EVs were correlated with a higher tumor grade and detrimental survival. Based on that, ANXA6, LRP1, and TSP1 had a proven clinical utility suggested by its diagnostic and predictive value [77].

A typical feature of PC is its local tissue and vascular invasion with subsequent distant metastases. Matrix metalloproteinase-2 (MMP-2), an endopeptidase with proteolytic activity targeting the degradation of the basement membrane during EMT, is secreted from PC stroma and associated with vascular invasion and metastases [78, 79]. MMP-deficient PCCs shed their trans-membrane glycoprotein basigin (BSG) from their cell surface and stimulate the production of MMP from PSCs [78]. In vivo studies and examination of postoperative human species confirmed stromal overexpression of MMP-2 and MMP-6 and correlated that overexpression to the histologic invasion of large veins [80]. MMP-2 and MMP-6 have been shown to degrade collagen type IV, a major component of the venous basement membrane [80].

From this, PSCs secretion of MMPs offers a partial mechanistic explanation underlying tissue and vascular invasion. TGF-β a key signaling mediator involved in PC stroma, as well as IL-32α, hinders and reverses the invasive behavior of PC via counteracting the MMP secretory and invasive effects of IL-6/STAT-3 signaling and IL-1, respectively [81, 82]. Pancreatic stellate cells express pro-angiogenic factors such as VEGF, VEGF receptor, and angiopoietin-1 while also secreting anti-antiogenic factors vasohibin-1 and endostatin [39]. The role of PSCs in the pre-metastatic niche were found to migrate from the primary tumor to multiple metastatic sites in mice injected with male PSCs and female PCCs. These mice had enhanced angiogenesis via upregulation of the endothelial cell marker CD31 [83], and PSC migration is controlled via calcium-sensitive potassium channels (Kca3.1) along with other cytoskeletal and cell adhesion dynamics [84].

Conclusions

PC is a dismal prognosis due to the propensity for early and quick metastatic spread coupled with ineffective treatments. The cellular environment and all of the components for which the pancreatic tumor exists collaboratively determine tumor growth. Interactions between cancerous cells, noncancerous cells, and noncellular components comprise the TME. Activated PSCs are implicated in most all PCC processes and tumorigenesis. Prominent secretory cancer-associated fibroblasts promote tumor growth and proliferation through modulation of metabolism, ECM structure, and immunosuppression. Tumor cells manipulate and evade antitumor immunity while cellular plasticity through EMT facilitates cancer progression and metastasis. PSCs boost PCC metastatic potential through paracrine signaling and EV protein trafficking. In addition, PSCs augment PCC invasive nature directly through paracrine signaling and EV pathways. Through understanding the molecular pathways involved in PSC and PCC communication and deliberately targeting these interactions is a promising strategy to combat PC.

Abstract

Inherited genetic changes, from high-penetrance mutations to common genetic variants of modest effect, play a significant role in pancreatic cancer risk both in the familial and nonfamilial forms of the disease. Approximately 20% of the familial clustering of pancreatic cancer is explained by inherited mutations in *BRCA2*, *BRCA1*, *CDKN2A*, *PALB2*, *ATM*, *PRSS1*, *STK11*, *MLH1*, *MSH2*, *MHS6*, and *PMS2*. Even among families without an identifiable germline mutation, the presence of a family history of pancreatic cancer is a strong risk factor for the development of pancreatic cancer. Given the substantial increased risk of pancreatic cancer associated with a family history, many clinical trials aimed at the early detection of pancreatic cancer in this population are underway. The goal of this chapter is to review the evidence supporting the importance of a family history of pancreatic cancer as a risk factor for pancreatic cancer and the clinical and pathological features of familial pancreatic cancer.

Keywords

Familial pancreatic cancer · BRCA2 · ATM · Inherited susceptibility

Introduction

Pancreatic cancer is a devastating disease that affects over 200,000 people worldwide and approximately 50,000 people in the United States (USA) each year [1]. Patients with a diagnosis of pancreatic cancer often have a dismal prognosis. Between 1975 and 2013, the 5-year survival rate for pancreatic cancer has risen from 5% to 8%; however, pancreatic cancer still has the worst prognosis of any major tumor type (Fig. 1) [2].

Pancreatic cancer is a disease of increasing age, with a median age of onset of 71 years [1]. It is projected that pancreatic cancer will be become the second leading cause of cancer-related death in the United States by 2020 [3].

Familial Pancreatic Cancer (FPC)

The presence of a family history of pancreatic cancer is the strongest risk factor for the development of pancreatic cancer identified to date other than age [4, 5]. Up to 10% of pancreatic cancer cases report a history of pancreatic cancer in a close relative [6]. The current criteria for familial pancreatic cancer are the occurrence of two first-degree relatives (a parent and child or two siblings) with pancreatic ductal adenocarcinoma (PDAC) in a kindred [7]. While the occurrence of a familial clustering of pancreatic cancer can be due to an underlying genetic susceptibility, environmental risk factors, or stochastic effects, inherited genetic factors have been shown to play an important role, both due to high-penetrance gene mutations [8] and lower-penetrance common variants [9].

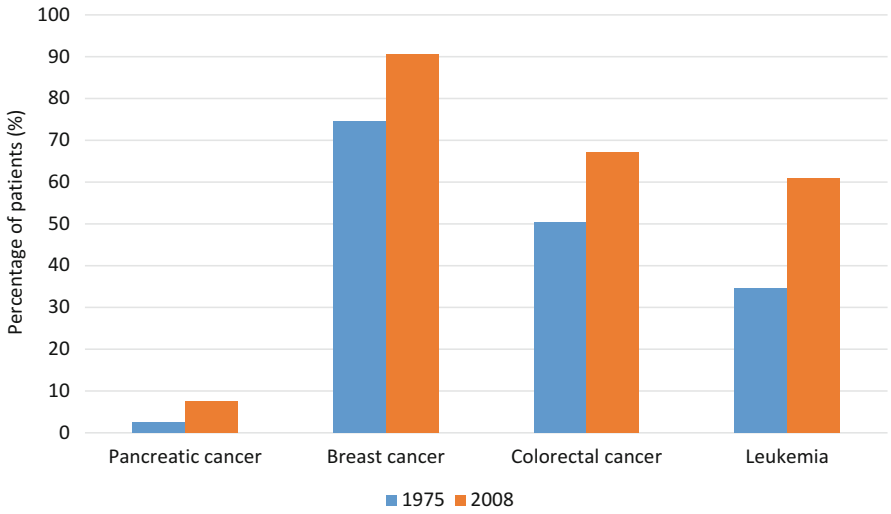

Fig 1 5-year survival rate for patients diagnosed with pancreatic cancer, breast cancer, colorectal cancer, and leukemia in 1975 and 2008. Graph compiled from the National Cancer Institute, Surveillance, Epidemiology, and End Results (SEER) Program data. Only females are included in breast cancer data [2]

The first reports in the literature of the clustering of pancreatic cancer in families were in the early 1970s. These include reports of multiple siblings with pancreatic cancer to small series of families with multiple pancreatic cancers. These initial case reports were followed by more rigorous controlled observational studies demonstrating increased risk of pancreatic cancer risk among individuals with a family history of the disease [10–18]. The risk estimates from these studies were highly variable, ranging from 1.5 to 13. However, a recent study, which pooled data from 1,183 cases and 1,205 controls with the Pancreatic Cancer Cohort Consortium, reported a multivariate-adjusted odds ratios (ORs) = 1.76, 95% confidence interval (CI) = 1.19–2.61 when comparing reported family history of pancreatic cancer in cases compared with controls [18]. However, the overall percentage of cases that reported a family history was quite low, and too few families met the criteria for familial pancreatic cancer to obtain a meaningful risk estimate in this group. In addition, due the nested case control design, family history may have been ascertained many years prior to the onset of pancreatic cancer in the cases, and the prevalence of a family history of pancreatic cancer at diagnosis may be higher than that reported [18]. In contrast to these population-based studies, numerous registries of familial pancreatic cancer kindred have been established in Europe, Japan, and the United States. One of the largest is the National Familial Pancreatic Tumor Registry at Johns Hopkins. Studies of incident pancreatic cancers that developed in at-risk family members who were disease-free when the families enrolled in the registry have shown that members of familial pancreatic cancer kindreds have at least a sevenfold increased risk of developing

pancreatic cancer [4, 5]. In contrast, individuals who had only a single relative with pancreatic cancer or multiple cases of pancreatic cancer in more distance relatives had about a 2.5-fold increased risk. Risk increases as the number of affected family members increases [4].

Familial pancreatic cancer is unlike inherited cancer syndromes where there is a strong association between family history and age of onset, with higher proportion of younger patients reporting a family history compared to older patients. Overall, the mean age of onset of pancreatic cancer in familial pancreatic cancer kindreds is at most only 6 years younger than the mean age of onset in those without a family history of pancreatic cancer, with many studies reporting no significant difference in age of onset between patients with and without a family history of pancreatic cancer [4, 16, 19, 20].

In addition to pancreatic cancer, other cancers occur more frequently than expected due to chance alone in familial pancreatic cancer kindreds. Relatives of patients with familial pancreatic cancer are also at an increased risk of dying from cancer at other sites including breast (weighted standardized mortality ratio (wSMR) 1.66, 95% CI 1.15–2.34), ovarian (wSMR 2.05, 95% CI 1.10–3.49), and bile duct cancers (wSMR 2.89, 95% CI 1.04–6.39) [21]. Mortality from cancer was elevated among relatives of all pancreatic cancer cases, both those who were members of familial pancreatic cancer kindreds (wSMR 1.41, 95% CI 1.26–1.58) and members of apparently sporadic pancreatic cancer kindreds (SMR 1.55, 95% confidence interval (95% CI) 1.39–1.73) [21].

While the increased risks described above could be attributed to shared environmental factors or genetic factors, both twin studies and segregation models support shared genetic factors as the basis of the clustering of pancreatic cancer in some families. Heritability estimates from twin studies suggest 36% (95% confidence interval 0.00–0.53) of the variability in pancreatic cancer is due to shared genetic effects [22]. Segregation analysis supported a dominantly inherited major gene(s) with a population prevalence of ~0.7% responsible for the clustering of pancreatic cancer in families. Lifetime risk in gene carriers was estimated to be 32% by age 85 [8].

Pathology of Familial Pancreatic Cancer

Oftentimes the cancers that arise in individuals with a hereditary cancer syndrome have a different pathological phenotype than cancers that develop in individual with a family history of cancer. For example, mismatch repair-deficient cancers are far more common among individuals with Lynch syndrome patients [23, 24] and triple-negative breast cancers are more common among *BRCA1* mutation carriers [25]. However, to date no study had identified a significant difference between pancreatic cancers that develop in individuals who report a family history of pancreatic cancer and the pancreatic cancers that develop among individuals

Table 1 Pancreatic Cancer Susceptibility Genes and associated extrapancreatic malignancies

Gene	Extrapancreatic malignancies/associated syndrome
ATM	
BRCA1	Breast cancer, ovarian cancer
BRCA2	Breast cancer, ovarian cancer
CDKN2A	Melanoma
Mismatch repair genes (MLH1, MSH2, MSH6, PMS2)	Colorectal cancer, endometrial cancer
PALB2	Breast cancer
PRSS1	–
STK11	Colorectal cancer

with no family history (apparently sporadic cancers). Recently a detailed review was conducted, blinded to family history, of 519 familial and 651 sporadic pancreatic cancers [26]. In this study no statistically significant differences between familial and apparently sporadic invasive pancreatic cancers in histologic subtypes were reported. When a focused analysis was conducted on early-stage cancers that underwent surgical resection, no significant differences in mean tumor size, location, angiolymphatic invasion, perineural invasion, lymph node metastasis, or pathologic stage were observed.

In addition to tissue studies, no significant differences have been observed between familial and apparently sporadic pancreatic cancers at the genetic level. The frequency of mutations in the established pancreatic cancer driver genes of *KRAS*, *P53*, *SMAD4*, and *CDKN2A* was quite similar [27]. However, examination of the pancreata adjacent to the pancreatic cancer in resected tissue samples from patients with both familial and sporadic pancreatic cancers reported that individuals with familial pancreatic had a significantly higher rate of PanIN per square centimeter 2.75 (95% CI, 2.05–3.70: adjusted for age) than patients with sporadic pancreatic cancer. In addition, familial pancreatic cancer patients had a higher rate of PanIN-3 lesions 4.20 (95% CI, 2.22–7.93) and high-grade IPMNs was were observed only in patients with familial pancreatic cancer [28]. Thus, the current data indicates that while the cancers that develop in patients with familial pancreatic cancer are similar histologically and genetically to the cancers that develop in patients with apparently sporadic disease, familial patients have more precursors and more advanced precursors than apparently sporadic patients.

In 15–20% of familial pancreatic cancer patients, susceptibility to pancreatic cancer can be attributed to deleterious germline variants in one of the 11 established familial pancreatic cancer susceptibility genes that include *ATM*, *BRCA1*, *BRCA2*, *CDKN2A*, *MLH1*, *MSH2*, *MSH6*, *PALB2*, *PMS2*, *PRSS1*, and *STK11* (Table 1) [29–31]. In the remaining 80–85% of familial pancreatic cancer patients, the underlying cause of disease susceptibility is unknown (Fig. 2). Therefore, there are likely unidentified susceptibility genes driving increased pancreatic cancer risk in these patients and families.

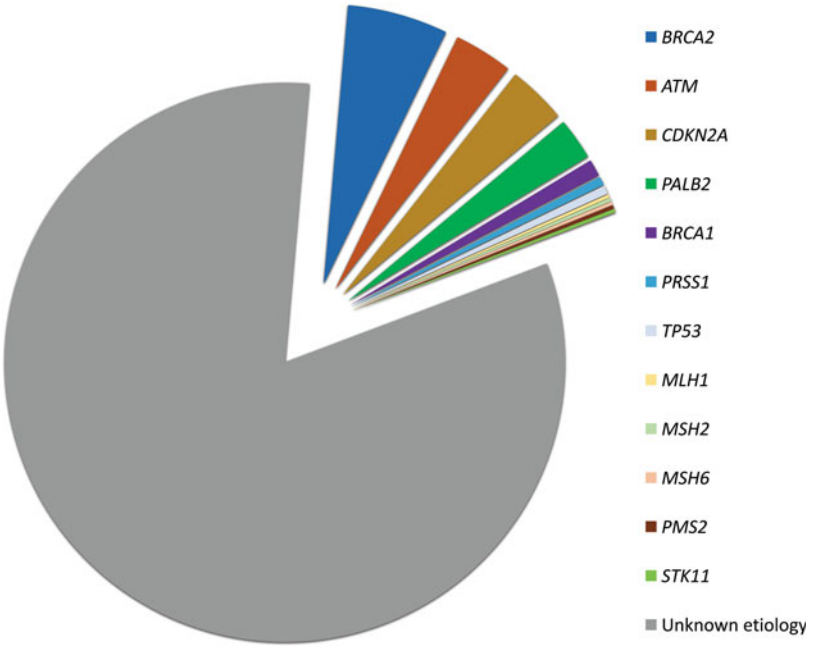

Fig 2 Fraction of familial pancreatic cancer attributable to established susceptibility genes

Familial Pancreatic Cancer Susceptibility Genes

Ataxia-Telangiectasia Mutated (ATM)

ATM is a 3,056-amino acid, 351 kDa, serine-threonine kinase that mediates DNA double-strand break repair through association with the MRE11–RAD50–NBS1 (MRN) complex, autophosphorylation of serine residues, and activation of numerous downstream effectors [32]. Located on chromosome 11, inheritance of biallelic deleterious germline variants in *ATM* results in the classic clinical syndrome ataxia-telangiectasia (A-T). A-T is a rare disorder that results in progressive neurological symptoms such as cerebellar ataxia, cutaneous telangiectasias, immunological deficiencies, and cancer susceptibility [32].

Using an unbiased approach to search for pancreatic cancer susceptibility genes, Roberts and colleagues sequenced the germline exomes of 22 individuals from 10 families and the germline genomes of 16 individuals from 6 families. Using a filter-based approach, they identified heterozygous deleterious germline variants in *ATM* in two families that segregated with disease. In a replication cohort of 166 familial pancreatic cancer patients and 190 spousal controls, four heterozygous deleterious germline variants were found in cases compared to none in controls. This association was even stronger for the most severely affected familial pancreatic

cancer kindreds, with three or more affected relatives [33]. This finding has been replicated in other studies [31, 34, 35]. Furthermore, whole-exome sequencing of pancreatic adenocarcinomas identified *ATM* somatic alterations, mutations, and copy number loss events, in 8% of patients, lending further support for the role that *ATM* plays in pancreatic tumorigenesis [36].

BRCA2, DNA Repair Associated (BRCA2)

BRCA2, also known as *FANCD*, encodes a protein whose function is to repair DNA double-strand breaks and interacts with *BRCA1* and *PALB2*. *BRCA2* was first identified through the study of families with an aggregation of early-onset breast cancer as well as the observation of a homozygous deletion in the region harboring the *BRCA2* gene on chromosome 13 in a pancreatic cancer. Women with a deleterious mutation in *BRCA2* have marked increase risk of cancer. In particular, they carry a 49% (95% CI, 40–57%) lifetime risk of breast cancer and an 18% (95% CI, 13–23%) risk of ovarian cancer. Males are at an increased risk of breast cancer as well. The first study identifying an important role for germline *BRCA2* mutations in pancreatic cancer risk was a case series of 41 pancreatic cancer patients where 4 (7%) harbored deleterious *BRCA2* mutations [37]. The prevalence of deleterious *BRCA2* mutations does increase as family history of pancreatic cancer increases with up to 16% of patients from families with three or more pancreatic cancers carrying germline *BRCA2* mutations [38]. A German study identified 12% of patients from familial pancreatic cancer kindreds had deleterious *BRCA2* mutations [39]. In 180 pancreatic cancer patients with either a first- or second-degree relative with pancreatic cancer, ten deleterious germline mutations in BRCA2 were found, representing 6% of familial kindreds [40]. While the prevalence of deleterious *BRCA2* mutations is higher among those with familial pancreatic cancer, a significant fraction of pancreatic cancer patients with apparently sporadic disease are also found to have deleterious *BRCA2* mutations. This was first demonstrated in an initial study by Goggins et al. and supported by more recent studies including a Canadian study where up to 3.6%, pancreatic cancer patients, unselected for family history, were found to have deleterious mutations in *BRCA2* [41]. Similarly, 4.6% of unselected Ashkenazi Jewish pancreatic cancer patients undergoing resection are reported to harbor a deleterious germline mutation in BRCA2 [42]. Given the strong association of *BRCA2* mutations with risk of breast and ovarian cancers, many pancreatic cancer patients with deleterious *BRCA2* mutations report a family history of one of these cancers. However many do not [37, 38].

There is still considerable uncertainty of the precise risk of pancreatic cancer associated with *BRCA2* mutations, in part because the studies of lifetime risk of pancreatic cancer among *BRCA2* carriers are limited to families ascertained based on history of breast/ovarian cancer. These studies suggest the *BRCA2* mutation carriers have a 3.51–5.79-fold increased risk [43, 44] of pancreatic cancer.

BRCA1, DNA Repair Associated (BRCA1)

Like BRCA2, the BRCA1 gene plays an important role in DNA repair [27, 28] and confers an increased risk of pancreatic cancer. Mutations in *BRCA1* confer a lifetime risk of breast cancer of 57% (95% CI, 47–66%) and lifetime risk of ovarian cancer of 40% (95% CI, 35–46%). Studies examining the association of *BRCA1* and pancreatic cancer are less consistent than those examining the association between *BRCA2* and pancreatic cancer. One study reported a *BRCA1* mutation prevalence of 1.2% among familial pancreatic cancer patients [45]. However, other studies did not report an excess *BRCA1* mutations among patient with pancreatic cancer [42, 46], but this lack of association could be due to a lack of power to detect the modest association between *BRCA1* and pancreatic cancer. This risk of pancreatic cancer among BRCA1 carriers, as ascertained from kindreds with a clustering of breast and ovarian cancer, is 2.26–4.11 fold higher than the general population [44, 47]. A family history of breast and ovarian cancer in addition to pancreatic cancer can strongly suggest a *BRCA1* mutation. This is particularly true for ovarian cancer where a significant fraction of ovarian cancer is explained by *BRCA1* mutations. However, not all pancreatic cancer patients with inherited *BRCA1* mutations present with a family history of pancreatic, breast, or ovarian cancer.

Partner and Localizer of BRCA2 (PALB2)

PALB2, also known as *FANCN*, encodes a protein that is a critical effector in homology-directed repair of DNA double-strand breaks and interacts with *BRCA1* and *BRCA2* [48, 49]. PALB2 is also a component of the Fanconi anemia pathway, and biallelic deleterious germline variants result in a Fanconi anemia phenotype similar to loss of *BRCA2* [49]. Furthermore, monoallelic deleterious germline variants result in an increased risk of breast and pancreatic cancers.

The identification of *PALB2* mutations in individuals with a family history of pancreatic cancer was the first study to demonstrate that whole-exome sequencing can identify the cause of a hereditary disease. In this study, the entire coding regions of 20,661 genes were sequenced in germline and tumor DNA from a patient with familial pancreatic cancer [50]. Jones and colleagues employed a novel filter-based approach and were able to identify a germline heterozygous, protein-truncating variant in *PALB2* that was rare in the general population, and importantly, occurring with a somatic mutation in *PALB2* in the tumor of the sequenced patient. In an independent panel of 96 familial pancreatic cancer patients, the authors identified three patients with premature truncating variants in *PALB2*. These observations provided the first evidence implicating *PALB2* in pancreatic cancer susceptibility, and it was the first time the gene responsible for an inherited syndrome had been identified using whole-exome sequencing.

Since the initial identification of *PALB2* as a familial pancreatic cancer susceptibility gene, additional studies have confirmed the association of deleterious germline

variants in *PABL2* with pancreatic cancer. In one study, *PALB2* was sequenced in 254 patients with either sporadic or familial pancreatic cancer resulting in the identification of a single patient with a heterozygous germline deletion that encompassed multiple exons [51]). In a European study of 81 familial pancreatic cancer families without a known deleterious germline variant in *BRCA2*, three deleterious variants in *PALB2* were identified [52]. In a recent Pancreatic Cancer Genetic Epidemiology (PACGENE) Consortium study, 727 unrelated pancreatic cancer patients, including 521 patients that met the criteria for familial pancreatic cancer, had their germline DNA sequenced to Clinical Laboratory Improvement Amendments (CLIA) standards. In this study, only four deleterious germline variants, representing 0.6% of sequenced patients, were identified in *PALB2*. Similarly, Roberts and colleagues sequenced the germline genomes of 638 familial pancreatic cancer patients from 593 kindreds and found 5 deleterious variants in PALB2, representing 0.8% of kindreds [31].

The lifetime risk of pancreatic cancer in individuals with a deleterious germline variant in *PALB2* is still unclear. Relatives of breast cancer patients with a deleterious germline variant in *PALB2*, however, have a 5.93-fold increased risk of developing breast cancer (95% confidence interval, 2.41–14.56) [53]. Recent evidence, however, suggests that deleterious germline variants in *PALB2* explain about 1% of familial pancreatic cancer. Future studies will be needed to assess the magnitude of increased risk associated with deleterious germline variants of *PALB2* and assess whether routine clinical testing of familial pancreatic cancer patients is warranted.

Mismatch Repair Genes (MLH1, MSH2, MSH6, PMS2)

The mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2* are essential components of DNA repair resulting from base pair mismatches during replication. Deleterious germline variants in these genes result in Lynch syndrome (also known as hereditary nonpolyposis colorectal cancer), an autosomal dominant condition that carries a significant lifetime risk of colorectal cancer. Tumors arising in Lynch syndrome patients are deficient in mismatch repair due to the presence of a deleterious germline variant and second somatic hit in the same mismatch repair gene. As a consequence, tumors in Lynch syndrome patients have demonstrable microsatellite instability (MSI) and a high number of somatic mutations.

In addition to colorectal cancer, patients with Lynch syndrome are also at an increased risk of extracolonic malignancies that include urinary tract cancers, endometrial cancer, breast cancer, small intestinal cancer, gastric cancer, liver cancer, prostate cancer, and pancreatic cancer [54]. The increased risk of pancreatic cancer associated with a deleterious germline variant in a mismatch repair gene is estimated to be 8.7-fold to age 70 (95% confidence interval: 4.7–15.7-fold) [55]. Recent genome-wide sequencing studies have found limited numbers of such deleterious germline variants in familial pancreatic cancer patients, with estimated prevalence between 0% and 2.1% [35], [31]. Lynch syndrome, therefore, may be a rare cause of familial pancreatic cancer.

Protease Serine 1 (PRSS1)

The *PRSS1* gene encodes cationic trypsin. Inherited inactivating mutations in this gene result in hereditary pancreatitis, a debilitating disorder of early-onset, recurrent, severe pancreatitis that affects one to six people per million [56]. While deleterious germline variants in *PRSS1*, specifically p.R122H and p.N29I, are most commonly observed in hereditary pancreatitis patients, other genes are also known to contribute either directly or indirectly through multigene interactions to increase pancreatitis risk; these include variants in *SPINK1*, *CPA1*, *CTRC*, and *CFTR* [56, 57].

Hereditary pancreatitis patients also have a significantly increased risk of pancreatic cancer, with a cumulative risk to age 70 of 40–44% and age 75 of 54% [57–59]. Hereditary pancreatitis patients who are smokers are twice as likely to develop pancreatic cancer, and the mean age of onset of pancreatic cancer in smokers with chronic pancreatitis is 20 years younger than hereditary pancreatitis patients who are not smokers [60]. Interestingly, compared to all other established familial pancreatic cancer susceptibility genes, *PRSS1* is not a tumor suppressor gene, and its action is not intrinsic to the pancreatic cancer cell of origin. Instead, *PRSS1* acts an external factor to promote tumorigenesis, presumably through repeated instances of injury, inflammation, and repair.

Serine/Threonine Kinase 11 (STK11)

STK11, also known as liver kinase B1 (LKB1), is a serine/threonine kinase located on chromosome 19. Inherited deleterious variants in *STK11* are the predominant cause of Peutz–Jeghers syndrome, an autosomal dominant condition associated with hamartomatous polyps of the gastrointestinal tract and mucocutaneous hyperpigmentation [61]. Patients with Peutz–Jeghers syndrome also have a greatly increased risk of various gastrointestinal and extra-gastrointestinal malignancies [62, 63]. Specifically, in a large series of Italian Peutz–Jeghers syndrome patients, relative overall cancer risk was 15.1-fold higher than the general population, with gastrointestinal and pancreatic malignancies showing the greatest increases of 126.2-fold and 139.7-fold, respectively [64].

Cyclin-Dependent Kinase Inhibitor 2A (CDKN2A)

CDKN2A is a tumor suppressor gene that encodes both the $p16^{INK4A}$ and $p14^{ARF}$ proteins through transcription of alternate open reading frames. p16 acts to limit cell cycle progression through interactions with cyclin-dependent kinase 4 (CDK4) that inhibits retinoblastoma protein phosphorylation and subsequent release of E2F transcription factors [65]. p14 expression results in p53 stabilization and inhibition of cell cycle progression through binding MDM2, a negative regulator of p53 [66]. As a critical component of several cell cycle pathways, it is

unsurprising that *CDKN2A* is the most commonly mutated or deleted tumor suppressor gene in pancreatic cancers, with functional loss in up to 90% of tumors [67]. Furthermore, somatic mutation or deletion of *CDKN2A* appears to be an early event in pancreatic tumorigenesis, with functional loss observed in pancreatic intraepithelial neoplasms, an early pancreatic adenocarcinoma precursor lesion [68–70].

Deleterious germline variants in *CDKN2A* are the underlying cause of melanoma in up to 40% of families with an inherited predisposition to the disease [71, 72]. Deleterious germline variants in *CDKN2A* have been also identified in individuals with pancreatic cancer. McWilliams and colleagues found that 0.6% of pancreatic cancer patients unselected for family history had deleterious germline variants in *CDKN2A* [73]. When considering only those patients with a family history of pancreatic cancer, 3.3% of patients had a deleterious variant in *CDKN2A*.

The risk of pancreatic cancer in individuals harboring a deleterious germline variant in *CDKN2A* is increased 32-fold (95% confidence interval: 1.5–47.7-fold), with an estimated cumulative risk of 57.6% by age 80 (95% confidence interval, 7.8–85.7%) (74). The risk of pancreatic cancer is also significantly increased 7.4-fold (95% confidence interval: 2.3–18.7-fold) in first-degree relatives of melanoma patients with a deleterious germline variant in *CDKN2A* compared to the first-degree relatives of melanoma patients without a deleterious germline variant in *CDKN2A* [74]).

Candidate Familial Pancreatic Cancer Susceptibility Genes

Advances in sequencing and genotyping technology over the last 10 years have allowed rapid, high-throughput genome-wide determination of germline single nucleotide variants, insertions, deletions, and copy number alterations in individuals with familial pancreatic cancer. These powerful technologies have been coupled with filter-based analyses that utilize operator-defined criteria and thresholds integrating variant-level, gene-level, and population-level data with knowledge of disease epidemiology and genetics. Such approaches have led to the identification of the familial pancreatic cancer susceptibility genes *ATM* and *PALB2* [33, 50].

Recent whole-genome and whole-exome sequencing of familial pancreatic cancer patients has highlighted the genetic heterogeneity underlying susceptibility to pancreatic cancer and the difficulties in identifying further susceptibility genes [31]. Using a filter-based approach to assess variants most likely deleterious to and contributing to pancreatic cancer susceptibility, specifically, rare heterozygous premature truncating variants, has led to the identification of candidate susceptibility genes, for example, *APC*, *BUB1B*, *CPA1*, *FANCC*, *FANCG*, *FAN1*, *NEK1*, and *RHNO1* [31, 75]. Interestingly, several of these candidate genes are associated with other hereditary cancer syndromes, implicated in DNA repair, or chromosome maintenance. Furthermore, deleterious germline variants in *CPA1* have recently been

associated with hereditary pancreatitis, a significant risk factor for pancreatic cancer [76, 77]. However, further validation and characterization of these candidate genes is necessary before integrating them into clinical decision-making.

Low-Risk Common Genetic Variants Associated with Pancreatic Cancer

The development of high-density SNP arrays enabled large-scale genome-wide association studies to identify low-penetrance common genetic variants that are associated with pancreatic cancer risk. To date, genome-wide association studies have identified common variants in the following regions as significantly associated with pancreatic cancer risk: 9q34 (*ABO*), 13q21, 1q31 (NR5A2), 5p15.33 (*CLPTM1L* and *TERT*), 7q32.3, 16q23.1 (*BCAR1/CTRB1/CTRB2*), 13q12.12 (*PDX1*), 22q12.1 (*ZNRF3*), 2p13.3 (near *ETAA1*), 3q29 (*TP63*), 7p13 (*SUGCT*), and 17q25.1 (*LINC00673*) [78–82]. While each of these variants has only a small effect on pancreatic cancer risk, with per-allele odds ratios ranging from 1.1 to 1.3, overall they explain approximately 3% of the underlying heritability of pancreatic cancer. Many of these same variants have been shown also to have a similar association with familial pancreatic cancer [9].

Screening of High-Risk Individuals

The overall 5-year survival rate for pancreatic is less than 8%. Survival among individuals with early-stage disease who undergo surgical resection exceeds 40%. Identifying early-stage disease or individuals with advanced precursor lesions including high-grade intraductal papillary mucinous neoplasm (IPMN) or high-grade pancreatic intraepithelial neoplasia (PanIN-3) offers the best hope for potentially curative therapeutic interventions.

While early detection screening is not recommended, consensus screening guidelines have been developed to guide ongoing early detection studies for high-risk individuals. For screening studies, high-risk is typically defined as a first-degree relative of a patient meeting the criteria for familial pancreatic cancer, an individual with a known deleterious germline variant in a familial pancreatic cancer susceptibility gene, and at least one affected first-degree relative [83]. Ideally, all screening should occur as part of an ongoing clinical trial or at a center with expertise in early detection screening for pancreatic cancer. Screening of these patients is recommended to include endoscopic ultrasound (EUS) and/or magnetic resonance imaging (MRI). While there is also considerable debate about when to begin screening, most studies begin screening in the fifth decade of life or 10 years younger than the earliest age-of-onset of pancreatic cancer in the family. As not all high-risk patients have the same pancreatic cancer risk, the diagnostic yield as measured by incident cases detected is likely to vary based on patient characteristics including germline mutation status.

Personalized Therapeutic Approaches

As cancer is in essence a genetic disease, much effort has been made to identify novel therapeutic approaches to target the specific genetic changes underlying the development of a tumor in a patient. Knowledge of the genetics underlying pancreatic cancer susceptibility in familial pancreatic cancer provides an uncommon opportunity to realize the promise of such personalized therapeutic approaches.

Biallelic loss of *ATM*, *BRCA1*, *BRCA2*, or *PALB2* in the tumor results in defects in DNA double-stand break repair and an opportunity for personalized therapeutic approaches. Biallelic loss of one of these genes in high-risk patients is often the result of a deleterious germline variant and a second somatic mutation or loss-of-heterozygosity event in the tumor. Biallelic somatic loss of one of these genes, however, is also a possibility and would result in similar therapeutic vulnerability. Specifically, patients with tumors harboring defects in homology-directed DNA double-strand break repair are more susceptible to DNA-damaging agents such as platinum-based chemotherapy, DNA cross-linkers including mitomycin-C [84], and ionizing radiation. Furthermore, such tumors are also susceptible to poly [ADP-ribose] polymerase 1 (PARP-1) inhibitors through synthetic lethal inhibition of base excision repair [85–90].

Another subset of patients that may benefit from personalized therapeutic approaches are those with mismatch repair-deficient tumors. Similar to defects in DNA double-strand break repair, mismatch repair-deficient tumors can occur either through the acquisition of an inherited deleterious germline variant in one of the four mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*), coupled with a somatic alteration in the same gene, or purely by virtue of somatic loss of one of these genes. In either situation, mismatch repair-deficient tumors are more susceptible to programmed death 1 (PD-1) blockade than tumors proficient in mismatch repair [91]. While reported inheritance of deleterious variants in mismatch repair genes and mismatch repair deficiency in pancreatic cancers is uncommon and possibly associated with a medullary phenotype [92], the responses seen in this subset of patients warrant appropriate germline and/or tumor analysis and classification [31, 35].

Conclusion

The understanding of the genetic etiology of pancreatic cancer in high-risk individuals remains incomplete. Despite recent advances in the understanding of the genetic basis of pancreatic cancer risk, the etiology of increased risk in the majority of familial pancreatic cancer kindreds is still unknown and only a fraction of the heritability of pancreatic cancer is explained. In addition, improved early detection methods are needed in order to reduce the burden of pancreatic cancer in these high-risk populations. Finally, knowledge of the inherited and somatic genetics that underlie the development of pancreatic cancer has led to advancements in personalized therapies, for example, the use of PARP-1 inhibitors in patients with

homology-directed repair-deficient tumors or the use of PD-1 inhibitors in patients with mismatch repair-deficient tumors. Future efforts are necessary to guide patient selection, assess combination therapies, and determine optimal dosing strategies to fully leverage these therapies in the treatment of pancreatic cancer.

Abstract

Pancreatic neuroendocrine neoplasias (pNENs) may arise sporadically or in the setting of an inherited tumor syndrome. These syndromes comprise the multiple endocrine neoplasia type 1 (MEN1), the von Hippel-Lindau (VHL) syndrome, and the neurofibromatosis type 1 (NF-1). The prevalence and the different entities of pNENs differ significantly between these syndromes resulting in distinct treatment and screening recommendations.

Treatment of pNENs in the setting of an inherited tumor syndrome should consider the natural history of the disease, clinical symptoms, and the potential for malignant transformation which has to be considered individually for every patient.

Multiple Endocrine Neoplasia Type 1 (MEN1)

Introduction

MEN1 is an autosomal dominant inherited disease caused by germ line mutations in the *Menin* gene on chromosome 11q13 [1–3]. It has a penetrance of over 90% by the age of 50 years, and the incidence is estimated to be between 2 and 20 per

100 000 [4]. As first described by Wermer in 1954, affected patients display an "adenomatosis of endocrine glands" [5]. Before 1997, when the *Menin* gene was identified, an involvement of more than two characteristically affected organs was suspicious for MEN1. Patients can develop endocrine lesions in the parathyroid glands, the pancreas or duodenum, the anterior pituitary gland, and the adrenals, respectively. The wide spectrum of tumors also includes neuroendocrine tumors of thymus and bronchial tree, lipomas, cutaneous fibromas, and thyroid neoplasms (Table 1). Since the identification of the causative *Menin* gene, more than 1,000 mutations have been identified [3]. So far genotype-phenotype studies have not detected any statistical relevant direct correlations [6]; nevertheless, in some family cases, recurrent tumor patterns are notified. The large MEN1 cohort of the GTE (Groupe d'etude des Tumeurs Endocrines) group revealed that MEN1 patients harboring a mutation in the JunD interaction domain have a higher risk of death [7]. A retrospective analysis of a prospective collected database revealed that there exists a genotype-phenotype correlation regarding pNENs. MEN1 patients with mutations leading to CHES1-LOI (loss of interaction with the checkpoint kinase 1) have a higher risk of malignant pNENs with an aggressive course of disease. Furthermore, an aggressive course of disease was hypothesized for MEN1 patients with large *MEN1* gene deletions.

Table 1 Expression of MEN1

Affected organ	Tumor	Frequency (%)	Hormone	Clinical syndrome
Parathyroid gland	Hyperplastic parathyroid	90	Parathyroid hormone	Primary hyperthyroidism
Pancreas and duodenum	Gastrinoma	20–30	Gastrin	ZES
	Insulinoma	5–10	Insulin	Hypoglycemia
	NF-pNEN	50–80	PP	None, local tumor growth
	Vipoma	1	VIP	WDH
	Glucagonoma	3	Glucagon	Glucagonoma S
Pituitary gland	Prolactinoma	20–60	Prolactin	Galactorrhea
	nf		None	Visual loss
Adrenal gland	nf	20–60	None	None
	f		Aldosterone, cortisol	Cushing's S, Conn S
Thymus	NEN	2	CgA	
Lung	NEN	3	Serotonin, CgA	Carcinoid S
Stomach	NEN	3	CgA	
Skin	Lipoma	Up to 20	None	None
	Fibroma	Up to 80	None	None

ZES Zollinger-Ellison syndrome, *nf-pNEN* nonfunctioning pancreatic neuroendocrine neoplasia, *PP* pancreatic polypeptide, *VIP* vasoactive intestinal polypeptide, *WDH* watery diarrhea and hypokalemia, *nf* nonfunctioning, *NEN* neuroendocrine neoplasia, *CgA* chromogranin A, *S* syndrome

Clinical symptoms which are associated with hormone excess comprise in declining frequency hypercalcemia, nephrolithiasis, peptic ulcer disease, hypoglycemia, visual field loss, galactorrhea-amenorrhea, and rarely Cushing's syndrome. The onset of the different manifestations varies considerably, although hypercalcemia is frequently the first manifestation by the age of 20, followed by Zollinger-Ellison syndrome between 30 and 40 years of age.

Primary hyperparathyroidism is observed in up to 97% of MEN1 patients, and the parathyroid glands are therefore the most frequently affected organs [1]. Pancreatic neuroendocrine neoplasias (pNENs) are the second most manifestation with a frequency of 60–90%. Since medical treatment of ulcer disease has improved by introducing proton pump inhibitors (PPI), malignant pNENs became the most important determinant of survival in MEN1 patients [8]. PNENs can be either functioning (gastrinoma, insulinoma, vipoma, glucagonoma) or nonfunctioning. Gastrinomas, which are mostly located in the duodenal wall, account for 60% of functioning pNENs followed by insulinoma with approximately 20%.

Patients with MEN1 have a decreased life expectancy, with a 50% probability of death by the age 50. The major determinant of survival is malignant pNENs (G1/G2), including malignant gastrinomas, since up to 50% develop liver or other distant metastases [8]. The surgical management of pNENs in MEN1 patients remains controversial, because they have unique features compared to sporadic pNENs. They are multiple and distributed through the entire pancreas, which has been proven in autopsy studies and studies with resected specimen of MEN1 patients [9]. However, total pancreatectomy seems to be an "overtreatment" in these patients, especially since postoperative brittle diabetes might be a life-threatening condition.

Lifelong screening comprising careful hormonal assessments and regular imaging studies is supposed to detect malignant transformation at the earliest stage and is therefore strongly emphasized in current expert clinical practice guidelines for MEN1 patients. In addition, if MEN1 is suspected based on the personal and family history, a genetic testing of the index patient for a *MEN1* gene mutation should be performed after genetic counseling. The identification of a *MEN1* mutation in the index patient gives the possibility of a predictive genetic testing of family members after obligate genetic counseling. Mutation-positive family members should be enrolled in controlled screening programs, whereas mutation-negative family members can be omitted from such screening.

Natural History of pNENs in Patients with MEN1

The natural history of pNENs in MEN1 patients is still difficult to define due to the variability and the rarity of the disease. Approximately 30–50% of MEN1-associated pNENs are functional and cause symptoms and distinct syndromes by a hypersecretion of distinct hormones (e.g., gastrin, insulin). Nonfunctioning pNENs (NF-pNENs) are responsible for the other 50–70% of pNENs and are characterized by the absence of peptide hypersecretion (a part from pancreatic polypeptide (PP)). They

sometimes become symptomatic due to local tumor growth and/or advanced disease and are commonly detected during regular screening. PNENs in MEN1 patients are often multiple (up to 50), and NF-pNENs often coexist besides a clinically dominant functioning lesion. Since 80% of MEN1 patients develop pNENs and these tumors represent the most common disease-related cause of death, the identification and management of these lesions requires high awareness.

Gastrinoma is the most common functional pNEN in MEN1 patients and in contrast to its sporadic counterpart located in over 90% within the duodenal wall underlying the mucosa [10]. Duodenal tumors are often small measuring from 1 to 10 mm and had developed lymph node metastases in 40–60% at the time of diagnosis [11, 12]. However distant metastases to the liver and bones are less frequent than in sporadic disease, and MEN1-associated gastrinoma is suggested to follow a less aggressive course compared to its sporadic counterpart [13]. Nevertheless Gibril et al. report also an aggressive gastrinoma phenotype in 23% of MEN1 patients which is associated with large (>30 mm) pancreatic tumors, high serum gastrin levels, and liver and bone metastases [14].

Insulinoma is the second most frequent functioning pNEN in MEN1 patients with a prevalence of 10–20% [15]. Malignancy has been rarely reported and may develop in up to 9% of patients [16]. Coexistence with gastrinoma is observed in approximately 10%, although one tumor is dominating the hormone excess and consequently the clinical syndrome.

Vipomas occur rarely, are almost exclusively malignant, and are located in the pancreatic body or tail. Patients suffer from watery diarrhea with severe electrolyte disbalances, especially if they present already with liver metastases.

Glucagonomas develop in less than 3% of MEN1 patients and glucagon excess is not necessarily associated with a clinical syndrome. Especially small tumors (<3 cm) are often asymptomatic, but tumors are usually large and tend to be malignant in up to 80% [17, 18]. In cases with diffuse metastases, migratory, necrolytic skin rash, glossitis, stomatitis, angular cheilitis, diabetes, severe weight loss, and diarrhea may occur (Table 1).

Nonfunctioning pNENs with a prevalence of 50–80% are increasingly diagnosed based on modern imaging modalities in controlled screening programs. A high prevalence of these lesions could already be detected in young MEN1 patients in the second decade of life [19]. The malignant potential of these tumors varies considerably, but the tumor size seems to be a predictor for malignant transformation. In small retrospective series, an incidence of 20% lymph node metastases (LNM) in tumors larger than 1 cm and an incidence of LM (liver metastases) of 30% in tumors larger than 2 cm have been reported, which means vice versa that LNM and LM have not been observed in tumors smaller than 1 cm [20, 21]. The increasing number of resected NF-pNENs in prospective controlled screening programs revealed that malignancy is rarely observed in tumors smaller than 10–20 mm. Follow-up studies with endoscopic ultrasound suggested that most small NF-pNENs grow very slowly, but they definitely own a malignant potential [22] (Table 2).

Table 2 Screening in MEN1 at the Marburg ENETS Center of Excellence

Screening in MEN1 patients	
Biochemical (annually)	
Parathyroid glands	Calcium, parathyroid hormone
pNEN	Gastrin, pancreatic polypeptide, chromogranin A
	Fasting test, if an insulinoma is suspected
	Secretin provocation test, if a gastrinoma is suspected
Pituitary gland	Prolactin, IGF-1, ACTH
Imaging	
MRI abdomen	Annually or if tumor is suspected
Ga-68 DOTATOC-PET/CT	If tumor is suspected or every 2–3 yrs.
MRI of the pituitary gland	Every 3 yrs. or in case of hormone excess, visual impairment
EUS	Annually or if tumor is suspected
CT of the chest	Every 3 yrs. or if a thymic or bronchial carcinoid is suspected

pNEN pancreatic neuroendocrine neoplasia, *IGF-1* insulin-like growth factor 1, *ACTH* adrenocorticotropic hormone, *5-HIAA* 5-hydroxyindoleacetic acid, *yrs.* years, *MRI* magnetic resonance imaging, *CT* computed tomography

Clinical Management

Regarding the surgical management of MEN1-associated pNENs, the diagnostic workup and the surgical strategy have to be adopted to the tumor entity, the patients' health condition, and his/her preferences after detailed counseling. However, some controversies exist concerning the extent, timing, and benefit of pancreatic resections in MEN1 patients, especially since profound evidence-based data are still lacking. However, a consensus conference has proposed guidelines for the treatment of MEN1-pNENs [1].

Gastrinoma

Clinical Symptoms

The clinical appearance of MEN1-associated Zollinger-Ellison syndrome is similar to its sporadic counterpart (see previous chapter). It is characterized by abdominal pain due to peptic ulcers and heartburn with or without diarrhea. Hypercalcemia increases symptoms in MEN1 patients with concomitant primary hyperparathyroidism. Quite the contrary is observed in patients after parathyroid surgery with hypocalcemia resulting in milder symptoms and even false-negative secretin provocation tests. This has led to the recommendation to first cure the pHPT before the resection of gastrinoma [23].

Diagnostic Procedures

The diagnosis is established by clinical symptoms, an elevated serum gastrin level in the presence of acid in the stomach (pH <4), and a positive secretin-provocation test

(see sporadic gastrinoma). To prevent a false-positive secretin test, a coexisting primary hyperparathyroidism should be treated before testing and a 48-h pause of proton pump inhibitor treatment prior to secretin-provocation test should be initiated.

After the biochemical diagnosis is established, further workup should include endoscopic ultrasound (EUS) supplemented by magnetic resonance imaging (MRI) and SRS PET-CT imaging (e.g., Ga-68-DOTATOC-PET/CT) to visualize pNENs and potential metastases. In contrast to sporadic gastrinoma, MEN1-associated gastrinomas are predominantly localized in the second and third portion of the duodenum (50% vs. >90%) and are in the majority less than 10 mm in size. Therefore, they often cannot be localized by preoperative imaging. Although an exact preoperative localization of MEN1 gastrinoma is often difficult, the gastrin source can be regionalized by a selective arterial secretin injection test (Imamura technique) [24]. This regionalization facilitates the decision for the adequate surgical procedure which might include a pylorus-preserving partial pancreaticoduodenectomy. For further therapy in MEN1-ZES patients, it should be considered that the majority of these patients have concomitant pNENs besides gastrinomas [25].

Treatment

The target organ of MEN1-ZES is the duodenum and rarely the pancreas. The management of ZES in MEN1 patients is controversial reaching from medical treatment with proton pump inhibitors alone to extensive pancreatic resections. This controversy has several reasons. On one hand, the course of disease is rather mild, and MEN1-ZES is considered by many experts as a surgically incurable disease. Therefore, recent expert guidelines suggest medical management using PPI for the majority of patients [1]. On the other hand, it has been shown that medically treated ZES patients developed liver metastases more frequently than surgical-managed patients (29% vs. 5%) [26]. Thus, there is some evidence that surgery may reduce the malignant spread of gastrinoma and increase survival. However, there is no consensus on the indication and the timing of surgery, since there is yet no proven parameter that indicates an aggressive course of disease, and long-term survival is excellent in the majority of patients. As long as this is the case, an imageable pNEN >2 cm, although most likely nonfunctioning, seems to be a good surrogate parameter to indicate surgery in order to prevent distant metastatic disease. However, the higher chance of cure when performing a partial pancreaticoduodenectomy (PPD) resection at the time of biochemical ZES evidence should be discussed with regard to benefits and risks. Although there is disagreement on the optimal surgical procedure, it is obvious that any operation for MEN1-ZES should include duodenotomy or even resection of the duodenum to provide a chance of cure. PPD resection results in the highest chance of long-term biochemical cure [27], but the excellent long-term survival after less-aggressive non-PPD resections and the potential increased postoperative mortality and long-term morbidity of PPD resections make its current role unclear. Although prospective controlled studies are warranted to clarify these issues, it is unlikely that such long-term studies will be

performed given the rarity of the disease and the necessity of long-term protocols. Therefore, MEN1 patients should be cared for by multidisciplinary teams comprising relevant specialists with experience in the diagnosis and treatment of neuroendocrine tumors. It would be a major goal to identify molecular or other parameters that indicate an aggressive course of MEN1-ZES to facilitate the decisions regarding the timing and type of surgery. At present, the indication and type of surgical procedure should be individualized according to preoperative findings, patient's history (e.g., age, preexisting insulin-dependent diabetes), and patient's preference.

Some experts recommend an aggressive surgical approach as soon as the biochemical diagnosis of ZES is established [25]. The goal of this philosophy is to prevent the development of liver metastases and to improve long-term survival, although biochemical long-term cure might not be achieved.

Surgery can be indicated in patients with MEN1-ZES when diffuse metastatic spread has been excluded by preoperative imaging and a coexisting pHPT has been cured before. At surgery a duodenotomy and excision of palpable tumors and enucleation of pancreatic head tumors and spleen-preserving distal pancreatectomy to the level of the portal vein with peripancreatic lymphadenectomy as recommended by Thompson et al. [28] were considered the standard procedure. The biochemical cure rate of this procedure is low and varies between 0% and 33%, but the development of liver metastases during long-term follow-up does not exceed 16% (Table 3). Therefore, some authors proposed a pylorus-preserving partial pancreaticoduodenectomy (PPPD) for MEN1-ZES [27]. The rationale is that MEN1 is a genetically determined disease and that the ZES will recur as long as the target organ duodenum exists. In addition, it has been shown that MEN1-associated gastrinomas are associated with hyperplastic gastrin cell lesions and very small gastrin-producing microtumors less than 500 μm in diameter [29] which cannot be removed by local excision since they are not palpable. Finally, 95% of MEN1 gastrinomas are located within the gastrinoma triangle and occur multiple in the duodenum [30]. PPPD has been evaluated in smaller case series and achieved biochemical cure rates from 77% to 100% [27] (Table 4). However, before PPPD can be suggested as a standard procedure in MEN1 patients with ZES, much more data need to be analyzed, especially the long-term side effects that have to be

Table 3 Results after surgical excision and/or non-PD resections of MEN1-associated gastrinoma (Modified from Bartsch and Albers [25])

PD pancreaticoduodenectomy, *ST* secretin provocation test, *LM* liver metastases

carefully evaluated. Pancreatic-preserving duodenectomy might be another favorable alternative, but it is a technically demanding procedure, and the cure rates are lower after PPD, and the morbidity is high.

In recurrent or persistent MEN1-associated ZES, surgery has to be carefully indicated in every patient.

The decision depends on the severity of ZES, the type of the initial procedure, the presence of lymph node or liver metastases, and the patients' health condition. Given the relatively slow progression of the disease, the reoperation should avoid the situation of a total pancreaticoduodenectomy, since the side effects of this procedure might be more life-threatening than the ZES.

Prognosis

Compared to sporadic gastrinomas, MEN1-associated gastrinomas have a more favorable prognosis. The overall survival of operated MEN1-associated gastrinomas is excellent with 10- and 20-year survival rates of 96% and 85%, although 40–60% of patients have lymph node metastases at initial laparotomy [36].

Insulinoma

Clinical Symptoms

Symptoms are mainly caused by hypoglycemia and are described in detail in the chapter of sporadic pancreatic endocrine tumors.

Diagnostic Procedures

The biochemical diagnosis is established by a supervised positive 72-h fasting test, defined by a pathological insulin-glucose index and symptomatic hypoglycemia. CT, MRI, SRS imaging, and US demonstrated a decreased sensitivity (0–60%) in the

preoperative localization compared to EUS (60–95%) (see sporadic insulinomas). Most MEN1 patients have multiple, frequently nonfunctioning tumors in the pancreas making the identification of the insulinoma difficult. In some cases, with multiple pNENs >1 cm, it might be useful to perform a preoperative selective arterial calcium injection (SACI) angiography to regionalize the source of insulin overexpression.

Treatment

Like in sporadic insulinoma, surgery is always indicated, if the biochemical diagnosis of organic hyperinsulinism is established and diffuse metastatic disease is excluded by imaging. Surgical treatment options range from enucleation to partial pancreatectomy or distal pancreatectomy. Enucleation and limited resections are preferred as surgical treatment options and provide long-term cure for MEN1 patients with solitary dominant tumors [39], whereas a distal spleen-preserving pancreatectomy to the level of the portal vein with enucleation of pancreatic head tumors should be performed in patients with multiple, equally sized pNENs (Figs. 1 and 2). Nowadays the procedures can also

be performed safely using laparoscopic- and robot-assisted approaches [40, 41]. A peripancreatic lymphadenectomy is only mandatory, if malignancy is suspected by gross invasion or lymph node metastases.

Prognosis

Biochemical cure is achieved in 57–100% of cases in the absence of distant metastases (Table 5). MEN1 patients with an insulinoma are usually younger (20–30 years) than patients with sporadic insulinoma (40–60 years) [1]. Malignancy is rarely reported and occurs in 5–9%.

Vipomas and Glucagonomas

Vipomas and glucagonomas are rare functional pNENs in MEN1 patients occurring in 1–3% of patients. Malignancy is frequently observed occurring in 50–80% of patients [47].

Clinical Symptoms

Vipoma is associated with profuse watery diarrhea and hypotension, also referred to as WDHA syndrome. Tumors are often large (>5 cm) and liver metastases are frequently present at the time of diagnosis. Glucagon excess infrequently causes specific symptoms, but glucagonoma, usually large at diagnosis, may cause abdominal pain due to local tumor growth. In case of advanced tumors, a migratory, necrolytic skin rash might be the leading symptom. In addition, glossitis, stomatitis, angular cheilitis, diabetes, and severe weight loss may occur.

Diagnostic Procedures

The biochemical diagnosis is based on the measurement of elevated serum levels for VIP or glucagon. Preoperatively CT or MRI and SRS imaging should be performed to obtain an adequate staging.

Treatment

Recommendations for surgical treatment are rather based on general proposals following oncologic principles than on a widespread experience. The only chance of cure is the complete surgical resection, as these tumors are frequently malignant. Glucagonomas and vipomas are mainly located in the pancreatic body or tail making a distal splenopancreatectomy with peripancreatic lymph node dissection the procedure of choice. In case of pancreatic head vipoma or glucagonoma, a PPD should be performed. Debulking procedures are indicated if the majority (~90%) of the tumor burden can be resected, since they lead to an improvement of the clinical syndrome caused by the hormone excess.

Besides surgical approaches, medical treatment with somatostatin analogs (e.g., octreotide) or chemotherapy (e.g., streptozotocin and 5-fluorouracil or dimethyltriazeno-imidazole carboxamide) is also a successful options in some patients [1]. Target therapies as everolimus or sunitinib are novel therapy options which are recommended in patients with advanced and metastatic diseases [48]. In SSTR-positive tumors, peptide receptor radionuclide therapy (PRRT) is also a valuable option.

Nonfunctioning pNENs

The incidence of NF-pNENs in MEN1 patients varies from 30% to 80% [30, 50]. NF-pNENs in MEN1 patients have been reported to be malignant in 30–50% and are less frequently malignant than their sporadic counterparts with 70%. Retrospective data on sporadic NF-pNENs have revealed that 20% of patients with tumors larger >1 cm had lymph node metastases and 30% of patients with tumors >2 cm had liver metastases, respectively. However, there is no conclusive association between tumor size and risk of malignancy in MEN1-associated NF-pNENs. Even small (10–20 mm) NF-pNENs with lung and liver metastases have been reported in MEN1 patients [18]. In sporadic NF-pNENs, a lack of specific symptoms results in a delayed diagnosis associated with a poorer overall survival compared to functioning pNENs [51]. This is different in MEN1-associated NF-pNENs, since these tumors will be nowadays diagnosed early by regular screening due to the increased sensitivity of imaging methods. Thus, NF-pNENs are the most common tumors of the pancreaticoduodenal region in adult MEN1 patients. This is of importance as NF-pNENs are a significant cause of death in MEN1 mutation carriers [8, 52].

Clinical Symptoms

Symptoms are commonly unspecific, as hormone excess-related symptoms are lacking. In large tumors, local tumor growth-associated symptoms such as jaundice, abdominal pain or discomfort, and weight loss may frequently occur.

Diagnostic Procedures

After a careful biochemical evaluation in order to detect hormone oversecretion, especially with regard to subclinical ZES, imaging should include especially EUS and MRI of the abdomen. EUS is the superior preoperative imaging modality in MEN1 patients, especially if the tumor size is below 10 mm [53, 54]. It has to be highlighted that NF-pNENs in MEN1 are often multiple and may be associated with functioning tumors.

Treatment

The timing and extent of surgery are an ongoing discussion. In the past, some authors advocated the most aggressive approach with surgical exploration in case of biochemical evidence, even if imaging failed to visualize pancreatic lesions [49, 55]. The majority of authors indicated surgery when pNENs >10 mm in size could be visualized on imaging [56]. Meanwhile two retrospective studies have demonstrated that a surgical treatment is not beneficial [57, 58]. Therefore, current ENETS Consensus Guidelines recommend surgical resection only for tumors ≥2 cm [70]. In case of surgery, spleen-preserving distal pancreatectomy with enucleation of pancreatic head tumor or parenchyma-sparing enucleations of solitary pNENs are the preferred surgery procedures. Nowadays the procedures can be safely performed using minimal-invasive approaches.

Treatment of Liver Metastases in MEN1-Associated pNENs

Liver and other distant metastases are the most important predictor of survival in patients with MEN1 pNENs. The treatment in MEN1 patients with advanced disease attempts to reduce symptoms related to the hormone excess and to repress the tumor progression. Treatment options for metastatic MEN1-associated pNENs are the same as for sporadic pNENs, which are summarized in detail in the chapter of sporadic pancreatic endocrine tumors. If possible, cytoreductive surgery should be performed, even if a multivisceral resection is necessary. Other treatment options comprise biotherapy with somatostatin analogs and interferon, chemotherapy (streptozotocin, doxorubicin), targeted therapies (e.g., everolimus, sunitinib), embolization and chemoembolization, radiofrequency ablation, laser-induced tumor ablation, liver transplantation, peptide receptor radiotherapy, and selective intraarterial

radiotherapy [48]. In patients with ZES and metastatic, non-resectable distant metastases, symptoms can be controlled by high dose administration of proton pump inhibitors.

Screening and Surveillance in MEN1 Patients

Genetic testing for a *MEN1* mutation is suggested in patients suspicious for MEN1. The identification of a *MEN1* mutation in the index patient gives the possibility of a predictive genetic testing of family members. A predictive genetic testing requires obligating a genetic counseling prior testing. Mutation-positive family members should be enrolled in controlled screening programs according to the clinical practice guidelines for MEN1 patients [1], whereas mutation-negative family members can be spared from further investigations. However, in approximately 10% of patients with MEN1, a mutation cannot be identified. In these cases, large deletions of the *MEN1* gene should be tested.

Regular screening should include biochemical parameters and imaging procedures every 1–3 years according to the clinical practice guidelines for MEN1 [1] (see Table 2). Hormonal assessment should include PP, gastrin and CgA, calcium, intact parathyroid hormone, and secretin stimulation test (ZES). To avoid repeated radiation exposure, MRI is the preferred initial diagnostic tool to identify lesions in the pancreas, adrenal glands, lymph nodes, and liver. However, its accuracy in detecting small pNENs is limited, as duodenal tumors will always and pNENs smaller than 10 mm will often missed. SRS imaging, especially Ga-68 DOTATOC-PET/CT and EUS, is superior in the detection of pNENs in MEN1 patients (Table 2). Regular screening intends to detect lesions in involved glands at their earliest stage, especially to prevent the development of advanced metastatic disease by timely interventions.

Guidelines for screening in MEN1 patients, especially for pNENs, are provided by the NIH Consensus Conference 2012 [1] and the ENETS [60].

Von Hippel-Lindau Syndrome (VHL)

Introduction

The VHL syndrome is an autosomal dominant inherited syndrome that most commonly causes retinal, spinal, adrenal, renal, and pancreatic lesions. The annual incidence is estimated to be 1 of 36,000 with more than 90% penetrance by the age of 65 years [61]. The VHL gene, located at chromosome 3p25–26, is coding a tumor suppressor gene which plays a pivotal role in the transduction of hypoxia-driven signals. Over 200 mutations have been reported to be associated with the VHL syndrome, and the mutated VHL protein leads to an

Table 6 Phenotypes of VHL

Phenotype classification in families with VHL	
Type	Phenotype
Type 1	Retinal hemangioblastoma
	CNS hemangioblastoma
	Renal cell carcinoma
	Pancreatic neoplasms and cysts
Type 2A	Pheochromocytomas
	Retinal hemangioblastomas
	CNS hemangioblastomas
Type 2B	Pheochromocytomas
	Retinal hemangioblastomas
	CNS hemangioblastomas
	Renal cell carcinoma
	Pancreatic neoplasm and cysts
Type 2C	Pheochromocytomas

CNS central nervous system

increased transcription of hypoxia-induced genes. This results in an increased growth and survival of endothelial and stromal cells and lastly promotes their malignant transformation.

Regarding morbidity, the most serious lesions are hemangioblastomas and retinal angiomas as they impair the vision and other neurological functions. Mortality is mostly determined by renal cell carcinoma and malignant pNENs. VHL has been classified in four distinct phenotypes by the National Cancer Institute (Table 6) which represent the four clinical phenotypes 1, 2A, 2B, and 2C based on the different lesions [62]. Pancreatic neoplasms only occur in phenotypes 1 and 2B.

Prognosis

The lifetime expectancy in VHL patients was less than 50 years before surveillance protocols were developed. The major cause of death is renal cell carcinoma. Pancreatic lesions occur in 50–77% of VHL patients, most commonly pancreatic cysts and cystadenomas. The development of distant metastases of these both types of lesions has not been reported. Pancreatic neuroendocrine tumors (pNENs) are less common (9%) [63] but own a malignant potential. Pancreatic cysts or serous cystadenoma may coexist, but pNENs are usually smaller and solid. The median age of diagnosis is approximately 36 years, and the vast majority of pNENs are nonfunctioning. The most frequent sites of metastases are the liver and bones. Libutti reported that 17% of VHL patients with pNENs had distant metastases or developed them during follow-up [64]. The probability for malignancy increases with a tumor size of more than 30 mm from 0% to 20%.

Prevalence of Pancreatic Lesions and Clinical Symptoms

The most common pancreatic lesions are pancreatic cysts, which are present in 17–56% of VHL patients [65]. These lesions exhibit no malignant potential. Pancreatic cysts are detected commonly by CT or MRI scans of the abdomen or EUS by routine imaging in asymptomatic patients. Pancreatic cysts can rarely lead to duodenal compression and/or abdominal discomfort.

Serous cystadenoma is uncommon but has been reported to be associated with VHL. Lesions typically grow slowly, and malignant transformation in the setting of VHL has yet not been reported. Serous cystadenomas may lead to endocrine or exocrine insufficiency as well as to stenosis of the bile duct, if they grow to substantial size by compressing the pancreatic parenchyma.

Since almost all pNENs in VHL are nonfunctioning, they are clinically inapparent and will be generally detected during screening. Fifty percent of pNENs in VHL patients are located in the pancreatic head, whereas 25% each are located in the pancreatic corpus and tail, respectively.

Diagnostic Procedures

A hormonal assessment is not necessary since pNENs in VHL patients are usually nonfunctional. Imaging can be managed by CT scan or MRI and EUS which is superior in the detection of pNENs. A pheochromocytoma has to be excluded before scheduling VHL patients for pancreatic surgery.

Treatment

If cystadenoma or pancreatic cysts are symptomatic due to a compression of the bile duct, the duodenum pancreatic resection may be necessary.

There are no evidence-based guidelines with respect to the time point and the extent of surgery for pNENs in VHL patients. It has been suggested that the probability for malignancy increases significantly, if the tumor size exceeds 30 mm compared to tumors which are less than 3 cm [66]. Lesions between 10 and 30 mm require a personally adopted approach with respect to patients' age, comorbidity, and growth behavior. The extremely rare functioning pNENs and nonfunctioning pNENs exceeding 30 mm require surgical resection. Based on small series, most experts recommend follow-up by MRI or EUS every 12 months for lesions smaller than 30 mm [67]. The surgical strategy should aim to preserve as much pancreatic parenchyma as possible. Therefore, most experts recommend enucleation whenever feasible. Intraoperative ultrasound is obligatory to visualize the relationship of the tumor to the main pancreatic duct and major vessels. A laparoscopic approach is justified in preoperatively imaged lesions, if they are located in the pancreatic body/tail or in the ventral surface of the pancreatic head.

Screening and Surveillance

Although recent studies contributed to the understanding of phenotype-genotype correlation, mutation-based screening has yet not been recommended. Most experts warrant routine screening including all VHL-associated lesions. With respect to the endocrine manifestations, screening for pheochromocytoma in VHL type 2 patients comprises an assessment of catecholamine excretion in 24-h urine, MRI, and MIBG scan annually starting by the age of 10. Nonfunctioning pNENs should be screened by MRI or EUS every 1–2 years starting >16 years (www.vhl.org).

Neurofibromatosis (NF) Type 1

Introduction

Neurofibromatosis comprises a group of hereditary conditions predisposing to neurocutaneous manifestations. The genetically most amenable conditions are neurofibromatosis types 1 and 2. Neurofibromatosis type 1 is associated with pheochromocytoma, pNENs, and other tumor manifestations affecting the central and peripheral nervous system. Neurofibromatosis type 2 is characterized by bilateral acoustic neurinomas, whereas pheochromocytomas and pNENs are not part of this syndrome.

Neurofibromatosis type 1 affects 1 in 3,000 live births and 50% are caused by spontaneous mutations. The penetrance is almost 100%, but the clinical phenotype varies considerably. A phenotype-genotype correlation has not been defined so far. The *NF-1* gene is located on chromosome 17q11.2 and is coding for *neurofibromin* gene which acts as a tumor suppressor gene. *Neurofibromin* appears to be involved in the activation of the proto-oncogene *p21-Ras* and belongs to the family of Ras GTPases. Mutations of *neurofibromin* can result in a loss of inactivation of *p21-Ras*; in other words, the oncogene becomes activated.

The NIH criteria for neurofibromatosis lead to a safe diagnosis, if two or more of the following criteria are present [68]:

- Six or more café-au-lait macules over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
- Two or more neurofibromas of any type or one plexiform neurofibroma
- Freckling in the axillary or inguinal regions
- Optic glioma
- Two or more Lisch nodules (iris hamartomas)
- A distinctive osseous lesion such as sphenoid dysplasia or thinning of the long bone cortex with or without pseudarthrosis
- A first-degree relative (parent, sibling, or offspring) with NF-1 by the above criteria

Prognosis

Compared to the healthy population, NF-1 patients exhibit a four times increased risk for malignant tumors, especially carcinomas and sarcomas. An analysis of death certificates in the USA revealed a decreased lifetime expectancy of 20 years compared to the general population with a mean age of death of 50 years for males and 54 years for females, respectively. The relative risk for connective and soft tissue carcinomas was increased by 34-fold. The incidence of pNENs including duodenal somatostatinomas is relatively low in NF-1patients [69]. However, in these cases, pNENs with NF-1 seem to include a great potential for malignancy.

Clinical Spectrum and Symptoms

Besides benign and malignant tumors of the peripheral and central nervous system, typical cutaneous manifestation such as café-au-lait spots and freckling of non-sun-exposed areas occur. Twenty-five percent develop an involvement of the gastrointestinal tract, the most common intestinal fibromas. Furthermore, pheochromocytoma (3–13%) and rarely pNENs including duodenal somatostatinomas (0–10%) have been reported to be associated to the disease [69, 70]. The gastrointestinal involvement which is observed in 25% of NF-1 patients includes hyperplasia of the plexus myentericus, neurofibromas, gastrointestinal stromal tumors (GIST), adenocarcinomas, pheochromocytomas, tumors of the papilla vateri, and pNENs. Klein et al. analyzed 37 VHL cases of periampullary neoplasms and found that the majority originates from the papilla (54%), followed by the duodenum (38%) and the pancreas (8%) [71].

Somatostatinoma is a distinct entity of periampullary neoplasms and mostly causes symptoms of duodenal obstruction such as jaundice, weight loss, abdominal pain, and gastrointestinal bleeding. A somatostatinoma syndrome related to a somatostatin excess with hyperglycemia, cholecystolithiasis, and imperfect digestion has yet not been reported in NF-1 patients.

Diagnostic Procedures

With regard to periampullary neuroendocrine tumor duodenoscopy, magnetic resonance cholangiopancreatography (MRCP) and EUS should be the first-line diagnostic tools followed by CT or MRI. Pancreatic neoplasms require EUS, MRI or CT scan, and SRS imaging (e.g., Ga-68 DOTATOC-PET/CT) as an adequate preoperative staging.

Treatment

Since pNENs in NF-1 patients are rare, recommendations for their treatment are only based on small case series and reach at most evidence level 4. Thus, the adequate

treatment of VHL-associated pNENs is still a matter of debate. If a tumor at the papilla vateri is smaller than 20 mm in size with no signs of metastatic spread after careful examination with endoscopy, EUS and MRI, a local excision, either endoscopically or surgically seem to be justified. In small pNENs (<20 mm), enucleation or parenchyma-sparing resections should be considered. pNENs larger than 20 mm or malignant spread requires distal pancreatectomy for pNENs located in the pancreatic tail and body or a PPD for pNENs located in the pancreatic head or the duodenum.

Screening and Surveillance

Screening in NF-1 patients has not been defined and general recommendations are lacking. Due to the low incidence of pheochromocytoma (0.1–5.7%) and pNENs (1%), regular screening is not generally recommended [68]. An expert panel and the Genetics Committee of the American Academy of Pediatrics have published diagnostic and health supervision guidelines for children with NF-1 in 2008 [72].

Conclusion

- MEN1

  Genetic screening and counseling are mandatory.
  Patients should be referred to specialized centers.
  Patients should be enrolled in regular screening programs.
  Gastrinoma is the most frequent functional pNEN.
  Malignant pNENs are the most common cause of death.

- Gastrinoma in MEN1

  Assess gastrin in every MEN1 patient.
  The duodenum is the target organ.
  Consider surgery in case of the biochemical diagnosis after exclusion of diffuse metastatic spread to provide a chance of cure.
  Duodenotomy with excision of all duodenal gastrinomas and lymphadenectomy are essential; PPPD is an alternative.

- Insulinoma in MEN1

  Preoperative localization is important for the operative strategy.
  EUS is superior to CT and MRI.
  Surgical treatment ranges from enucleation to partial pancreatectomy or distal pancreatectomy.
  Laparoscopic approaches are feasible.

- NF-pNENs in MEN1

  EUS is superior to CT and MRI.
  NF-pNENs are often multiple.
  Surgical treatment is indicated if the size exceeds 20 mm; in smaller tumors, surveillance is justified.
  Distal pancreatic resection and enucleation of pancreatic head tumors is the standard procedure, and enucleation for solitary tumors is an alternative.
  Laparoscopic approaches are feasible and safe.

Future Research Directions

- Prospective randomized multicenter trials are required to assess the use of regular screening on an EBM level.
- A general/worldwide accepted screening protocol for MEN1 patients.
- Establishing a genotype-phenotype correlation for MEN1-associated pNENs.
- Evaluation of pancreaticoduodenectomy as standard procedure for MEN1-associated ZES.

Clinical Management of Pancreatic Cancer

Clinical Decision-Making in Pancreatic Cancer

Abstract

The management of pancreatic cancer relies on clinical staging for the majority of patients. High-quality cross-sectional imaging, and in some cases adjunctive staging modalities, partitions pancreatic cancer into one of four categories: localized and potentially resectable, borderline resectable, locally advanced/unresectable, or metastatic. Subsequent decisions regarding specific anticancer therapies and palliative interventions should be based on patient-centered, defined goals of care. Clinical decision-making should be evidence based, accounting for the patient's performance status and psychosocial circumstances, and developed with multidisciplinary input. Presently, surgical resection provides the only meaningful chance for long-term survival and, in general, is relevant only to those patients with potentially resectable or borderline resectable disease. However, there appears to be an expanding subset of patients with locally advanced disease who may eventually be considered surgical candidates. Nevertheless, surgical resection with curative intent should be linked to the delivery of additional therapy either as adjuvant therapy or neoadjuvant treatment. Enrollment in prospective clinical trials is always encouraged provided participation is not an undue burden on the patient or caregivers. Lastly, patients in need of expert clinical services should be encouraged to seek cancer care in pancreatic cancer centers of excellence as current evidence suggests improved outcomes in these settings.

Keywords

Resectable · Borderline resectable · Locally advanced · Metastatic · Adjuvant · Neoadjuvant · Gemcitabine · Nab-paclitaxel · FOLFIRINOX · Radiation

Introduction

Clinical decision-making as a disciplined exercise is not a new concept in medicine, or in oncology, yet its application to the management of patients with pancreatic cancer has previously been limited by the narrow range of available therapies. More recently, newer chemotherapeutic regimens and an expanding array of local therapies have provided a wider assortment of therapeutic options for all stages of this disease. Despite these advances, the prognosis for most patients with pancreatic cancer remains poor. Given the grim realities of pancreatic cancer, decision-making should be a shared endeavor, with a patient-centered focus. Importantly, as oncology care becomes increasingly multidisciplinary, clinicians from a variety of specialties must be aware of the assortment of interventions which may be utilized to minimize morbidity and toxicity, maximize palliation, and optimize patient survival. Furthermore, clinicians and patients alike face an intimidating challenge owing to the impressive dynamism of pancreatic cancer. This can result in the rapid onset of metastatic disease, local tumor progression associated with worsening pain or obstruction, venous thromboembolism, hemorrhage, or infection, especially involving the biliary tract. Clinicians must therefore be prepared for flexibility in clinical decision-making and to openly communicate how the goals of care may require sudden modification.

This chapter will be partitioned according to recognized clinical stages of pancreatic cancer and will attempt to provide a thoughtful, evidence-based approach to decision-making. Of note, any proposed interventions must be considered in the context of the patient's medical and psychosocial circumstances, and, whenever possible, multidisciplinary input should be sought prior to conclusive treatment planning. Moreover, enrollment in a clinical trial should always be encouraged, but understanding the potential burden of participation for the patient and caregivers is required.

Clinically Defined Stages of Pancreatic Cancer and Curative Potential

While some areas of controversy persist, there is emerging consensus that patients diagnosed with pancreatic cancer must undergo sufficient staging studies in order to classify them as having potentially resectable, borderline resectable (BR), locally advanced (LA), or metastatic disease. This allows oncologists to identify the minority of patients with localized disease with potential for curative therapy and to distinguish them from the larger group who present with non-curable disease.

Patients with localized pancreatic cancer, comprised of those with potentially resectable tumors and those with BR disease, have the greatest chance of cure or prolonged survival. Importantly, while surgery remains the only curative intervention, it can be morbid and lead to inadequate recovery which may impede or prevent the delivery of subsequent adjuvant therapy [1]. Of further note, if surgery is misapplied due to inadequate staging, it may nullify any meaningful chance for cure

[2]. If proper staging is utilized and its implications fully recognized, patients can be better informed of the options which may maximize their chances for prolonged survival or cure.

In general, patients with locally advanced pancreatic cancer (LAPC) do not have curative potential, but with appropriate management, durable local control and palliation can be achieved, and for many, the cancer's natural history can be altered [3]. For those presenting with metastatic disease, palliation should be paramount, and therapeutic options should not necessarily include the delivery of cytotoxic therapy. An open discussion of the goals of therapy for patients with established LA or metastatic disease should generally occur on the initial visit with the oncologist, and unrealistic expectations should not be endorsed or encouraged by any responsible physician.

Clinical Decision-Making in Patients Having Potentially Resectable Disease

Potentially resectable disease can only be defined if high-quality, dual-phase helical computed tomography (CT) or magnetic resonance (MR) imaging has been obtained. Resectable tumors do not involve critical venous or arterial structures, and furthermore, all imaging studies should have no evidence of distant metastatic disease. Resectable tumors should only be considered as such if there is a relatively high probability of an R0 resection (grossly and microscopically negative surgical margins).

For years, the standard of care for potentially resectable pancreatic cancer has been upfront resection, the most widely applied approach to date. Whenever possible, surgical resection should be followed by adjuvant therapy since modern clinical studies support a conclusive role for adjuvant therapy in patients who have undergone resection of the primary tumor with curative intent [4–6]. Some specific tenets about the role of upfront surgery for potentially resectable disease are enumerated below.

Seven Tenets for Potentially Resectable Pancreatic Cancer

1. Surgery at a high-volume center improves both short-term and long-term survival.
2. Surgery alone for resectable pancreatic cancer leads to poor survival.
3. Adjuvant therapy improves overall and 5-year survival after surgery with curative intent.
4. Upfront surgery is not always followed by the delivery of adjuvant therapy.
5. Preoperative performance status predicts the ability to receive postoperative therapy.
6. Preoperative CA 19-9 determinations are prognostic.
7. Positive surgical margins portend poor survival.

Surgery at a High-Volume Center Improves Both Short-Term and Long-Term Survival

There is an expanding literature to support the referral of patients with potentially resectable disease to centers that see a large number of pancreatic cancer patients [7, 8]. Analysis of SEER and Medicare databases in the USA also demonstrates better survival when patients receive therapy at academic medical centers, presumably representing high-volume university-based hospitals [9]. Furthermore, when pancreatic cancer surgical care is centralized, results suggest better overall outcomes [10]. Clinicians should therefore encourage patients to consider referral to a center of excellence whenever initial staging shows localized disease. While there may be socioeconomic factors which limit the feasibility of such a referral, the effort to make the referral or the time lag involved in the process should not be major impediments.

Surgery Alone for Resectable Pancreatic Cancer Leads to Poor Survival

Results from a number of studies and single-institution reports clearly demonstrate patients who undergo surgery as the only intervention for resectable pancreatic cancer have poor survival with early trials describing median overall survivals ranging from 10 to 13 months. More modern trials to include ESPAC-1, ESPAC-3 (v1), and CONKO 001 have all shown somewhat longer survival times for patients who were randomized to observation alone after surgical resection with curative intent with median survival times ranging from 17 to 20 months [5, 6]. These improved survival times likely reflect improvements in patient selection for surgery, surgical technique, and postoperative care in addition to better systemic therapy at the time of relapse. Nevertheless, the 5-year survival rate for patients who do not receive adjuvant therapy remains a dismal 10%. Thus, surgery alone is an inadequate strategy for patients with potentially resectable pancreatic cancer, and whenever a "surgery first" approach is being considered for a patient with resectable disease, it must be linked to the patient's potential to recover sufficiently to received postoperative therapy.

Adjuvant Therapy Improves Overall and 5-Year Survival After Surgery with Curative Intent

The data regarding adjuvant therapy for resected pancreatic cancer is discussed in greater detail elsewhere in the text. Beginning with ESPAC 1, originally reported in 2004, four large randomized trials of adjuvant therapy have established (a) there is no conclusive evidence that chemoradiation is a necessary component of adjuvant therapy, (b) systemic therapy improves survival over surgery alone, (c) gemcitabine monotherapy has equivalent efficacy and less toxicity compared with bolus

fluorouracil and folinic acid, and (d) the combination of gemcitabine with capecitabine leads to superior overall survival and 5-year survival compared with gemcitabine alone [4, 6, 11, 12].

At present, most authorities would consider upfront surgery and adjuvant therapy (now using gemcitabine and capecitabine) as the standard of care for patients with potentially resectable pancreatic cancer. However, as shown below, the data regarding upfront surgery and adjuvant therapy must be interpreted with caution.

Upfront Surgery Is Not Always Followed by the Delivery of Adjuvant Therapy

Five large adjuvant therapy trials have been completed and reported since 2004: ESPAC-1, RTOG 9704, ESPAC 3 (v2), CONKO 001, and most recently ESPAC 4 [4, 6, 11–13]. Together, these trials enrolled more than 3,000 patients. Unfortunately, the results from these trials have been limited to those patients who underwent an R0 or R1 resection and had adequate recovery from surgery to enroll in a clinical trial. None of these trials reported on the much larger number of patients who were taken to the operating room at the participating sites with plans to remove the primary tumor and deliver subsequent postoperative therapy. This is critical, since oncologists must recognize that of patients who present with potentially resectable pancreatic cancer and undergo surgery, slightly more than half go on to receive adjuvant therapy. Single-institution reports and analyses of large national databases show that only 50–60% of patients who undergo upfront surgery receive some form of adjuvant therapy [1, 9, 14]. The reasons for dropout from the time of surgery to administration of adjuvant therapy are likely related to three postoperative events. First is postoperative death. In an analysis of over 20,000 pancreatectomies registered in the National Cancer Data Base (USA), 30-day mortality was 3.7%; however, by 90 days, mortality increased to 7.4% [15]. Second are postoperative complications. In a separate analysis of over 2,000 pancreatectomies from the American College of Surgeons National Surgical Quality Improvement Program and the National Cancer Data Base, the delivery of adjuvant chemotherapy was only 58% [1]. The rate was 62% for patients with no significant complications and as low as 43% for those patients who developed at least one serious postoperative complication.

The third factor that likely precludes the delivery of adjuvant therapy is disease relapse in the immediate postoperative period. Unfortunately, the proportion of patients who undergo surgery with curative intent and subsequently develop overt metastatic disease during the usual recovery period from surgery (6–12 weeks) have not been rigorously analyzed or reported. However, in an analysis of seven previously published trials of neoadjuvant therapy for potentially resectable disease, 18% of enrolled patients developed radiographically detectable metastatic disease within 6–12 weeks from protocol enrollment [16]. It is therefore likely that of the patients who undergo pancreatectomy with curative intent, at least 15–20% will develop relapsing disease during their recovery period. Thus, when anticipated survival

results are discussed with patients prior to surgery, clinicians should be clear whether they are describing a "best-case scenario" or results that are applicable to the average patient since almost half do not receive postoperative therapy, a critical component of treatment beyond surgery.

Preoperative Performance Status Predicts the Ability to Receive Postoperative Therapy

While some have advocated surgical resection of primary pancreatic cancers as a palliative maneuver, survival of patients who undergo surgery as the only intervention is similar to the survival of patients with locally advanced, unresectable pancreatic cancer treated nonoperatively [3, 17]. Therefore, when surgery is being considered for a patient with potentially resectable disease, it should be realistically linked to that patient's potential to receive postoperative therapy. Preoperative clinical parameters which predict the likelihood of sufficient recovery to deliver postoperative therapy have not been well defined. Some data comes from a review of 85 patients undergoing upfront surgical resection for pancreatic cancer at the University of Texas, M.D., Anderson Cancer Center (UTMDACC) between 1994 and 2004 [18]. Three groups of patients were defined. Group 1 consisted of 13 patients who required emergent pancreaticoduodenectomy, group 2 had 63 patients having a preoperative Eastern Cooperative Oncology Group (ECOG) performance status (PS) 0 or 1, and group 3 was comprised of nine patients with ECOG PS of 2 or 3. Delayed recovery precluded the delivery of adjuvant therapy in 23% of patients in group 1, only 6% of those in group 2, and 44% of patients in group 3. Patients of advanced age (defined as >70 years) also appeared to have a lower chance of receiving postoperative therapy, but on multivariate analysis, only the urgency of surgery and the preoperative PS were identified as independent predictors of recovery which would allow for or preclude the delivery of postoperative therapy. Thus, when a patient presents with potentially resectable disease combined with compromised functional status, a decision to defer surgery is not unreasonable, and the option of initial nonoperative cancer-directed therapy is therefore an appropriate alternative.

Preoperative CA 19-9 Determinations Are Prognostic

The carbohydrate antigen 19-9 (CA 19-9) was initially characterized in a tumor cell line derived from a patient with colorectal cancer, and it can be elevated in a variety of malignancies. However, this serum tumor marker is frequently used to guide clinical care for patients with pancreatic cancer. In the setting of localized disease, preoperative CA 19-9 levels have been found to be prognostic. Patients who present with significantly elevated CA 19-9 levels despite radiographic evidence of potentially resectable disease have a worse prognosis compared with patients presenting with lower preoperative CA 19-9 levels. Unfortunately, published results will not

allow for an absolute cutoff to guide clinical decision-making, but in general preoperative CA 19-9 levels above 300 units/milliliter (U/mL) should lead to caution and possibly further staging evaluation prior to surgical intervention. For example, in a study reported by investigators in Liverpool, 159 patients who appeared to have resectable pancreatic cancer based on CT imaging underwent staging laparoscopy. Of the 63 patients with a preoperative CA 19-9 <150 U/mL, 60 (95%) had no evidence of metastatic disease at the time of laparoscopy, whereas only 78% of the 96 patients with a CA 19-9 above 150 U/mL were without metastatic disease [19]. Another study from Memorial Sloan Kettering Cancer Center lends further support to the use of preoperative CA 19-9 to increase the yield from laparoscopic staging using a cutoff of 130 U/mL [20].

After an analysis of data from the NCDB, the group from the Mayo Clinic has made a more controversial suggestion and advised neoadjuvant therapy for patients with potentially resectable pancreatic cancer having a serum CA 19-9 above the normal range [21]. In that study, the investigators divided patients who underwent surgical resection with curative intent into one of three groups: those with undetectable preoperative serum CA 19-9 levels, those with normal pre-op CA 19-9 levels, and those having elevated pre-op CA 19-9 levels. There was no difference in overall survival for those patients having undetectable or normal CA 19-9 levels pre-op. However, survival was inferior for those patients who presented with any elevation in CA 19-9 prior to surgical resection. The authors concluded that for patients who present with elevated preoperative CA 19-9 levels (after adequate biliary decompression), neoadjuvant therapy should be considered as initial therapy prior to surgical resection.

Surgeons should therefore consider using preoperative CA 19-9 determinations to identify patients who have radiographic evidence of potentially resectable pancreatic cancer, but whose preoperative CA19-9 level is sufficiently elevated to warrant staging laparoscopy or even to be referred for neoadjuvant therapy as initial treatment.

Positive Surgical Margins Portend Poor Survival

Over the past two decades, single-institution reports and results from large randomized trials have shown that microscopically positive surgical margins at the time of resection (R1) are associated with worse survival compared with the survival of patients undergoing an R0 (microscopically negative margins) resection [11, 12, 16]. This is irrespective of the delivery of postoperative therapy. These findings, coupled with improved imaging techniques, and reports of higher R0 resection rates for patients undergoing preoperative therapy have facilitated the recognition of BR disease. [22].

In summary, while surgical intervention for potentially resectable disease is always a desired goal, its benefits are limited if radiographically occult metastatic disease is present, an R0 resection is not achieved, or if subsequent adjuvant therapy cannot be delivered. Figure 1 depicts important parameters to consider in clinical decision-making which should initially limit the pool of patients advised to undergo

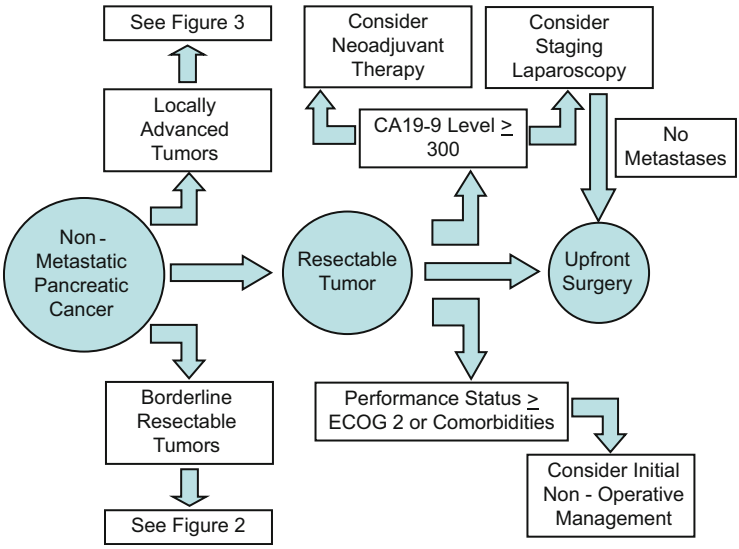

Fig. 1 Decision forks for patients with localized pancreatic cancer. The goal is to initially limit surgery to those patients at low risk for positive surgical margins, metastatic disease, or delayed post-operative recovery. Surgical decisions can be deferred for the remaining patients until after non-surgical therapies are delivered

immediate surgical resection. Patients with BR pancreatic cancer are by definition at high risk for positive surgical margins with upfront surgery, and under most circumstances, surgery should be deferred until some form of neoadjuvant therapy has been delivered as discussed below.

Clinical Decision-Making in the Setting of Borderline Resectable Disease

Over the last several years there has been growing recognition of a distinct subset of localized pancreatic cancers: those described as borderline resectable (BR) [22]. Three factors have led to this: the emergence of high-quality, dual-phase helical CT imaging and MR imaging, an onslaught of reports demonstrating the negative consequences of positive surgical margins on survival, and the ability of preoperative therapy to achieve higher rates of R0 resections [11, 12, 23, 24]. Detailed information on the definitions of BR disease can be found in the chapter entitled ▶ "Borderline Resectable Pancreatic Cancer". For the purposes of this chapter, a BR tumor is one which has a relatively high probability of a positive surgical margin if surgery is applied first. In clinical practice, BR pancreatic cancer needs to be recognized more frequently and fosters a discussion about preoperative therapy as an alternative to upfront surgical intervention. The four tenets listed below should inform clinical decision-making in patients with localized disease.

Four Tenets for Borderline Resectable Pancreatic Cancer

1. Positive surgical margins are frequent using upfront surgery in pancreatic cancer resections.
2. Borderline resectable tumors must be recognized.
3. Preoperative therapy for resectable pancreatic cancer leads to reduction in both the frequency of positive surgical margins and the risk of local failure.
4. Preoperative therapy should be considered as an alternative to upfront surgery in the setting of borderline resectable disease.

Positive Surgical Margins Are Frequent Using Upfront Surgery in Pancreatic Cancer Resections

Reports from the USA, Europe, and Asia all show that positive surgical margins occur among 37–60% of patients undergoing surgical resection with curative intent [12, 16]. Furthermore, although data suggest that postoperative therapy may provide some survival advantage compared with observation alone after a margin-positive resection, this rarely leads to cure [6]. These bleak statistics have focused attention on the need to achieve negative surgical margins at the time of resection to ensure any chance of long-term survival [2]. Since positive surgical margins with upfront surgery virtually eliminate any meaningful chance of cure, surgery as the initial intervention for a localized cancer should be limited to tumors which can be removed with a high probability of negative surgical margins. In centers which rely on strict radiographic criteria to define resectable disease, the rate of positive surgical margins with upfront surgery is around 20% [25].

Borderline Resectable Tumors Must Be Recognized

If BR disease is not recognized by the surgeon and radiologist, upfront surgical resection is likely to result in an R1 resection, and any meaningful chance for long-term survival is lost. If, however, high-quality preoperative imaging is acquired and properly interpreted, a subset of patients will be recognized as having BR tumors and better informed as to the choices between immediate resection and deferral of surgical intervention until preoperative therapy has been delivered. Therefore, radiologists and surgeons must confer on the results of high-quality cross-sectional imaging with attention to evidence for tumor-vessel abutment.

Preoperative Therapy for Resectable Pancreatic Cancer Leads to Reduction in Both the Frequency of Positive Surgical Margins and the Risk of Local Failure

In the setting of potentially resectable disease, preoperative therapy remains investigational. However, survival results using preoperative therapy are at least equivalent, if

not superior to upfront surgery and adjuvant therapy. Preoperative therapy has three significant potential advantages compared with upfront surgery and postoperative therapy. First, it provides a selection mechanism to identify those patients with resistant and rapidly progressive disease who will not benefit surgery. In trials conducted to date, approximately 18% of patients develop radiographically evident metastatic disease in the face of preoperative therapy [16]. Second, single-institution experience with preoperative therapy suggests rates of positive surgical margins as low as 6–11% [26, 27]. Third, local failure rates are lower using preoperative therapy than those reported with a surgery-first approach [28]. Importantly, isolated local tumor progression which precludes surgery after preoperative therapy is rare. [26, 27].

Preoperative Therapy Should Be Considered as an Alternative to Upfront Surgery in the Setting of Borderline Resectable Disease

Although a localized rectal cancer has less propensity to disseminate compared with localized pancreatic cancer, the radial or circumferential margin of a rectal cancer has similarities to the retroperitoneal or superior mesenteric artery (SMA) margin in pancreatic cancer (the margin most likely to be positive after a pancreaticoduodenectomy) [25]. When either the radial margin is positive in rectal cancer or the SMA margin is positive in pancreatic cancer, the patient is placed at higher risk for relapse and death compared with an R0 resection [2, 29]. A large body of literature in rectal cancer and a more modest data set in resectable pancreatic cancer both suggest that preoperative therapy, specifically involving radiation, reduces the risk of a positive surgical margin and local failure [24, 28].

These principles are now being applied to patients with BR pancreatic cancer. Retrospective data have been available for some years. In a report from UTMDACC, three groups of borderline patients were defined: those having radiographic evidence of a tumor that was borderline for resection (group A), those whose preoperative imaging had equivocal evidence of metastatic disease (group B), and those patients whose physiologic status or medical comorbidities put them at increased risk for postoperative complications or hampered recovery [30]. Of the 84 patients in group A, 32 (38%) ultimately underwent surgery with curative intent after preoperative therapy, with all but one undergoing an R0 resection. The survival for the subset ultimately undergoing resection was impressive with a median overall survival of 40 months. Other groups have also reported on the ability of preoperative or neoadjuvant therapy to convert marginally resectable or locally advanced pancreatic cancer to resectable disease [31]. Recently, the utilization of modern chemotherapy regimens for BR disease has begun to appear in the literature. Two groups have reported on the use of folinic acid, fluorouracil, irinotecan, and oxaliplatin (FOLFIRINOX) or modified FOLFIRINOX as induction chemotherapy followed by chemoradiation to allow for resection rates between 61% and 67% in their patients with BR disease [32, 33]. Among the resected patients, R0 margins were achieved for 82–100%. Most recently, a multi-institutional trial of FOLFIRINOX and capecitabine-based chemoradiation delivered to 22 patients has been published

[34]. The overall resection rate was 68% with all but one patient undergoing an R0 resection. Of further note, 33% of resected specimens had <5% viable tumor present. (Survival data from this trial are not available yet.)

There is less information on the use of gemcitabine and nab-paclitaxel as neoadjuvant therapy for borderline resectable or locally advanced pancreatic cancer. However, this regimen has been reported as an acceptable regimen for preoperative therapy in resectable pancreatic cancer [35]. For patients with BR or LAPC, an Italian phase I trial has reported on a combination of gemcitabine, nab-paclitaxel, capecitabine, and cisplatin as having potential to downstage tumors to surgical resection [36]. Among the 25 patients enrolled, six underwent surgical resection with an R0 resection rate of 50%. Whether radiation is a necessary component of neoadjuvant therapy for BR pancreatic cancer will require well-conducted randomized clinical trials. Nevertheless, taken together, the results above support the principle that preoperative therapy can be sufficiently destructive to tumor, to ultimately allow for R0 resections in patients previously defined as having BR disease.

Clinicians may be concerned that if no attempt is made to resect a BR tumor with upfront surgery, the window of opportunity to do so may be lost. However, if surgery proceeds and the patient is left with microscopic or macroscopic tumor, the postoperative prognosis is poor. Figure 2 depicts a decision tree that emphasizes neoadjuvant chemotherapy, chemoradiation, or both with subsequent restaging studies prior to consideration of surgical intervention.

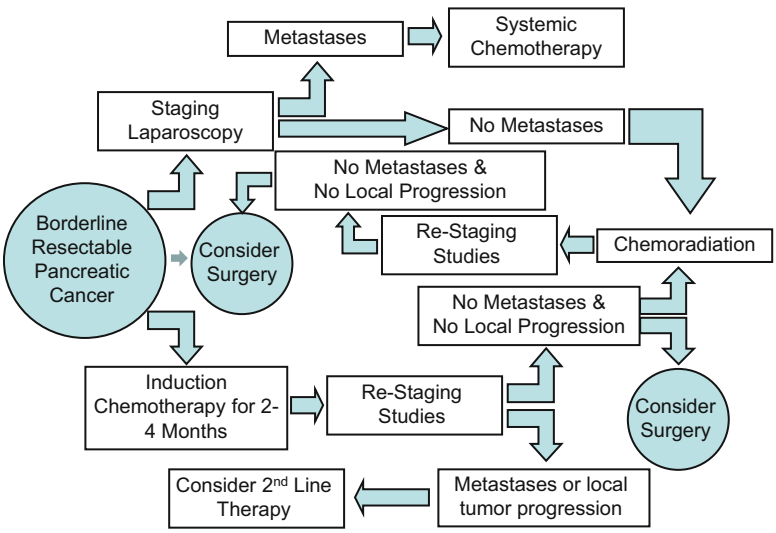

Fig. 2 Decision-tree for patients with borderline resectable disease. While no standard approach exists, neoadjuvant chemotherapy, chemoradiation, or both is generally recommended over upfront surgery

Importantly, the response criteria used to support attempt at surgical resection after deliver of neoadjuvant therapy remains poorly defined and currently relies on clinical parameters (such as reduction in pain or drop in serum CA19-9 levels). Reports are beginning to emerge in the literature that the use of radiographic criteria to determine resectability after a period of neoadjuvant therapy is a challenge (with the exception of interval development of metastases) [37].

Although the delivery of preoperative therapy for potentially resectable pancreatic cancer is encouraged in the context of a clinical trial, the data regarding preoperative therapy is sufficiently compelling to consider it for patients defined as having BR disease. The National Comprehensive Cancer Center Network (NCCN) pancreatic cancer subcommittee recommends preoperative therapy as preferred over upfront surgery in the setting of BR pancreatic cancer [38]. However, preoperative therapy for BR disease is not endorsed by the International Study Group of Pancreatic Surgery unless it is delivered as part of a clinical trial [39].

Decision Analysis in Patients with LAPC

The majority of patients staged with locally advanced pancreatic cancer have incurable disease, and all clinical decisions should keep palliation as a top priority. Furthermore, locally advanced tumors often put patients at risk for local invasion to include gastric outlet obstruction, biliary obstruction, and portal vein thrombosis. Thus, clinicians should be mindful of local control even when interventions intended to address it do not necessarily prolong survival. Currently, management strategies for locally advanced pancreatic cancer fall into two categories: cancer-directed therapies and palliative interventions to include surgical bypass, endoscopic and percutaneous procedures, and other supportive measures. Fortunately, these interventions are not mutually exclusive, and when appropriate, patients may embark on cancer-directed therapies as other palliative interventions are considered as components of care. However, clinicians should not recommend cancer-directed therapy until the patient is sufficiently stable to do so. Initiating potentially toxic therapy in patients with dynamic clinical status or poorly controlled symptoms is often counterproductive and should be discouraged, even when the patient or caregivers are anxious to proceed.

At the time of initial consultation, a thorough appraisal of the patient's social support, prior and current functional status, nutrition, and symptoms should be completed. In addition, a careful physical examination may uncover findings not evident from laboratory or radiographic studies to include the discovery of Virchow's nodes or the presence of superficial or deep venous thromboses. Immediate problems should be addressed during that visit, and although treatment options may be discussed, clinical decisions about cancer-directed therapy may need to be deferred until better symptom control is achieved.

The management of locally advanced disease has been in evolution over the last 10–15 years. In an earlier era, fluorouracil-based chemoradiation was often the initial treatment. Thereafter, numerous clinical trials investigated other chemoradiation

regimens, with the majority leading to median survival durations of 10–12 months. However, with the approval of gemcitabine for the treatment of patients with locally advanced or metastatic pancreatic cancer, the delivery of radiation as a necessary component of treatment for locally advanced disease became an open question. Results from two randomized trials (one in Europe and one in the USA) offered conflicting results. European investigators questioned whether chemoradiation followed by gemcitabine was superior to gemcitabine alone for the treatment of patients with locally advanced disease [40]. This trial randomized 119 patients to receive an intensive course of chemoradiation with 5-FU and cisplatin followed by post-chemoradiation gemcitabine or to receive gemcitabine monotherapy alone. The results showed that the intensive chemoradiation program with subsequent gemcitabine was more toxic than the delivery of gemcitabine alone. In addition, median survival for patients randomized to chemoradiation and subsequent gemcitabine was only 8.6 months; this was inferior to the survival of patients treated with gemcitabine alone (13 months, $p = 0.03$). Given the toxicity associated with the intensive chemoradiation, it may be that the worse survival of the patients randomized to receive chemoradiation was a reflection of toxicity and not superior efficacy using single-agent gemcitabine.

In a similar fashion, ECOG conducted a trial in which 74 patients were randomized to receive gemcitabine alone or gemcitabine plus radiation followed by gemcitabine [41]. Patients who were randomized to gemcitabine plus radiation had a median survival of 11.4 months which was statistically superior to the median survival of those patients randomized to gemcitabine alone (9.6 months, $P < 0.03$). However, the survival curves revealed that the addition of radiation to gemcitabine only provided a survival advantage to those patients surviving more than 6 months; there was no difference in survival between the two arms for patients with shortened survival. These results implied that local control was only relevant to the subset of patients with more favorable tumor biology, and thus induction chemotherapy might provide a selection mechanism to identify patients with rapid onset of metastatic disease and distinguish them from a larger subset of patients more likely to benefit from follow-on chemoradiation. Retrospective studies and prospective clinical trials appeared to support this approach, and median survivals in these publications ranged from 12 to 19 months. Of note, during the period of induction chemotherapy, roughly 30% of patients manifest aggressive tumor biology which precluded the subsequent delivery of radiotherapy. This subset of patients was observed to have poor survival.

Very recently, however, the paradigm of induction chemotherapy followed by chemoradiation as an optimal strategy has been refuted [17]. In LAP07, a large international, multicenter trial coordinated by the Groupe Coopérateur Multidiciplinaire en Oncologie (GERCOR), patients who remained progression free after 4 months of gemcitabine monotherapy or gemcitabine plus erlotinib were subsequently randomized to continue gemcitabine +/− erlotinib for two additional months or to switch to treatment with capecitabine-based chemoradiation. Radiation was delivered to a total dose of 54 Gy. There was no significant difference in median survival between those who continued gemcitabine +/− erlotinib (16.5 months) and

those who received follow-on chemoradiation (15.2 months). Of note, fairly consistent with earlier trials of induction chemotherapy, 40% of the initial cohort of patients dropped out during the first 4 months of induction chemotherapy prior to randomization to continued chemotherapy versus a switch to chemoradiation, predominantly based on progressive disease. These results, combined with findings from other studies highlighted below, lead to the following tenets in regard to clinical decision-making for patients with locally advanced disease.

Five Tenets for Locally Advanced Pancreatic Cancer

1. Laparoscopy has a limited role in the current staging of patients with LAPC.
2. Patients staged with locally advanced pancreatic cancer and having adequate PS with manageable symptoms should undergo initial treatment with systemic therapy.
3. Local therapeutic strategies may have a role in management after a period of systemic therapy for subsets of patients with LAPC.
4. Surgical resection with curative intent is possible for some patients with LAPC.
5. Options for less invasive or nonoperative palliation of biliary obstruction and gastric outlet obstruction are expanding.

Laparoscopy Has a Limited Role in the Current Staging of Patients with LAPC

High-quality cross-sectional body imaging has allowed for more accurate staging of pancreatic cancer, and the yield of staging laparoscopy appears to be decreasing over time. Nevertheless, some experts have advocated laparoscopy as a routine staging procedure. Several studies have shown that laparoscopy can upstage a subset of patients with locally advanced disease by visualizing small surface liver metastases or peritoneal implants or cytologic examination of peritoneal washings. However, with systemic therapy now the standard of care for patients with locally advanced cancer, the documentation of radiographically occult metastases becomes less relevant. Furthermore, if a patient subsequently develops radiographic or other clinical evidence of metastatic disease after induction chemotherapy, the need for a staging laparoscopic examination diminishes further. Currently, staging laparoscopy is most appropriate for patients in whom local therapies (radiotherapy or ablative techniques) are being considered after an initial period of systemic chemotherapy. In these circumstances, laparoscopy may indeed impact clinical decision-making.

Importantly, there may be clinical situations in which local interventions may be justified even when small volume metastatic disease is evident or suspected. These would include bleeding from ulcerated gastrointestinal mucosa infiltrated with tumor, intractable pain not responsive to medical management or neurolytic plexus block, and possibly when there appears to be an increased risk of gastric outlet

obstruction secondary to tumor encroachment on the duodenum, or recurrent biliary obstruction related to tumor ingrowth.

Patients Staged with Locally Advanced Pancreatic Cancer and Having Adequate PS with Manageable Symptoms Should Undergo Initial Treatment with Systemic Therapy

Based on the results from LAP07, there is no survival advantage to consolidating conventional chemoradiation after an initial period of induction chemotherapy. While some might argue that the available data supports the delivery of gemcitabine monotherapy as the standard regimen, various investigators have begun to report on the administration of either FOLFIRINOX or gemcitabine/nab-paclitaxel as frontline therapy for patients with locally advanced disease [42, 43]. Currently, there is no definitive evidence to prefer one systemic regimen over another in the setting of locally advanced disease [44]. However, there may be distinct subsets of patients with locally advanced disease who may be candidates for more aggressive combination regimens rather than treatment with gemcitabine alone. These may include very fit patients with no comorbidities or contraindications to treatment with a platinum-containing regimen such as FOLFIRINOX. Conversely, both FOLIRINOX and gemcitabine/nab-paclitaxel may be less attractive initial options for patients with long-standing diabetes or having peripheral neuropathy from other causes. Moreover, given that the majority of patients with locally advanced disease will develop metastatic disease, delivering FOLFIRINOX as initial therapy will limit therapeutic options at the time of progression.

Lastly, although relatively few, there are distinct patients with locally advanced disease in whom an aggressive multimodal approach may provide an opportunity for prolonged local control and even ultimate surgical resection with curative intent. Such patients represent a minority of those who present with locally advanced disease, and their management will be discussed below.

Local Therapeutic Strategies May Have Role in Management After a Period of Systemic Therapy for Subsets of Patients with LAPC

LAP07 demonstrated no survival advantage using chemoradiation after 4 months of systemic gemcitabine compared with two additional months of gemcitabine. However, there were some clinical benefits for those patients who were randomized to receive chemoradiation. First, local tumor progression was decreased with chemoradiation compared to continued systemic therapy (32% vs 46%). Second, in both arms of the trial, all therapy was discontinued after a total of six cycles of gemcitabine or 4 months of gemcitabine and subsequent chemoradiation. For those randomized to chemoradiation, there was a longer chemotherapy-free interval prior to resumption of additional chemotherapy (6.1 months vs 3.7 months, $p = 0.02$). At present, the American Society for Clinical Oncology recommends radiation only for

those patients who have local tumor progression (without evidence of metastases) after a period of induction chemotherapy [44]. In addition, radiation may be an alternative to continued chemotherapy for those patients with LAPC, who develop intolerable side effects to chemotherapy. However, for patients with very favorable tumor biology and a durable response to induction chemotherapy, consolidation with locally ablative therapies may provide a longer chemotherapy-free interval and improve quality of life.

Importantly, the options for local therapies are expanding and now include radiation given as stereotactic body radiotherapy (SBRT), microwave ablation (MA) or radiofrequency ablation (RFA), and irreversible electroporation (IRE) as an alternative or adjunct to radiotherapy for patients with LAPC. SBRT, MA, RFA, and IRE are attractive technologies in that their delivery is of short duration and allow the patient to resume systemic therapy relatively quickly. In addition, these modalities may provide longer more durable chemotherapy-free intervals to enhance quality of life.

Phase II trials of SBRT in LAPC are now appearing in the literature with doses ranging from 33 Gy up to 45 Gy with most patients previously treated with induction chemotherapy [45, 46]. Survival durations with SBRT appear comparable if not superior to those reported in LAP07. These results suggest that SBRT given in five to six fractions is better tolerated and more convenient than standard chemoradiation, with similar efficacy.

In the future, delivery of SBRT after a 4–6 month period of systemic therapy with no interval development of metastatic disease may offer the advantage of a relatively brief intervention for improved local control that can soon be followed by a return to systemic therapy, or alternatively, a period of observation, and for a small, select subset, surgical resection [47].

IRE is a locally ablative strategy that does not lead to thermal injury to surrounding tissues, specifically vascular and ductal structures. The largest experience with IRE in localized pancreatic cancer comes from a multi-institutional trial conducted by the University of Louisville. Investigators there reported on their experience with IRE in 54 patients with pancreatic cancer (90% of whom were previously treated with systemic therapy) and suggested this intervention had the potential to prolong survival over traditional strategies utilizing systemic therapy and chemoradiation [48]. Other centers are beginning to report on their experience with IRE to include percutaneous, image-guided localization of the electrodes [49].

Other locally ablative techniques (MA and RFA) are being reported in the medical literature in more limited fashion. Based on current literature, however, there appears to be growing enthusiasm for IRE, particularly for patients with BR pancreatic cancer or LAPC [50]. However, as previously emphasized, given the propensity for metastases, systemic therapies should precede any local therapeutic intervention (chemoradiation, RFA, SBRT, IRE, or surgery). Moreover, experience with SBRT and locally ablative techniques is currently limited to a few centers, and well-conducted clinical trials are needed to better define the role of these technologies in the future management of patients with locally advanced pancreatic cancer. Nevertheless, these newer modalities are certain to be refined, and their incorporation into the management of some patients with LAPC is anticipated.

Surgical Resection with Curative Intent Is Possible for Some Patients with LAPC

Current criteria to define LAPC generally include tumors with >180° involvement of the SMA or celiac trunk. In an earlier time period, such tumors were rarely downstaged to the point of resectability after treatment with neoadjuvant therapy. However, the growing number of reports of successful resection of BR tumors after neoadjuvant therapy (with encouraging survival durations), coupled with the availability of more active systemic cytotoxic regimens, has led to recent reports of successful resection of pancreatic adenocarcinomas previously considered locally advanced and unresectable. In general, reports of neoadjuvant therapy to downstage LAPC have relied on initial systemic therapy followed by a local therapy (conventional radiotherapy, SBRT, or IRE).

For example, investigators at Moffitt Cancer Center reported on 159 patients with BR (110) or LAPC (49) [47]. Among the patients with LAPC, 21 received FOLFIRINOX as induction therapy, and 28 received various other chemotherapy regimens. Among the patients treated with FOLFIRINOX, five (24%) ultimately underwent an R0 resection after further therapy with SBRT. None of the patients treated with other systemic regimens underwent an R0 resection. Of further note, among the patients with BR or LAPC who underwent R0 resection, median survival was 34.2 months.

In another report from the group at the Johns Hopkins Hospital, patients who underwent a distal pancreatectomy were matched 3:1 to patients who had celiac axis encasement requiring celiac axis resection as a component of the distal pancreatectomy (modified Appleby's procedure) [51]. Of the patients who underwent celiac axis resection/distal pancreatectomy, 88% initially underwent neoadjuvant therapy usually with FOLFIRINOX and SBRT. There was no difference in survival between those requiring a modified Appleby's and those who underwent distal pancreatectomy alone implying that aggressive neoadjuvant multimodal therapy may expand the proportion of patients with LAPC who are eligible for ultimate resection with curative intent.

Further evidence that modern systemic chemotherapy may facilitate tumor downstaging in LAPC comes from a systematic analysis of patients treated with FOLFIRINOX [52]. This study involved 365 patients with LAPC treated with FOLFIRINOX, of whom 57% also received radiation. Of the 365 patients, 103 (28%) underwent subsequent resection with an R0 rate of 77%. Of note, among those patients treated with FOLFIRINOX alone (without radiation), only 12% went on to surgical resection (70% R0) suggesting radiotherapy may be of additional benefit in downstaging LAPC.

In addition to more aggressive combination chemotherapy with or without subsequent radiation, intraoperative IRE as an adjunct to surgical resection in BR or LAPC is also being explored. Investigators at the University of Louisville have described the potential of IRE to provide for "margin accentuation," thereby increasing the chances of an R0 resection for patient initially staged as having BR or LAPC [53].

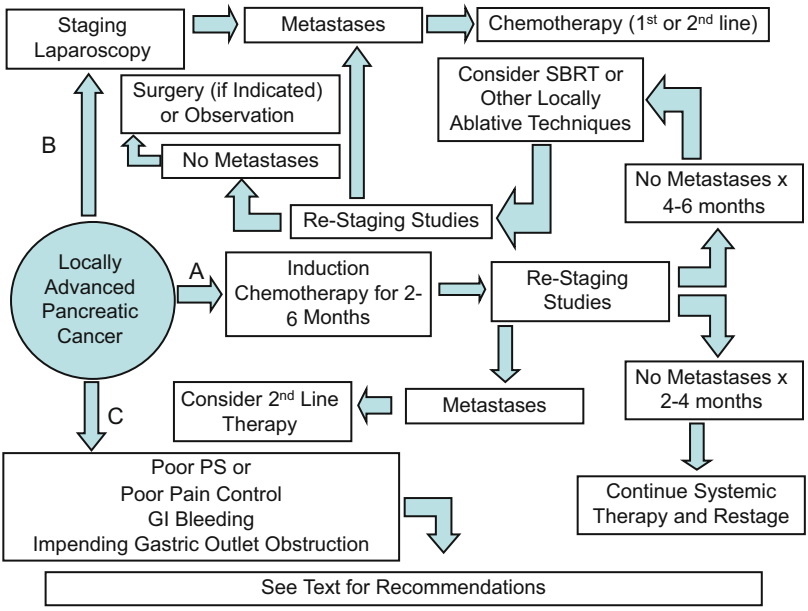

Fig. 3 Decision pathway for patients with LAPC. Pathway (**a**) utilizes induction chemotherapy without need for staging laparoscopy. Pathway (**b**) utilizes laparoscopy to upstage some patients. Pathway (**c**) is for the small group of patients with poor PS or immediate local control problems irrespective of the presence of low-volume metastatic disease

In summary, as systemic therapy for pancreatic cancer improves and various ablative techniques are further developed, an expanding subset of patients with LAPC may be considered for curative surgical resection. Thus, for a patient with LAPC having good PS and a stable or responding primary tumor (with no interval metastatic disease after 4–6 months of systemic therapy), referral to a center of excellence should be encouraged. See Fig. 3 below for a more detailed decision tree.

Options for Less Invasive or Nonoperative Palliation of Biliary Obstruction and Gastric Outlet Obstruction Are Expanding

Although palliative interventions are appropriate for patients with all stages of pancreatic cancer, clinical decision-making, particularly as it pertains to palliative surgery, remains a challenge. In years past, many patients underwent exploratory laparotomy for potentially resectable disease with intraoperative discovery of radiographically occult metastatic disease or unresectable tumor. While most surgeons would agree with operative biliary bypass for unresectable patients undergoing exploratory laparotomy, for tumors in the head of the pancreas, there is no consensus about prophylactic gastrojejunostomy. Therefore, prophylactic gastrojejunostomy should be left to the surgeon's best judgement considering the extent of local disease, the metastatic

tumor burden encountered, comorbidities, and the patient's life expectancy. Of note, this clinical decision is probably less relevant today, and the role of palliative surgery for patients with pancreatic cancer appears to be waning. There are three reasons for this. First, better preoperative imaging is now distinguishing potentially resectable tumors from borderline resectable and locally advanced tumors; the latter two categories have more limited indications for initial surgery. Second, high-quality imaging also appears to be improving the detection of low-volume metastatic disease. Third, these imaging advances occurring as nonoperative interventions to address biliary and gastric outlet obstruction are also expanding.

For patients with LAPC, where prognosis is intermediate to resectable and metastatic disease, the array of options to manage biliary obstruction include surgical bypass, endoscopic biliary stenting, and percutaneous biliary decompression with or without transhepatic deployment of a stent [54]. Previously, nonoperative approaches were often not durable or required periodic stent or catheter exchanges related to occlusion and ongoing potential for cholangitis. With the availability of self-expanding metal stents (covered or uncovered) which can be inserted by either a transhepatic or an endoscopic approach, durable biliary drainage can be accomplished for a growing proportion of patients. Among patients with LAPC, the management of bile duct obstruction may be more complicated, especially for those with longer life expectancy. In general, nonsurgical approaches are durable for most patients, although some may require metal stent revision, usually related to occlusion from debris or tumor ingrowth.

The management of gastric outlet obstruction also requires careful deliberation. This complication may occur in isolation, but is often accompanied by disease progression beyond the primary tumor. Here too, options for management are expanding and include open gastrojejunostomy, laparoscopic gastrojejunostomy, duodenal stenting, and, for some patients, decompressive gastrostomy tube. For surgical candidates, laparoscopic gastrojejunostomy appears to be at least equivalent to open gastrojejunostomy in terms of length of hospital stay and resumption of oral feeding. Surgical intervention should be limited to patients having local tumor progression without evidence of metastatic disease or having very limited metastatic tumor burden. The presence of ascites or peritoneal disease would be relative contraindications to surgical intervention. For patients with documented metastatic disease, particularly those having progressive metastases, or otherwise considered as poor surgical candidates, insertion of a duodenal stent appears to be safer, more effective, and less costly. There is a small group of patients with functional outlet obstruction or multifocal bowel obstruction due to intra-abdominal metastases. For these patients endoscopic or percutaneous insertion of a decompressing gastrostomy tube may be more appropriate.

Whenever possible, patients with locally advanced pancreatic cancer should be referred to a center of excellence in pancreatic cancer in order to develop an initial strategy for symptom management and anticancer therapy. For patients with jaundice, decompression of the biliary tree should occur prior to the delivery of cytotoxic therapy. Whether oncologic therapy is subsequently delivered in a community clinic or a tertiary center, frequent follow-up to monitor toxicities of treatment, signs and

symptoms of cholangitis, venous thromboembolism, pain, hemorrhage, or onset of gastric outlet obstruction is required. Moreover, for patients who develop complex local control problems, multidisciplinary input from surgeons, gastroenterologists, interventional radiologists, and oncologists should be encouraged. This is also important for the small number of patients who may benefit from other technically advanced procedures such as portal venous stenting or neurolytic pain blocks performed using a percutaneous image-guided approach or under endosonographic guidance [55–57].

Clinical Decisions in Metastatic Pancreatic Cancer

Since the last edition of this text, the chemotherapeutic options for patients with metastatic disease have expanded, and overall, expected survival for patients with metastatic disease and adequate PS have improved modestly. Three new regimens have been developed and approved for patients with metastatic disease: FOLFIRINOX, gemcitabine/nab-paclitaxel, and, as a second-line treatment, nanoliposomal irinotecan (nal-iri) administered with folinic acid and fluorouracil (FF) [58–60]. These drug combinations were approved based on large randomized clinical trials with varying patient eligibility criteria, and these variations should be appreciated in clinical decision-making. FOLFIRINOX was studied in previously untreated patients with enrollment limited to patients with ECOG PS 0 or 1 [58]. The trial demonstrated a survival advantage for treatment with FOLFIRINOX over gemcitabine (11.6 months vs 6.7 months, respectively, $p = 0.002$). The Metastatic Pancreatic Cancer Trial (MPACT) which led to the approval of nab-paclitaxel as frontline therapy in combination with gemcitabine had more relaxed eligibility criteria and allowed trial entry for patients with Karnofsky Performance Status (KPS) $\geq$70% (roughly equivalent to ECOG $\leq$2) [59]. MPACT demonstrated a survival advantage for patients randomized to gemcitabine/nab-paclitaxel compared with those who received gemcitabine alone (median overall survival 8.5 months vs 6.7 months, $p = 0.001$). Lastly, nanoliposomal irinotecan (nal-iri) was approved for use in second-line therapy for patients who had failed initial therapy with gemcitabine alone. In a trial which enrolled 417 patients, the combination of FF with nal-iri led to a median survival of 6.1 months compared with 4.2 months for patients who received FF (hazard ratio for death 0.67, $p = 0.012$) [60].

When considering treatment it must be recognized that patients with metastatic pancreatic cancer often present with significant symptom burden and marginal functional status for cytotoxic therapy. Such patients generally have poor survival, and importantly, some analyses suggest that combination therapy may be detrimental to survival compared with less aggressive therapy. Therefore, questions to be posed in decision-making include whether or not systemic therapy should be advised, how aggressive it should be, and, at some point, if second-line therapy should be offered. With this in mind, some general tenets of anticancer therapy are discussed below.

Five Tenets for Patients with Metastatic Pancreatic Cancer

1. Chemotherapy prolongs survival over best supportive cancer in patients with advanced pancreatic cancer.
2. Patients with good performance status benefit from combination chemotherapy over treatment with gemcitabine alone.
3. Patients with poor performance status may do worse with combination chemotherapy compared with monotherapy and may not benefit from the delivery of any cytotoxic therapy.
4. Second-line therapy may be appropriate for some patients who progress after frontline therapy.
5. Surgery or other noninvasive ablative strategies may be relevant for a small subset of stage IV patients with limited metastatic and/or persistent local disease after initial systemic therapy.

Chemotherapy Prolongs Survival Over Best Supportive Cancer in Patients with Advanced Pancreatic Cancer

In years past, chemotherapy trials using older regimens have shown improvements in survival compared with best supportive care. A meta-analysis of several trials demonstrated a clear survival benefit for patients treated with systemic therapy compared with those receiving best supportive care [61]. This analysis, which included 51 trials and 9,970 enrolled patients, showed improved survival with chemotherapy (hazard ratio = 0.64; 95% CI, 0.42–0.98). At present, however, it remains somewhat uncertain what level of functional status is necessary for a patient to actually benefit from the delivery of cytotoxic therapy. As will be discussed later, some results suggest that patients with poor PS may not receive any meaningful benefit from cytotoxic chemotherapy, and others imply that more aggressive combination therapy may be detrimental to survival compared with treatment using monotherapy.

Patients with Good Performance Status Benefit from Combination Chemotherapy Over Treatment with Gemcitabine Alone

As discussed above, for patients with metastatic disease having ECOG PS 0–1, FOLFIRINOX is clearly superior to gemcitabine alone in terms of objective response rate and overall survival. The same is true for gemcitabine plus nab-paclitaxel for patients with KPS $\geq$70%. Of interest, the MPACT investigators did an analysis of overall survival based on KPS score on trial entry. For patients with KPS >80%, the median survival for patients treated with gemcitabine/nab-paclitaxel was 9.7 months, whereas for patients with KPS 70–80%, the median survival was only 7.6 months [62]. Clinicians should therefore recognize that the benefits of combination therapy are more robust when reserved for patients with well-preserved performance status. This is supported by an earlier analysis of five

randomized trials comparing gemcitabine doublets to gemcitabine monotherapy and suggested that a survival advantage with combination therapy was only conferred on those patients with KPS >80% [63].

Patients with Poor Performance Status May Do Worse with Combination Chemotherapy Compared with Monotherapy and May Not Benefit from the Delivery of Any Cytotoxic Therapy

The link between performance status and survival in patient with pancreatic cancer has been known for decades. Although FOLFIRINOX and gemcitabine/nab-paclitaxel are more active combinations, they are also more toxic compared with gemcitabine monotherapy. Thus, careful evaluation of a patient's PS is critical for informed decision-making. For example, although a survival advantage was observed using gemcitabine/nab-paclitaxel among patients with KPS = 70%, the median survival of this subgroup was quite poor using either the doublet or gemcitabine monotherapy (3.9 months vs 2.8 months, respectively) [62]. Further evidence for caution in advising patients with marginal PS comes from the subset analysis of the randomized trials of other gemcitabine doublets versus gemcitabine alone. This analysis suggested that for those patients with poor performance status (KPS <80%), combination therapy led to worse survival compared with the delivery of gemcitabine alone [63]. This result is not surprising, and while not definitive, more aggressive, toxic therapy may be detrimental for poor PS patients. Furthermore, whether any cytotoxic treatment is beneficial for patients with marginal PS is questionable. Sobering data comes from a randomized trial conducted by the Cancer and Leukemia Group B which compared gemcitabine and bevacizumab to gemcitabine plus placebo in patients with advanced pancreatic cancer. There was no difference in survival between the group treated with gemcitabine and bevacizumab and the group assigned to gemcitabine and placebo [64]. Importantly though, there was a clear difference in survival based on patient performance status at study entry. Those patients reported to have an ECOG PS of 0 had a median survival of 8 months, while those with ECOG PS 1 had a median survival of 4.8 months, and patients with an ECOG PS 2 had a median survival of only 2.8 months. Although some of the patients reported to have an ECOG PS of 2 probably had an ECOG PS closer to 3, a median survival less than 3 months suggests no meaningful benefit from the delivery of chemotherapy. Clinicians should therefore be cautious when facing a patient with poor PS, and any inclination to offer cytotoxic therapy should be tempered by this data (Fig. 4).

Second-Line Therapy May Be Appropriate for Some Patients Who Progress After Frontline Therapy

Although it is common for disease progression to be associated with worsening PS, there is a subset of patients who will maintain sufficient PS to consider second-line

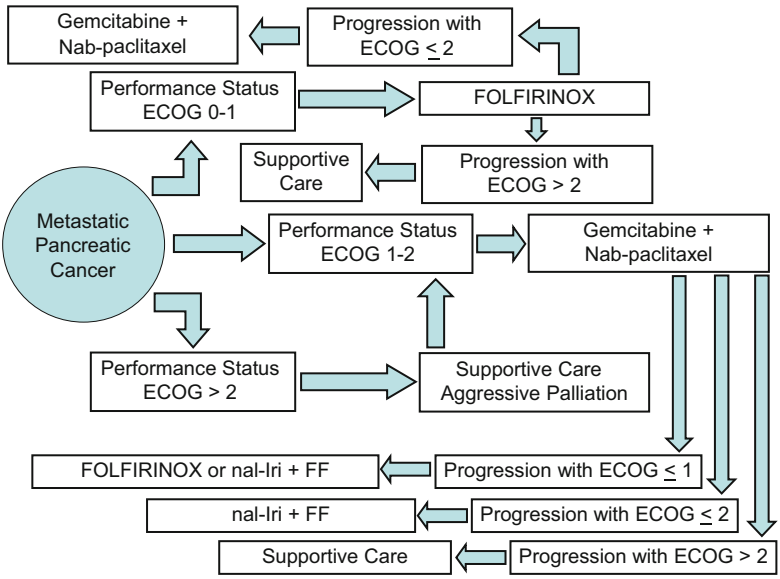

Fig. 4 Decision-analysis in patients with metastatic disease. Multiagent cytotoxic chemotherapy should be limited to those patients with good PS (ECOG 0-2) with distinctions for choosing gemcitabine/nab-paclitaxel vs FOLFIRINOX. Clinicians should be mindful of patients who have worsening PS during evaluation phase or when failing front line therapy. Supportive care may lead to improved PS increasing the potential benefit of cytotoxic therapy while decreasing its risks. Second line therapy is appropriate for those patients maintaining PS after progression on front line therapy

therapy. After the establishment of gemcitabine as standard treatment, there was some effort to establish a second-line regimen for patients who progressed on frontline gemcitabine-based therapy. Two distinct regimens of fluorouracil and oxaliplatin have been evaluated in randomized trials with conflicting results. CONKO-03 reported on a regimen of oxaliplatin, folinic acid, and fluorouracil (OFF) which is less dose intense than FOLFOX [65]. The study randomized 160 advanced pancreatic cancer patients with KPS $\geq$ 70%. Patients who randomized to OFF had a median overall survival of 26 weeks which was statistically and clinically significant in comparison to an overall median survival of 13 weeks for patients randomized to FF ($p = 0.014$). However in the PANCREOX trial conducted in Canada, there was no difference in PFS for the patients randomized to either modified FOLFOX6 (mFOLFOX6) or FF (3.1 months vs 2.9 months, $p = 0.99$) [66]. Of note, there was a difference in OS with patients randomized to FF having a median survival of 9.9 months versus 6.1 months for FOLFOX, $p = 0.02$. This difference was possibly explained by the higher use of third-line therapy among those patients randomized to FF compared with those randomized to FOLFOX (25% vs 6.8%, respectively).

FOLFIRI has also been investigated as a potential second-line therapy after initial gemcitabine-based treatment. Of note however, based on a small randomized trial conducted in patients with gemcitabine-refractory pancreatic cancer, there appears to

be no significant difference between second-line treatment with FOLFOX or with FOLFIRI [67].

Most recently, a large randomized trial reported on the benefits of nal-iri in combination with FF for patients previously treated in first-line with gemcitabine-based therapy. [60] The trial enrolled 417 patients with KPS $\geq$ 70% in a 1:1:1 randomization between nal-iri with FF, nal-iri monotherapy, or FF. Importantly, all patients had previous treatment with gemcitabine or a gemcitabine combination with approximately 30% of patients having prior therapy with a platinum analog. As previously described, the combination of FF and nal-irinotecan was superior to the other arms in terms of OS (6.1 months vs 4.9 months for nal-irinotecan or 4.2 months for FF; $p = 0.012$). Based on these results, nal-iri has been approved for use in patients who have failed frontline gemcitabine-based therapy.

Given the shift in systemic therapy to gemcitabine/nab-paclitaxel and FOLFIRINOX, it is currently uncertain what role nal-iri/FF will play in second-line therapy for patients with pancreatic cancer. For patients with KPS = 70% who have failed prior gemcitabine monotherapy or gemcitabine/nab-paclitaxel, therapy with FF/nal-iri appears reasonable. However, for patients who have failed gemcitabine-based frontline therapy and who maintain KPS $\geq$ 80%, whether to use FOLFIRINOX or FF/nal-iri is an open question. Lastly, it seems unlikely that patients who have previously failed FOLFIRINOX will benefit from FF/nal-iri, and in the community setting, gemcitabine/nab-paclitaxel is frequently used after front-line therapy with FOLFIRINOX. Support for this strategy comes from a retrospective analysis of 57 patients who received gemcitabine/nab-paclitaxel after FOLFIRINOX failure [68]. The objective response rate was 17.5% with a median OS from the start of second-line therapy of 8.8 months. Of note however, grade 3–4 toxicities were reported for 40% of these patients.

No matter what the initial frontline therapy, when clinicians decide on the merits of any second-line therapy, it may be worth considering a retrospective analysis from the University of Heidelberg [69]. The progression-free and overall survival of 46 patients who progressed after receiving palliative therapy at that institution was tracked. Patients with time to progression (TTP) less than 6 months on frontline therapy (TTP1) had a TTP on second-line therapy (TTP2) of only 2.2 months and a residual survival of 4.4 months. However, for patients with TTP1 >6 months, the residual overall survival was 7.5 months with second-line therapy. Although this finding has not been confirmed in a prospective trial, it still may influence a patient or clinician's enthusiasm for second-line therapy.

Surgery or Other Noninvasive Ablative Strategies May Be Relevant for a Small Subset of Stage IV Patients with Limited Metastatic and/or Persistent Local Disease After Initial Systemic Therapy

With wider use of FOLFIRINOX and gemcitabine/nab-paclitaxel, some dramatic responses are being reported in patients with pancreatic cancer [70, 71]. When such results are coupled with an expanding array of radiation options and noninvasive

ablative techniques, discussions about the merits of other aggressive interventions (to include surgery) are beginning to emerge [72, 73]. At the present time, there is no data to support or repudiate efforts to enhance systemic therapy with radiation, ablative strategies, or even surgical resection for limited metastatic disease or the primary tumor. However, some guiding principles may allow for a disciplined approach to decisions about interventions beyond systemic therapy for patients who present with metastatic disease [74].

The Ultimate Decision: Withholding or Terminating Anticancer Therapy

It is not particularly uncommon for patients with advanced pancreatic cancer to die during active anticancer therapy related to the underlying malignancy more so than toxicity. In an analysis of GI cancer patients treated on randomized trials at the Royal Marsden Hospital from 1992 to 2001, the 60-day all-cause mortality among 171 advanced pancreatic cancer patients was 13% [75]. Almost all of these deaths were attributed to the cancer itself with very few related to treatment toxicity. Nevertheless, the majority of pancreatic cancer patients will have to confront the decision to withhold or terminate cancer-directed therapy prior to their death. Most oncologists recognize that as a patient's condition declines or as proven therapies are exhausted, the risk of further cytotoxic therapy begins to outweigh its potential benefits. Importantly though, analysis of Medicare beneficiaries reveals that although the use of hospice services is increasing over time, the proportion of patients with pancreatic cancer who receive chemotherapy within the last month of life is also rising [76].

With this in mind, it is important for oncologists to communicate goals of care openly and early in the patient's disease course. With rare exception, patients with advanced disease should be informed on initial consultation that therapy will not be curative but the palliative benefits may be significant. Moreover, they should be told that if a particular therapy leads to tumor control or regression, it will be finite in its duration and that eventually, subsequent cancer-directed therapies will be ineffective. It should also be acknowledged that disease progression will ultimately lead to a decline in performance status making the delivery of further cytotoxic therapy not only futile, but possibly detrimental. Importantly, patients should be assured that even when active therapy is not recommended at all, or when discontinuation is advised, the patient's care needs will continue to be met. Lastly, while not comfortable for many physicians, a willingness to discuss spirituality and how spiritual beliefs may impact decisions about cancer-directed treatment or life-sustaining interventions may be both informative and gratifying.

Conclusion

Clinical decisions in pancreatic cancer can be challenging, particularly given the physical and emotional distress associated with this disease. Selection of patients for initial surgery requires high-quality staging studies, a careful evaluation of the patient's

potential for recovery, a full understanding of the current evidence, and a minimal amount of emotion. This will identify the patients most apt to benefit from surgical intervention and adjuvant therapy. For patients with BR pancreatic cancer, neoadjuvant therapy is the preferred initial intervention based on NCCN guidelines, but this approach is not accepted worldwide. In LAPC, systemic therapy is the standard of care. However, for the subset of patients who remain with local disease only, stable or progressing, SBRT and other novel ablative techniques are being investigated. Furthermore, up to 25% of patients with LAPC may be eligible for surgical resection with curative intent after aggressive multimodal therapy. Lastly, for those patients who present with metastatic disease, careful assessment of PS is critical to decision-making in regard to the utility of systemic therapy, how aggressive it should be, and whether second-line therapy is appropriate. For all patients, thoughtful clinical decision-making is a critical ingredient of compassionate cancer care.

Paraneoplastic Syndromes in Pancreatic Cancer

Jens Werner and Stephan Herzig

Contents

Abstract

Paraneoplastic syndromes are defined as signs and symptoms which present distant to the site of primary cancer or metastases. However, they are closely associated with the malignant disease and comprise metabolic, dystrophic, and/or degenerative symptoms, which are consequences of humoral or hormonal factors. The clinical symptoms vary widely and include systemic and organ-specific manifestations. In some cases, these can become the major clinical problems

determining survival. Systemic manifestations include frequent symptoms of pancreatic cancer patients such as fever and cachexia. Organ-specific symptoms may represent as cutaneous, neurological, hematological, or endocrine symptoms. A special focus of this chapter is on diabetes mellitus associated with pancreatic tumors. The best-understood syndromes result from tumor production of biologically active substances or, to a lesser extent, from autoimmune phenomena. Biological active agents may promote the growth of the tumor directly. In turn, growth-promoting agents of this type may become the focus of new approaches to anticancer treatment. After successful treatment of the underlying malignant disease, paraneoplastic symptoms may resolve completely. Thus, early recognition of paraneoplastic syndromes is very important in the management of patients with pancreatic cancer. In the following chapter, the most common paraneoplastic syndromes are described in detail.

Introduction

In most cases, pancreatic tumors produce clinical symptoms as a result of local expansion, with obliteration of normal tissues, as the malignant cells proliferate within the confines of the involved organ. Subsequently, the tumor compresses and infiltrates blood vessels, lymphatics, and nerve fibers as well as surrounding organs. Thus, the principal clinical presentation of pancreatic carcinoma includes abdominal pain and jaundice. While endocrine tumors may present with typical signs and symptoms as a consequence of the overproduction of specific hormones, benign and cystic tumors of the pancreas are mainly detected on routine radiographic evaluations in asymptomatic patients.

Paraneoplastic syndromes are defined as signs and symptoms which present distant to the site of primary cancer or metastases. However, they are closely associated with the malignant disease and comprise metabolic, dystrophic, and/or degenerative symptoms, which are consequences of humoral or hormonal factors. The clinical symptoms vary widely and include systemic and organ-specific manifestations. In some cases, these can become the major clinical problem and determine survival. Systemic manifestations include frequent symptoms of pancreatic cancer patients such as fever and cachexia. Organ-specific symptoms may present as cutaneous, neurological, hematological, or endocrine symptoms. The best-understood syndromes result from tumor production of biologically active substances or, to a lesser extent, from autoimmune phenomena. These would appear

to be probable mechanisms in many recognized paraneoplastic syndromes of uncertain etiology and perhaps in some unrecognized paraneoplastic syndromes.

The incidence of paraneoplastic syndromes is more frequent than generally suspected. Syndromes may occasionally be helpful in the diagnosis of cancer or in monitoring response to cancer therapy. They may produce symptoms as a result of their intrinsic biological activity. Biologically active agents produced by malignant cells may serve as markers early in the course of the disease and may increase the chance of early recognition and subsequent cure. In some patients, amelioration of the syndromes can reverse the patient's dominant symptoms and thus provide significant clinical palliation. Biological active agents may promote the growth of the tumor directly. In turn, growth-promoting agents of this type may become the focus of new approaches to anticancer treatment. After successful treatment of the underlying malignant disease, paraneoplastic symptoms may resolve completely. Thus, early recognition of paraneoplastic syndromes is very important in the management of patients with pancreatic cancer. In the following chapter, the most common paraneoplastic syndromes are described in detail.

Classical Symptoms of Pancreatic Cancer

The classical symptoms of pancreatic cancer include abdominal pain, jaundice, or an episode of acute pancreatitis.

Abdominal pain present in two-thirds of patients with pancreatic cancer [1]. Pain has usually been present to some degree for 2–3 months before presentation to the primary physician and is mainly a constant pain located in the epigastric region. Back pain may also be observed and seems to be a consequence of retroperitoneal infiltration of the plexus and nerves in large tumors which are often located in the corpus and tail of the pancreas. However, even pain may be a paraneoplastic symptom.

Jaundice is an early symptom of pancreatic head cancers and occurs in almost half of all patients with pancreatic tumors secondary to bile duct obstruction. Painless jaundice is typical as patients rarely present with biliary colics. Nevertheless, most of the patients have pain to a certain degree. While most cancers of patients with jaundice are located in the head of the pancreas, some cancers might be located in the distal portion of the pancreas and obstruct the bile duct by metastasis of the periportal lymph nodes.

A small number of patients with pancreatic cancer will present with an initial episode of acute pancreatitis. This is mostly the consequence of pancreatic duct obstruction by cancer or mucin derived from main duct IPMN's. Thus, especially in elderly patients without typical risk factors for acute pancreatitis, pancreatic cancer should be ruled out by additional diagnostics in those patients.

However, the described "typical symptoms" are not specific enough to allow the clinician to make a confident diagnosis of pancreatic cancer without an additional laboratory, radiological, or pathological examinations.

Endocrine tumors of the pancreas often present with specific symptoms as a consequence of an overproduction of organ-specific hormones. The different types of endocrine pancreatic tumors and their syndromes are described in detail in this chapter (endocrine paraneoplastic syndromes), as well as in chapters 21 and 44 of this book.

Clinical Manifestation and Diagnostics of Paraneoplastic Syndromes

The clinical symptoms of paraneoplastic syndromes vary widely and include systemic and organ-specific manifestations.

Systemic Manifestation

Cachexia

One of the major and most characteristic problems observed in cancer patients is weight loss, usually associated with anorexia. Compared to other tumors, pancreatic cancer has the highest incidence of cachexia reaching as much as 80% of all patients at the time of diagnosis [2]. As a consequence, palliation of this occurrence remains one of the most important therapeutic targets in clinical practice. Over the past years, important new developments regarding the pathogenesis of pancreatic cancer associated cachexia have been achieved.

Anorexia represents the failure of usual appetite signals whereas cachexia is the debilitating state of involuntary weight loss. This syndrome is defined as the "cancer anorexia-cachexia syndrome" [3]. This syndrome usually consists of a combination of anorexia, tissue wasting, malnutrition, weight loss, abnormalities of taste and smell, and the impossibility to increase oral intake to adapt energy expenditure. The cause for this commonly observed and often life-limiting disturbance remains to be determined in spite of the fact that many contributing factors have been identified. The pathogenesis is multifactorial.

The patients often simply can not ingest food, despite the need for increased nourishment. An aversion to meat and nausea is often observed. Early satiety is probably also the consequence of gastroparesis, delayed gastric emptying, and postprandial bloating. Malignant gastroparesis may result from cancer itself or may be a complication of its treatment including surgery, radiotherapy, or chemotherapy [4]. Potential pathophysiological mechanisms of malignant gastroparesis include postvagotomy syndrome, malignant infiltration of the autonomic nervous system, and paraneoplastic dysmotility with autoantibody-mediated destruction of the enteric nervous system. In addition, the loss of appetite and weight is a consequence of abdominal pain, restricted food intake due to duodenal stenosis, and maldigestion secondary to exocrine insufficiency.

Specific disorders of carbohydrate, protein, lipid, and energy metabolism also play a crucial role in the pathophysiology of the catabolic state observed in most

patients with pancreatic cancer. Biochemical abnormalities in energy metabolism have been well characterized. Fatty acids are oxidized in preference to glucose, and anaerobic glucose metabolism is increased while oxidative phosphorylation is reduced. This results in an inefficient expenditure of ATP, and a subsequent energy deficit. A complex network of cytokines, neuroendocrine hormones, and tumor-derived factors seem to further mediate the catabolic changes [5]. Increase of proinflammatory cytokines including IL-1, IL-6, TNF-a, TGF-B, and others initiate the release of leptin, a hormone that is secreted by adipose tissue, and which is responsible for the homeostasis of body weight via a central negative feedback mechanism. High levels of leptin reduce hypothalamic orexigeneic mediators (e.g., orexin, ghrelin, neuropeptide Y) and increase anorexigenic mediators including thyroid-releasing hormone, glucagon-like peptide. As a consequence, a continuous increase of energy expenditure is induced [6].

Treatment of cachexia today includes symptomatic administration of hypercaloric parenteral and/or enteral nutrition. However, these management approaches have not been proven to be beneficial to improve symptoms or survival in pancreatic cancer patients [7]. Today, next to the application of progestogens (e.g., megestrol acetate) and corticosteroids, several experimental approaches such as inhibitors of pro-inflammatory cytokines are presently under investigation [8]. Thalidomide, an inhibitor of tumor necrosis factor-alpha, has recently been shown to stop weight loss in patients with cachexia and pancreatic cancer [9].

Fever

Fever is another frequent systemic sign which can be observed in about 10% of all patients with malignancy. However, infections including infections by endogenous bacteria or fungi need to be ruled out first, before it is considered to be paraneoplastic. The pathophysiological mechanisms of fever as a paraneoplastic symptom include increased cytokine release by cancer cells or immunoreactions of the tumor with subsequent IL-1 release by monocytes.

Other systemic paraneoplastic symptoms include arthritis, digital necrosis, or lactate acidosis. However, these syndromes are rarely observed in patients with pancreatic cancer.

Cutaneous Manifestation

Paraneoplastic dermatoses are markers of internal malignancy, characterized by being relatively uncommon, associated with certain forms of cancer and occurring in connection with cancer either before, during, or after the diagnosis has been made. Furthermore, the skin symptoms typically run a parallel course with the cancer. Most paraneoplastic dermatoses disappear when the primary tumour is removed and reappear in the case of recurrence or metastases of the cancer. Adult dermatomyositis is especially associated with breast and lung cancer. Cutaneous manifestations of patients with pancreatic cancer are very rare. Although larger series have not been reported, almost all kind of cutaneous paraneoplastic lesions have been described in

association with pancreatic tumors in case reports. Subsequently, the most frequent cutaneous manifestations are described.

Necrolytic Migratory Erythema

Necrolytic migratory erythema is a cutaneous paraneoplastic manifestation, which is usually associated with a glucagon-secreting pancreatic tumor (alpha-2 cell carcinomas of the pancreas). Although it also may occur in other circumstances in which serum glucagon is elevated, as in hepatic cirrhosis, it is more specific than all other cutaneous paraneoplasias for a certain tumor entity, the glucagon-secreting pancreatic tumors. Glucagonoma syndrome is a paraneoplastic phenomenon characterized by an islet alpha-cell pancreatic tumor, necrolytic migratory erythema, diabetes mellitus, weight loss, anemia, stomatitis, thromboembolism, and gastrointestinal and neuropsychiatric disturbances. These clinical findings in association with hyperglucagonemia and demonstrable pancreatic tumor establish the diagnosis. Glucagon itself is responsible for most of the observed signs and symptoms, and its induction of hypoaminoacidemia is thought to lead to necrolytic migratory erythema [10]. Necrolytic migratory erythema is characterized by a figurative eruption with erosions and a rapid centrifugal progression, that become necrotic and hyperpigmentated after healing. They are mainly located at groin, axillae, but can manifest everywhere (Fig. 1a, b).

Erythema Nodosum

Erythema nodosum is defined as painful subcutaneous nodules mainly located on the anterior surfaces of the legs. Physical examination reveals numerous firm, tender, erythematous and violaceous, subcutaneous nodules on the lower extremities, with marked bilateral pitting edema, and characteristic changes of fat necrosis [11] (Fig. 2a, b). Erythema nodosum may be observed in any pancreatic cancer, but is most common for acinar cell carcinoma. A concentration can be detected in the fluids from the cutaneous lesion which cause the subcutaneous inflammation and necrosis.

Acanthosis Nigricans

Acanthosis nigricans represents a localized hyperpigmentation with a velvety surface most often located in the neck, axillae, and groin, and occasionally on the

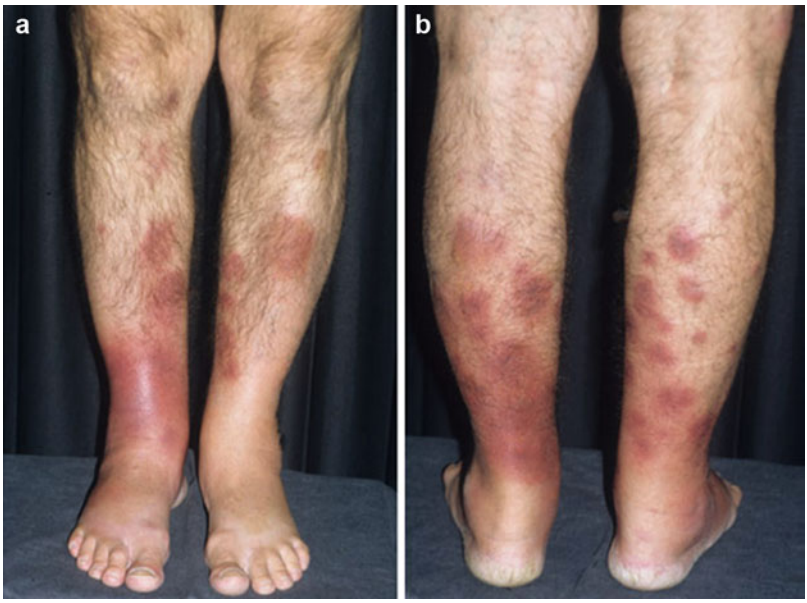

Fig. 2 (**a** and **b**) Erythema nodosum is characterized by subcutaneous nodules on the surfaces of the legs

dorsum of the hand and corners of the mouth. The malignant form is characterized by a rapid progression and pruritus. It is almost always associated with malignancies and therefore cancer search should be initiated once the diagnosis is established [12].

Leser-Trelaut

The Leser-Trelaut syndrome is defined by rapid development of multiple seborrheic lesions, which are often associated with skin tags and acanthosis nigricans. They are mostly located on the back, although it can manifest everywhere.

Akrokeratosis Paraneoplastica

Bazex syndrome is a rare cutaneous paraneoplastic phenomenon which is normally associated with cancers of the upper respiratory tract and digestive tract, which has also been reported in association with pancreatic neuroendocrine tumors. It may be treated successfully with octreotide. It is mainly located in the nose, ears, or fingertips, and has to be distinguished from psoriasis and Lupus.

Eczematous Dermatitis

Skin diseases may be the presenting sign of malignancy, but strict criteria are required to make the diagnosis of a paraneoplastic syndrome. Common dermatoses may also be associated with an underlying malignancy. Thus, in case of unresponsive eczematous dermatitis, an underlying malignant disease, including pancreatic cancer, should be considered in certain cases. This is especially true, if

the lesions behave in an atypical or aggressive manner or are not successfully treated by standard therapies.

Neurological Manifestation

Neoplasms can derange neurologic function in a number of ways, including direct invasion, metastatic invasion, by opportunistic infections, as complications of antineoplastic treatment, metabolic complications, or paraneoplastic syndromes. Depression is a frequent manifestation of advanced cancer and may be an initial symptom of some patients with pancreatic cancer [13]. Depression may be a specific biological attribute of the disease or, since it is mainly diagnosed at a late stage, a secondary manifestation of a life-threatening illness.

Paraneoplastic neurological syndromes present heterogeneous. Nevertheless, they share several characteristics. Paraneoplastic neurological manifestations are clinically dramatic and arise subacutely within several weeks or even days to produce neurologic symptoms that may be very disabling. The syndromes may precede the detection of the malignancy by months. Similarly to the cutaneous manifestations, almost every symptom and even more than one syndrome may be induced by a certain neoplasm. However, certain clinical manifestations are associated with particular types of tumors in the majority of cases [14]. Pancreatic tumors are rarely associated with neurological paraneoplastic syndromes. While paraneoplastic neurological syndromes of the brain and cerebellum and the spinal cord are not associated with pancreatic neoplasms, polyneuropathies and neuromuscular paraneoplasias such as myasthenia gravis and pseudomyasthenia have been reported to be associated with pancreatic neoplasms in some cases. Autoimmune mechanisms have been implicated in these paraneoplastic disorders, which are characterized by highly specific patterns of reactivity with neural tissue or muscle. In both, the myasthenia gravis and the pseudomyasthenia syndrome, circulating antibodies that are directed at synaptic proteins have been identified. In addition, both diseases have been reproduced in animals by passive administration of fractionated immunoglobulins.

Neuromuscular Paraneoplastic Syndromes

Myasthenia Gravis

Fifteen percent of the cases are associated with thymoma. Rarely, other tumors including pancreatic neoplasias are the underlying cause. Myasthenia gravis is characterized by exercise-induced muscle weakness caused by antibody-mediated reduction in the number of acetylcholine receptors at the postsynaptic junction.

Pseudomyasthenia (Lambert-Eaton.Syndrome)

This syndrome is characterized by weakness, myalgias, and fatigue, typically pronounced in the lower extremities and proximal muscles. The incidence of underlying malignant disease is about 70%. Typically, there is a striking reduction of strength in

rest and a transient improvement of energy on repetitive exercise. Common associated features are dryness of mouth and eyes, diminished sweating, and orthostatic symptoms. The syndrome is believed to be an autoimmune disorder with diminished release of acetylcholine and a decreased number of active zones in the presynaptic terminal.

Dermatomyositis, Polymyositis

Up to 3% of patients with dermatomyositis or polymyositis have a malignant underlying disease, which mostly is diagnosed within 1 year after the first symptoms [15]. Malignant disease has to be considered especially in older patients with myositis. The main clinical symptom is a progressive weakness of the proximal muscles, with muscle enzymes being increased. The EMG is pathological and biopsies reveal necrosis and a mild inflammation. The cause of this paraneoplastic syndrome is either an altered immune status or an occult viral infection.

Polyneuropathies

Paraneoplastic polyneuropathies are the most frequent tumor-associated neurological diseases. They are observed with almost any tumor, although lung carcinoma and ovarian carcinoma are the most commonly observed entities. The clinical symptoms are unspecific and cannot be distinguished from neuropathies of other etiologies. The symptoms include atrophy of muscles, distal hypoesthesia, and pain. A treatment is not known, but symptoms improve after management of the underlying malignant disease.

Hematologic Manifestation

Disorders of all three cell lines of the hematopoetic system and the coagulation cascade are frequently observed in carcinoma patients (about 5% of all cancer patients). The most frequent cause is the infiltration of the bone marrow, infectious or toxic complications.

Anemia is found with increased incidence in advanced tumor stages of malignant diseases. The etiology of anemia cannot be determined in most of the cases. In addition, there is no association of anemia with a special type of carcinoma. In general, the mechanisms accounting for anemia are almost exclusively extrinsic to the tumor and include the destruction of erythrocytes from hypersplenism, microangiopathic hemolysis, and autoantibodies, as well as anemia secondary to gastrointestinal bleeding and many other circumstances.

Microcystic pancreatic tumors are reported to be associated with an autoimmune-induced hemolytical anemia, and patients with mucin-producing adenocarcinomas of the pancreas have been reported to develop microangiopathic-induced hemolytic anemia. Pathogenetically, tumor cell invasion induce endothelial lesions and disturbances of the microcirculation with subsequent fragmentation of erythrocytes. A thrombotic-thrombocytopenic purpura or a hemolytic-uremic syndrome, and finally a clinical disseminated coagulopathy (DIC) may develop.

Pancreatic tumors associated with **polycythemia** have not been described.

Similarly, a **leukocytopenia** has not been reported as a paraneoplastic syndrome in patients with pancreatic cancer.

In contrast, **leukocytosis** is frequently found in different malignant diseases including pancreatic carcinomas. The pathophysiological mechanism is a cytokine-mediated increase of growth-factors (e.g., G-CSF, GM-CSF). In general, leukocytosis is asymptomatic, but leukemoid reactions have been described in pancreatic cancer [16]. An **eosinophilia** has been associated with several malignancies and also with pancreatic cancers. Fever, allergic reactions, and an eosinophilic pulmonary infiltration might be observed in these patients. Another rare disease is the **Sweet-syndrome,** which is associated with malignancies including pancreatic cancers in about 20%. It is characterized by an acute febrile dermatosis which is associated with arthralgia, myalgia, pulmonary infiltrations, and glomerulonephritis.

Thrombocytosis is frequently associated with almost any malignant disease, but is rarely of any pathological significance. Symptomatic thrombosis and hemorrhagias are rarely observed. **Thrombocytopenia** is not associated with patients with pancreatic cancer.

However, pancreatic cancer patients and patients with mucin-producing tumors and adenocarcinomas of the pancreas are frequently (about 18%) associated with a hypercoagulable state and a clinical **disseminated coagulopathy**. Consequently, venous thrombosis and pulmonary embolism, as well as nonbacterial endocarditis develop quite frequently. Pathophysiological mechanisms are increased thromboplastin levels which are increased in tumor compared to normal tissue and a direct activation of factor X by tumor-derived procoagulatory factors.

Endocrine Manifestation

The term “ectopic hormone secretion” defined tumor-derived hormone production of tissues which normally do not release any hormones. Although this term is still used today, it is well known that many human tissues apart from the typical endocrine tissues produce hormones. The following criteria should be fulfilled to define “ectopic hormone production”:

- Reduction of hormone level and decrease of paraneoplastic symptoms after removal of tumor
- Persistence of increased hormone levels after resection of the organ which normally produces the hormone
- Identification of an artero-venous difference of hormone concentrations in the vascular system of the tumor
- Detection of hormones in the tumor tissue and production of hormones in the in vitro cultures of the tumor tissue

Pathogenetic cause of the hormone production is the genetic depression and genetic mutations during tumorigenesis [17].

Pancreatic tumors may be associated with the following paraneoplastic endocrine syndromes:

- **Acromegaly**: The increased production of Growth hormone–releasing hormone (GHRH) and growth hormone (GH) in the absence of a pituitary adenoma. Most of these pancreatic tumors are located in the tail of the pancreas. The clinical manifestation is identical to acromegaly.
- **Syndrome of inadequate ADH-secretion** (Vasoactive intestinal peptide): Schwartz and Bartter described the first cases in 1957 which presented with symptoms including hyponatremia, hypervolemia, and increased urine osmolality. The syndrome is caused by an increased level of vasopressin, which may be the consequence of increased ADH or ANP production. Clinical symptoms may develop and include headache, nausea, vomiting, disorientation, and convulsions.

Diabetes Mellitus

Classification of Diabetes Mellitus

Diabetes mellitus comprises a group of heterogeneous metabolic disorders, which has an increase in blood glucose levels in common. Whereas the so-called type I diabetes results from the autoimmune destruction of pancreatic beta cells, type II diabetes is caused by the insensitivity of peripheral organs such as muscle, fat, and liver against the action of the pancreatic peptide hormone insulin (i.e., insulin resistance), combined with an inability of the beta cell to respond normally to glucose by appropriately increasing insulin secretion [18]. Thereby, type II diabetes accounts for more than 90% of diabetes worldwide [19]. While the relative contribution of these two defects to type 2 diabetic pathogenesis is still under debate, longitudinal studies in high-risk individuals suggest that insulin resistance is an early phenomenon, occurring many years before any signs of glucose intolerance, whereas the beta cell failure develops later in the pathogenesis of disease [20]. Both hallmarks of type 2 diabetes, insulin resistance and beta cell failure, seem to arise from a complex interplay between different genetic and environmental pathways and factors. In this regard, estimates suggest that 30–70% of type 2 diabetes risk can be attributed to genetic factors in a polygenic and heterogeneous manner [21]. This indicates that a variety of distinct genes and different genetic combinations are involved in type 2 diabetic pathogenesis, which in turn intertwine with a number of environmental conditions and risk factors (e.g., high-caloric food intake, life style, aging) [22].

Apart from type 1 and type 2 diabetes, there are additional specific types of diabetes including paraneoplastic, maturity onset, or gestational diabetes. Particularly exo- and endocrine tumors of the pancreas display a high prevalence of diabetes mellitus as a paraneoplastic syndrome, most likely reflecting the close interrelationship between exocrine and endocrine cells within the pancreas and their importance for overall energy homeostasis under nonneoplastic conditions [23].

In clinical terms, several criteria may be used to establish the diagnosis of diabetes. (A) a 75 g oral glucose tolerance test with a 2 hour value of 200 mg/dL or more, (B) a random plasma glucose of 200 mg/dL or more with typical symptoms

of diabetes, or (C) a fasting plasma glucose of 126 mg/dL or more on more than one occasion [7]. In most cases, fasting glucose values are preferred for their convenience, reproducibility, and correlation with increased risk of microvascular complications. In this context, impaired fasting glucose has been defined as fasting plasma glucose of 110 or more but less than 125 mg/dL on two different days. In addition, impaired glucose tolerance is defined as a plasma glucose value of 140 or more along with less than 200 mg/dL during an oral glucose tolerance test 2 hours after [24].

Control of Metabolism in Health and Diabetes through Pancreatic Hormones

Under normal, nonneoplastic conditions, the pancreatic beta cell hormone insulin triggers the fast uptake and oxidative catabolism of glucose in liver, muscle, and adipose tissue, and simultaneously inhibits glycogenolysis and gluconeogenesis in liver during feeding [25, 26].

All of the actions of insulin are mediated by its membrane-bound receptor, a member of the tyrosine kinase receptor family [27]. Upon insulin binding, the intrinsic tyrosine kinase activity of the insulin receptor at the cell surface becomes activated and leads to the subsequent tyrosine phosphorylation of multiple signaling components, involving phosphoinositide-3-kinase and the Ser/Thr kinase protein kinase (PK) B/Akt, thereby transducing the insulin signal to downstream cytoplasmic and nuclear effectors which then ultimately control insulin's metabolic effects [27–32].

In particular, insulin signaling results in translocation of glucose transporter 4 from its intracellular pool to the plasma membrane and glucose transport into skeletal muscle and adipose tissue [33, 34], thereby effectively lowering circulating blood glucose levels. In adipose tissue, insulin acts also antilipolytic, whereby it inhibits the release of fatty acids from adipocytes by decreasing the activity of hormone-sensitive lipase and adipose triglyceride lipase (ATGL). In the liver, insulin prevents the release of glucose from the liver by inhibiting hepatic glycogen breakdown to glucose and the expression/activity of key enzymes in the de novo glucose production pathway (i.e., gluconeogenesis) [35, 36]. The importance of functional insulin signaling for whole-body survival and homeostasis can be most dramatically demonstrated in mouse models of total body deficiency in insulin receptor expression, leading to severe ketoacidosis and death of the affected animals shortly after birth [37].

Low plasma glucose levels during fasting and exercise trigger a series of hormonal cues that promote a switch in whole body energy usage. Along with a drop in insulin levels, counter-regulatory hormones gain metabolic control. In particular, the peptide hormone glucagon from alpha cells within the pancreatic islets and adrenal glucocorticoids are released into the circulation [38–41]. These hormones activate triglyceride breakdown via the induction of hormone-sensitive lipase in white adipose tissue and contribute to glycogen degradation in both muscle and liver, thereby leading to the release of previously stored glucose depots and an elevation of blood glucose concentrations [26].

In addition, the high availability of circulating, adipose tissue-derived lipids determines the enhanced mitochondrial oxidation of free fatty acids (FFA) in the

liver. The oxidation end product, acetyl-CoA, serves as a substrate for the synthesis of ketone bodies that are exported from the liver and used as primary energy source by skeletal muscle or brain after prolonged starvation periods. Apart from providing acetyl-CoA, FFA beta-oxidation represents a critical energy provider for hepatic gluconeogenesis. The gluconeogenic pathway represents a prominent feature of liver metabolism and acts as the primary defense mechanism against hypoglycemic conditions in response to glucagon/glucocorticoid signaling during fasting through the provision of glucose for extrahepatic tissues such as erythrocytes, renal medulla, and brain [42–45].

The execution of gluconeogenesis and FFA oxidation during fasting and the consequent provision of energy substrates are supported by the concomitant inhibition of insulin-dependent anabolic pathways. In this regard, under the influence of glucagon and glucocorticoids, mitochondrial FFA utilization is promoted by the simultaneous repression of insulin-dependent hepatic lipid storage and synthesis (lipogenesis), and end-products of FFA oxidation, acetyl-CoA, and NADH, serve as allosteric inhibitors of insulin-dependent glycolytic enzymes, isocitrate dehydrogenase, and pyruvate dehydrogenase [26, 46–50]. On the other hand, insulin efficiently and actively blocks counter-regulatory gluconeogenic and beta-oxidation pathways to ensure appropriate energy storage in the fed state [51, 52].

Endocrine regulatory circuits of pancreatic islet peptide hormones, thereby represent critical checkpoints in the overall metabolic adaptation of glucose and energy homeostasis in response to dietary or environmental challenges.

Consequently, either loss or impairment of insulin signaling, insensitivity against its action (i.e., insulin resistance), or a nonphysiological dominance of counter-regulatory hormones, particularly glucagon, results in severe metabolic dysfunctions such as hyperglycemia and dyslipidemia, ultimately leading to the manifestation of diabetes mellitus.

In this context, relative or absolute insulin deficiency and/or elevated glucagon action are causative for decreased insulin-dependent glucose uptake into skeletal muscle and adipose tissue, derepression/activation of hepatic glucose production in the liver, and increased lipolysis in adipose tissue, leading to systemic hyperglycemia and dyslipidemia. Indeed, even a dysfunctional metabolic response of an individual tissue to imbalances in hormone levels can cause severe systemic pathologies. To this end, a defective insulin response in the liver has been shown to importantly contribute to the development of overall peripheral insulin resistance [53–55]. Mice bearing a targeted disruption of the insulin receptor gene in liver display hyperglycemia, hyperinsulinemia, and impaired glucose tolerance [56]. Also, inhibition of the PI3K/Akt-dependent insulin signaling pathway in the liver by the Akt-inhibitor TRB3 leads to hyperglycemia and glucose intolerance [57]. In contrast, reconstitution of insulin signaling by transgenic expression of a constitutively active insulin receptor specifically in liver reverses hyperglycemia and improves glucose tolerance as well as survival of insulin receptor deficient mice [58].

Interestingly, in addition to the manifestation of endocrine pancreatic tumors which can directly disrupt physiologic hormone balance and levels (see below),

many lines of evidence have shown that chronic activation of proinflammatory pathways within insulin target cells can lead to impairment of insulin signaling and diabetes.

Indeed, in addition to classical acute inflammation, metabolic diseases, such as obesity, atherosclerosis, and cancer, have been recognized as low-grade, subacute inflammatory conditions, contributing to the development of end-stage diseases such as diabetes [59, 60]. All of these conditions are characterized by elevated levels of proinflammatory cytokines, such as tumor necrosis factor (TNF) alpha, interleukins (IL) 1beta and 6, and various chemokines [60–62].

Toward this end, TNF alpha, IL6, IL1beta as well as other cytokine levels are elevated in patients and mouse models of impaired insulin signaling [63–65]. In this respect, ablation of the TNF alpha gene or of its receptor renders mice resistant to the development of insulin resistance and associated metabolic disorders [66, 67]. And, a common polymorphism of the IL6 receptor gene interacts with energy intake and affects adipose tissue mass in humans [68], underlining the critical impact of pro-inflammatory cytokine signaling for metabolic diseases. Consistent with this, elevated levels of the proinflammatory cytokines TNF-α, IL-6, and C-reactive protein (CRP) have been shown in individuals with insulin resistance and diabetes [69, 70]. At the cellular level, the inhibitory effects of proinflammatory cytokines on insulin action are mostly mediated via phosphorylation of certain serine residues on insulin receptor substrate (IRS)-1, including Ser312 (Ser307 in the rodent IRS-1 protein), Ser636 (Ser632 in the rodent IRS-1 protein), and Ser1101. Specifically, phosphorylation of these serine residues impedes the normal association of IRS-1 with the insulin receptor, thereby impairing downstream propagation of insulin signaling [71, 72].

Ultimately, alterations of insulin and/or glucagon signaling strength are translated into the activation or repression of gene-regulatory proteins, the so-called transcription factors, which in turn determine the activity status of tissue-specific genetic programs and consequent changes in cellular metabolism.

Research over the past decades has identified key molecular mediators of pancreatic hormone actions.

The FoxO proteins belong to a subfamily of Forkhead transcription factors which all have the so-called “winged-helix” like DNA-binding structure in common. In mammals, three major insulin-regulated FoxO-family transcription factors have been identified so far: FoxO1 (FKHR), FoxO3a (FKHRL1), and FoxO4 (AFX). In addition to the N-terminal “winged-helix-domain,” these three FoxO-proteins share several structural and functional characteristics. All of them have a C-terminal transactivation domain, a nuclear localization signal (NLS), a nuclear exclusion sequence (NES), and three RxRxxS/T consensus sites for phosphorylation by PKB/Akt. Phosphorylation of FoxO-proteins in response to insulin by PKB results in nuclear exclusion and thereby transcriptional inactivation of these proteins [73, 74]. Indeed, in vitro studies have linked FoxO proteins with the transcriptional regulation of insulin-responsive genes involved in carbohydrate and lipid metabolism [75]. The expression of most of the genes, e.g., gluconeogenic phosphoenolpyruvate carboxykinase (PEPCK) and the glucose-6-phosphatase catalytic subunit

(G6Pase), is suppressed by insulin, and the inhibition of FoxO-activity by insulin-induced phosphorylation is regarded as the major mechanism for this regulation [76]. In agreement with this, the binding sites of FoxO proteins within these gene promoters have been characterized as insulin-responsive cis-regulatory DNA elements in this setting [77]. Interestingly, these sites were frequently characterized as insulin-responsive elements long before they were characterized as Foxo-binding sites. Systemically, the partial loss of Foxo1 function decreases hepatic glucose production and promotes adipogenesis and beta cell development [78, 79], processes critically involved in the maintenance of systemic energy homeostasis and glycemic control.

In addition to FoxO transcription factors, members of the nuclear receptor transcription factor family have been identified as major insulin-responsive regulatory factors, most notably the peroxisome proliferator-activated receptor (PPAR) γ. PPARγ is expressed in all major insulin-sensitive tissues, with highest levels in adipose tissue [80]; and its transcriptional activity has been causally linked to the maintenance of peripheral insulin sensitivity in humans [81, 82] as well as animal models [83–89]. Importantly, the antidiabetic action of insulin sensitizers of the thiazolidinedione (TZD) drug family is conferred through their ligand and activation function for PPARγ, establishing PPARγ as the major molecular target molecule in diabetes therapy [90–92].

Genetic Susceptibility to Diabetes

In combination with environmental, hormonal, and/or inflammatory factors, susceptibility for diabetes mellitus seems to be also determined by genetic factors and predispositions [93]. Indeed, the role of genetics in type 2 diabetes is indicated by the familial clustering of insulin sensitivity and secretion, the higher concordance rate of typ II diabetes in monozygotic versus dizygotic twins, and the high prevalence of type II diabetes in certain ethnic groups (e.g., Pima Indians or Mexican Americans) [94, 95].

To this end, recent genome-wide association studies have identified a number of chromosomal loci associated with an increased risk for the development of diabetes.

In this regard, the strongest association of diabetes risk was found so far for the TCF7L2 locus. Individuals homozygous for the high-risk allele have about a doubling of diabetes risk [96, 97]. TCF7L2 represents a nuclear receptor for beta-catenin, critically involved in cell proliferation, adipogenesis, and pancreatic islet development [98]. In addition to TCF7L2, several other loci have been found to be significantly associated with diabetes risk, including the zinc transporter SLC30A8 [99], the homeobox transcription factor HHEX/insulin-degrading enzyme (IDE)/kinesin interacting factor (KIF) 11 locus comprising at least three potential diabetes genes [100], and the CDK5 regulatory subunit-associated protein 1-like 1 gene [101, 102]. Notably, all of these gene products have been implicated in beta cell insulin secretion, pancreas development and insulin degradation, or insulin gene expression, respectively [93], again pointing toward a tight cross-talk between acute (hormones) and permanent (genetic variants) determinants in the control of diabetic hyperglycemia and systemic energy balance.

Consistent with this notion, genome-wide association studies confirmed the importance of nuclear receptor PPARγ (see above) for insulin sensitivity and glucose homeostasis also on the genetic level with an odds ratio of 1.14 ($p = 1.7 \times 10^{-6}$) [103–105]. Genetic association studies thereby supported the impact of a long-known Pro12-to-Ala (P12A) polymorphism in the PPARγ2 gene on diabetes susceptibility. Resistance to diabetes is associated with the minor (Ala12) allele and susceptibility with the major allele (Pro12), which has a prevalence of about 85% among nondiabetic individuals and 88% among diabetic subjects. The genetic variation occurs specifically in the PPARγ2 isoform of the gene which is specifically expressed in adipose tissue and targeted by insulin sensitizer of the thiazolidinedione drug family [82, 106].

As variations of the above-described loci are linked to the susceptibility for metabolic dysfunctions under conditions of impaired insulin signaling and/or increased hormonal counter-regulation (glucagon), it is tempting to speculate that certain genetic variants may also determine the severity and outcome of paraneoplastic diabetes in the context of pancreatic tumor growth.

Pancreatic Endocrine Tumors

During development, endocrine and exocrine cell types within the pancreas arise from common precursors in the foregut endoderm. Within human pancreatic islets, insulin-producing beta cells are centrally located, whereas the islet periphery is populated by alpha, delta, and PP cells, secreting glucagon, somatostatin, and pancreatic polypeptide, respectively [107].

As islet cells demonstrate hormone coexpression during embryonic development, it is believed that pancreatic endocrine tumors (PETs) originate from multipotent cells in the ductal epithelium that retain their ability to differentiate into the corresponding endocrine cell type [108]. PETs are rare neoplasms of the pancreas accounting for less than 5% of all primary pancreatic malignancies [109]. In general, the prognosis for PETs is superior to the one of the more common ductal adenocarcinoma, even in metastasizing cases [110, 111]. As tumors originating from endocrine cells within the pancreatic islets, clinical syndromes associated with these malignancies mostly reflect the impact of the hormone secreted by the respective tumor. Consistently, the so-called insulinomas, glucagonomas, and somatostatinomas are characterized by dysfunctional systemic glucose homeostasis and paraneoplastic diabetes [112, 113]. Collectively, these neoplasms are classified as functional PETs, whereas endocrine tumors not associated with a clinical syndrome are referred to as a nonfunctioning PET. In contrast to functional lesions, nonfunctional PETs lack signs of hormonal hypersecretion and most commonly occur as space-occupying lesions with obstructive jaundice, gastrointestinal obstruction, bleeding, or upper abdominal pain, often presenting with a slow growth rate and developing in the head of the pancreas [113]. In contrast to functional PETs, which can be diagnosed on the basis of clinical symptoms and elevated blood hormone levels, the diagnosis of nonfunctional PETs relies on imaging techniques and histopathologic features. In this respect, multidetector computed tomography of

the abdomen is the most widely applied method for assessing the local extent of PET expansion and the presence of metastases [111, 112].

Among all PETs, insulinomas arising from insulin-producing beta cells represent the most common type of endocrine neoplasms (roughly 30–40% of all PET cases) [114].

Malignant insulinomas invade locally and metastasize to regional lymph nodes and the liver. Outcome depends on the stage of the disease. Malignant insulinomas are generally solitary and larger than their benign counterparts. The presence or absence of liver metastases is a predictor of survival. Despite their malignant potential, the majority of insulinomas are benign (90%) and localized within the pancreatic parenchyma [114, 115].

Within the pancreas, insulinomas are equally distributed throughout the gland and only found at ectopic locations in a small percentage of cases (3%), with the duodenal mucosa being the most common site of ectopic insulinoma growth. Due to an unchecked insulin production and secretion, insulinomas consequently present with hypoglycemia, sometimes accompanied by confusion, behavioral changes, blurred vision, fatigue, seizures, coma, and even death [111].

In diagnostic terms, an insulinoma represents a rare cause of hypoglycemia, and it is therefore mandatory to ensure that hyperinsulinemia is secondary to endogenous insulin production. Particularly, C-peptide and sulphonylurea levels should be assessed as low C-peptide concentrations are indicative of exogenous insulin administration, whereas sulphonylureas produce glucose and C-peptide levels similar to those found with insulinomas [116–118]. The following parameters are diagnostic for insulinoma: blood glucose $\leq$2.5 mmol/l, insulin $\geq$6 μunits/ml, c-peptide $\geq$0.2 nmol/l, and a negative sulphonylurea screen, obtained during a supervised fast with blood assessment every 6 h [111].

Following a biochemical diagnosis, tumor localization is important to plan treatment options, particularly surgical resection as the treatment of choice. Procedures employed include enucleation, distal pancreatectomy, and pancreaticoduodenectomy. As the majority of these tumors are benign, enucleation of the lesion may be feasible when preoperative scans and intraoperative ultrasonography demonstrate that the tumor is separate from the pancreatic duct by 2–3 mm and surrounding vascular structures [119]. As stated above, insulinomas are equally distributed throughout the pancreas. Consequently, a blind resection would fail to remove the tumor in 50% of cases. Intensive pre- and intraoperative localization of biochemically confirmed tumor is, therefore, mandatory to ensure maximum surgical success [120].

As described above, glucagon is the main counter-regulatory hormone of insulin action, being responsible for the maintenance of blood glucose levels during fasting under non-neoplastic conditions. Tumors of the pancreatic alpha cells are rare, but they may cause an increase in glucagon levels, resulting in impaired systemic glucose regulation and diabetic hyperglycemia [111]. Along with diabetes, glucagonomas typically present with dermatitis, deep vein thrombosis, and depression, commonly referred to as the 4 “Ds” [121, 122]. The pathognomic rash is known as necrolytic migratory erythema and may appear before other symptoms of

hyperglucagonemia. It is the presenting feature in 70% of patients with glucagonoma. In particular, glucagon-driven hepatic gluconeogenesis induces a later hypoacidemia, which is one of the causes favoring the onset of the skin lesions [123]. At the time of presentation, glucagonomas are commonly large, so that intraglandular localization is normally not problematic. In contrast to the even distribution of insulinomas throughout the pancreas, glucagonomas typically develop in the tail of the gland [111]. Concerning possible therapeutic options, the elective treatment of glucagonoma is the surgical resection of the lesion, possibly in combination with adjuvant chemotherapeutic protocols. In this respect, glucagonomas are typically associated with a good prognosis, even in the presence of liver metastases [124].

In addition to glucagonomas, also rare somatostatinomas are associated with diabetes and a hyperglycemic phenotype [125–127]. Somatostatin is secreted by a range of tissues, including the pancreatic islet delta cells, and particularly inhibits alpha and beta cell glucagon and insulin secretion in a paracrine manner, respectively. Also, somatostatin interferes with cholecystkinin-mediated release of pancreatic enzymes. Hypersecretion of somatostatin consequently presents with diabetes, malabsorption, steatorrhoea, and cholelithiasis due to reduced gallbladder contractility [128]. As these symptoms are relatively nonspecific, the majority of somatostatinomas are diagnosed incidentally and confirmed with a fasting somatostatin level $>$ 14 mol/L [128]. At the time of diagnosis, most cases of somatostatinomas are correlated with metastases [111].

The Reverse Connection: Type 2 Diabetes as a Risk Factor for Pancreatic Ductal Adenocarcinoma

Whereas endocrine neoplasms of the pancreas directly trigger imbalances in systemic glucose homeostasis and eventually lead to diabetes, epidemiological studies over the past decade have also established obesity-related type 2 diabetes as an important risk factor for exocrine pancreatic tumors, in particular pancreatic ductal adenocarcinoma (PDAC) [129]. Elevated levels of insulin represent a common feature of metabolic conditions associated with PDAC, such as obesity and type 2 diabetes mellitus. Indeed, insulin has been shown to directly stimulate pancreatic cancer cell growth, partly via the MAP kinase pathway, and to promote energy turnover in pancreatic cancer cells by inducing expression of specific glucose transporters [130]. These effects are further enhanced by high intrapancreatic insulin levels and by the expression of insulin as well as IGF-1 receptors on pancreatic cancer cells, thereby providing a distinct growth advantage to these cells [131]. Of note, even the cancer-promoting consequences of a high-fat diet might, at least in part, rely on compensatory beta cell proliferation and hyperinsulinemia in response to systemic insulin resistance [132].

In this regard, the general importance of beta cells for PDAC manifestation has been demonstrated by previous reports showing that specific destruction of this cell population by streptozotocin treatment protects hamsters from experimental pancreatic

cancer development [133]. Apart from the loss of growth-promoting insulin action, the beneficial effects of beta cell depletion on cancer development might also point toward a role of the endocrine cell compartment as a cellular precursor pool for PDAC, although this remains speculative in the setting of human PDAC [129].

Cancer cells take up high amounts of glucose, which is utilized for ATP production by aerobic glycolysis and generation of building blocks for nucleotide, amino acid, and lipid biosynthesis. Thus, increased concentrations of glucose in the circulation (hyperglycemia), as a hallmark of type 1 and type 2 diabetes mellitus, could contribute to tumorigenesis. Indeed, a number of epidemiological studies suggest that diabetes is associated with higher prevalence as well as increased mortality for certain types of cancer, including PDAC [134, 135]. The risk connection between diabetes and cancer is complex and might be based on various mechanisms including increased levels of proinflammatory cytokines as well as oncogenic effects of hyperglycemia which are not directly linked to glucose as an energy substrate, e.g., antiapoptosis, induced cell migration and invasion as well as hyperglycemic memory effects [136]. Despite the clear epidemiological connection between insulin resistance, obesity, and type 2 diabetes and PDAC development, neither the molecular mechanisms of insulin-dependent cancer growth nor the potential role of endocrine cells as the potential origin of ductal adenocarcinoma is fully understood to date, still providing a major challenge for biomedical research in the future.

Conclusion

Paraneoplastic syndromes are defined as signs and symptoms which present distant to the site of primary cancer or metastases. The best-understood syndromes result from tumor production of biologically active substances or, to a lesser extent, from autoimmune phenomena. The clinical symptoms vary widely and include systemic (fever, cachexia, etc.) and organ-specific manifestations (cutaneous, neurological, hematological, endocrine, etc.). In some cases, these can become the major clinical problems determining survival.

After successful treatment of the underlying malignant disease, paraneoplastic symptoms may resolve completely. Thus, early recognition of paraneoplastic syndromes is very important for the diagnosis of patients with pancreatic cancer, as is the follow up for monitoring disease progression.

Abstract

Pancreatic adenocarcinoma is the fourth leading cause of cancer death and the most deadly of all solid malignancies. Current methods for the early detection and diagnosis of pancreatic adenocarcinoma are largely ineffective and not feasible for uncovering small, often treatable precursor lesions in the general population. The discovery of biomarkers that aid in the early detection of pancreatic cancer would help to improve outcomes in patients and be of invaluable clinical benefit. This review discusses important considerations for the development of diagnostic biomarkers and profiles the promising molecular markers that have been evaluated in recent years.

Keywords

Pancreatic cancer · PanIN (pancreatic intraepithelial neoplasia) · IPMN (intraductal papillary mucinous neoplasm) · MCNs (mucinous cystic neoplasms) · CA19-9 · Circulating tumor DNA · EUS (endoscopic ultrasound) · Early detection · KRAS · Mutation · Pancreatic juice · Pancreatic cyst

Introduction

Pancreatic adenocarcinoma is the third leading cause of cancer death in the USA and is the most lethal of all solid malignancies. It is estimated that over 53,000 individuals will be diagnosed with pancreatic cancer in the USA in 2016, and nearly 42,000 will die from the disease [1]. The incidence of the disease has been increasing, and in the next few years, it is expected to be the second most common cause of cancer death in the USA [2]. Patients with pancreatic cancer often present late and respond poorly to chemotherapy and radiation, and the 5-year survival rate for this disease is currently less than 7%. Although imaging tests such as CT, EUS, and MRI can readily identify most pancreatic cancers, they can miss small cancers, and since even small pancreatic cancers of ~2 cm diameter are usually not curable, there is a need to be able to detect very small (subcentimeter pancreatic cancers) that have a greater

chance of being cured. Circulating tumor marker tests are used in clinical settings to help identify which patients would benefit from an imaging test.

Much effort has gone into identifying better diagnostic markers that could improve the detection of early-stage pancreatic cancer and its precursors. A suitable diagnostic marker test could be used to screen individuals at significantly increased risk of developing pancreatic cancer such as those with a strong family history of pancreatic cancer and those who carry germline mutations in pancreatic cancer susceptibility genes [3, 4]. Another high-risk group that is of interest to screen are older adults with new-onset diabetes [5].

Tumor markers have been defined as "a naturally occurring molecule that is measured in serum, plasma, other body fluids or in tissue extracts or paraffin-embedded tissue to identify the presence of cancer, to assess patient prognosis, or to monitor a patient's response to therapy with the overall goal of improving the clinical management of the patient" [6]. They may also be defined to include biological measurements such as the RECIST (Response Evaluation Criteria in Solid Tumors) imaging criteria for evaluating changes in tumor size with treatment. Thanks to improvement in data processing, the resolution of CT continues to improve, but CT is not currently being used as a screening test to detect pancreatic neoplasms primarily because of concerns about cumulative doses of radiation.

Pancreatic cancer tumor markers can be isolated from the blood, urine duodenal fluid, stool, and pancreatic tissue. Blood is advantageous given its ease of access and acceptability to the patient, but circulating marker levels are much lower in blood than in samples collected from the pancreas, often necessitating much more sensitive tests [7]. Pancreatic juice can be collected from the duodenum during an upper endoscopy with secretin stimulation. Pancreatic juice collection allows for biomarker analysis in patients with pancreatic abnormalities visualized by imaging but no defined mass or as a way to look at the pancreatic ductal system as part of screening protocols to detect microscopic neoplasia in individuals with an elevated risk of developing pancreatic cancer.

Pancreatic sampling is an invasive procedure, rendering it inappropriate as a screening tool for the general population. However, in patients at high-risk for developing pancreatic cancer, pancreatic juice sampling allows for sampling of abnormal areas with minimal side effects. This approach has been carried out in the Cancer of the Pancreas Screening (CAPS) studies [8, 9], in which patients with at least one first-degree and one second-degree relative with pancreatic cancer undergo pancreatic screening with EUS and MRI [10], generally beginning at age 55,to facilitate the early detection of asymptomatic pancreatic precursor lesions. There is suggestive evidence that pancreatic screening of high-risk individuals can improve outcomes [3, 4] (such as the detection of mostly resectable pancreatic cancers rather than advanced-stage cancers in screened patients and the detection of PanIN-3 and high-grade dysplasia in IPMN), but further studies are needed to evaluate long-term outcomes.

Combining molecular markers of pancreatic neoplasia with sensitive pancreatic imaging may ultimately prove to be a more effective screening tool for the early

detection of pancreatic cancer. Pancreatic cancer is the most deadly of all solid malignancies. Current therapies are largely ineffective once the disease has spread, emphasizing the need for accurate diagnostic biomarkers for asymptomatic precursor lesions. A variety of genetic, epigenetic, and protein changes occur as pancreatic neoplasms progress. Mutations, DNA methylation alterations, microRNAs, and protein alterations sampled from the blood, pancreatic juice, and cyst fluid have all been evaluated as potential diagnostic biomarkers for pancreatic cancer.

Using Diagnostic Tests to Identify Early-Stage Pancreatic Cancer

Pancreatic cancer is an almost universally lethal disease, but patients can be cured if precursor lesions are detected early and resected. Thus, there is considerable interest in designing a screening tool. Unfortunately, the majority of patients (>85%) are diagnosed with advanced, inoperable disease when current therapies are largely ineffective. Detecting pancreatic cancer in its earliest stages offers patients the best chance of being cured; however, there are a number of inherent challenges in identifying markers of pancreatic cancer precursors. Current imaging tests fail to detect small lesions that may progress to pancreatic cancer. Additionally, the prevalence of pancreatic precursor lesions increases with age, but many will never develop into pancreatic cancer. A comprehensive understanding of the genetic and histological differences that drive the formation and development of these different precursors is imperative as there are potentially significant consequences for both failing to identify precursor neoplasms and to over treating them. Furthermore, identifying diagnostic biomarkers to screen the general public for pancreatic cancer is largely impractical as the overall prevalence of this disease is low in the general population. While targeted screening of high-risk patients improves the positive predictive value of a screening test, this approach does not help improve the early detection of sporadic forms of pancreatic cancer. These and other important considerations for diagnostic biomarker development are discussed more comprehensively below.

Characterization of Pancreatic Cancer Precursor Lesions

A number of precursor lesions can give rise to pancreatic cancer. The most common of these neoplastic precursors, pancreatic intraepithelial neoplasm or PanIN, are microscopic lesions not readily detected by clinical imaging tests. The acquired genetic alterations that have been identified in pancreatic tumors have also been observed in PanINs, albeit at a lower prevalence [11]. The prevalence of PanIN-1 lesions increases with age in individuals without pancreatic disease; however, high-grade PanINs are typically observed in patients with invasive pancreatic cancer [12, 13]. In those patients with a family history of pancreatic cancer, resecting advanced PanIN lesions may be able to prevent the development of pancreatic cancer [14].

A second precursor neoplasm is the intraductal papillary mucinous neoplasm (IPMN). IPMNs are large, cystic neoplasms (≥1 cm) with a broad spectrum of

malignant potential. As pancreatic imaging technologies become increasingly sensitive, these lesions are more frequently diagnosed and treated [15]. Additionally, IPMNs are discovered incidentally in patients undergoing abdominal imaging [16]. Main-duct IPMNs have a higher malignant potential compared to branch-duct IPMNs. Branch-duct IPMNs are more likely to progress to invasive cancer if the lesions grow to >3 cm in size and are symptomatic or if they are associated with dilatation of the main pancreatic duct [17]. IPMNs are classified in a number of ways. There are histological subtypes, including gastric, intestinal, pancreaticobiliary, and mixed. They are also graded as either low grade (benign) or high grade (carcinoma in situ) (there is an emerging consensus among experts that the intermediate grade of dysplasia should be removed) [18]. A tumor marker's behavior can be expected to vary with the histological subtype and grade of IPMN lesion. Furthermore, while there are similarities in the genetic alteration characteristic of IPMNs, PanINs, and pancreatic cancer, there are also key genetic differences. High-grade PanIN lesions sometimes exhibit loss of *DPC4/SMAD4*, whereas IPMNs rarely inactivate this gene [19, 20].

A third, less common precursor neoplasm in the pancreas is the mucinous cystic neoplasm (MCN). MCNs, which are found more often in women, are cystic lesions that produce mucin and are defined by their ovarian-type, fibrous stroma. The ability to differentiate cystic lesions with varying malignant potential is important, as patients who undergo a pancreatic resection for IPMNs or MCNs that do not have infiltrating pancreatic adenocarcinoma are usually cured. If left untreated, these lesions can progress to invasive carcinoma. Mucinous cysts that have malignant potential require surveillance, whereas some cysts have little or no malignant potential such as serous cystadenomas and pseudocysts. Distinguishing these cysts by imaging and cyst fluid markers is useful as it determines how these lesions should be followed.

Distinguishing Benign Lesions from Precursor Neoplasms

As suggested above, not all pancreatic lesions have the same propensity to develop into infiltrative pancreatic cancer. It is estimated that approximately 20% of pancreatic cysts that are removed are found to be benign [21, 22]. In light of the fact that surgical resections of pancreatic lesions are associated with significant morbidity, considerable effort has been put forth to design better methods of distinguishing truly benign and low-grade lesions from high-grade precursors that warrant treatment. Exome sequencing analysis of pancreatic lesions has begun to delineate patterns of genetic alteration characteristic to each cystic precursor type. For example, IPMNs and MCNs frequently exhibit mutations in *KRAS*, *RNF43*, *TP53*, and *CDKN2A*, IPMNs but not MCNs frequently harbor mutations in *GNAS* [23, 24], and both MCNs and IPMNs can harbor *SMAD4* mutations, but this is often a late event often only seen in the invasive component [19, 25]. In contrast, the more indolent serous cystadenomas harbor mutations in *VHL* and solid pseudopapillary neoplasms, a rare neoplasm usually found in young people harbors*CTNN1* [23, 24].

Differentiating PanIN lesions that will ultimately give rise to infiltrative adenocarcinoma from those that will not progress has proven to be a more challenging task. The prevalence of low-grade PanINs increases with increasing age in patients without pancreatic disease; however, Terhune and colleagues estimate that over 99% of these lesions will never develop into invasive cancer [26].To date, the only way to accurately characterize PanINs is to remove them for histological evaluation. As imaging technologies become more advanced, and the detection of smaller lesions becomes possible, an even greater need will exist for tools to distinguish harmless precursors from high-grade lesions. See also the chapter on the ▶ "The Molecular Pathology of Precursor Lesions of Pancreatic Cancer".

Identifying High-Risk Patients for Screening

While there is considerable excitement that advancements in imaging capabilities and molecular diagnostics should lead to better detection and classification of pancreatic precursors, it remains challenging to develop a screening tool that could be utilized broadly. Although the incidence of pancreatic cancer is increasing and the lifetime risk of developing the disease is ~1.5% in the USA, the incidence of the disease at any one point in time is much lower. Even if a screening test were to be developed with 95% sensitivity and specificity, a significant number of patients would be falsely identified as positive, and they would subsequently be subjected to further evaluation.

Targeting populations with a higher prevalence of pancreatic cancer (those with an increased risk for developing the disease) improves the positive predictive value of a diagnostic test. High-risk groups with a significantly higher risk of developing pancreatic cancer include those with a family history of the disease, particularly those multiple first-degree relatives who have been diagnosed with pancreatic cancer [14, 27]. Additionally, patients with germline mutations in genes such as *BRCA2, ATM*, *CDKN2A*, and *PALB2*, as well as individuals with inherited causes of recurrent acute pancreatitis such as from germline *PRSS1*mutations, are also at increased risk for developing pancreatic cancer [28, 29]. Ultimately, as the goal of screening is to identify and treat precursor lesions before they progress into invasive cancer, patients at increased risk for developing this disease are likely to benefit greatly from improvements in molecular diagnostics and imaging. Screening high-risk populations enables the opportunity to detect more stage I cancers. Studying biomarker behavior in the main setting where a screening blood test for high-risk individuals is the best way to evaluate the test. See also the chapter on ▶ "Familial Pancreatic Cancer" screening for inherited pancreatic cancer.

Implications of Disease Heterogeneity

Pancreatic cancer is a highly heterogeneous disease, with distinctive pathological, molecular, and clinical presentations. For example, pancreatic adenocarcinomas that

arise from IPMNs differ molecularly from those that progress from PanINs [19]. Certain variants, such as those with medullary histology, frequently exhibit microsatellite instability and lack mutations in a common driver of pancreatic cancer, *KRAS* [30]. Others have classified pancreatic cancers by their etiologies or pattern of inheritance; however, it is not yet understood whether such distinctions aid in predicting either tumor or tumor marker behavior. For example, hereditary gastric and colorectal cancers are pathologically distinct from sporadic tumors at these sites. In pancreatic cancer, preliminary data suggests that familial and sporadic pancreatic adenocarcinomas are very similar at the genetic and epigenetic level, but additional studies are necessary to further define the molecular and pathological profiles of familial and sporadic pancreatic cancer [31, 32]. Given the degree of molecular [33] and pathological heterogeneity inherent in pancreatic cancers, it is unlikely that a single tumor marker will be accurate and sensitive enough to distinguish each of the variants of this disease.

Importance of Disease Controls and Early-Stage Samples in Assessing Biomarker Behavior

In addition to pathological and genetic heterogeneity, the clinical presentation of pancreatic cancer can be variable, which may in turn influence tumor biomarker behavior. As pancreatic cancer progresses, patients may suffer from secondary complications from their disease such as cachexia, diabetes, and obstructive jaundice. Differences in the clinical manifestations in pancreatic cancer are likely a result of differences in the pathophysiology of the disease. Importantly, proteomic, epigenetic, and expression changes are likely to occur in response to these complications and could be identified as novel diagnostic biomarkers in preliminary studies. However, many of these candidate markers will lack the appropriate specificity.

For this reason, it is necessary to include the appropriate disease controls for diseases that can mimic or coexist with pancreatic cancer in studies evaluating novel diagnostic biomarkers for pancreatic cancer. For example, obstructive jaundice is observed frequently in patients with pancreatic cancer, but many studies fail to include individuals that develop obstructive jaundice in the absence of pancreatic cancer. CA19-9, the current gold standard for pancreatic diagnostic markers, is known to be elevated in patients with benign causes of obstructive jaundice.

Another important disease control group for pancreatic cancer marker studies are patients with diabetes, as nearly 25% of patients have this condition when diagnosed with pancreatic cancer. An additional 40% will have impaired glucose tolerance [34, 35]. It remains uncertain as to whether the pancreatic cancer causes the development of diabetes in these patients, although surgical resection of the tumor often results in curing the patient of this metabolic condition. There is growing interest in screening older patients with new-onset diabetes, as it may lead to the early detection of asymptomatic and early-stage pancreatic cancer in these patients [36].Metabolic syndrome, a very common condition in the population and an important risk factor for pancreatic cancer [37], is likely to exert an important influence on many candidate biomarkers.

Chronic pancreatitis is another condition that can mimic pancreatic cancer. Areas of focal pancreatitis can resemble a pancreatic cancer with pancreatic imaging tests used in clinical practice, and patients may have to undergo surgical resection to receive an accurate diagnosis. Individuals with autoimmune pancreatitis often exhibit symptoms that are similar to those observed in patients with pancreatic cancer, such as an enlarged pancreas with common bile duct obstruction [38]. In addition to mimicking the clinical manifestations of pancreatic cancer, chronic pancreatitis is a known risk factor for the development of pancreatic cancer. This increased risk is particularly noteworthy in patients who develop pancreatitis at a young age or those with an inherited form of the disease [39]. Many potential markers can accurately distinguish patients with pancreatic cancer from healthy controls, but they cannot reliably differentiate individuals with chronic pancreatitis. For example, CA19-9 can be elevated in patients with chronic pancreatitis. This may not necessarily mean the biomarker would not have diagnostic value, because the clinical syndrome of chronic pancreatitis is not common in the population. However, many more patients have chronic inflammation from other causes, and the inability of a biomarker to distinguish chronic pancreatitis from pancreatic cancer raises the likelihood that the biomarker will not be as specific in patients with other inflammatory comorbidities. In some diagnostic scenarios, it is important to be to distinguish between these two conditions. For example, pancreatic imaging may identify nonspecific abnormalities that could be due to focal areas of pancreatitis or to a neoplasm. A diagnostic biomarker applied to pancreatic samples should be able to distinguish these two pathologies but often cannot. For example, low concentrations of mutant *KRAS* are found in pancreatic juice samples from patients undergoing screening for their family history of pancreatic cancer, from patients with chronic pancreatitis, and even occasionally in patients without known pancreatic disease [40]. This mutant *KRAS* is thought to arise from microscopic PanIN lesions.

An important challenge to evaluating diagnostic biomarkers is that there are few patients who are enrolled in screening studies in the diagnostic setting where an early detection test would be applied. Instead, biomarker studies evaluate the candidate biomarker performance in patients with pancreatic cancer, and most of these patients have advanced-stage disease. As pancreatic cancer spreads, secondary changes including inflammation, fibrosis, weight loss, obstructive jaundice, and diabetes arise that affect biomarkers. Many candidate markers identified in late-stage disease turn out to reflect these secondary metabolic changes. Such biomarkers will not have good diagnostic utility in the screening setting.

Evaluating Diagnostic Biomarker Candidates

Several sets of guidelines are available to help clinicians and investigators assess diagnostic biomarkers. For example, the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) and the Standards for Reporting of Diagnostic Accuracy (STARD) are guidelines for evaluating diagnostic markers and reporting diagnostic accuracy [41]. When assessing candidate diagnostic biomarkers, it is imperative to

consider both the benefits and potential problems with implementing a potential marker in clinical practice. The utility of any diagnostic marker depends on the clinical setting it is employed in. Thus, the performance requirements for a diagnostic marker will vary depending on factors such as the accessibility of the biological sample, the clinical question being addressed, and the implications of the results of the test. For pancreatic cancer, tumor markers can be assayed from blood, stool, pancreatic tissues, and fluids such as cyst fluid and pancreatic juice. Blood is advantageous given its ease of access and acceptability to the patient, but circulating marker levels are much lower in blood than in samples collected from the pancreas, often necessitating much more sensitive tests [7]. Additionally, levels of some tumor markers may not become detectable in the blood until invasive carcinoma has developed. An example of this point is CA19-9, which is elevated in >80% of patients with late-stage disease. In contrast, only ~65% of patients with early-stage pancreatic cancer have increased levels of CA19-9 [42].

When assessing the clinical utility of a diagnostic screening tool, it is important to understand the settings in which it will be applied. For example, when a patient presents with symptoms that are strongly suggestive of pancreatic cancer, pancreatic imaging is done. A pancreatic protocol CT scan will often identify a pancreatic neoplasm, and further marker studies would not be necessary. In contrast, a patient with nonspecific symptoms would benefit from a highly accurate blood test, as more invasive testing when the probability of a cancer diagnosis is low would not be justified. In light of the criteria and considerations outlined above, the remainder of this chapter will be devoted to examining the most important candidate biomarkers that have been assessed to aid in the diagnosis of pancreatic cancer.

Blood-Based Biomarkers for Early Detection

A diagnostic biomarker for pancreatic cancer can be measured in many biological fluids including blood and urine, pancreatic cyst fluid, pancreatic juice, pancreatic tissue, and stool. While developing a circulating biomarker would have a lot of clinical utility, circulating tumor markers are generally found at significantly lower concentrations in the blood compared to other biological samples, necessitating an assay that is highly accurate at detecting very low levels of analyte [7]. If the goal is to screen asymptomatic patients with microscopic precursor lesions, this is likely not even possible with a blood test as tiny precursor lesions likely do not shed detectable levels of candidate biomarkers into the bloodstream. Indeed, it has been estimated that several billion neoplastic cells (a pure tumor mass of ~2 mm diameter) are needed to elevate levels of a typical circulating biomarker [43]. Since much of a pancreatic cancer cell mass consists of non-neoplastic stroma, for pancreatic cancer this estimate would correspond to pancreatic tumor mass of at least 3–4 mm. Despite these challenges, considerable effort has been expended to identify circulating biomarkers that could improve the early detection of pancreatic cancer in patients.

CA 19-9

Despite its limitations, carbohydrate antigen 19-9 (CA19–9) remains the gold standard for pancreatic adenocarcinoma tumor markers. CA19-9 is a sialylated lacto-N-fucopentaose II related to the Lewis[a] blood group antigen on MUC-1 and is recognized by a specific monoclonal antibody [44]. The CA19-9 antigen is relatively specific for pancreatic cancer but is seen in benign conditions such as chronic and acute pancreatitis, biliary obstruction, cirrhosis, cholangitis, and cholecystitis. Levels can also be elevated in non-pancreatic malignancies like ovarian and colorectal cancer [45, 46]. Furthermore, up to 10% of individuals do not express the Lewis blood group antigen and thus would not have measureable CA 19-9 levels [6]. Importantly, although CA 19-9 levels are elevated in ~80% of patients with advanced pancreatic cancer, it is elevated in only ~60% of patients with resectable disease, and most of these patients already have lymph node metastases [46]. Indeed, high CA19-9 levels at diagnosis predict poor outcome [46]. For these reasons, CA 19-9 has largely been used to monitor patient's responses to therapy rather than as a diagnostic marker [46]. Multiple societies have all issued guidelines for its use in patients with pancreatic cancer [47, 48]. Despite its limitations, several studies have evaluated the utility of using CA19-9 as a test for the early detection of pancreatic cancer. Patient cohorts have been used to examine CA19-9 behavior before clinical diagnosis. Many patients will have elevated CA19-9 1 year or more prior to a clinical diagnosis of pancreatic cancer, but it is suspected that many of these patients already have advanced disease [49, 50].

In an attempt to improve the diagnostic utility of CA19-9, some investigators have determined if it would be better to have a test that targeted other modified carbohydrate antigens on MUC-1 or other proteins, but to date none of these biomarkers have been found to be more effective than CA19-9.

Combining CA 19-9 with Other Markers

Many groups have explored whether combining other markers with CA19-9 can improve the sensitivity and specificity of a screening test for patients. Typically these studies initially evaluate new markers in the setting of advanced pancreatic cancer since it is more difficult to recruit sufficient patients with early-stage disease.

Some of the better performing markers have been evaluated in combination with CA19-9. These markers include serum CEA, MIC-1, TIMP-1, HIP (PAP or REG3A), and others [51, 52] and were often identified as candidate biomarkers by comparing pancreatic tumor vs. normal pancreas samples for alterations in gene expression. One such marker is MIC-1 (macrophage inhibitory cytokine 1) a member of the TGF-ß super family of proteins, which is overexpressed in primary pancreatic cancers and is elevated in the serum of patients with resectable pancreatic cancer. The combination of serumMIC-1 and CA19-9 achieved higher diagnostic accuracy over using either marker alone (AUC 0.87) [42].

Brand examined a panel of markers and found that combining CA19-9 with carcinoembryonic antigen (CEA) and TIMP-1 could differentiate patients with

mostly advanced pancreatic cancer from those with benign disease with a sensitivity/specificity of 76% and 90%, respectively [52].

Some investigators are exploring the value of using large panels of protein markers as a diagnostic test. A multi-marker circulating panel has been shown to significantly improve the diagnosis of pancreatic cancer compared to CA19-9 alone [53], but it remains to be seen if such approaches can improve the diagnosis of very-early-stage pancreatic cancer.

Since many circulating proteins are shed in the urine, this sample has been evaluated as a source of biomarkers. In one study, Costello et al. used a mass spectrometry approach to identify novel biomarkers and identified a thre-protein panel that had good ability to distinguish patients with pancreatic cancer from controls [54]. Further studies are needed to evaluate if a urine biomarker panel could have diagnostic utility. (see also the chapter on the "▶ Development of Novel Diagnostic Pancreatic Tumor Biomarkers").

DNA Mutations

Detecting somatic mutations has the advantage that these mutations are not normal, so in principle, the presence of these somatic mutations should reflect disease. In contrast, most other markers have a normal range, and their value as diagnostic markers is closely related to their concentration. However, somatic mutations generally emerge in benign neoplasms, so somatic mutations detected in pancreatic samples often reflect the presence of benign neoplasms. In the blood, the presence of somatically mutated DNA is very concerning for the presence of cancer. DNA shed from cancer cells can be detected in the blood as cell-free circulating tumor DNA (ctDNA). Some cancer types shed relatively large amounts of ctDNA into the circulation (~1% of total DNA), particularly with advanced disease, others such as pancreatic cancer typically shed very low amounts of ctDNA (<0.1%) [55]. Until recently, the difficulty of detecting low concentrations of mutant DNA in the circulation has limited their utility as diagnostic biomarkers. Over 90% of invasive pancreatic adenocarcinomas harbor mutations in *KRAS*. ctDNA tests rely on PCR amplification to detect mutant DNA, and these tests can generate false-positive results that approach the levels seen in the circulation [56]. For this reason, it is particularly important that studies involving ctDNA employ extensive testing to determine the specificity of their assay.

Since levels of circulating tumor DNA are low, highly sensitive and specific technologies are needed to detect these mutations. Several useful strategies have been developed to detect ctDNA. Kinde and colleagues employed an approach termed Safe-Sequencing System (SafeSeqS). It involves assigning a unique identification DNA sequence (UID) to each fragment of DNA followed by an amplification step that produces UID families. When greater than 95% of a UID family contains the same mutation, it is termed a super mutant. Thus, a true mutation would be present in nearly all DNA fragments with the UID and give rise to a super mutant, whereas a mutation that occurs during amplification would not

[56]. Utilizing SafeSeqS, mutant *KRAS* was detected in the plasma of 85% of patients with advanced pancreatic cancer but only 45% of individuals with localized disease [55].Digital droplet PCR (ddPCR) technology has also been used to detect mutant *KRAS* ctDNA [57, 58] in patients with pancreatic cancer and has the advantage of being a simpler method but has the limitation that a specific probe is required for each mutation of interest. One small study found that ctDNA can be detected in patients with IPMNs, but this study included only small numbers of control patients and needs to be confirmed [59].

The challenges of reliably detecting low levels of ctDNA has limited its evaluation as a potential screening test for pancreatic and other cancers to date, but it is likely to become a useful test in the future. Since most patients with early-stage pancreatic cancer have not been found to have detectable ctDNA with existing technologies, ctDNA cannot be relied upon as a diagnostic test but could be a useful adjunct. ctDNA detection is being evaluated as a tumor marker to monitor early recurrence and tumor burden [58, 60], and it is expected to become a useful clinical test in this setting.

Circulating Tumor Cells (CTCs)

CTCs are intact cells that contain nucleic acids and can be separated from normal cells within the circulation [61]. Although the term CTCs implies that the cells being detected are cancer cells, many use the term CTC for all circulating cells expressing epithelial markers despite the fact that these cells are also found in many patients who do not have cancer [62, 63]. For this reason, tests are being developed to selectively isolate cancer cells and not all circulating epithelial cells. Such tests rely on either flow cytometry separation of cells based on surface molecules, selection based on size using microfluidic chips or filter-based methods, or molecular characterization of isolated cells. In patients with pancreatic cancer, CTCs are usually detected in patients with advanced-stage disease rather than early-stage disease suggesting that CTC-based tests are likely to have more value in disease monitoring rather than patient diagnosis. See also the chapter on ▶ "Circulating Tumor Cells".

Other circulating biomarkers have been evaluated as possible diagnostic markers including microRNAs and other noncoding RNAs, exosomes, and autoantibodies.

RNA Biomarkers

In addition to interrogating tumor DNA as potential diagnostic biomarkers for pancreatic cancer, many groups have begun to look closer at circulating RNA molecules. While most types of RNA molecules are subject to rapid degradation by RNases, microRNAs (miRNAs) are more stable. In addition, RNA molecules can be protected from RNases if they are incorporated into extracellular vesicles.

microRNAs

MicroRNAs (miRNAs) are small, noncoding RNAs that regulate gene expression. Derived from larger RNA transcripts that are degraded by the enzyme DICER,

miRNAs then associate with the RNA-induced silencing complex (RISC) and bind to the 3′ untranslated regions of a gene. This results in either RNA degradation or translational repression. In cancer, miRNA expression tends to be decreased; however, there are several miRNAs that have been identified as overexpressed and could therefore be potentially targeted as diagnostic markers. Numerous miRNAs including miR-21, miR-155, miR-196, miR-200, miR-1246, and miR-1290 have been identified as overexpressed in pancreatic adenocarcinomas. Several studies have measured circulating miRNA levels to determine its potential as a diagnostic test. Li et al. identified miR-1290 as having good diagnostic performance [64], and similar results were found for the noncoding RNA RNU2 which has close homology to miR-1246 and miR-1290 [65]. Several of these miRNAs are elevated in other cancers, so while it is possible that certain miRNAs could have value for a pan-cancer screening test, they are not likely to serve as a diagnostic test for a specific cancer type. Despite these initial studies, there has been a lack of uniformity in the results of different studies that is thought to reflect a variety of challenges related to assay performance and study design that need to be overcome before miRNA can be used as diagnostic tests.

Exosomes

There is growing interest in the potential uses of extracellular vesicles such as exosomes as diagnostic, prognostic, and therapeutic biomarkers for a variety of diseases. Exosomes are small, membrane vesicles between 30–100 nm in size that are secreted by many cell types and commonly express the tetraspanin molecules CD9, CD63, and CD81. Exosomes are metabolically active and express surface molecules that allow them to communicate with and influence the behavior of distant cells and tissues. They are known to carry various macromolecules including proteins and nucleic acids and so could be a valuable source of cancer biomarkers. Most circulating exosomes are thought to derive from platelets so there is considerable interest in identifying cancer-specific exosomes. Melo et al. recently reported that it may be possible to differentiate pancreatic cancer-derived exosomes based on increased expression of glypican-1 (GPC1), but problems with this study necessitate that further studies are needed before this biomarker can be considered promising [66]. It remains to be determined whether there is a test that could specifically detect exosomes released from pancreatic cancer or pancreatic precursor lesions into the circulation that could be used as a diagnostic test (see also chapter on ► "Cancer Exosomes for Early Pancreatic Cancer Diagnosis and Role in Metastasis").

Autoantibodies

Autoantibodies are generated from the recognition of the antigens arising from mutant gene products as well as novel splice variants and proteins. Serum autoantibodies have been observed in patients with a variety of different tumor types and are sometimes observed prior to a cancer diagnosis. Autoantibodies to p53 protein are among the most common autoantibodies detected in patients with cancer, but overall

autoantibodies are only detected in a minority of patients with cancer. It remains to be seen whether a panel of autoantibodies can be used as an aid to diagnosis.

Pancreatic Cyst Fluid Markers

Pancreatic cysts are commonly identified as incidental findings among patients undergoing abdominal imaging. The prevalence of these increases with age with over 10% of individuals over age 70 having one or more pancreatic cysts [67]. Most of these pancreatic cysts are thought to be IPMNs. Since some pancreatic cancers arise from cysts, it is important to determine the neoplastic nature of a pancreatic cyst, because it can provide an opportunity to intervene to treat these lesions before they are fatal. However, only a small minority of pancreatic cysts become malignant, and effective diagnostic tests are needed to classify and grade pancreatic cysts for their malignant potential. The imaging characteristics of a cyst are helpful in determining cyst pathology and the likely presence of malignancy. Guidelines have been developed based on expert opinion, such as the Fukuoka guidelines, that rely on pancreatic imaging to help clinicians determine who requires surveillance and who requires an operation [68]. However, these guidelines are not sufficient enough to predict the neoplastic nature of a cyst [69, 70]. Biomarkers that could better classify and grade the neoplastic nature of a pancreatic cyst are needed to minimize over-or undertreatment. In general IPMNs with low-grade dysplasia can be monitored, but IPMNs with high-grade dysplasia or an associated invasive cancer require treatment. It is not yet clear that a circulating biomarker could be used as a test that indicates the presence of an IPMN. In principle, circulating blood tests could in principle identify the emergence of invasive cancer in patients with cysts, but cyst fluid sampling using EUS-guided fine needle aspiration (EUS-FNA) is more likely to be informative. Cyst fluid can be evaluated for the presence of protein markers such as CEA, but newer markers such as mutated and methylated DNA, miRNAs, mucins, telomerase activity, and other markers have been examined in cyst fluid for their potential as diagnostic biomarkers.

Cyst Fluid DNA Markers

Since mucinous neoplasms harbor mutated DNA, the diagnostic utility of cyst fluid mutant DNA marker panels has been evaluated in multiple studies.

Exome sequencing analysis of pancreatic cystic neoplasms has been very helpful to identify the genes mutated in each type of neoplastic cyst, and this information has been very useful for cyst fluid biomarker studies. *GNAS* mutations are commonly found in IPMNs (~60–70% of lesions) and are very specific for IPMN compared to other types of pancreatic cysts [24]. In addition to mutations in *GNAS* and *KRAS* (one of these mutations are found in over 90% of IPMNs), IPMNs frequently exhibit mutations in *RNF43*, *TP53*, and *CDKN2A*. In contrast, the more indolent serous

cystadenomas and solid pseudo papillary neoplasms harbor mutations in *VHL* and *CTNN1*, respectively [23, 24]. In keeping with these results, studies have demonstrated that the detection of a *KRAS or GNAS* mutation in cyst fluid is specific marker that indicates the presence of a mucinous cyst, but because these mutations generally arise relatively early in the evolution of a cystic neoplasm, the detection of these mutations in cyst fluid does not reliably distinguish benign and malignant pancreatic cysts [71].

Molecular analysis of cyst fluid samples using next-generation sequencing assays designed to detect low-abundance mutations across a panel of genes as well as chromosomal alterations can accurately distinguish mucinous from non-mucinous cysts and has a very good ability to gauge the neoplastic grade of a pancreatic cyst [72].

Telomerase Activity

Telomere length dictates how long a cell will live, as short telomeres act as signals to the cell to stop dividing and enter senescence. The enzyme telomerase adds telomere repeat sequences to the ends of telomeres. Without it, telomeres would eventually shorten to critical levels and result in the fusion of chromosome ends. Telomerase is typically inactive in somatic cells but becomes active mainly in stem cells, as well as most cancer cells and precancerous cells with high-grade dysplasia.

Hata and colleagues recently evaluated the diagnostic performance of cyst fluid telomerase activity measured using an assay that relies on digital droplet technology and the telomerase repeat amplification protocol (TRAP) assay. Among cyst fluid samples from the surgical resections from 219 patients, telomerase activity had an overall diagnostic accuracy of 88% for distinguishing cysts with high-grade dysplasia/invasive cancer from those with lower grades of dysplasia and those without dysplasia. The diagnostic performance of telomerase activity for cysts that were characterized as having "worrisome features" was also high (AUC of 0.84) [73].

Aberrant DNA Methylation

A variety of genome-wide methylation studies have been done to identify aberrantly methylated genes in pancreatic cancers and precursor lesions. Initial studies evaluating the diagnostic performance of a panel of DNA methylation markers in cyst fluid have found that they have promising diagnostic utility.

Other Cyst Fluid Markers

Mucinous neoplasms produce abundant mucin, and in preliminary studies mucin profiles of cystic neoplasms have been found to discriminate between mucinous cysts from non-mucinous cysts [74]. MicroRNA alterations arise in IPMNs and other cystic neoplasms, but further studies are needed to better evaluate their

diagnostic utility. One protein biomarker of IPMNs known as mDas has been shown to be overexpressed primarily in IPMNs of intermediate and high-grade dysplasia, and in preliminary studies cyst fluid mDas levels predicted the grade of dysplasia of an IPMN with very good accuracy [75]. See also the chapter on the "► Management of Cystic Neoplasms of the Pancreas Including IPMNs."

Diagnostic Markers for Pancreatic Juice

Pancreatic juice tests are being evaluated as an adjunct to endoscopic evaluation of the pancreas. Pancreatic juice is collected after secretin infusion when patients are undergoing an endoscopic ultrasound as part of their pancreatic screening evaluation. In the pancreatic screening setting, pancreatic juice is collected from the duodenal lumen. Purer pancreatic juice samples can be obtained during an ERCP procedure, but this test is too invasive for routine use in the screening setting.

Since mutation concentrations in pancreatic juice collected from the duodenum are very low (0.1–1%), sensitive mutation detection technologies have been employed to detect mutations. Using secretin-stimulated pancreatic juice samples from patients enrolled in the CAPS study, Kanda and colleagues assayed *GNAS* mutations and found that their detection was highly specific for the presence of a pancreatic cyst, highlighting the utility of duodenal collections of pancreatic juice as a source of markers of pancreatic ductal neoplasia [76]. Subsequent studies found that *p53* mutations in duodenal collections of pancreatic juice were found only in patients with high-grade lesions and invasive ductal adenocarcinoma [77]. Among patients undergoing pancreatic screening, *KRAS* mutations are commonly detected, even in patients without pancreatic cysts; these mutations are also occasionally detected in patients without any suspicion of pancreatic disease and are thought to reflect the presence of mostly low-grade PanIN in these patients. However, mutant *KRAS* DNA was also detected in 19% of control patients [40]. More recently, next-generation sequencing technology has been employed to detect a panel of mutations in pancreatic juice. Since mutations are present at very low concentrations in pancreatic juice samples, a digital next-generation sequencing method was used which found that overall mutation concentrations and in particular *SMAD4* and *TP53* mutations were very useful at distinguishing patients with pancreatic cancer from those with IPMN and normal pancreata [78].

In addition to the genetic mutations that have been described above, epigenetic alterations (DNA methylation alterations) are common in pancreatic cancer. Initial studies evaluated these biomarkers in pure pancreatic juice samples isolated during ERCP. Subsequent studies have investigated candidate pancreatic cancer DNA methylation markers in pancreatic fluid samples collected from the duodenum. Further studies are needed to evaluate whether such a test could be used to evaluate the pancreas of patients undergoing pancreatic screening and surveillance.

Biomarkers as Molecular Imaging Targets

Molecular imaging approaches are being developed for imaging small cancers [79]. Several targets have been evaluated in preclinical models to determine if they could improve the molecular imaging of pancreatic cancer or its precursors. Candidate targets that have been evaluated are overexpressed membrane proteins, but more studies are needed.

Conclusions

Pancreatic cancer is an almost universally lethal disease, with most patients developing symptoms only after metastasis has occurred. Early detection and surgical resection offer the best chance for a cure, but this necessitates the development of a screening tool that can detect asymptomatic precursor lesions. While progress has been made in the characterization of genetic and epigenetic alterations in pancreatic precursor lesions and pancreatic cancer, the current gold standard for clinical diagnostic biomarkers is still CA19-9.As the prevalence of this disease is very low in the general population, it is particularly challenging to identify markers with a high enough specificity to avoid unacceptably high false-positive rates. Screening high-risk individuals has aided in identifying novel candidate diagnostic biomarkers. As not all potential markers are able to adequately distinguish pancreatic cancer from diseases that mimic it (chronic pancreatitis), carefully designed studies with the correct disease controls are essential. As imaging technologies become more sensitive and pancreatic lesions are increasingly found, it will be important for clinicians to be able to distinguish lesions with high malignant potential from those that will likely never progress to cancer. A number of promising markers have been identified in recent years, and further rigorous investigation into their diagnostic potential is necessary to improve the early detection of this disease.

Key Summary Points

- Pancreatic adenocarcinoma is the third leading cause of cancer death in the USA and is the most lethal of all solid malignancies.
- Tumor markers are naturally occurring molecules that can be used to identify cancer, assess a patient's prognosis, and monitor their response to therapy.
- There are currently no biomarkers recommended for general population screening. Individuals with a sufficiently increased risk for developing pancreatic cancer can undergo screening with EUS and MRI once they reach the appropriate age. Since it is not certain how beneficial pancreatic screening is, pancreatic screening is best undertaken as part of a research study.
- Despite its limitations as a diagnostic biomarker, CA19-9 is still the gold standard circulating pancreatic cancer biomarker against which other markers are evaluated.

- The accurate detection of circulating tumor DNA such as mutant KRAS DNA could be a useful test for the early diagnosis of pancreatic cancer but more studies are needed. Other biomarkers are still investigational. A current limitation of many studies evaluating candidate diagnostic biomarkers is that biomarker performance is not evaluated in the early detection setting, due the paucity of patients with stage I disease. Initial studies of candidate diagnostic biomarkers often do not enroll demographically matched enough disease controls to account for how biomarkers will perform in the clinical setting in which the biomarker would be used.
- It is likely that advancements in the early detection of pancreatic cancer will come as a result of screening high-risk patients with pancreatic imaging coupled with markers that sensitive and specific at detecting stage I pancreatic cancer and PanIN-3.

74:2913–2921, 2014). As a result, early detection, correct staging, and adequate peri- and posttherapeutic imaging strategies must play a very important role in present and future oncology in general and in pancreatic adenocarcinoma in particular. This will be outlined and discussed in this chapter. Early tumor detection is one of the key factors for a potential cure by surgical resection. Major advances in MDCT (multidetector computed tomography), including 2D and 3D reconstruction, are highly useful in improving staging and postsurgical care. PET-CT is particularly helpful in differentiating between malignant and benign in complex clinical problems such as discriminating between autoimmune pancreatitis and pancreatic adenocarcinoma, identifying distant metastastic disease in the pretheraupeutic staging workup, and, furthermore, discriminating between benign fibrotic tissue and tumor recurrence in the follow-up after surgical resection.

During the last years, startling epidemiologic facts find pancreatic adenocarcinoma to be on the rise with rapidly increasing relevance for public health. Recent projections for the year 2030 predict pancreatic adenocarcinoma to range among the top three deadly cancers in the Western world [1, 2]. As a result, early detection, correct staging, and adequate peri- and posttherapeutic imaging strategies must play a very important role in present and future oncology. This will be outlined and discussed in the following chapters.

Primary Imaging and Tumor Detection

Starting at the early nineties with the advent of multidetector computed tomography (MDCT), primary diagnosis of pancreatic adenocarcinoma has become feasible at tumor sizes below 3 cm and, furthermore, including a better depiction of involved organs and adjacent structures [3–5] (Figs. 1, 2, 3, 4, and 5). This came parallel to advances in surgical strategies to improve the dismal prognosis of advanced tumor stages of pancreatic adenocarcinoma. Already in 1996, Conlon described the long-term survival of up to 20% in patients with potentially resectable stages. Hence, adequate progress in imaging and, specifically, early detection is crucial for improving life expectancy [6]. During the last decade and with the widespread availability of either dual-source CT imaging or at least advanced multidetector systems ($\geq$ 256), modern MDCT provides improved accuracy in early tumor detection which in

Fig. 1 T1 pancreatic adenocarcinoma of the head. The hypoattenuation sign. (**a**) arterial phase MDCT. Small hypoattenuating focal lesion immediately dorsal to the superior mesenteric vein without infiltration signs. Note the distinct contrast uptake between normal surrounding pancreatic tissue during arterial phase: high in normal low in tumor parenchyma. (**b**) Venous phase MDCT. Slightly better lesions conspicuity compared to the arterial phase. The small hypoattenuating focal lesion immediately dorsal to the superior mesenteric vein is relative sharply demarcated (not a regular finding). Note again the distinct contrast uptake between normal surrounding pancreatic tissues during venous phase: high in normal low in tumor parenchyma

Fig. 2 T4 pancreatic adenocarcinoma of the body. The hypoattenuation sign. (**a**) Arterial phase MDCT. Large hypoattenuating focal lesion immediately left to the superior mesenteric artery with infiltration signs in the adjacent structures (mesentery, retroperitoneum, lesser sac, along-side the celiac axis). Marked hypoattenuation of the tumor tissue compared to normal surrounding pancreatic tail tissue during arterial phase. (**b**) Venous phase MDCT. Deep tumorous infiltration signs into the retroperitoneum, lesser sac, occlusion of the splenic vein, broad contact of the tumor with the celiac axis. Tumor parenchyma markedly hypoattenuating

the most recent studies shows to overpass the initial range of around 88–90% to detection rates higher than 95% [7–11]. The improved spatial and temporal resolution of these modern scanners allows the acquisition of images with a vascular enhancement ideal for tumor delineation and differential diagnosis. Current MDCT protocols utilize dual-phase techniques based on bolus tracking software to optimize

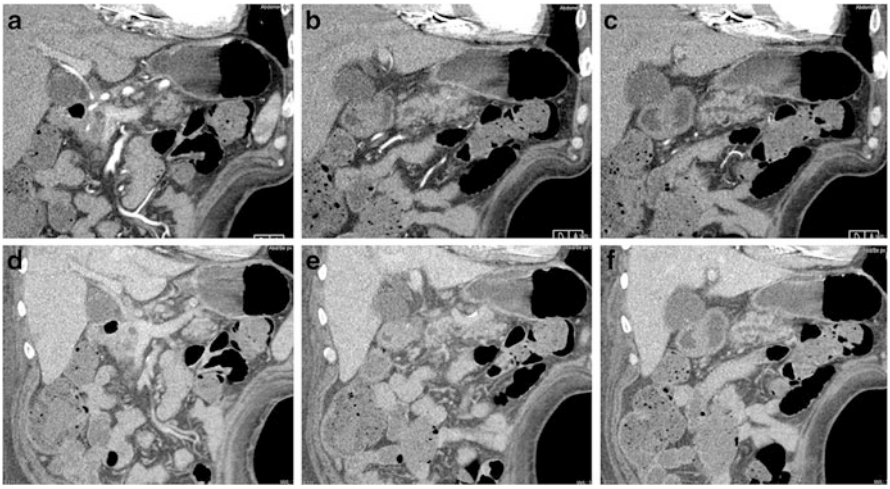

Fig. 3 T1/2 pancreatic adenocarcinoma of the head. The ductal occlusion sign. (**a**) Arterial phase MDCT axial plane at tumor level: a faintly visible tumor of the pancreatic head of around 18 mm in diameter immediately right lateral to the superior mesenteric vein. Cranial to the only minimally attenuating tumor abrupt dilatation of the pancreatic duct; (**b**) Arterial phase MDCT axial plane 10 mm more cranial than (**a**): focal dilatation of the pancreatic duct to around 10 mm; (**c**) arterial phase MDCT axial plane 20 mm more cranial than (**a**): dilatation of the pancreatic duct to around 10 mm extending to the tail; (**d**) venous phase MDCT axial plane at the same level as (**a**): as in (**a**), tumor of the pancreatic head only faintly visible without infiltrating signs to the superior mesenteric vein. Abrupt dilatation of the pancreatic duct well-demarcated; (**e**) venous phase MDCT axial plane at the same level as (**b**): focal dilatation of the pancreatic duct to around 10 mm; (**f**) venous phase MDCT axial plane at the same level as (**c**): dilatation of the pancreatic duct to around 10 mm extending to the tail

the dynamic scan parameters and acquisition following intravenous high flow injection of contrast material (4–6 ml/s, nonionic iodine dye), with depiction of the pancreas at an arterial phase (15–30s) and at a portal venous phase, respectively (40–60s). Arterial phase images are used for detection of the primary pancreatic tumor, optimal evaluation of the arterial abdominal vasculature and its relationship with the tumor, and CT angiographic delineation of vascular pathologies for staging and surgical planning (see below). Moreover, arterial phase images allow pancreatic adenocarcinoma to be distinguished from pancreatic neuroendocrine tumors, which are classically hypervascular and well enhancing in the arterial phase [7].

Particularly because of the above-mentioned characteristics, its widespread availability, its high grade of standardization CT has assumed a leading role in the diagnosis (and staging, see below) of pancreatic adenocarcinoma [7, 12, 13]. Lesion conspicuity and the discrimination between normal and tumorous tissue as contributed by MDCT are largely based on the so-called attenuation pattern during distinct phases of contrast material uptake after intravenous injection (Figs. 1 and 2). Typically, pancreatic adenocarcinoma presents as a hypoattenuating mass within the pancreatic tissue or outside when involving adjacent structures either in the

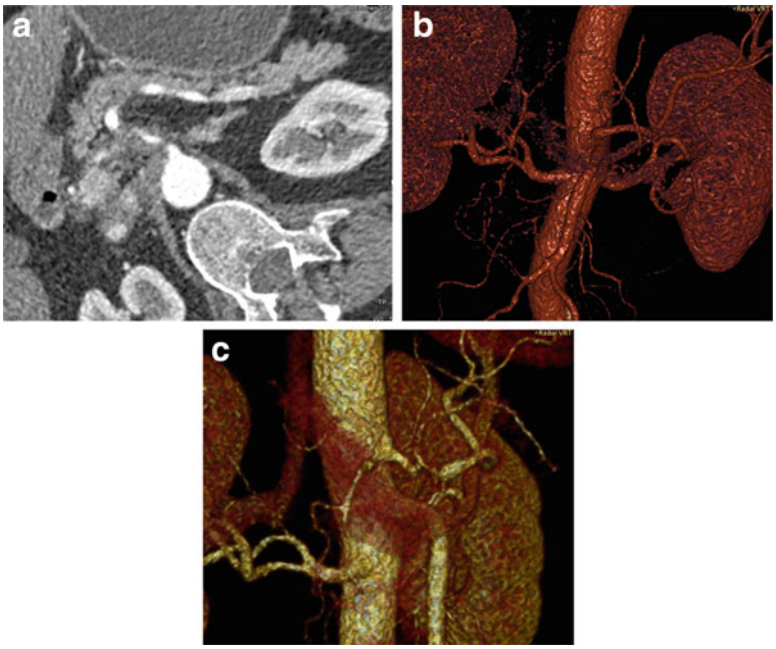

Fig. 4 Autoimmune peripancreatic vasculitis of the celiac axis mimicking infiltration by pancreatic adenocarcinoma. (**a**) Axial plane at the level of the celiac axis showing abutment and encasement of the celiac trunk and short segment occlusion of the common hepatic artery; (**b**) 3D reconstruction of the arterial phase confirming occlusion of the common hepatic artery in ap projection; (**c**) 3D reconstruction of the arterial phase confirming occlusion of the common hepatic artery in magnified right oblique projection

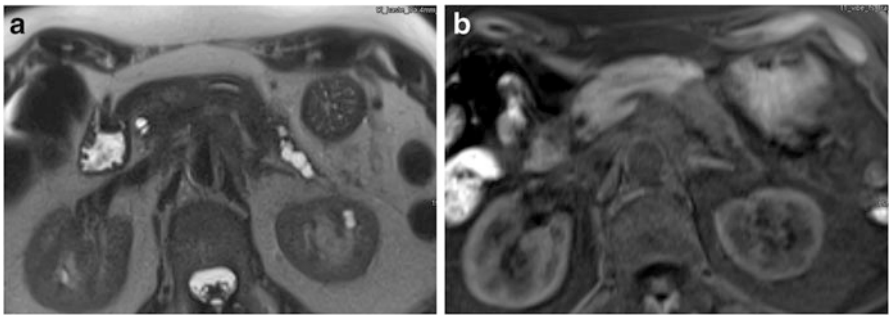

Fig. 5 MRI of a small indeterminate lesion. (**a**) Axial plane in a HASTE sequence (special high contrast and high spatial resolution water-weighted sequence): abrupt duct occlusion secondary to a small lesion of the tail of the pancreas; (**b**) axial plane noncontrast T1 gradient echo sequence showing a very high parenchymal contrast difference between tumors and normal pancreatic tissue

arterial phase after intravenous iodinated contrast material injection or at later phases, e.g., in the parenchymal (= portal venous) phase (Figs. 1 and 2). This hypoattenuation results from the significant pathologic changes in the stromal microenvironment of pancreatic adenocarcinoma versus normal pancreatic tissue. Normal pancreatic tissue displays a well-defined rise in density (= attenuation) after intravenous injection of iodinated contrast material in MDCT as expressed by the respective rise of measured Hounsfield units throughout the arterial until the parenchymal (venous) phase. Similarly, it shows a well-defined decline in density throughout the "wash-out" phase when an equilibrium of the circulating iodine contrast material in the body is reached. Such behavior at CT imaging is the direct surrogate of parenchymal vascularity reflecting an orderly and characteristic tissue structure given for each of the human organs. The microenvironment of pancreatic adenocarcinoma is widely different. Early-on, with the rising use of CT imaging (or MRI), it was noted that the tumorous tissue has a much more reduced vascular density as compared to normal pancreatic tissue [4]. Such was explained by a specific desmoplastic reaction of pancreatic adenocarcinoma. Applying anatomic imaging by MDCT (or MRI), this desmoplasia is the surrogate for the characteristic hypoattenuation at imaging. Ever since, a great amount of research has been directed toward the understanding of such specific tumor behavior as it was hoped to identify new strategy lines targeting at these microenvironmental characteristics: almost two decades ago, it was found that significant changes in gene expression are involved in the stromal desmoplasia [14]. Myofibroblasts have been described as the effector cells [15]. Cohen identified the fibroblast activation protein (FAP) as one of the major molecular pathways [16] in the pathologic tumorous microenvironment and which, furthermore, is more expressed in more advanced stages. Also, he found that the highest expression (= tissue concentration) was at the borderline between tumor and parenchyma, which is the direct reflection of imaging findings at MDCT [3–5, 17–19]. Recently, Neuzillet elucidated the counterintuitive role of SPARC (= secreted protein acid and rich in cystein) which is overexpressed in pancreatic adenocarcinoma and which, however, assumes a progression suppressing function in other solid tumors (e.g, colorectal, ovarian, prostate, breast, melanoma, and glioblastoma). The apparent contradictory function of SPARC in pancreatic adenocarcinoma, presumably, is based on the inhibition of angiogenesis via inhibition of vascular endothelial growth factor (VEGF), while promoting epithelial-to-mesenchymal transition and invasion through matrix metalloprotease expression [20]. This was supported very recently by Patsouras who described a much higher molecular concentration of FAP vs VEGF in tumor tissue from patients with IIb stages versus patients with IIa stages [21]. These findings corroborate and explain imaging characteristics at MDCT of tumor invasion into vessels, neural structures, and other surrounding tissue during the local progression of pancreatic adenocarcinoma. Hence, it might be understood now, why vascular invasion in general and into venous structures, in particular, is seen at MDCT at already relatively small tumor sizes. For example, mesenteric or portal venous invasion and obstruction are typical findings in locally advanced pancreatic adenocarcinoma and are essential features for tumor detection and differential diagnosis. Despite all these advances over the
